In the somatic nervous system, the cell bodies of somatic motor neurons are in the CNS. The axons of these somatic motor neurons extend from their location in the CNS to skeletal muscle (figure 16.1a). The neuron arrangement between the CNS and the effectors of the ANS is different from that of the somatic motor system. In contrast to a single neuron, the ANS has two neurons in a series extending between the CNS and the innervated organs (figure 16.1b). The first neuron of the series is called the **preganglionic neuron**. Its cell body is located in the CNS within either the brainstem or the lateral horn of the spinal cord gray matter, and its axon extends to an autonomic ganglion located outside the CNS. The **autonomic ganglion** contains the cell body of the second neuron of the series, which is called the **postganglionic neuron**. Preganglionic neurons synapse with postganglionic neurons in the autonomic ganglia. The axons of postganglionic neurons extend from autonomic ganglia to effector organs, where they synapse with their target tissues.

Another interesting difference between the somatic nervous system and the ANS is the myelination of axons. The axons of all somatic motor neurons are myelinated. In the ANS, the axons of preganglionic neurons are myelinated, but the axons of postganglionic neurons are unmyelinated.

Many movements controlled by the somatic nervous system are conscious, whereas ANS functions are unconsciously controlled. The effect of somatic motor neurons on skeletal muscle is always excitatory, but the effect of autonomic motor neurons on target tissues can be either excitatory or inhibitory. For example, after a meal the ANS can stimulate stomach activities, but during exercise the ANS can inhibit those activities. Table 16.1 summarizes the differences between the somatic nervous system and the ANS.

FIGURE 16.1 Organization of Somatic and Autonomic Nervous System Neurons

(a) The cell body of the somatic motor neuron is in the CNS, and its axon extends to and synapses with a skeletal muscle. (b) The cell body of the preganglionic neuron is in the CNS, and its axon extends to an autonomic ganglion and synapses with a postganglionic neuron. The postganglionic neuron extends to and synapses with its effector.

Sensory neurons are not classified as somatic or autonomic. These neurons propagate action potentials from sensory receptors to the CNS and can provide information for reflexes mediated through the somatic nervous system or the ANS. For example, stimulation of pain receptors can initiate somatic reflexes, such as the withdrawal reflex, and autonomic reflexes, such as an increase in heart rate. Although some sensory neurons primarily affect somatic functions and others primarily influence autonomic functions, functional overlap makes attempts to classify sensory neurons as either somatic or autonomic meaningless.

ASSESS YOUR PROGRESS

3. Contrast the somatic nervous system with the ANS for each of the following:
 - a. number of neurons between the CNS and the effector organ
 - b. location of neuron cell bodies
 - c. structures each innervates
 - d. inhibitory or excitatory effects
 - e. conscious or unconscious control
 - f. neurotransmitter(s) used

TABLE 16.1

Comparison of the Somatic and Autonomic Nervous Systems

	Somatic Nervous System	Autonomic Nervous System
Effector	Skeletal muscle	Smooth muscle, cardiac muscle, and glands
Regulation	Controls all conscious and unconscious movements of skeletal muscle	Unconscious regulation, although influenced by conscious mental functions
Response to Stimulation	Skeletal muscle contracts.	Target tissues are stimulated or inhibited.
Neuron Arrangement	One neuron extends from the central nervous system (CNS) to skeletal muscle.	There are two neurons in series; the preganglionic neuron extends from the CNS to an autonomic ganglion, and the postganglionic neuron extends from the autonomic ganglion to the target tissue.
Neuron Cell Body Location	Neuron cell bodies are in motor nuclei of the cranial nerves and in the ventral horn of the spinal cord.	Preganglionic neuron cell bodies are in autonomic nuclei of the cranial nerves and in the lateral part of the spinal cord; postganglionic neuron cell bodies are in autonomic ganglia.
Number of Synapses	One synapse between the somatic motor neuron and the skeletal muscle	Two synapses; first is in the autonomic ganglia, and second is at the target tissue
Myelination of Axons	Myelinated	Preganglionic axons are myelinated; postganglionic axons are unmyelinated.
Neurotransmitter Substance	Acetylcholine	Preganglionic neurons release acetylcholine; postganglionic neurons release acetylcholine, norepinephrine, or epinephrine.
Receptor Molecules	Receptor molecules for acetylcholine are nicotinic.	In autonomic ganglia, receptor molecules for acetylcholine are nicotinic; in target tissues, receptor molecules for acetylcholine are muscarinic. In target tissues, receptor molecules for norepinephrine are either α - or β -adrenergic.

4. Differentiate between preganglionic neurons and postganglionic neurons.
5. Why are sensory neurons not classified as somatic or autonomic?

16.3 Anatomy of the Autonomic Nervous System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the divisions of the ANS.
- B. Describe the arrangement of sympathetic neurons and ganglia.
- C. Describe the arrangement of parasympathetic neurons and ganglia.
- D. Explain what an autonomic nerve plexus is and list the major autonomic nerve plexuses in the body.
- E. Discuss the organization of the ENS.

As described earlier, the ANS is subdivided into the **sympathetic division**, the **parasympathetic division**, and the **enteric (en-ter'ik; bowels) nervous system (ENS)**. The sympathetic and parasympathetic divisions differ anatomically in (1) the location of their preganglionic neuron cell bodies within the CNS and (2) the location of their autonomic ganglia in the peripheral nervous system. The ENS is a complex network of neuron cell bodies and axons within the wall of the digestive tract. The ENS is considered part of the ANS because sympathetic and parasympathetic neurons are an important part of it. The anatomy of the sympathetic and parasympathetic divisions of the ANS will be described first, followed by a description of the ENS.

Sympathetic Division

The sympathetic division of the ANS is sometimes called the *thoracolumbar division* because the sympathetic preganglionic neurons are associated with the thoracic and lumbar regions of the spinal cord. Specifically, the cell bodies of sympathetic preganglionic neurons are in the lateral horns of the spinal cord gray matter between the first thoracic (T1) segment and the second lumbar (L2) segment (figure 16.2). The axons of the preganglionic neurons exit through the ventral roots of spinal nerves T1–L2. These axons course through the spinal nerves for a short distance before they exit the nerves and project to sympathetic ganglia.

There are two types of sympathetic ganglia: sympathetic chain ganglia and collateral ganglia. **Sympathetic chain ganglia** are located along the left and right sides of the vertebral column. These ganglia are connected to each other forming a chain, thus the name sympathetic chain. The sympathetic chain ganglia are also called *paravertebral* (alongside the vertebral column) *ganglia* because of their location. Although the sympathetic division originates in the thoracic and lumbar vertebral regions, the sympathetic chain ganglia extend into the cervical and sacral regions. As a result of ganglia fusion during fetal development, there are

typically 3 pairs of cervical ganglia, 11 pairs of thoracic ganglia, 4 pairs of lumbar ganglia, and 4 pairs of sacral ganglia. **Collateral** (meaning “accessory”) **ganglia** are unpaired ganglia located in the abdominopelvic cavity. They are also called *prevertebral ganglia* because they are anterior to the vertebral column.

The axons of preganglionic neurons are small in diameter and myelinated. The preganglionic axons pass through a short connection between a spinal nerve and a sympathetic chain ganglion called a **white ramus communicans** (rā'mīs kō-mū'ni-kans; pl. rami communicantes, rā'mī kō-mū-ni-kan'tēz) because of the whitish color of the myelinated axons (figure 16.3).

Sympathetic axons exit the sympathetic chain ganglia by the following four routes:

1. *Spinal nerves* (figure 16.3a). Preganglionic axons synapse with postganglionic neurons in sympathetic chain ganglia.

FUNDAMENTAL Figure

FIGURE 16.2 Sympathetic Division

The location of sympathetic preganglionic (solid blue) and postganglionic (dashed blue) neurons. The preganglionic cell bodies are in the lateral gray matter of the thoracic and lumbar parts of the spinal cord. The cell bodies of the postganglionic neurons are within the sympathetic chain ganglia or within collateral ganglia. **APR**

(a) Preganglionic axons from a spinal nerve pass through a white ramus communicans into a sympathetic chain ganglion. Some axons synapse with a postganglionic neuron at the level of entry; others ascend or descend to other levels before synapsing. Each postganglionic axon exits the sympathetic chain through a gray ramus communicans and enters a spinal nerve.

(b) Part (b) is like part (a), except that each postganglionic neuron exits a sympathetic chain ganglion through a sympathetic nerve.

(c) Preganglionic neurons do not synapse in the sympathetic chain ganglia, but exit in splanchnic nerves and extend to a collateral ganglion, where they synapse with postganglionic neurons.

(d) Part (d) is like part (c), except that the preganglionic axons extend to the adrenal medulla, where they synapse with specialized adrenal medullary cells.

FIGURE 16.3 Routes Taken by Sympathetic Axons

Preganglionic axons are illustrated as *solid blue lines* and postganglionic axons as *dashed blue lines*. **APR**

They can synapse at the same level that the preganglionic axons enter the sympathetic chain, or they can pass superiorly or inferiorly through one or more ganglia and synapse with postganglionic neurons in a sympathetic chain ganglion at a different level. Axons of the postganglionic neurons pass through a **gray ramus communicans** and reenter a spinal nerve. Postganglionic axons are unmyelinated, thereby giving the gray ramus communicans its grayish color. All spinal nerves receive postganglionic axons from a gray ramus communicans. The postganglionic axons then project through the spinal nerve to the skin and blood vessels of skeletal muscles.

2. **Sympathetic nerves** (figure 16.3b). Preganglionic axons enter the sympathetic chain and synapse in a sympathetic chain ganglion at the same or a different level with postganglionic neurons. The postganglionic axons leaving the sympathetic chain ganglion form **sympathetic nerves**, which supply organs in the thoracic cavity.
3. **Splanchnic** (splanġ'nik) **nerves** (figure 16.3c). Some preganglionic axons enter sympathetic chain ganglia and, without synapsing, exit at the same or a different level to form **splanchnic nerves**. Those preganglionic axons extend to collateral ganglia, where they synapse with postganglionic neurons. Axons of the postganglionic neurons leave the collateral ganglia through small nerves that extend to effectors in the abdominopelvic cavity. Splanchnic nerves are different from the sympathetic nerves discussed earlier, in that splanchnic nerves are composed of preganglionic axons, whereas sympathetic nerves are composed of postganglionic axons.
4. **Innervation to the adrenal gland** (figure 16.3d). The sympathetic innervation to the adrenal gland is through a splanchnic nerve, but it is different from other ANS nerves. In the case of the adrenal glands, the axons of the preganglionic neurons do not synapse in sympathetic chain ganglia or in collateral ganglia. Instead, the axons pass through those ganglia and synapse with cells in the medulla of the adrenal gland. The **adrenal medulla** (me-dool'ă) is the inner portion of the adrenal gland and consists of specialized cells derived during embryonic development from neural crest cells (see figure 13.2), which are the same cells that give rise to the postganglionic cells of the ANS. Adrenal medullary cells are round, have no axons or dendrites, and are divided into two groups, depending on what substance they secrete. About 80% of the cells secrete **epinephrine** (ep'i-nef'rin), also called **adrenaline** (ă-dren'ă-lin), and about 20% secrete **norepinephrine** (nōr'ep-i-nef'rin), also called **noradrenaline** (nōr-ă-dren'ă-lin). Stimulation of these cells by preganglionic axons causes the release of epinephrine and norepinephrine. These substances circulate in the blood and affect all tissues having receptors to which they can bind. The general response to epinephrine and norepinephrine released from the adrenal medulla is to prepare the individual for physical activity. Secretions of the adrenal medulla are considered hormones because they are released into the bloodstream and travel some distance to the effectors (see chapters 17 and 18).

ASSESS YOUR PROGRESS

6. Where are the cell bodies of sympathetic preganglionic neurons located?
7. What types of axons (preganglionic or postganglionic, myelinated or unmyelinated) are found in the white and gray rami communicantes?
8. Where do preganglionic axons synapse with the postganglionic neurons in spinal and sympathetic nerves?
9. Where do preganglionic axons that form splanchnic nerves (except those to the adrenal gland) synapse with postganglionic neurons?
10. What is unusual about the splanchnic nerve innervation to the adrenal gland? What do the specialized cells of the adrenal medulla secrete, and what is the effect of these substances?
11. Describe the lengths of the preganglionic and postganglionic neurons of the sympathetic division.

Parasympathetic Division

The parasympathetic division is sometimes called the *craniosacral* (kră'nē-ō-să'krăł) *division* because the cell bodies of parasympathetic preganglionic neurons are located either within cranial nerve nuclei in the brainstem or within the lateral parts of the gray matter in the sacral region of the spinal cord from S2 to S4 (figure 16.4).

Axons of the parasympathetic preganglionic neurons from the brain are in cranial nerves III, VII, IX, and X. The axons associated with the sacral region are in **pelvic splanchnic nerves**. The preganglionic axons course through these nerves to **terminal ganglia**, where they synapse with postganglionic neurons. The axons of the postganglionic neurons extend relatively short distances from the terminal ganglia to the effectors. The terminal ganglia are either near or embedded within the walls of the organs innervated by the parasympathetic neurons. Many of the parasympathetic ganglia are small, but some, such as those in the wall of the digestive tract, are large.

Table 16.2 summarizes the structural differences between the sympathetic and parasympathetic divisions.

ASSESS YOUR PROGRESS

12. Where are the cell bodies of parasympathetic preganglionic neurons located?
13. In what structures do parasympathetic preganglionic neurons synapse with postganglionic neurons? Where are these structures located?
14. What nerves are formed by the axons of parasympathetic preganglionic neurons?
15. Describe the lengths of the preganglionic and postganglionic neurons of the parasympathetic division.

Autonomic Nerve Plexuses and Distribution of Autonomic Nerve Fibers

In the previous sections, the major pathways for preganglionic and postganglionic neurons of the sympathetic and parasympathetic

FIGURE 16.4 Parasympathetic Division

The location of parasympathetic preganglionic (solid red) and postganglionic (dashed red) neurons. The preganglionic neuron cell bodies are in the brainstem and the lateral gray horns of the sacral part of the spinal cord, and the postganglionic neuron cell bodies are within terminal ganglia. **APR**

divisions were described. This section will detail the distribution of the autonomic nerve fibers to the target organs (figure 16.5). In some cases, the postganglionic axons extend directly through nerves to the target organ. In other cases, the postganglionic axons become part of autonomic nerve plexuses. **Autonomic nerve plexuses** are complex, interconnected neural networks formed by neurons of the sympathetic and parasympathetic divisions. Axons of sensory neurons also contribute to these autonomic nerve plexuses. The autonomic nerve plexuses are typically named according to the organs they supply or the blood vessels along which they are found. For example, the cardiac plexus supplies the heart, and the thoracic aortic plexus is found along the thoracic aorta. Plexuses following the route of blood vessels are a major means by which autonomic axons are distributed throughout the body. Since they contain both sympathetic and parasympathetic neurons, autonomic nerve plexuses are associated with both the sympathetic and parasympathetic divisions.

Sympathetic Division Distribution

Sympathetic outflow is through spinal nerves, sympathetic nerves, and splanchnic nerves (see figure 16.3). Branches of these nerves either extend directly to effectors or join autonomic nerve plexuses to be distributed to effectors. The major means by which sympathetic postganglionic axons reach effectors include the following:

1. *Spinal nerves.* From all levels of the sympathetic chain, some postganglionic axons project through gray rami communicates to spinal nerves. The axons extend to a specific region innervated by each pair of spinal nerves, regulating the activity of sweat glands in the skin, the smooth muscle in the blood vessels of the skin, and the smooth muscle of the arrector pili. See figure 12.14 for the distribution of spinal nerves to the skin.
2. *Head and neck nerve plexuses.* Most of the sympathetic nerve supply to the head and neck is derived from the superior cervical sympathetic chain ganglion (figure 16.5). Postganglionic axons of sympathetic nerves form plexuses that extend superiorly to the head and inferiorly to the neck. The plexuses associated with the head and neck give off branches to regulate the

TABLE 16.2 Comparison of the Sympathetic and Parasympathetic Divisions		
	Sympathetic Division	Parasympathetic Division

activity of structures of the skin such as sweat glands, the smooth muscle in the blood vessels of the skin, and the smooth muscle of the arrector pili. Axons from the plexuses also join branches of the trigeminal nerves (cranial nerve V) to regulate

the activity of the skin of the face, the salivary glands, the iris, and the ciliary muscles of the eye.

3. *Thoracic nerve plexuses.* The sympathetic innervation for organs of the thorax is mainly derived from the cervical and

upper five thoracic sympathetic chain ganglia. Postganglionic axons in sympathetic nerves contribute to the **cardiac plexus**, regulating the heart; the **pulmonary plexus**, regulating the lungs; and other thoracic plexuses (figure 16.5).

4. **Abdominopelvic nerve plexuses.** Sympathetic chain ganglia from T5 and below mainly innervate the abdominopelvic organs. The preganglionic axons of splanchnic nerves synapse with postganglionic neurons in the collateral ganglia of abdominopelvic nerve plexuses. Postganglionic axons from the collateral ganglia innervate smooth muscle and glands in the abdominopelvic organs. There are several abdominopelvic nerve plexuses (figure 16.5). The **celiac** (sē'lē-ak) **plexus** has two large celiac ganglia and other, smaller ganglia. The celiac plexus innervates the diaphragm, stomach, spleen, liver, gallbladder, adrenal glands, kidneys, testes, and ovaries. The **superior mesenteric** (mez-en-ter'ik) **plexus** includes the superior mesenteric ganglion and innervates the pancreas, small intestine, ascending colon, and transverse colon. The **inferior mesenteric plexus** includes the inferior mesenteric ganglion and innervates the transverse colon to the rectum. The **superior** and **inferior hypogastric plexuses** innervate the descending colon to the rectum, urinary bladder, and reproductive organs in the pelvis.

Parasympathetic Division Distribution

Parasympathetic preganglionic fibers extend from the CNS through cranial and pelvic splanchnic nerves. Branches of these nerves either directly innervate organs or join nerve plexuses to be distributed to organs. The major means by which parasympathetic postganglionic axons reach effectors include the following:

1. **Cranial nerves innervating the head and neck.** Three pairs of cranial nerves have parasympathetic preganglionic axons that extend to terminal ganglia in the head. Postganglionic neurons from the terminal ganglia innervate and thereby regulate nearby structures. The following are the parasympathetic cranial nerves, their terminal ganglia, and the structures innervated (figure 16.5; see table 13.5):
 - a. The **oculomotor (III) nerve**, through the **ciliary** (sil'ē-ar-ē) **ganglion**, innervates the ciliary muscles and the iris of the eye.
 - b. The **facial (VII) nerve**, through the **pterygopalatine** (ter'i-gō-pal'ā-tīn) **ganglion**, innervates the lacrimal gland and the mucosal glands of the nasal cavity and palate. The facial nerve, through the **submandibular ganglion**, also innervates the submandibular and sublingual salivary glands.
 - c. The **glossopharyngeal (IX) nerve**, through the **otic** (ō'tik) **ganglion**, innervates the parotid salivary gland.
2. **The vagus nerve and thoracic nerve plexuses.** Although cranial nerve X, the **vagus nerve**, has somatic motor and sensory functions in the head and neck, its parasympathetic distribution is to the thorax and abdomen. Preganglionic axons extend through the vagus nerves to the thorax. Within the thorax, the axons pass through branches of the vagus nerves to contribute to the cardiac plexus, which innervates the heart, and the pulmonary plexus, which innervates the lungs. The vagus nerves

continue down the esophagus and give off branches to form the **esophageal plexus**.

3. **Abdominal nerve plexuses.** After the esophageal plexus passes through the diaphragm, some of the vagal preganglionic axons innervate terminal ganglia in the wall of the stomach, whereas others contribute to the celiac and superior mesenteric plexuses. Through these plexuses, the preganglionic axons synapse in terminal ganglia in the walls of the gallbladder, biliary ducts, pancreas, small intestine, ascending colon, and transverse colon.
4. **Pelvic splanchnic nerves and pelvic nerve plexuses.** The parasympathetic preganglionic axons whose cell bodies are in the S2–S4 region of the spinal cord pass to the ventral rami of spinal nerves and enter the pelvic splanchnic nerves. The pelvic splanchnic nerves innervate terminal ganglia in the transverse colon to the rectum, and they contribute to the hypogastric plexus. The hypogastric plexus and its derivatives innervate the lower colon, rectum, urinary bladder, and organs of the reproductive system in the pelvis.

Sensory Neurons in Autonomic Nerve Plexuses

The axons of sensory neurons run alongside ANS axons within ANS nerves and plexuses. These sensory neurons are not strictly part of the ANS, but they play important roles in monitoring the activity of structures regulated by the ANS. Some sensory neurons are part of reflex arcs regulating organ activities. Sensory neurons also transmit pain and pressure sensations from organs to the CNS. The cell bodies of these sensory neurons are found in the dorsal root ganglia of spinal nerves and in the cranial nerve sensory ganglia, which are swellings on the nerves close to their attachment to the brain.

ASSESS YOUR PROGRESS

16. From what are sympathetic autonomic nerve plexuses formed? How are they normally named?
17. Describe the four major ways by which sympathetic axons pass from sympathetic chain ganglia to effectors. Name four thoracic and four abdominopelvic autonomic nerve plexuses.
18. List the four major means by which parasympathetic axons reach effectors. List the cranial nerves and ganglia that supply the head and neck.
19. What are the roles of sensory neurons in the ANS?

Enteric Nervous System

The enteric nervous system consists of nerve plexuses within the wall of the digestive tract (see chapter 24). The plexuses have contributions from three sources: (1) sensory neurons that connect the digestive tract to the CNS, (2) ANS motor neurons that connect the CNS to the digestive tract, and (3) enteric neurons, which are confined to the enteric plexuses. The CNS is capable of monitoring the digestive tract and controlling its smooth muscle and glands through autonomic reflexes (see section 16.5). For example, sensory neurons detect stretch of the digestive tract, and action potentials are transmitted to the CNS. In response, the CNS sends action potentials to glands in the digestive tract, causing them to secrete.

There are three major types of enteric neurons:

1. *Enteric sensory neurons* detect changes in the chemical composition of the contents of the digestive tract or detect stretch of the digestive tract wall.
2. *Enteric motor neurons* stimulate or inhibit smooth muscle contraction and gland secretion.
3. *Enteric interneurons* connect enteric sensory and motor neurons to each other.

A unique feature of enteric neurons is that they are capable of monitoring and controlling the digestive tract independently of the CNS through local reflexes (see section 16.5). For example, stretch of the digestive tract is detected by enteric sensory neurons, which stimulate enteric interneurons. The enteric interneurons stimulate enteric motor neurons, which stimulate glands to secrete. Although the enteric nervous system is capable of controlling the activities of the digestive tract completely independently of the CNS, the two systems normally work together.

ASSESS YOUR PROGRESS

20. What is the enteric nervous system (ENS), and where is it located?
21. What three sources contribute to ENS plexuses?
22. Name three major types of enteric neurons. How do enteric neurons monitor and control the digestive tract?

16.4 Physiology of the Autonomic Nervous System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Explain dual innervation of the ANS.**
- B. Describe the role of the sympathetic division during activity or stress and the general effects on the body.**
- C. Describe the role of the parasympathetic division during rest and the general effects on the body.**
- D. Differentiate between cholinergic and adrenergic neurons as to the neurotransmitter secreted and the type of neuron that secretes the neurotransmitter.**
- E. Contrast the two types of cholinergic receptors.**
- F. Describe the types of adrenergic receptors and their subtypes.**
- G. List effectors and the type(s) of receptors they have.**

Sympathetic Versus Parasympathetic Activity

The sympathetic and parasympathetic divisions of the ANS maintain homeostasis by adjusting body functions to match the level of physical activity. The ANS innervates most organs via sympathetic and parasympathetic fibers (figure 16.6). Examples of dually innervated organs are the gastrointestinal tract, heart, urinary bladder,

and reproductive tract. However, dual innervation of organs by both divisions of the ANS is not universal. For example, sweat glands and blood vessels are innervated by sympathetic neurons almost exclusively. In addition, where dual innervation exists, one division may be more predominant than the other division. For example, parasympathetic innervation of the gastrointestinal tract is more extensive and exerts a greater influence than does sympathetic innervation.

In cases of dual innervation of a single organ, the sympathetic division has a major influence under conditions of physical activity or stress, whereas the parasympathetic division has a greater influence under resting conditions. However, the sympathetic division is not inactive during resting conditions; rather, it plays a major role during rest by maintaining blood pressure and body temperature.

In general, during physical exercise the sympathetic division shunts blood and nutrients to structures that are active and decreases the activity of the nonessential organs. This is sometimes referred to as the **fight-or-flight response** (see Clinical Impact, “Biofeedback, Meditation, and the Fight-or-Flight Response”). Typical responses produced by the sympathetic division during exercise include the following:

1. Increased heart rate and force of contraction increase blood pressure and the movement of blood.
2. Vasodilation of blood vessels of muscle occurs during exercise. As skeletal or cardiac muscle contracts, oxygen and nutrients are used and waste products are produced. The decrease in oxygen and nutrients and the accumulation of waste products stimulate vasodilation (see chapter 21). Vasodilation is beneficial because it increases blood flow, bringing needed oxygen and nutrients and removing waste products. Too much vasodilation, however, can lower blood pressure, thereby decreasing blood flow. Conversely, increased stimulation of blood vessels of skeletal muscle by sympathetic nerves during exercise causes vasoconstriction, which prevents a drop in blood pressure (see chapter 21).
3. Vasoconstriction occurs in blood vessels of tissues not involved in exercise. For example, vasoconstriction in the abdominopelvic organs reduces blood flow through them, making more blood available for the exercising tissues.
4. Dilation of air passageways increases airflow into and out of the lungs.
5. Increased breakdown of stored energy sources occurs during exercise. Skeletal muscle cells and liver cells (hepatocytes) are stimulated to break down glycogen to glucose. Skeletal muscle cells use the glucose, and liver cells release it into the blood for use by other tissues. Adipocytes break down stored lipids, releasing fatty acids into the blood, which are used as an energy source by skeletal muscle and cardiac muscle.
6. Body temperature increases as exercising muscles generate heat. Vasodilation of blood vessels in the skin brings warm blood close to the surface, where heat is lost to the environment. Sweat gland activity increases, resulting in increased sweat production, and evaporation of the sweat removes additional heat.
7. During exercise, the activities of nonessential organs decrease. For example, the process of digesting food slows as digestive glands decrease their secretions and the contractions of smooth muscle that mix and move food through the gastrointestinal tract decrease.

FIGURE 16.6 Innervation of Organs by the ANS

Preganglionic fibers are indicated by *solid lines*, and postganglionic fibers are indicated by *dashed lines*.

Clinical IMPACT

Biofeedback, Meditation, and the Fight-or-Flight Response

Biofeedback is a technique that uses electronic instruments or other methods to monitor and change subconscious activities, many of which are regulated by the ANS. For example, skin temperature, heart rate, and brain waves can be monitored electronically. Then, by watching the monitor and using biofeedback techniques, a person can learn to consciously reduce his or her heart rate and blood pressure and regulate blood flow in the limbs. For example, some people claim they can prevent the onset of migraine headaches or reduce their intensity by learning to dilate the blood vessels in the skin of their forearms and hands. Increased blood vessel dilation increases skin temperature, which is correlated with a decrease in the severity of the migraine. Some people use biofeedback methods to relax by learning to reduce their heart rate or change the pattern of their brain waves. Biofeedback techniques can also be used to reduce the severity of some stomach ulcers, high blood pressure, anxiety, and depression.

Meditation is another technique that influences autonomic functions. Some people use meditation techniques to reduce heart rate, blood pressure, the severity of ulcers, and other symptoms associated with stress.

The fight-or-flight response occurs when an individual is subjected to stress, as in a threatening, frightening, embarrassing, or exciting situation. Whether a person confronts or avoids the stressful situation, the nervous system and the endocrine system are involved, either consciously or unconsciously. The autonomic part of the fight-or-flight response results in a general increase in sympathetic activity, including heart rate, blood pressure, sweating, and other responses that prepare the individual for physical activity. The fight-or-flight response is adaptive because it also enables a person to resist or move away from a threatening situation.

Increased activity of the parasympathetic division is generally consistent with resting conditions, as in the following examples:

1. The parasympathetic division regulates digestion by stimulating the secretions of glands, promoting the mixing of food with digestive enzymes and bile, and moving materials through the digestive tract.
2. The parasympathetic division controls defecation and urination.
3. Increased parasympathetic stimulation lowers the heart rate, which lowers blood pressure.
4. Increased parasympathetic activity constricts air passageways, decreasing air movement through them.

In summary, although neither the sympathetic nor the parasympathetic divisions are chronically active, or chronically inactive, there are different levels of regulation, depending on the body's activity level. These differences in regulation of the same organs are the result of the unique neurotransmitters released by the postganglionic fibers and the specific receptors on the target cells.

Neurotransmitters

Sympathetic and parasympathetic nerve endings secrete one of two neurotransmitters: acetylcholine or norepinephrine. If the neuron secretes acetylcholine, it is called a **cholinergic** (kol-in-er'jik) **neuron**; if it secretes norepinephrine (epinephrine), it is called an **adrenergic** (ad-rě-ner'jik) **neuron**. Adrenergic neurons are so named because at one time they were believed to secrete adrenaline, or epinephrine. All preganglionic neurons of the sympathetic and parasympathetic divisions are cholinergic. All postganglionic neurons of the parasympathetic division are also cholinergic. Almost all postganglionic neurons of the sympathetic division are adrenergic, but a few postganglionic neurons that innervate thermoregulatory sweat glands are cholinergic (figure 16.7).

Substances other than the regular neurotransmitters have been extracted from ANS neurons. These substances include nitric oxide; fatty acids, such as eicosanoids; peptides, such as gastrin, somatostatin, cholecystokinin, vasoactive intestinal peptide, enkephalins, and substance P; and monoamines, such as dopamine, serotonin, and histamine. The specific roles that many of these compounds play in regulating the ANS is unclear, but they appear to function as either neurotransmitters or neuromodulator substances (see chapter 11).

Receptors

Receptors for acetylcholine and norepinephrine are located in the plasma membranes of certain cells. Earlier we described neurons as cholinergic or adrenergic based on the type of neurotransmitter released. (*Cholinergic* refers to acetylcholine, and *adrenergic* refers to norepinephrine and epinephrine.) Similarly, receptors are identified as cholinergic and adrenergic based on the type of neurotransmitter that binds to the receptor. It can be very confusing when learning this information, but just remember that the neurons release the neurotransmitter, which then binds to the receptor.

The combination of neurotransmitter and receptor functions as a signal to cells, causing them to respond. Depending on the type of cell, the response is excitatory or inhibitory. Table 16.3 summarizes the sympathetic and parasympathetic effects, as well as the specific receptor types, for the various effectors of the body.

Other substances, such as drugs, can also interact with receptors to alter the activity of the ANS. **Agonists** bind to specific receptors and activate them, whereas **antagonists** bind to specific receptors and prevent them from being activated. Examples of these types of drugs are described in more detail in Clinical Impact, "Influence of Drugs on the Autonomic Nervous System."

Cholinergic Receptors

Cholinergic receptors are receptors to which acetylcholine binds. Cholinergic receptors are classified as either **nicotinic** (nik-ō-tin'ik) **receptors** or **muscarinic** (mūs-kā-rin'ik) **receptors**. The classification of these receptors is based on laboratory findings that nicotine, an alkaloid in tobacco, can bind to some cholinergic receptors, whereas muscarine, an alkaloid extracted from poisonous mushrooms, can bind to other cholinergic receptors. Although nicotine and muscarine are not naturally in the human body, these substances demonstrate the differences

(a) **Nicotinic receptors**, which respond to acetylcholine (ACh), are located on the cell bodies of both sympathetic and parasympathetic postganglionic neurons in autonomic ganglia. Binding of ACh to nicotinic receptors has an excitatory effect.

(b) **Muscarinic receptors**, which respond to ACh, are located on the cells of all parasympathetic effectors and some sympathetic effectors, such as sweat glands. Binding of ACh to muscarinic receptors may be excitatory or inhibitory, depending on the specific effectors.

(c) **Adrenergic receptors**, which respond to norepinephrine (NE), are located on most sympathetic effectors. Binding of NE to adrenergic receptors may be excitatory or inhibitory, depending on the specific effector.

FIGURE 16.7 Locations of ANS Receptors

between the two classes of cholinergic receptors and, thus, are used to distinguish the two.

Nicotinic receptors are located in the membranes of all postganglionic neurons in autonomic ganglia and the membranes of skeletal muscle cells (figure 16.7a). Muscarinic receptors are located in the membranes of effector cells that respond to acetylcholine released from postganglionic neurons (figure 16.7b).

Predict 2

Would structures innervated by the sympathetic division or the parasympathetic division be affected after the consumption of nicotine? After the consumption of muscarine? Explain.

Acetylcholine binding to nicotinic receptors has an excitatory effect because it results in the direct opening of Na⁺ channels and the production of action potentials. When acetylcholine binds to muscarinic receptors, the cell's response is mediated through G proteins (see chapters 3 and 17). The response is either excitatory or inhibitory, depending on the effector in which the receptors are found (table 16.3). For example, acetylcholine binds to muscarinic

receptors in cardiac muscle, thereby reducing heart rate, and acetylcholine binds to muscarinic receptors in smooth muscle cells of the stomach, thus increasing its rate of contraction.

Predict 3

Bethanechol (be-than'ē-kol) chloride is a drug that binds to muscarinic receptors. Explain why this drug can promote emptying of the urinary bladder. Which of the following side effects would you predict: abdominal cramps, asthmatic attack, decreased tear production, decreased salivation, dilation of the pupils, or sweating?

Adrenergic Receptors

Adrenergic receptors are receptors to which norepinephrine or epinephrine binds. They are located in the plasma membranes of effectors innervated by the sympathetic division (figure 16.7c). The response of cells to norepinephrine or epinephrine binding to adrenergic receptors is mediated through G proteins (see chapters 3 and 17). Depending on the effector, the activation of G proteins can result in excitatory or inhibitory responses (table 16.3).

TABLE 16.3 Effects of the Sympathetic and Parasympathetic Divisions on Various Effectors

Effector	Sympathetic Effects and Receptor Type*	Parasympathetic Effects and Receptor Type*
Adipose tissue	Lipid breakdown and release of fatty acids (α_2 , β_1)	None
Arrector pili muscle	Contraction (α_1)	None
Blood (platelets)	Increased coagulation (α_2)	None
Blood vessels		
Arterioles (carry blood to tissues)		
Digestive organs	Constriction (α_1)	None
Heart	Constriction (α_1), dilation (β_2) [†]	None
Kidneys	Constriction (α_1 , α_2), dilation (β_1 , β_2)	None
Lungs	Constriction (α_1), dilation (β_2)	None
Skeletal muscle	Constriction (α_1), dilation (β_2)	None
Skin	Constriction (α_1 , α_2)	None
Veins (carry blood away from tissues)	Constriction (α_1 , α_2), dilation (β_2)	
Eye		
Ciliary muscle	Relaxation for far vision (β_2)	Contraction for near vision (m)
Pupil	Dilation (α_1) [‡]	Constriction (m) [‡]
Gallbladder	Relaxation (β_2)	Contraction (m)
Glands		
Adrenal	Release of epinephrine and norepinephrine (n)	None
Gastric	Decreased gastric secretion (α_2)	Increased gastric secretion (m)
Lacrimal	Slight tear production (α)	Increased tear secretion (m)
Pancreas	Decreased insulin secretion (α_2)	Increased insulin secretion (m)
Salivary	Decreased exocrine secretion (α)	Increased exocrine secretion (m)
Sweat		
Apocrine	Constriction of blood vessels and slight production of thick, viscous saliva (α_1)	Dilation of blood vessels and thin, copious saliva (m)
Eccrine	Thick, organic secretion (m)	None
Eccrine	Watery sweat from most of the skin (m), sweat from palms and soles (α_1)	None
Heart	Increased rate and force of contraction (β_1 , β_2)	Decreased rate of contraction (m)
Liver	Glucose released into blood (α_1 , β_2)	None
Lungs	Dilated air passageways (β_2)	Constricted air passageways (m)
Metabolism	Increased up to 100% (α , β)	None
Sex organs	Ejaculation (α_1), erection [§]	Erection (m)
Skeletal muscles	Breakdown of glycogen to glucose (β_2)	None
Stomach and intestines		
Wall	Decreased tone (α_1 , α_2 , β_2)	Increased motility (m)
Sphincter	Increased tone (α_1)	Decreased tone (m)
Urinary bladder		
Wall (detrusor)	None	Contraction (m)
Neck of bladder	Contraction (α_1)	Relaxation (m)
Internal urinary sphincter	Contraction (α_1)	Relaxation (m)

*Receptor subtypes are indicated. The receptors are α_1 - and α_2 -adrenergic, β_1 - and β_2 -adrenergic, nicotinic cholinergic (n), and muscarinic cholinergic (m).

[†]Normally, blood flow increases through coronary arteries because of increased demand by cardiac tissue for oxygen (local control of blood flow is discussed in chapter 21). In experiments that isolate the coronary arteries, sympathetic nerve stimulation, acting through α -adrenergic receptors, causes vasoconstriction. The β -adrenergic receptors are relatively insensitive to sympathetic nerve stimulation but can be activated by epinephrine released from the adrenal gland and by drugs. As a result, coronary arteries vasodilate.

[‡]Contraction of the radial muscles of the iris causes the pupil to dilate. Contraction of the circular muscles causes the pupil to constrict (see chapter 15).

[§]Decreased stimulation of alpha receptors by the sympathetic division can cause vasodilation of penile blood vessels, resulting in an erection.

Clinical IMPACT

Influence of Drugs on the Autonomic Nervous System

Some drugs that affect the ANS have important value in treating certain diseases because they can increase or decrease activities normally controlled by the ANS. Chemicals that affect the ANS are also found in medically hazardous substances, such as tobacco and insecticides.

Both direct- and indirect-acting drugs influence the ANS. Direct-acting drugs bind to ANS receptors to produce their effects. For example, agonists, or *stimulating agents*, bind to specific receptors and activate them, and antagonists, or *blocking agents*, bind to specific receptors and prevent them from being activated. Here we focus on direct-acting drugs, but it should be noted that some indirect-acting drugs produce a stimulatory effect by causing the release of neurotransmitters or by preventing neurotransmitters from breaking down metabolically. Other indirect-acting drugs produce an inhibitory effect by preventing the biosynthesis or release of neurotransmitters.

Drugs That Bind to Nicotinic Receptors

Drugs that bind to nicotinic receptors and activate them are **nicotinic agents**. Nicotinic agents bind to the nicotinic receptors on all postganglionic neurons within autonomic ganglia and produce stimulation. Although these agents have little therapeutic value and are mainly of interest to researchers, nicotine is medically important because of its presence in tobacco.

Responses to nicotine are variable and depend on the amount taken into the body. Because nicotine stimulates the postganglionic neurons of both the sympathetic and parasympathetic divisions, the variability of its effects largely results from the opposing actions of these divisions. For example, in response to the nicotine in a cigarette, the heart rate may either increase or decrease. Heart rate rhythm tends to become less regular as a result of the simultaneous actions on the sympathetic division, which increase the heart rate, and the parasympathetic division, which decrease the heart rate. Blood pressure tends to increase because of the constriction of blood vessels, which are almost exclusively innervated by sympathetic neurons. In addition to its influence on the ANS, nicotine also affects the CNS; therefore, not all of its effects can be explained on the basis of

action on the ANS. Nicotine is extremely toxic, and even small amounts can be lethal.

Drugs that bind to and block nicotinic receptors are called **ganglionic blocking agents** because they block the effect of acetylcholine on both parasympathetic and sympathetic postganglionic neurons. However, the effect of these substances on the sympathetic division overshadows their effect on the parasympathetic division. For example, trimethaphan camsylate (trī-meth'ă-fan kam'sil-ăt), used to treat high blood pressure, blocks the sympathetic stimulation of blood vessels, causing the blood vessels to dilate, which decreases blood pressure. Ganglionic blocking agents have limited uses because they affect both sympathetic and parasympathetic ganglia. Whenever possible, more selective drugs, which affect receptors of effectors, are now used.

Drugs That Bind to Muscarinic Receptors

Drugs that bind to and activate muscarinic receptors are **muscarinic agents**, or *parasympathomimetic* (par-ă-sim'pă-thō-mi-met'ik) *agents*. These drugs activate the muscarinic receptors of effectors of the parasympathetic division and the muscarinic receptors of sweat glands, which are innervated by the sympathetic division. One of these drugs, muscarine, causes increased sweating, increased secretion of glands in the digestive system, decreased heart rate, constriction of the pupils, and contraction of respiratory, digestive, and urinary system smooth muscles. Bethanechol (be-than'ē-kol) chloride is a muscarinic agent used to stimulate the urinary bladder following surgery because the general anesthetics used for surgery can temporarily inhibit a person's ability to urinate.

Drugs that bind to and block the action of muscarinic receptors are **muscarinic blocking agents**, or *parasympathetic blocking agents*. For example, the activation of muscarinic receptors causes the constriction of air passageways. Ipratropium (i-pră-trō'pē-ŭm) is used to treat chronic obstructive pulmonary disease because it blocks muscarinic receptors, which promotes the relaxation of air passageways. Atropine (at'rō-pēn) is used to block parasympathetic reflexes associated with the surgical manipulation of organs.

Drugs That Bind to Alpha and Beta Receptors

Drugs that activate adrenergic receptors are **adrenergic agents**, or *sympathomimetic* (sim'pă-thō-mi-met'ik) *agents*. Drugs such as phenylephrine (fen-il-ef'rin) stimulate alpha receptors, which are numerous in the smooth muscle cells of certain blood vessels, especially in the digestive tract and the skin. These drugs increase blood pressure by causing vasoconstriction. On the other hand, albuterol (al-bū'ter-ol) is a drug that selectively activates beta receptors in bronchiolar smooth muscle. β -adrenergic-stimulating agents are sometimes used to dilate bronchioles in respiratory disorders, such as asthma.

Drugs that bind to and block the action of alpha receptors are **α -adrenergic-blocking agents**. For example, prazosin (pră'zō-sin) hydrochloride is used to treat hypertension. By binding to alpha receptors in the smooth muscle of blood vessel walls, prazosin hydrochloride blocks the normal effects of norepinephrine released from sympathetic postganglionic neurons. Thus, the blood vessels relax, and blood pressure decreases.

Propranolol (prō-pran'ō-lōl) is an example of a **β -adrenergic-blocking agent**. These drugs are sometimes used to treat high blood pressure, some types of cardiac arrhythmias, and heart attacks. Blockage of the beta receptors within the heart prevents sudden increases in heart rate and thus decreases the probability of arrhythmic contractions.

Future Research

Present knowledge of the ANS is more complicated than the broad outline presented here. In fact, each of the major receptor types has subtype receptors. For example, α -adrenergic receptors are subdivided into the following subgroups: α_{1A} , α_{1B} , α_{2A} , and α_{2B} -adrenergic receptors. The exact number of subtypes in humans is not yet known; however, their existence suggests the possibility of designing drugs that affect only one subtype, such as a drug that affects the blood vessels of the heart but not other blood vessels. Such drugs could produce specific effects but avoid undesirable side effects because they would act only on specific effectors.

Case STUDY

Eyedrops

Sally is a 50-year-old woman with diabetes. Every year, she has her eyes examined by an ophthalmologist because damage to the retina can be associated with diabetes. In addition to checking her vision using an eye chart, her doctor examines the insides of her eyes using an ophthalmoscope (see figure 15.15a). To see inside Sally's eyes better, the doctor applies eyedrops that cause the pupils to enlarge. The diameter of a typical pupil in normal room light is approximately 3–4 mm, whereas a dilated pupil measures 7–8 mm. Because Sally has complained in the past about light sensitivity as a result of the pupil-dilating eyedrops, the doctor applies pupil-constricting eyedrops after the eye exam.

➤ Predict 4

- Review the anatomy of the iris of the eye in chapter 15 (see section 15.3). Do the radial muscles or the circular muscles of the iris cause the pupil to dilate?
- Which division of the ANS controls the radial muscles? The circular muscles?
- Four types of drugs act on the receptors of target organs of the ANS (see Clinical Impact, "Influence of Drugs on the Autonomic Nervous System"). Which of these drugs could explain dilation of Sally's pupils? (*Hint:* See table 16.3.)
- A side effect of the pupil-dilating eyedrops is blurred vision—that is, an inability to see close objects clearly. Based on this observation, what causes the blurred vision and which type of drug is in the pupil-dilating eyedrops?
- Which type of drug could be in the eyedrops that reversed the dilation of Sally's pupils?
- A side effect of the pupil-constricting eyedrops is bloodshot eyes. Based on this observation, which type of drug is in the pupil-constricting eyedrops?

Adrenergic receptors are subdivided into two major categories: **alpha (α) receptors** and **beta (β) receptors**. Epinephrine has a greater effect than norepinephrine on most α and β receptors. The main subtypes of alpha receptors are α_1 - and α_2 -adrenergic receptors; the subtypes of beta receptors are β_1 - and β_2 -adrenergic receptors.

Adrenergic receptors can be stimulated in two ways: by the nervous system or by epinephrine and norepinephrine released from the adrenal gland. Sympathetic postganglionic neurons release norepinephrine, which stimulates adrenergic receptors within synapses (figure 16.7c). For example, blood vessels are continually stimulated to contract through the release of norepinephrine. Increased stimulation causes further constriction and reduces blood flow, whereas decreased stimulation results in dilation and increases blood flow. The control of blood vessel diameter plays an important role in regulating blood flow and blood pressure (see chapter 20).

Because the adrenal glands release epinephrine and norepinephrine into the blood, they can bind to adrenergic receptors located in the plasma membranes of cells that are not involved in synapses. For example, during exercise epinephrine and norepinephrine bind to β_2 receptors and cause blood vessels in skeletal muscles to dilate.

ASSESS YOUR PROGRESS

- Give two exceptions to the generalization that organs are innervated by both divisions of the ANS.
- Use the fight-or-flight response to describe the effects of sympathetic stimulation.
- What are the major roles of the parasympathetic division? Give several examples.
- Describe how a neuron would be classified as cholinergic or adrenergic. Which ANS neurons are cholinergic, and which are adrenergic?
- Name the two major types of cholinergic receptors. Where are they located?
- When acetylcholine binds to each receptor subtype, does it result in an excitatory or an inhibitory cell response?
- Where are adrenergic receptors located? Name the two major types of adrenergic receptors. What are the subtypes of each?
- In what two ways are adrenergic receptors stimulated?

16.5 Regulation of the Autonomic Nervous System

LEARNING OUTCOMES

After reading this section, you should be able to

- Explain the importance of autonomic reflexes to maintaining homeostasis.
- Describe several autonomic reflexes.
- Explain how a local reflex differs from other types of reflexes.

An individual's ability to maintain homeostasis is dependent on the regulatory activity of the ANS. Much ANS regulation occurs through autonomic reflexes. However, input from the cerebrum, the hypothalamus, and other areas of the brain allows conscious thoughts and actions, emotions, and other CNS activities to influence autonomic functions.

Autonomic reflexes involve adjustments to cardiac muscle, smooth muscle, and glandular tissues in response to stimuli. Like other reflexes, autonomic reflex arcs involve sensory receptors, sensory neurons, interneurons, motor neurons, and effector cells (figure 16.8; see chapter 12). For example, **baroreceptors** (stretch receptors) in the walls of large arteries near the heart detect changes in blood pressure, and sensory neurons transmit information from the baroreceptors through the glossopharyngeal and vagus nerves to the medulla oblongata. Interneurons in the medulla oblongata integrate the information, and action potentials

FIGURE 16.8 Autonomic Reflexes

Sensory input from the carotid baroreceptors is sent along the glossopharyngeal nerves to the medulla oblongata. The input is integrated in the medulla oblongata, and motor output is sent to the heart. (a) Parasympathetic reflex. Increased blood pressure results in increased stimulation of the heart by the vagus nerves, which increases inhibition of the heart and lowers the heart rate. (b) Sympathetic reflex. Decreased blood pressure results in increased stimulation of the heart by sympathetic nerves, which in turn increases stimulation of the heart and increases the heart rate and the force of contraction. **AP R**

are produced in autonomic neurons that extend to the heart. If baroreceptors detect a change in blood pressure, autonomic reflexes change the heart rate, which returns the blood pressure to normal. A sudden increase in blood pressure initiates a parasympathetic reflex, which inhibits cardiac muscle cells and reduces the heart

rate, thereby bringing blood pressure down toward its normal value. Conversely, a sudden decrease in blood pressure initiates a sympathetic reflex, which stimulates the heart to increase its rate and force of contraction, thereby increasing blood pressure.

Predict 5

Brad ran a 6.2 km race for his cross-country team. The weather was cool, but he started to sweat during the race and continued to sweat for a short time afterward. Evaporation of the sweat from his body then caused him to feel cold. Explain how the autonomic nervous system functioned to control Brad's body temperature during and after the race.

Other autonomic reflexes help regulate blood pressure (see chapter 21). For example, numerous sympathetic neurons transmit a low but relatively constant frequency of action potentials that stimulate blood vessels throughout the body, keeping them partially constricted. If the vessels constrict further, blood pressure increases; if they dilate, blood pressure decreases. Thus, altering the frequency of action potentials delivered to blood vessels along sympathetic neurons can either raise or lower blood pressure.

The brainstem and the spinal cord contain important autonomic reflex centers responsible for maintaining homeostasis (table 16.4). However, the hypothalamus is in overall control of the ANS. Almost any type of autonomic response can be evoked by stimulating a part of the hypothalamus, which in turn stimulates ANS centers in the brainstem or spinal cord. Although there is overlap, there is some division localization in the hypothalamus. For the most part, stimulation of the posterior hypothalamus produces sympathetic responses, whereas stimulation of the anterior hypothalamus produces parasympathetic responses. The hypothalamus also monitors and controls body temperature.

The hypothalamus has connections with the cerebrum and is an important part of the limbic system, which plays an important role in emotions. The hypothalamus integrates thoughts and emotions to produce ANS responses. For example, pleasant thoughts of a delicious banquet initiate increased secretion by salivary glands and by glands within the stomach, as well as increased smooth muscle contractions within the digestive system. These responses are controlled by parasympathetic neurons. Emotions such as anger cause sympathetic stimulation, which increases blood pressure by increasing the heart rate and constricting the blood vessels.

Clinical IMPACT

Effects of Spinal Cord Injury on ANS Functions

Spinal cord injury can damage nerve tracts, resulting in the loss of sensation and motor control below the level of the injury. Spinal cord injury also interrupts the control of autonomic neurons by ANS centers in the brain. For the parasympathetic division, effector organs innervated through the sacral region of the spinal cord are affected, but most effectors still have normal parasympathetic function because they are innervated by the vagus nerve. For the sympathetic division, brain control of sympathetic neurons is lost below the site of the injury. The higher the level of injury, the greater the number of body parts affected.

Immediately after spinal cord injury, spinal cord reflexes, including ANS reflexes, below the level of the injury are lost. With time, the reflex centers in the spinal cord become functional again. This recovery is particularly important for reflexes involving urination and defecation. Autonomic reflexes mediated through the vagus nerves or the enteric nervous system are not affected by spinal cord injury.

Predict 6

Important sensory receptors that monitor blood pressure are located in arteries in the chest above the heart and in arteries in the head. When Sarah does a headstand, gravity causes the blood in her arteries to flow toward her head, and the blood pressure in the arteries of her chest and head increases. When Sarah crouches for a short time and then stands up rapidly, gravity causes the blood in her arteries to flow away from her neck and head and toward her feet, and the blood pressure in the arteries of her chest and head decreases. How do the sympathetic reflexes that control blood vessels respond when Sarah does a headstand, and how do the sympathetic reflexes that control blood vessels respond if Sarah suddenly stands up after crouching for a short time?

TABLE 16.4 Higher Parts of the CNS Influencing Autonomic Functions

CNS Component	Effects on ANS
Cerebrum and limbic system	Thoughts and emotions can influence ANS functions through the hypothalamus
Hypothalamus	ANS integrating center that interacts with the cerebrum, limbic system, brainstem, and spinal cord; also regulates body temperature
Brainstem	ANS reflex centers for controlling pupil size, accommodation, tear production, salivation, coughing, swallowing, digestive activities, heart rate and force of contraction, blood vessel diameter, and respiration
Spinal cord	ANS reflex centers for regulating defecation, urination, penile and clitoral erection, and ejaculation

The enteric nervous system is involved with both autonomic reflexes and local reflexes that regulate the activity of the digestive tract. Autonomic reflexes help control the digestive tract because sensory neurons of the enteric plexuses supply the CNS with information about intestinal contents, and ANS neurons to the enteric plexuses affect the responses of smooth muscle and glands within the digestive tract wall. For example, sensory neurons detecting stretch of the digestive tract wall send action potentials to the CNS. In response, the CNS sends action potentials out the ANS, causing smooth muscle in the digestive tract wall to contract.

The neurons of the enteric nervous system also operate independently of the CNS to produce local reflexes. A **local reflex** does not involve the CNS, but produces an involuntary, unconscious, stereotypical response to a stimulus. For example, sensory neurons not connected to the CNS detect stretch of the digestive tract wall. These sensory neurons send action potentials through the enteric plexuses to motor neurons, causing smooth muscle to contract or relax. See chapter 24 for more information on local reflexes.

ASSESS YOUR PROGRESS

- Describe the autonomic reflex that maintains blood pressure by altering the heart rate or the diameter of blood vessels.
- What part of the CNS stimulates ANS reflexes and integrates thoughts and emotions to produce ANS responses?
- What is a local reflex? How is it different from other autonomic reflexes? How does the ENS produce local reflexes?

16.6 Functional Generalizations About the Autonomic Nervous System

LEARNING OUTCOME

After reading this section, you should be able to

- A. Explain opposite effects, cooperative effects, and general versus localized effects for the ANS.**

Several generalizations can be made about the influence of the ANS on effector organs. However, bear in mind that most of the following generalizations have exceptions.

Stimulatory Versus Inhibitory Effects

Both divisions of the ANS produce stimulatory and inhibitory effects. For example, the parasympathetic division stimulates contraction of the urinary bladder, causing urination, but inhibits the heart, causing a decrease in heart rate. The sympathetic division stimulates smooth muscle contraction in blood vessel walls, causing vasoconstriction, but inhibits smooth muscle contractions in the lungs, causing dilation of lung air passageways. Thus, it is *not* true that one division of the ANS is always stimulatory and the other is always inhibitory.

Opposite Effects

Most of the effectors of the ANS are dually innervated, meaning both the sympathetic division and the parasympathetic division regulate the effector. When a *single* structure is innervated by both autonomic divisions, the two divisions usually produce opposite effects on the structure. As a consequence, the ANS is capable of both increasing and decreasing the activity of the structure. In the gastrointestinal tract, for example, parasympathetic stimulation increases secretion from glands, whereas sympathetic stimulation decreases secretion. However, in a few instances the effect of the two divisions is not clearly opposite. For example, both divisions of the ANS increase salivary secretion: The parasympathetic division initiates the production of a large volume of thin, watery saliva, and the sympathetic division causes the secretion of a small volume of viscous saliva.

Cooperative Effects

The ANS regulates the activity of many structures that cooperate to carry out a specific function. This may involve activity of just one division or both. One autonomic division can coordinate the activities of *different* structures. For example, the parasympathetic division stimulates the pancreas to release digestive enzymes into the small intestine and stimulates contractions of the small intestine to mix the digestive enzymes with the food. These responses enhance the digestion and absorption of the food.

Alternatively, both divisions of the ANS can act together to coordinate the activity of *different* structures. In the male, the parasympathetic division initiates erection of the penis, whereas the sympathetic division stimulates the release of secretions from male reproductive glands and helps initiate ejaculation.

General Versus Localized Effects

The effect of the ANS may be general, in that many areas of the body are involved, or the effect may be local, only altering the activity of structures in a specific region of the body. In addition,

the extent to which the autonomic divisions affect many areas of the body at the same time is not equal. The sympathetic division has a more general effect than the parasympathetic division because activation of the sympathetic division often causes secretion of both epinephrine and norepinephrine from the adrenal medulla. These hormones circulate in the blood and stimulate effectors throughout the body. Because circulating epinephrine and norepinephrine can persist for a few minutes before being broken down, they can also produce an effect for a longer time than the direct stimulation of effectors by postganglionic sympathetic axons.

The sympathetic division diverges more than the parasympathetic division. Each sympathetic preganglionic neuron synapses with many postganglionic neurons, whereas each parasympathetic preganglionic neuron synapses with about two postganglionic neurons. Consequently, stimulation of sympathetic preganglionic neurons can result in greater stimulation of an effector.

Sympathetic stimulation often activates many different kinds of effectors at the same time as a result of CNS stimulation or epinephrine and norepinephrine release from the adrenal medulla. It is possible, however, for the CNS to selectively activate effectors. For example, vasoconstriction of cutaneous blood vessels in a cold hand is not always associated with an increased heart rate or other responses controlled by the sympathetic division.

ASSESS YOUR PROGRESS

34. What kinds of effects, excitatory or inhibitory, do the sympathetic and parasympathetic divisions produce?
35. When a single organ is innervated by both divisions of the ANS, how would you describe their effects?
36. Explain how the ANS coordinates the activities of different organs.
37. Which ANS division produces the most generalized effects? How does this happen?

Diseases and Disorders

TABLE 16.5

Autonomic Nervous System

Condition	Description
Raynaud disease	Spasmodic contraction of blood vessels and poor circulation, particularly in the fingers, resulting in cold hands prone to ulcerations and gangrene; results from blood vessels that show exaggerated sensitivity to sympathetic innervations; treatments include preganglionic denervation (cutting the preganglionic neurons)
Hyperhidrosis (hī'per-hī-drō'sis)	Excessive sweating caused by exaggerated sympathetic innervation of the sweat glands
Achalasia (ak-ă-lă'zē-ă)	Difficulty in swallowing and in controlling contraction of the esophagus where it enters the stomach; caused by abnormal parasympathetic regulation of the swallowing reflex
Dysautonomia (dis'aw-tō-nō'mē-ă)	Autosomal recessive genetic disorder characterized by reduced tear gland secretion, poor vasomotor control, trouble swallowing, and other symptoms
Hirschsprund disease	Also known as <i>megacolon</i> , a functional obstruction in the lower colon and rectum that inhibits peristaltic contractions, leading to accumulation of feces in the affected area; caused by ineffective parasympathetic stimulation and a predominance of sympathetic stimulation of the colon

Answer

Learn to Predict From page 553

Describing the neural pathways involved in Officer Smith's muscular movements, increased heart rate, and changes in digestive functions requires an understanding of the somatic motor pathways described in chapter 14, the visual pathway described in chapter 15, and the autonomic pathways described in this chapter. The changes in Officer Smith's activity were initiated when she saw the speeding car. Action potentials were conducted from her eyes via the optic nerve (cranial nerve II) to the occipital lobe of the cerebral cortex, where conscious awareness of the situation occurred. The changes in her muscle movements occurred when action potentials were then conducted to the frontal lobe of the cerebrum, where voluntary motor activity is controlled. Action potentials initiated in the motor area of the frontal lobe traveled through descending pathways of the spinal cord. Somatic motor neurons carried action potentials from the spinal cord to the involved skeletal muscles, allowing the movements necessary for Officer Smith to drive her car.

In addition, action potentials also traveled from the cerebral cortex to the limbic system, including the hypothalamus, and from the hypothalamus to motor pathways of the autonomic nervous system. In the autonomic nervous system, action potentials were conducted to the sympathetic chain ganglia. Sympathetic neurons that regulate heart rate carried the action potentials to the heart, causing Officer Smith's heart rate to increase. Sympathetic neurons that regulate digestive function passed through the sympathetic chain ganglia to activate the splanchnic nerves and synapsed in the collateral ganglia. These neurons then conducted the action potentials to the digestive tract, where they decreased the activity of enteric neurons and decreased digestive secretion and motility.

Answers to the rest of this chapter's Predict questions are in appendix G.

16.1 Overview of the Autonomic Nervous System (p. 554)

1. The autonomic nervous system (ANS) maintains homeostasis of the body by regulating many activities, including heart rate, breathing rate, body temperature, and digestive and urinary function.
2. The sympathetic division has more influence on effectors under conditions of increased physical activity or stress, whereas the parasympathetic division has more influence under conditions of rest.

16.2 Contrasting the Somatic and Autonomic Nervous Systems (p. 554)

1. The cell bodies of somatic motor neurons are located in the CNS, and their axons extend to skeletal muscles, where they have an excitatory effect, which is usually consciously controlled.
2. The cell bodies of the preganglionic neurons of the ANS are located in the CNS and extend to ganglia, where they synapse with postganglionic neurons. The postganglionic axons extend to smooth muscle, cardiac muscle, or glands and have an excitatory or inhibitory effect, which is usually unconsciously controlled.

16.3 Anatomy of the Autonomic Nervous System (p. 556)

Sympathetic Division

1. Preganglionic cell bodies are in the lateral horns of the spinal cord gray matter from T1 to L2.
2. Preganglionic axons pass through the ventral roots to the white rami communicantes to the sympathetic chain ganglia. From there, four courses are possible:

Summary

- Preganglionic axons synapse (at the same or a different level) with postganglionic neurons, which exit the ganglia through the gray rami communicantes and enter spinal nerves.
- Preganglionic axons synapse (at the same or a different level) with postganglionic neurons, which exit the ganglia through sympathetic nerves.
- Preganglionic axons pass through the chain ganglia without synapsing to form splanchnic nerves. Preganglionic axons then synapse with postganglionic neurons in collateral ganglia.
- Preganglionic axons synapse with the cells of the adrenal medulla.

Parasympathetic Division

1. Preganglionic cell bodies are in nuclei in the brainstem or the lateral parts of the spinal cord gray matter from S2 to S4.
 - Preganglionic axons from the brain pass to ganglia through cranial nerves.
 - Preganglionic axons from the sacral region pass through the pelvic splanchnic nerves to the ganglia.
2. Preganglionic axons pass to terminal ganglia within the wall of or near the organ that is innervated.

Autonomic Nerve Plexuses and Distribution of Autonomic Nerve Fibers

1. Sympathetic axons reach organs through spinal nerves, head and neck nerve plexuses, thoracic nerve plexuses, and abdominopelvic nerve plexuses.
2. Parasympathetic axons reach organs through cranial nerves, thoracic nerve plexuses, abdominopelvic nerve plexuses, and pelvic splanchnic nerves.
3. Sensory neurons run alongside sympathetic and parasympathetic neurons within nerves and nerve plexuses.

Enteric Nervous System

1. The enteric nerve plexus is within the wall of the digestive tract.
2. The enteric plexus consists of sensory neurons, ANS motor neurons, and enteric neurons.

16.4 Physiology of the Autonomic Nervous System (p. 562)

Sympathetic Versus Parasympathetic Activity

1. Most organs are innervated by both the sympathetic and parasympathetic divisions.
2. Sympathetic activity generally prepares the body for physical activity, whereas parasympathetic activity is more important for resting functions.

Neurotransmitters

1. Acetylcholine is released by cholinergic neurons (all preganglionic neurons, all parasympathetic postganglionic neurons, and some sympathetic postganglionic neurons).
2. Norepinephrine is released by adrenergic neurons (most sympathetic postganglionic neurons).

Receptors

1. Acetylcholine binds to nicotinic receptors (found in all postganglionic neurons) and muscarinic receptors (found in all parasympathetic and some sympathetic effectors).

2. Norepinephrine and epinephrine bind to alpha and beta receptors (found in most sympathetic effectors).
3. Activation of nicotinic receptors is excitatory, whereas activation of muscarinic, alpha, or beta receptors is either excitatory or inhibitory.

16.5 Regulation of the Autonomic Nervous System (p. 568)

1. Autonomic reflexes control most of the activity of visceral organs, glands, and blood vessels.
2. Autonomic reflex activity can be influenced by the hypothalamus and higher brain centers.
3. The sympathetic and parasympathetic divisions can influence the activities of the enteric nervous system through autonomic reflexes. The enteric nervous system can function independently of the CNS through local reflexes.

16.6 Functional Generalizations About the Autonomic Nervous System (p. 570)

1. Both divisions of the ANS produce stimulatory and inhibitory effects.
2. Usually, each division produces an opposite effect on a given organ.
3. Either division alone or both working together can coordinate the activities of different structures.
4. The sympathetic division produces more generalized effects than the parasympathetic division.

REVIEW AND COMPREHENSION

1. Given these phrases:
 - (1) neuron cell bodies in the nuclei of cranial nerves
 - (2) neuron cell bodies in the lateral gray horn of the spinal cord (T1–L2 and S2–S4)
 - (3) two synapses between the CNS and effectors
 - (4) regulates smooth muscle
 Which of the phrases are true for the autonomic nervous system?
 - a. 1,3
 - b. 2,4
 - c. 1,2,3
 - d. 2,3,4
 - e. 1,2,3,4
2. Given these structures:
 - (1) collateral ganglion
 - (2) sympathetic chain ganglion
 - (3) white ramus communicans
 - (4) splanchnic nerve
 Choose the arrangement that lists the structures in the order an action potential travels through them on the way from a spinal nerve to an effector.
 - a. 1,3,2,4
 - b. 1,4,2,3
 - c. 3,1,4,2
 - d. 3,2,4,1
 - e. 4,3,1,2
3. The white ramus communicans contains
 - a. preganglionic sympathetic fibers.
 - b. postganglionic sympathetic fibers.
 - c. preganglionic parasympathetic fibers.
 - d. postganglionic parasympathetic fibers.
4. The cell bodies of the postganglionic neurons of the sympathetic division are located in the
 - a. sympathetic chain ganglia.
 - b. collateral ganglia.
 - c. terminal ganglia.
 - d. dorsal root ganglia.
 - e. Both a and b are correct.
5. Splanchnic nerves
 - a. are part of the parasympathetic division.
 - b. have preganglionic neurons that synapse in the collateral ganglia.
 - c. exit from the cervical region of the spinal cord.
 - d. travel from the spinal cord to the sympathetic chain ganglia.
 - e. All of these are correct.
6. Which of the following statements regarding the adrenal gland is true?
 - a. The parasympathetic division stimulates the adrenal gland to release acetylcholine.
 - b. The parasympathetic division stimulates the adrenal gland to release epinephrine.
 - c. The sympathetic division stimulates the adrenal gland to release acetylcholine.
 - d. The sympathetic division stimulates the adrenal gland to release epinephrine.
7. The parasympathetic division
 - a. is also called the craniosacral division.
 - b. has preganglionic axons in cranial nerves.
 - c. has preganglionic axons in pelvic splanchnic nerves.
 - d. has ganglia near or in the wall of effectors.
 - e. All of these are correct.
8. Which of these is *not* a part of the enteric nervous system?
 - a. ANS motor neurons
 - b. neurons located only in the digestive tract
 - c. sensory neurons
 - d. somatic motor neurons
9. Sympathetic axons reach organs through all of the following *except*
 - a. abdominopelvic nerve plexuses.
 - b. head and neck nerve plexuses.
 - c. thoracic nerve plexuses.
 - d. pelvic splanchnic nerves.
 - e. spinal nerves.

10. Which of these cranial nerves does *not* contain parasympathetic fibers?
 - a. oculomotor (III)
 - b. facial (VII)
 - c. glossopharyngeal (IX)
 - d. trigeminal (V)
 - e. vagus (X)
11. Which of these events is expected if the sympathetic division is activated?
 - a. Secretion of watery saliva increases.
 - b. Tear production increases.
 - c. Air passageways dilate.
 - d. Glucose release from the liver decreases.
 - e. All of these are correct.
12. Which of the following statements concerning the preganglionic neurons of the ANS is true?
 - a. All parasympathetic preganglionic neurons secrete acetylcholine.
 - b. Only parasympathetic preganglionic neurons secrete acetylcholine.
 - c. All sympathetic preganglionic neurons secrete norepinephrine.
 - d. Only sympathetic preganglionic neurons secrete norepinephrine.
13. When acetylcholine binds to nicotinic receptors,
 - a. the cell's response is mediated by G proteins.
 - b. the response can be excitatory or inhibitory.
 - c. Na⁺ channels open.
 - d. the binding occurs at the effectors.
 - e. All of these are correct.
14. Nicotinic receptors are located in
 - a. postganglionic neurons of the parasympathetic division.
 - b. postganglionic neurons of the sympathetic division.
 - c. membranes of skeletal muscle cells.
 - d. Both a and b are correct.
 - e. all of these sites.
15. The sympathetic division
 - a. is always stimulatory.
 - b. is always inhibitory.
 - c. is usually under conscious control.
 - d. generally opposes the actions of the parasympathetic division.
 - e. Both a and c are correct.
16. A sudden increase in blood pressure
 - a. initiates a sympathetic reflex that decreases heart rate.
 - b. initiates a local reflex that decreases heart rate.
 - c. initiates a parasympathetic reflex that decreases heart rate.
 - d. Both a and b are correct.
 - e. Both b and c are correct.
17. Which of these structures is innervated almost exclusively by the sympathetic division?
 - a. gastrointestinal tract
 - b. heart
 - c. urinary bladder
 - d. reproductive tract
 - e. blood vessels

Answers in appendix E

CRITICAL THINKING

1. When a person is startled or sees a “pleasurable” object, the pupils of the eyes may dilate. What division of the ANS is involved in this reaction? Describe the nerve pathway involved.
2. Reduced secretion from salivary and lacrimal glands can indicate damage to what nerve?
3. Patients with diabetes mellitus can develop autonomic neuropathy, which is damage to parts of the autonomic nerves. Given the following parts of the ANS—vagus nerve, oculomotor nerve, splanchnic nerve, pelvic splanchnic nerve, outflow of gray ramus—match the part with the symptom it would produce if the part were damaged:
 - a. impotence
 - b. subnormal sweat production
 - c. relaxed stomach muscles and delayed emptying of the stomach
 - d. diminished pupil reaction (constriction) to light
 - e. bladder paralysis with urinary retention
4. A patient has been exposed to the organophosphate pesticide malathion, which inactivates acetylcholinesterase. Which of the following symptoms would you predict: blurring of vision, excess tear formation, frequent or involuntary urination, pallor (pale skin), muscle twitching, or cramps? Would atropine be an effective drug to treat the symptoms?

(See Clinical Impact, “Influence of Drugs on the Autonomic Nervous System,” for the action of atropine.) Explain.

5. Epinephrine is routinely mixed with local anesthetic solutions. Why?
6. A drug blocks the sympathetic division's effect on the heart. Careful investigation reveals that, after administration of the drug, normal action potentials are produced in the sympathetic preganglionic and postganglionic neurons. Also, injection of norepinephrine produces a normal response in the heart. Explain, in as many ways as you can, the mode of action of the unknown drug.
7. A drug is known to decrease heart rate. After cutting the white rami of T1–T4, the drug still causes the heart rate to decline. After cutting the vagus nerves, the drug no longer affects heart rate. Which division of the ANS does the drug affect? Does the drug affect the synapse between preganglionic and postganglionic neurons, the synapse between postganglionic neurons and effectors, or the CNS? Is the drug's effect excitatory or inhibitory?
8. Make a list of the responses controlled by the ANS in (a) a person who is extremely angry and (b) a person who has just finished eating and is relaxing.

Answers in appendix F

Functional Organization of the Endocrine System

Time's up. Please hand in your exams." These words may cause anxiety in some students' minds. Their hearts start pounding, and they might even feel shaky and short of breath. Why? The culprit for these sensations is an "adrenaline rush." Adrenaline, or epinephrine, is one of hundreds of chemical messengers, called hormones, that circulate in the body. These chemical messengers have differences, but they all share the fundamental property of transmitting signals to target cells. This chapter focuses on one of the two major control systems in the body, the endocrine system. The other major control system is the nervous system. Here, we present the general principles of hormones; chapter 18 then discusses specific hormones and their functions.

Learn to Predict

Liu Dan was one of the top wrestlers on his high school team, but he knew that his small size would make it difficult to compete at the college level. He had tried lifting weights, but that did not seem to be working. So Liu decided to try something he had never thought he would do—he began taking anabolic steroids. At first he was excited, because his muscles were larger and he felt stronger. After a few more weeks, though, he started noticing some troublesome changes: His pectoral muscles were getting larger, but they looked more feminine than masculine; his testes had shrunk; and he'd had some frightening episodes that could only be described as temper tantrums. **After reading this chapter, explain why anabolic steroids were able to alter muscle tissue growth and cause unintended changes in other tissues of the body.**

17.1 Principles of Chemical Communication

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the four classes of chemical messengers.
- B. Define *hormone* and *target tissue*.
- C. Distinguish between endocrine and exocrine glands.
- D. Compare and contrast the nervous system with the endocrine system.

Classes of Chemical Messengers

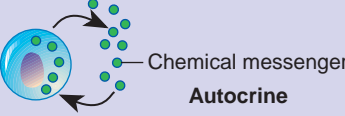

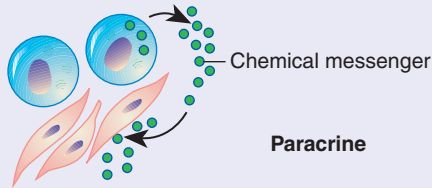

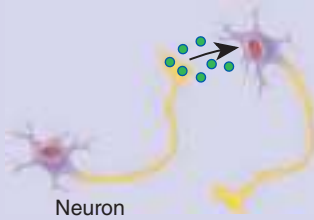

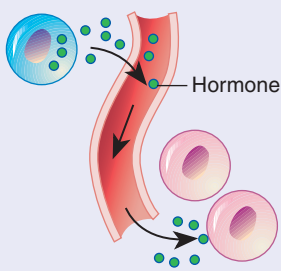

The body has a remarkable capacity for maintaining homeostasis despite having to coordinate the activities of over 75 trillion cells. Chemical messengers from both the nervous system and the endocrine system are the primary regulators of this coordination.

Chemical messengers allow cells to communicate with each other to regulate body activities.

Most chemical messengers are produced by a specific collection of cells or by a gland. Recall from chapter 4 that a gland is an organ consisting of epithelial cells. These cells specialize in **secretion**—the controlled release of chemicals from a cell. This text identifies four classes of chemical messengers based on the source of the chemical messenger and its mode of transport in the body (table 17.1). In this section, we describe chemical messengers in terms of how they function. But it is important to note that some chemical messengers fall into more than one functional category. For example, the chemicals called prostaglandins are listed in multiple categories because they have several functions and cannot be restricted to just one class. Therefore, the study of the endocrine system includes several of the following categories:

1. *Autocrine chemical messengers*. An autocrine (*auto-*, self) chemical messenger stimulates the cell that originally secreted it. Good examples of autocrine chemical messengers are those secreted by white blood cells during an infection. Several types of white blood cells can stimulate their own replication, so that

TABLE 17.1 Classes of Chemical Messengers

Chemical Messenger	Description	Example	
Autocrine	Secreted by cells in a local area; influences the activity of the same cell from which it was secreted	Eicosanoids (prostaglandins, thromboxanes, prostacyclins, leukotrienes)	 <p>Chemical messenger Autocrine</p>
Paracrine	Produced by a wide variety of tissues and secreted into extracellular fluid; has a localized effect on nearby tissues	Somatostatin, histamine, eicosanoids	 <p>Chemical messenger Paracrine</p>
Neurotransmitter	Produced by neurons; secreted into a synaptic cleft by presynaptic nerve terminals; travels short distances; influences postsynaptic cells	Acetylcholine, epinephrine	 <p>Neuron Neurotransmitter</p>
Endocrine	Secreted into the blood by specialized cells; travels some distance to target tissues; results in coordinated regulation of cell function	Thyroid hormones, growth hormone, insulin, epinephrine, estrogen, progesterone, testosterone, prostaglandins	 <p>Hormone Endocrine</p>

the total number of white blood cells increases rapidly (see chapter 22).

2. **Paracrine chemical messengers.** Paracrine chemical messengers act locally on neighboring cells. These chemical messengers are secreted by one cell type into the extracellular fluid and affect surrounding cells. An example of a paracrine chemical messenger is histamine, released by certain white blood cells during allergic reactions. Histamine stimulates vasodilation in nearby blood vessels.
3. **Neurotransmitters.** Neurotransmitters are chemical messengers secreted by neurons that activate an adjacent cell, whether it is another neuron, a muscle cell, or a glandular cell. Neurotransmitters are secreted into a synaptic cleft, rather than into the bloodstream (see chapter 11). Therefore, in the strictest sense neurotransmitters are paracrine agents, but for our purposes it is most appropriate to consider them as a separate category.
4. **Endocrine chemical messengers.** Endocrine chemical messengers are secreted into the bloodstream by certain glands and cells, which together make up the endocrine system. These chemical messengers travel through the general circulation to their target cells.

Characteristics of the Endocrine System

The **endocrine system** is composed of **endocrine glands** and specialized endocrine cells located throughout the body (figure 17.1). Endocrine glands secrete very small amounts of chemical messengers called **hormones** (hor'mōnz) into the bloodstream, rather than into a duct. Hormones circulate through the bloodstream to specific sites called **target tissues**, or *effectors*. At their target tissues, hormones stimulate a specific response. Thus, the term **endocrine**

FIGURE 17.1 Major Endocrine Glands and Tissues **APR**

(en'dō-krin), derived from the Greek words *endo*, meaning “within,” and *krino*, “to secrete,” appropriately describes this system.

Endocrine glands are not to be confused with **exocrine glands**. Exocrine glands have ducts that carry their secretions to the outside of the body, or into a hollow organ, such as the stomach or intestines. Examples of exocrine secretions are saliva, sweat, breast milk, and digestive enzymes.

The study of the endocrine system, known as **endocrinology**, is the topic of this chapter as well as chapter 18. In this chapter, we present the general principles of hormones and, in chapter 18, we discuss specific hormones and their functions. Hormones have a role in most physiological processes in the body. However, the endocrine system does not work completely alone for every process it regulates. It works in conjunction with the body's other major regulatory system, the nervous system. Thus, before focusing on the endocrine system, it is important to understand its relationship to the nervous system.

Comparison of the Nervous and Endocrine Systems

Together, the nervous system and the endocrine system regulate and coordinate the activities of essentially all body structures to achieve and maintain homeostasis. As you learned in chapter 11, the nervous system is a communication system. It transmits messages directly to its target cells through action potentials, which stimulate neurotransmitter release at synapses. Thus, the nervous system operates similarly to how you send a text to one or more people. In contrast, the endocrine system works more like Twitter. Your tweets are broadcast, so anyone can see them, but only those following you actually get them. But, instead of tweets, the endocrine system broadcasts information to the whole body through hormones circulating in the bloodstream. Cells with receptors for those hormones respond to them, whereas cells lacking receptors do not.

Given that both the nervous system and the endocrine system control their targets with chemical messengers, what is the difference between the two systems? In fact, it is difficult to completely separate the two systems because they have many similarities:

1. Both systems use structures in the brain. In chapter 13, the hypothalamus is discussed as a critical area of the brain responsible for many functions, including nervous system functions and hormone production. An example of nervous function is when the hypothalamus detects changes in body temperature; it sends action potentials to either the sweat glands or skeletal muscle, depending on whether the body is too hot or too cold. On the other hand, an example of endocrine function is when the hypothalamus sends hormones to the pituitary gland that regulate the secretion of hormones from the pituitary. In addition, hypothalamic neurons synthesize two hormones, antidiuretic hormone and oxytocin, which are secreted directly into the bloodstream. Thus, the hypothalamus plays a role in both the nervous and endocrine systems.
2. In many cases, the nervous system may use certain molecules as neurotransmitters, whereas the endocrine system may use these molecules as hormones. For example, when a neuron secretes epinephrine into a synaptic cleft, it is a neurotransmitter.

In contrast, when cells of the adrenal gland secrete epinephrine into the bloodstream, it is a hormone.

- The two systems work together to regulate critical body processes. For example, the introduction to this chapter pointed out that epinephrine, the hormone, is important in stressful situations. However, the initial, immediate release of epinephrine, the neurotransmitter, in times of crisis is from the nervous system. Thus, the two systems work almost simultaneously.
- Some neurons secrete hormones. In this case, the neuron's chemical messenger enters the bloodstream, where it functions as a hormone. As a strict part of their definition, recall that hormones circulate in the bloodstream. To help distinguish these chemical messengers from neurotransmitters and other hormones, they are often called **neuropeptides**, or **neurohormones**. An example of a neuropeptide is the labor-inducing hormone oxytocin.
- Both neurotransmitters and hormones can affect their targets through receptors linked to G proteins (see chapter 3).

In addition to the similarities between the nervous and endocrine systems, there are some important differences:

- Mode of transport.** The endocrine system secretes hormones, which are transported in the bloodstream, whereas the nervous system secretes neurotransmitters, which are released directly onto their target cells.
- Speed of response.** In general, the nervous system responds faster than the endocrine system. However, it is not accurate to say the endocrine system responds slowly; rather, it responds *more slowly* than the nervous system. Neurotransmitters, such as acetylcholine, are delivered to their target cells in milliseconds, whereas some hormones are delivered to their target cells in seconds.
- Duration of response.** The nervous system typically activates its targets quickly and only for as long as action potentials

are sent to the target. The target cells' response is terminated shortly after action potentials cease. In contrast, the endocrine system tends to have longer-lasting effects. Hormones remain in the bloodstream for minutes, days, or even weeks and activate their target tissues as long as they are present in the circulation. The target tissue products may remain active for a substantial length of time.

In summary, the hormones secreted by most endocrine glands can be described as **amplitude-modulated signals**. The term *amplitude* refers to the total amount of a signal that is produced. This type of signal consists of fluctuations in the *concentration* of hormones in the bloodstream (figure 17.2), over a period of time. This time period can range from minutes to hours. On the other hand, the all-or-none action potentials carried along axons can be described as **frequency-modulated signals**. The term *frequency* refers to how often a signal is sent in a certain period of time (figure 17.2). These types of signals vary in the number of signals sent but not in the amount of signal sent. A low frequency of action potentials is a weak stimulus, whereas a high frequency of action potentials is a strong stimulus. Thus, both the nervous system and the endocrine system work to maintain homeostasis using chemical messengers, but they differ from each other in the way their chemical messengers work to activate their target cells.

ASSESS YOUR PROGRESS

- Name and describe the four classes of chemical messengers.
- How does an endocrine gland differ from an exocrine gland?
- Describe the similarities between the nervous system and the endocrine system.
- In what ways does the nervous system differ from the endocrine system?

Amplitude-modulated system. The concentration of the hormone determines the strength of the signal and the magnitude of the response. For most hormones, a small concentration of a hormone is a weak signal and produces a small response, whereas a larger concentration is a stronger signal and results in a greater response.

Frequency-modulated system. The strength of the signal depends on the frequency, not the size, of the action potentials. All action potentials are the same size in a given tissue. A low frequency of action potentials is a weak stimulus, and a higher frequency is a stronger stimulus.

FIGURE 17.2 Regulatory Systems

17.2 Hormones

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the common characteristics of all hormones.**
- B. Define *binding protein*, *bound hormone*, and *free hormone* and discuss the effect of binding proteins on circulating hormone levels.**
- C. List and describe the two chemical categories of hormones.**
- D. Explain the influence of the chemical nature of a hormone on its transport in the blood, its removal from circulation, and its life span.**
- E. Describe the three main patterns of hormone secretion.**

The word *hormone* is derived from the Greek word *hormon*, which means “set into motion.” Hormones are very powerful molecules, which all share general characteristics.

General Characteristics of Hormones

Hormones share several characteristics:

1. *Stability.* For hormones to activate their targets continuously, they must remain active in the circulation long enough to arrive at their target cells. This means that hormone concentrations remain stable in the bloodstream; however, some hormones are more stable than others. The life span of a given hormone varies with its chemical nature. Larger, more complex hormones are more stable, whereas smaller, simpler hormones are less stable. A hormone’s life span can be expressed as its **half-life**, which is the amount of time it takes for 50% of the circulating hormone to be removed from the circulation and excreted. Some hormones have a short half-life, whereas others have a much longer half-life. For example, thyrotropin-releasing hormone (TRH) is a three-amino-acid hormone with a short half-life. Because of TRH’s simple composition, it is quickly degraded in the circulation and can activate only the target cells it can reach within 2 minutes of being secreted. On the other hand, cortisol is a steroid hormone with a longer half-life, 90 minutes. Due to its lipid-soluble nature, it is not easily degraded and can activate target cells for more than an hour.
2. *Communication.* Hormones must be able to interact with their target tissue in a specific manner in order to activate a coordinated set of events. For example, the formation of reproductive organs in the fetus is activated by reproductive steroid hormones. Without proper functioning of the male reproductive steroid testosterone, a newborn will have the outward appearance of a female despite being genetically male. Hormones must be able to regulate specific cellular pathways once they arrive at their targets and bind to their receptors.
3. *Distribution.* Hormones are transported by the blood to many locations and therefore have the potential to activate any cell in the body, including those far away from where they were produced. However, the blood contains many hydrolytic

enzymes, which break down substances, and is an aqueous solution. These factors can present a challenge when transporting hormones to their targets. Small, water-soluble hormones are quickly digested by hydrolytic enzymes in the blood, because, with their small size, they become inactive with very little alteration in their structure. In addition, they are easily filtered from the blood in the kidneys because they are so small. Still other hormones, such as lipid-soluble hormones, have low solubility in the blood plasma. Their chemical nature does not allow them to easily dissolve in the plasma. Thus, some hormones require a chaperone, which binds to and protects hormones so that they arrive safely at their target. Hormones requiring a transport chaperone bind to blood proteins called **binding proteins**. Once hormones attach to a binding protein, they are then called **bound hormones**. For small hormones, the binding protein protects them from degradation by hydrolytic enzymes and from being filtered from the blood in the kidney. For lipid-soluble hormones that are insoluble in plasma, being bound to a binding protein causes them to become more water-soluble. Hormones bind only to selective binding proteins. For example, thyroid hormones bind to a specific binding protein, transthyretin; testosterone binds to a different type of binding protein, called testosterone-binding globulin; and progesterone binds to yet another type of binding protein, called progesterone-binding globulin.

The binding of hormones to binding proteins is reversible. Hormones dissociate (detach) from their binding proteins at their target tissues. Once the hormones detach from the binding protein, they are then called **free hormones**. It is important to note that some hormones always exist as free hormones because they do not have specific binding proteins to which they attach. Thus, some hormones are “always free,” whereas other hormones are “sometimes free.” The binding protein’s affinity for its hormone determines the concentration of free hormones.

The reversible binding of hormones to their binding proteins is important because only free hormones are able to diffuse through capillary walls and bind to target tissues. When bound to a binding protein, a hormone is too large to pass through a capillary wall. The bound hormone thus serves as a reservoir for the hormone. If blood levels of the hormone begin to decline, some of the bound hormone is released from the binding proteins. Because of this reservoir function of the bound hormones, the circulating concentration of free hormones remains more stable than that of hormones that do not use binding proteins (figure 17.3). Consequently, hormones that attach to binding proteins tend to have longer half-lives than hormones that do not require binding proteins (figure 17.3).

Chemical Nature of Hormones

Hormones fit into two chemical categories: lipid-soluble hormones and water-soluble hormones, a distinction based on their chemical behavior. For example, recall from chapter 3 that the plasma membrane is a selectively permeable phospholipid bilayer that excludes water-soluble molecules but allows lipid-soluble molecules to pass through. Therefore, the entire basis of a hormone’s interaction with its target is dependent on the hormone’s chemical nature (table 17.2).

FIGURE 17.3 Effect of Binding Proteins

(a) Free hormones (those that circulate freely in the blood) immediately activate target cells once they are delivered from the blood. Thus, the blood levels of these hormones tend to fluctuate to a greater degree than the levels of hormones that attach to binding proteins; water-soluble hormones bind their receptors, which are membrane bound. (b) Hormones that are transported in the blood attached to binding proteins circulate in the blood as bound or free hormones. As the concentration of free hormones decreases, bound hormones are released from the binding proteins. This provides a chronic, stable supply of hormone and, thus, more consistent control of target cells. This is especially important for hormones that regulate basal metabolism. Lipid-soluble hormones bind their receptors in either the cytoplasm or the nucleus.

Within the two chemical categories, hormones can be subdivided into groups based on their chemical structures. Most hormones are categorized as amino acid derivatives, peptides, or proteins, including glycoproteins. However, there are two exceptions. Steroid hormones are derived from cholesterol, and thyroid hormones are derived from the amino acid tyrosine. Thyroid hormones are more like steroids in their chemical nature.

Lipid-Soluble Hormones

Lipid-soluble hormones are nonpolar and include steroid hormones, thyroid hormones, and fatty acid derivative hormones, such as certain eicosanoids.

Transport of Lipid-Soluble Hormones

Because of their small size and low solubility in aqueous fluids, lipid-soluble hormones travel in the bloodstream bound to binding proteins, proteins that chaperone the hormone. As a result, the rate at which lipid-soluble hormones are degraded or eliminated from the circulation is greatly reduced and their life spans range from a few days to as long as weeks.

Without the binding proteins, the lipid-soluble hormones would quickly diffuse out of capillaries and be degraded by

enzymes of the liver and lungs or be filtered from the blood by the kidneys. Circulating hydrolytic enzymes can also metabolize free lipid-soluble hormones. The breakdown products are then excreted in the urine or the bile.

Additionally, lipid-soluble hormones are removed from the circulation when specific enzymes in the liver attach water-soluble molecules to the hormones, a process called **conjugation** (kon-jŭ-gā'shŭn). These conjugation molecules are usually sulfate or glucuronic acid. Once the hormones are conjugated, the kidneys and liver excrete them into the urine and bile at a greater rate.

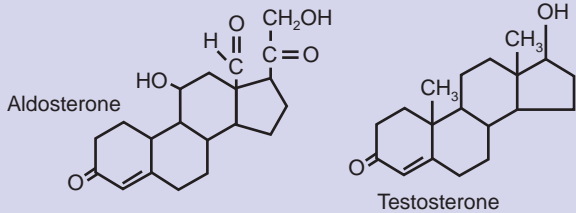

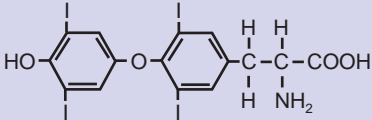

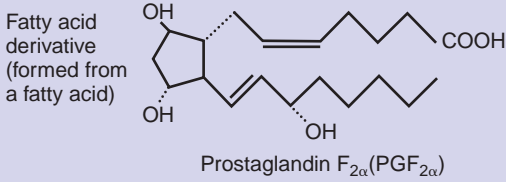

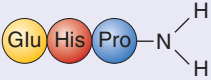

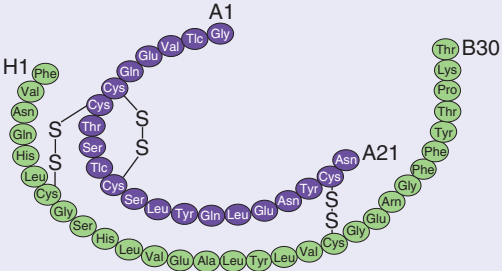

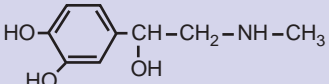

Water-Soluble Hormones

Water-soluble hormones are polar molecules; they include protein hormones, peptide hormones, and most amino acid derivative hormones.

Transport of Water-Soluble Hormones

Because water-soluble hormones can dissolve in the plasma of the blood, many circulate as free hormones, meaning that most of them dissolve directly into the plasma and are delivered to their target tissue without binding to a binding protein. Because many

TABLE 17.2 Chemical Nature of Hormones

Chemical Nature	Examples	Structures
Lipid-Soluble Hormones	Steroids (all cholesterol-based) Testosterone, aldosterone	 <p>Aldosterone</p> <p>Testosterone</p>
	Amino acid derivative (only one example of lipid-soluble) Thyroid hormone (thyroxine)	 <p>Tetraiodothyronine or thyroxine (T₄)</p>
	Fatty acid derivatives Prostaglandins	 <p>Fatty acid derivative (formed from a fatty acid)</p> <p>Prostaglandin F_{2α} (PGF_{2α})</p>
Water-Soluble Hormones	Proteins Thyroid-stimulating hormone, growth hormone	 <p>Thyroid-stimulating hormone (a glycoprotein)</p> <p>Growth hormone</p>
	Peptides Insulin, thyrotropin-releasing hormone	 <p>Thyrotropin releasing hormone</p>
		 <p>Insulin</p>
Amino Acid Derivatives Epinephrine		 <p>Epinephrine</p>

water-soluble hormones are quite large, they do not readily diffuse through the walls of all capillaries. Instead, they tend to diffuse from the blood into tissue spaces more slowly. Thus, capillaries of organs that are regulated by protein hormones tend to be very porous, or *fenestrated* (see chapter 21). On the other hand, other water-soluble hormones are quite small and require attachment to a larger protein, a binding protein, to avoid being filtered out of the blood.

All hormones are destroyed either in the circulation or at their target cells. The destruction and elimination of hormones limit the length of time they are active, and body processes change quickly when hormones are secreted and remain functional for only short periods.

The water-soluble hormones have relatively short half-lives because they are rapidly broken down by hydrolytic enzymes, called proteases, within the bloodstream. The kidneys then remove the hormone breakdown products from the blood. Target cells also destroy water-soluble hormones when the hormones are internalized via endocytosis. Once the hormones are inside the target cell, lysosomal enzymes degrade them. Often, the target cell recycles the amino acids of peptide and protein hormones and uses them to synthesize new proteins. Thus, hormones with short half-lives normally have concentrations that change rapidly within the blood and tend to regulate activities that have a rapid onset and short duration.

However, some water-soluble hormones are more stable in the circulation than others. In many instances, protein and peptide hormones are made more stable by having a carbohydrate attached to them and are then called glycoproteins. Other hormones are made more stable by having a modified terminal end. These modifications protect them from protease activity to a greater extent than water-soluble hormones lacking such modifications (table 17.2). In addition, some water-soluble hormones attach to binding proteins and therefore circulate in the plasma longer than free water-soluble hormones do.

Patterns of Hormone Secretion

As a result of the variation in transport and removal of lipid-soluble hormones and water-soluble hormones, the blood levels of hormones differ. In addition, blood levels of hormones are further determined by the overall pattern of secretion. The three main patterns of hormone secretion are chronic, acute, and episodic (figure 17.4):

- **Chronic hormone secretion** results in relatively constant blood levels of hormone over long periods of time. This type of secretion is exemplified by thyroid hormones, which circulate in the blood within a small range of concentrations. Recall that thyroid hormones are lipid-soluble and thus bind to binding proteins, which also helps maintain them at chronic levels.
- **Acute hormone secretion** occurs when the hormone's concentration changes suddenly and irregularly, and its circulating levels differ with each stimulus. This secretion pattern is represented by the amino acid derivative epinephrine, which is released in large amounts in response to stress or physical exercise. In addition, because epinephrine is small and usually circulates as a free hormone, it has a short half-life, which contributes to the fact that blood levels of epinephrine drop significantly within a few minutes of its secretion.

(a) **Chronic hormone secretion.** A relatively stable concentration of hormone is maintained in the circulating blood over a fairly long period, up to several weeks. This pattern is exemplified by the thyroid hormones.

(b) **Acute hormone secretion.** A hormone rapidly increases in the blood for a short time in response to a specific stimulus—for example, insulin (the blood sugar-regulating hormone) secretion following a meal. Note that the size of the stimulus arrow represents the stimulus strength. A smaller stimulus does not activate as much hormone secretion as a larger stimulus.

(c) **Episodic hormone secretion.** A hormone is stimulated so that it increases and decreases in the blood at a relatively consistent time and to roughly the same amount. Examples are the reproductive hormones regulating menstruation.

FIGURE 17.4 Patterns of Hormone Secretion

The overall pattern of hormone secretion is a result of the secretion, transport, and removal of the hormones, which is further dependent on the chemical nature of the hormones.

- **Episodic hormone secretion** occurs when hormones are secreted at fairly predictable intervals and concentrations. This pattern is often observed in steroid reproductive hormones, which fluctuate over a month in cyclic fashion during the human reproductive years. Additionally, because steroid hormones also often have binding proteins, they have longer half-lives than other hormones, which contributes to their relative stability in the circulation.

In general, lipid-soluble hormones exhibit the two regular secretion patterns (chronic and episodic), whereas because of their short half-life, water-soluble hormones tend to exhibit the irregular (acute) secretion pattern, but there are a few exceptions. For instance, some protein reproductive hormones exhibit episodic secretion.

ASSESS YOUR PROGRESS

5. What are the three general characteristics of hormones?
6. Explain how the half-life of a hormone relates to its stability.
7. Why do some hormones require a binding protein during transport in the blood?
8. What effect does a bound hormone have on the concentration of a free hormone in the blood?
9. What are the two chemical categories of hormones? Give examples of both types.
10. Describe how the chemical nature of a hormone affects its transport in the blood, its removal from circulation, and its half-life.
11. What happens to the half-life when a hormone binds to a binding protein? What kinds of hormones bind to binding proteins?
12. Why do organs regulated by protein hormones have fenestrated capillaries?

FIGURE 17.5 Humoral Regulation of Hormone Secretion

13. What kinds of activities are regulated by hormones with a short half-life? With a long half-life?
14. Describe chronic, acute, and episodic patterns of hormone secretion.

17.3 Control of Hormone Secretion

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List and describe the three stimulatory influences on hormone secretion and give examples of each.
- B. List and describe the three inhibitory influences on hormone secretion and give examples of each.
- C. Describe the major mechanisms that maintain blood hormone levels.

Three types of stimuli regulate hormone release: humoral, neural, and hormonal. No matter what stimulus releases the hormone, however, the blood level of most hormones fluctuates within a homeostatic range through negative-feedback mechanisms (see chapter 1). In a few instances, positive-feedback systems also regulate blood hormone levels.

Stimulation of Hormone Release

Control by Humoral Stimuli

Metabolites and other molecules in the bloodstream can directly stimulate the release of some hormones. These molecules are referred to as **humoral stimuli** because they circulate in the blood, and the word *humoral* refers to body fluids, including blood. The cells that secrete these hormones have receptors for certain substances in the blood. For example, glucose, Ca^{2+} , and Na^+ can stimulate hormone secretion. When the blood level of the particular substance changes, the hormone is released in response to the molecule's concentration (figure 17.5). For instance, if a runner has just finished a long race during hot weather, he may not produce urine for up to 12 hours after the race because his elevated concentration of blood solutes stimulates the release of a water-conservation hormone called antidiuretic hormone (ADH). Similarly, elevated blood glucose levels directly stimulate insulin secretion by the pancreas, and elevated blood potassium levels directly stimulate aldosterone release by the adrenal cortex.

Control by Neural Stimuli

The second type of hormone regulation involves **neural stimuli** of endocrine glands. Following action potentials, neurons release a neurotransmitter into a synapse with hormone-producing cells. In these cases, the neurotransmitter stimulates the cells to secrete their hormone.

PROCESS FIGURE 17.6 Control of Hormone Secretion by Direct Neural Innervation

Figure 17.6 illustrates the neural control of hormone secretion from cells of an endocrine gland. For example, in response to stimuli, such as stress or exercise, neurons of the sympathetic division of the autonomic nervous system (see chapter 16) stimulate the adrenal gland to secrete epinephrine and norepinephrine into the bloodstream. Responses include an elevated heart rate and increased blood flow through the exercising muscles. When the stimulus is no longer present, the neural stimulation declines, and the secretion of epinephrine and norepinephrine decreases.

Some neurons secrete chemical messengers directly into the blood when they are stimulated, making these chemical messengers hormones. These hormones are **neuropeptides**. Some neuropeptides stimulate hormone secretion from other endocrine cells and are called **releasing hormones**, a term usually reserved for hormones from the hypothalamus.

Control by Hormonal Stimuli

The third type of regulation uses **hormonal stimuli**. It occurs when hormones stimulate the secretion of other hormones (figure 17.7). The most common examples are hormones from the anterior pituitary gland, called **tropic** (trō'pik) **hormones**. Many tropic hormones are part of a complex process in which a releasing hormone from the hypothalamus stimulates the release of a tropic hormone from the pituitary gland. The pituitary tropic hormone then travels

- 1 Neurons in the hypothalamus release stimulatory hormones, called releasing hormones. Releasing hormones travel in the blood to the anterior pituitary gland.
- 2 Releasing hormones stimulate the release of tropic hormones from the anterior pituitary, which travel in the blood to their target endocrine cell.
- 3 The target endocrine cell secretes its hormone into the blood, where it travels to its target and produces a response.
- 4 The hormone from the target endocrine cell also inhibits the hypothalamus and anterior pituitary from secreting the releasing hormone and the tropic hormone. This is negative feedback.
- 5 In some instances, the hypothalamus can also secrete inhibiting hormones, which prevent the secretion of anterior pituitary tropic hormones.

PROCESS FIGURE 17.7 Hormonal Regulation of Hormone Secretion

to a third endocrine gland and stimulates the release of a third hormone (figure 17.7). For example, hormones from the hypothalamus and anterior pituitary regulate the secretion of thyroid hormones from the thyroid gland.

Inhibition of Hormone Release

Stimulating hormone secretion is important, but so is inhibiting hormone release. This process involves the same three types of stimuli: humoral, neural, and hormonal.

Inhibition of Hormone Release by Humoral Stimuli

Often when a hormone's release is triggered by a particular humoral stimulus, there exists a companion hormone whose release is inhibited by the same humoral stimulus. Usually, the companion hormone's effects oppose those of the secreted hormone and counteract the secreted hormone's action. For example, to raise blood pressure (as influenced by low blood Na^+ levels),

the adrenal cortex secretes the hormone aldosterone in response to low blood pressure. However, if blood pressure goes up (as influenced by high blood Na^+ levels), the atria of the heart secrete the hormone atrial natriuretic peptide (ANP), which lowers blood pressure. Therefore, aldosterone and ANP work together to maintain homeostasis of blood pressure.

Inhibition of Hormone Release by Neural Stimuli

Neurons inhibit targets just as often as they stimulate targets. If the neurotransmitter is inhibitory, the target endocrine gland does not secrete its hormone (figure 17.6).

Inhibition of Hormone Release by Hormonal Stimuli

Some hormones prevent the secretion of other hormones, which is a common mode of hormone regulation. For example, hormones, called **inhibiting hormones**, from the hypothalamus prevent the secretion of tropic hormones from the pituitary gland (figure 17.7, step 5). Another example is that thyroid hormones can control their own blood levels by inhibiting their pituitary tropic hormone. Without the original stimulus, less thyroid hormone is released.

Regulation of Hormone Levels in the Blood

Two major mechanisms maintain hormone levels in the blood within a homeostatic range: negative feedback and positive feedback (see chapter 1).

1. *Negative feedback.* Most hormones are regulated by a negative-feedback mechanism, whereby the hormone's secretion is inhibited by the hormone itself once blood levels have reached a certain point and there is adequate hormone to activate the target cell. The hormone may inhibit the action of other, stimulatory hormones to prevent the secretion of the hormone in question. Thus, it is a self-limiting system (figure 17.8a). For example, thyroid hormones inhibit the secretion of TRH from the hypothalamus and TSH from the anterior pituitary.
2. *Positive feedback.* Some hormones, when stimulated by a tropic hormone, promote the further synthesis and secretion of the tropic hormone in addition to stimulating their target cell. In turn, this stimulates even more secretion of the original hormone. Thus, it is a self-propagating system (figure 17.8b). For example, prolonged estrogen stimulation promotes a release of luteinizing hormone.

ASSESS YOUR PROGRESS

15. Describe and give examples of the three major ways hormone secretion is stimulated and inhibited.
16. Is hormone secretion generally regulated by negative-feedback or positive-feedback mechanisms?

PROCESS FIGURE 17.8 Negative and Positive Feedback

Case STUDY

Negative Feedback and Hypothyroidism

Josie owns a business and works hard to manage her employees and make time for her family. Over several months, she frequently felt weak, was often unable to concentrate, and felt cold when others did not. In addition, she began to gain weight, even though she had a small appetite. Finally, after noticing a large lump in her neck inferior and lateral to her larynx, Josie decided to see her physician. A blood sample was taken, and the results indicated low levels of thyroid hormones (hypothyroidism; see chapter 18), high levels of TSH, and low levels of iodine.

The doctor concluded that Josie had developed a goiter, or an enlarged thyroid gland. He explained that the goiter had probably formed because her dietary intake of iodine was too low over a prolonged time. Without iodine, Josie's thyroid gland was unable to synthesize thyroid hormones. Thus, in response to low thyroid hormone levels, the anterior pituitary gland continued to secrete the tropic hormone TSH, which caused the thyroid gland to keep getting bigger and bigger. In addition, the hypothalamus continued to stimulate the anterior pituitary in the absence of thyroid hormones.

Josie was treated with radioactive iodine (^{131}I) atoms, which were actively transported into her thyroid cells, where the radiation helped shrink her thyroid gland back to normal size. Subsequently, Josie had to take dietary iodine supplements and thyroid hormone supplements until her thyroid gland was able to produce thyroid hormones on its own again.

► Predict 2

- Name and explain the mechanism controlling TSH in Josie's blood. Why were TSH levels high and the levels of thyroid hormones low prior to treatment?
- Explain why the doctor could tell that Josie's condition was not the result of a tumor in the thyroid gland.
- What role did a lack of iodine play in Josie's condition?
- After treatment with iodine, predict how Josie's blood levels of thyroid hormones, as well as TSH, changed.
- Explain why Josie had to take thyroid hormone supplements. Will Josie have to do this for the rest of her life?

17.4 Hormone Receptors and Mechanisms of Action

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the general properties of a receptor and how a target cell may decrease or increase its sensitivity to a hormone.
- Explain the mechanisms of action for the two types of receptor classes.
- Define **amplification** and explain how, despite small hormone concentrations, water-soluble hormones can cause rapid responses.

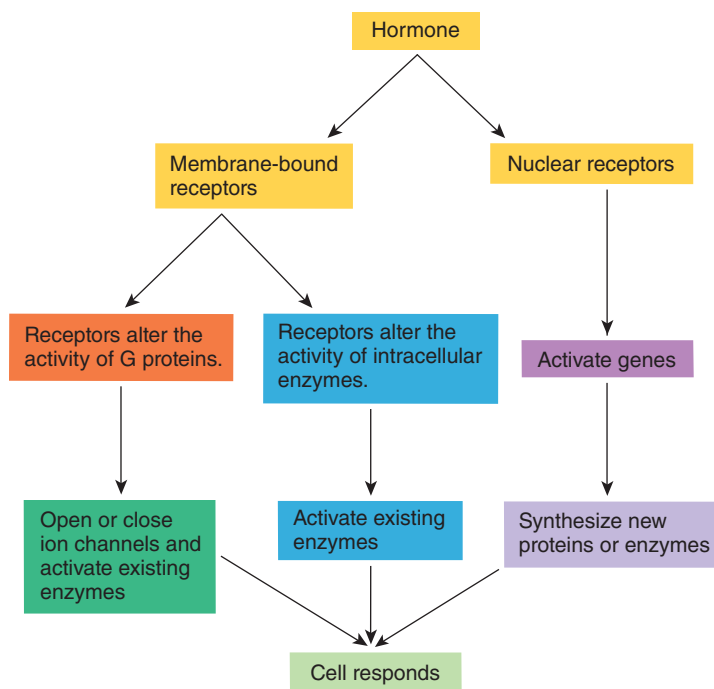

FIGURE 17.9 Overview of Responses to Hormones Binding to Their Receptors

Hormones exert their actions by binding to target cell proteins called **receptors** (figure 17.9). A hormone can stimulate only the cells that have the receptor for that hormone. The specific portion of each receptor molecule where a hormone binds is called a **receptor site**, and the shape and chemical characteristics of each receptor site allow only a specific type of hormone to bind to it. The tendency for each type of hormone to bind to one type of receptor, and not to others, is called **specificity** (figure 17.10). For example, insulin binds to insulin receptors, but not to receptors for thyroid hormones. However, some hormones, such as epinephrine, can bind to a “family” of receptors that are structurally similar. Because hormone receptors have a high affinity for the hormones that bind to them, they are very sensitive to low levels of the hormone. Thus, only a small concentration of a given hormone is needed to activate a significant number of its receptors.

Agonists and Antagonists

Drugs with structures similar to those of specific hormones may compete with those hormones for their receptors (see chapter 3). A drug that binds to a hormone receptor and activates it is called an agonist. A drug that binds to a hormone receptor and inhibits its action is called an antagonist. For example, certain drugs mimic epinephrine and can bind to its receptors. Some of these drugs, called epinephrine agonists, activate epinephrine receptors. In fact, the drugs in asthma inhalers often work by mimicking epinephrine and causing the smooth muscle in lung bronchioles to relax. In contrast, some antistroke medications are epinephrine

FIGURE 17.10 Target Tissue Specificity and Response

Hormones bind (physically attach) to receptor proteins. The shape and chemical nature of each receptor site allow only certain hormones to bind. This relationship is called specificity. Additionally, in order for a target cell to respond to its hormone, the hormone must bind to its receptor.

antagonists that prevent epinephrine-stimulated platelet aggregation and thus prevent the blockage of blood vessels.

Decrease in Receptor Number

Target tissues' sensitivity to hormone levels can change, for various reasons. Changing the receptor number at a target ensures an optimal target tissue response to a hormone. For example, the response of some target tissues rapidly decreases over time through desensitization. This happens because the cells' nutrient and energy supplies become depleted, causing the cells to lose the ability to respond to the hormone. Desensitization occurs when the number of receptors rapidly decreases after exposure to certain hormones, a phenomenon called **down-regulation** (figure 17.11a). Because most receptor molecules are degraded over time, a decrease in their synthesis rate reduces the total number of receptor molecules in a cell. Often, the target cells internalize the receptors and destroy them. For example, experimental exposure of anterior pituitary cells to the reproductive hormone gonadotropin-releasing hormone (GnRH) causes the number of receptor molecules for GnRH in the pituitary gland cells to decrease dramatically several hours after exposure to the hormone. This down-regulation causes the pituitary gland to become less sensitive to additional GnRH. Therefore, to ensure that the GnRH receptors are not down-regulated and that the pituitary gland remains responsive, the hypothalamus releases brief pulses of GnRH approximately once each hour. In this way, the reproductive system stays active and is less likely to stop working. From an organismal standpoint, because reproduction is one of the body's most protected functions, very tight regulation is necessary.

Increase in Receptor Number

In addition to down-regulation, a target tissue can also periodically increase sensitivity through up-regulation. **Up-regulation** results in an increase in the rate of receptor synthesis in the target cells, which increases the total number of receptor molecules in a cell (figure 17.11b). An example of up-regulation is a process that occurs to stimulate ovulation of the oocyte. During each menstrual cycle, there are an increased number of receptors for luteinizing hormone (LH) in ovary cells. Follicle-stimulating hormone (FSH) secreted by the pituitary gland increases the rate of LH receptor synthesis in ovary cells. This is important because a surge in LH will cause release of the oocyte. Thus, a tissue's exposure to one hormone can increase its sensitivity to a second hormone by causing the up-regulation of hormone receptors. This type of multilevel manipulation allows hormone levels to be very precisely controlled and enables the timing of certain processes to be tightly regulated.

Predict 3

Ovaries secrete the hormone estrogen in greater amounts after menstruation and a few days before ovulation. Among its many effects, estrogen causes the up-regulation of receptors in the uterus for another hormone secreted by the ovaries, called progesterone. Progesterone, which is secreted after ovulation, prepares the uterine wall for possible implantation of an embryo. Pregnancy cannot occur unless the embryo implants in the uterine wall. Predict the consequence of the ovaries' secreting too little estrogen.

Classes of Receptors

Lipid-soluble and water-soluble hormones each bind to their own unique class of receptors. Table 17.3 provides an overview of receptor type and mechanism of action.

1. *Lipid-soluble hormones bind to nuclear receptors.* Lipid-soluble hormones are relatively small and are nonpolar. Because of these properties, they easily diffuse through the plasma membrane and bind to **nuclear receptors** (figure 17.12a). Nuclear receptors are most often found in the cell nucleus, but they can also be located in the cytoplasm. These cytoplasmic receptors move to the nucleus when activated. When hormones bind to nuclear receptors, the hormone-receptor complex interacts with DNA in the nucleus or with cellular enzymes to regulate the transcription of particular genes in the target tissue. The lipid-soluble hormones include thyroid hormones and steroid hormones (testosterone, estrogen, progesterone, aldosterone, and cortisol). These hormones bind to nuclear receptors.
2. *Water-soluble hormones bind to membrane-bound receptors.* Water-soluble hormones are large molecules and cannot pass through the plasma membrane. Instead, they interact with **membrane-bound receptors**, which are proteins that extend across the plasma membrane, with their hormone-binding sites exposed on the plasma membrane's outer surface (figure 17.12b). When a hormone binds to a receptor on the outside of the plasma membrane, the hormone-receptor complex initiates a response inside the cell. Hormones that bind to membrane-bound receptors include proteins, peptides, and some amino acid derivatives, such as epinephrine and norepinephrine.

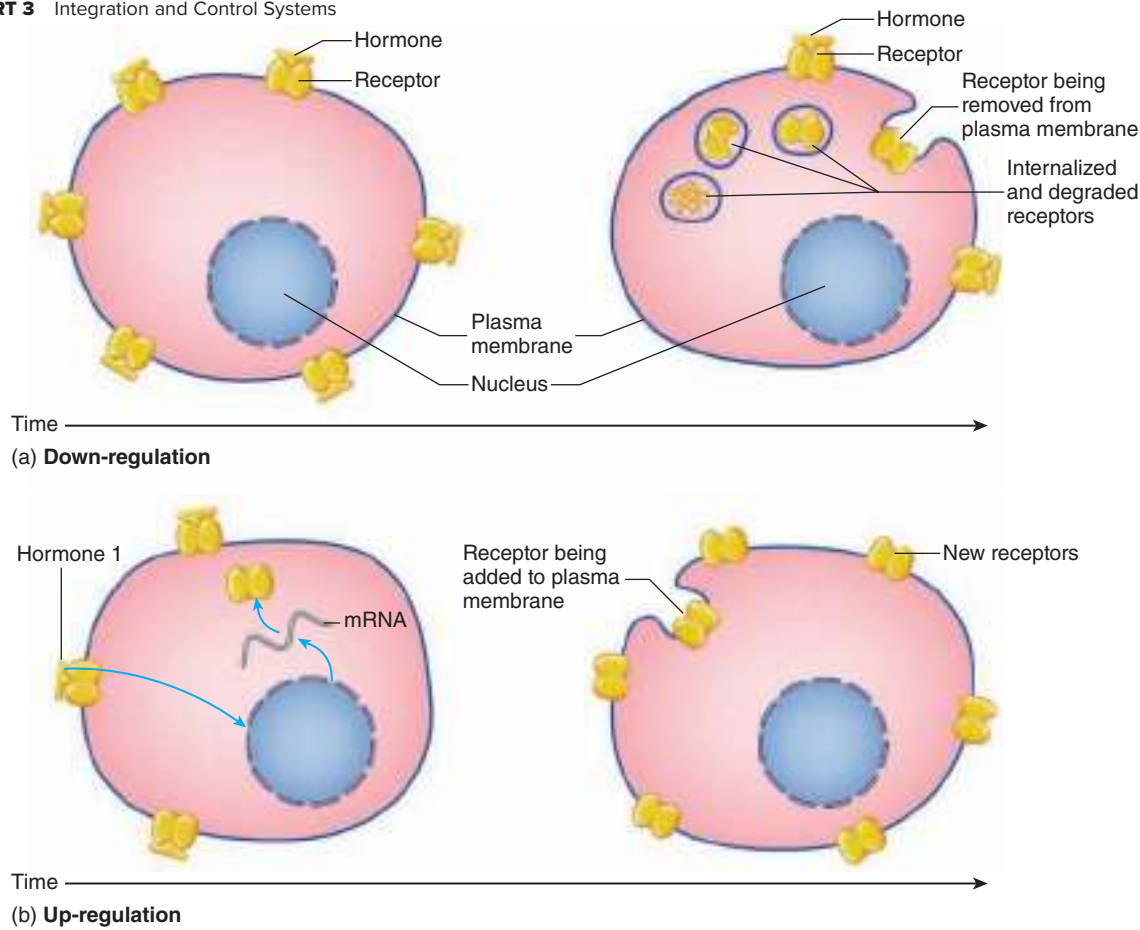

FIGURE 17.11 Down-Regulation and Up-Regulation of Target Cell Receptors

(a) Down-regulation occurs when the number of hormone receptors in a target cell decreases. Often, the target cells internalize the receptors and destroy them. (b) Up-regulation occurs when the number of receptors for a hormone in a target cell increases. Often, the hormone stimulates the synthesis of receptors in the target cells.

TABLE 17.3 Hormone Receptor Types and Mechanisms of Action

Hormone Category	Receptor Type	Hormone Examples	Mechanism of Action*
Lipid-soluble	Nuclear	Steroid hormones Testosterone Estrogen Progesterone Aldosterone Cortisol Thyroid hormone Vitamin D	Bind hormone to receptor within cell followed by hormone-receptor complex attachment to hormone response element on DNA; results in synthesis of mRNA specific to the particular hormone
Water-soluble	Membrane-bound	Luteinizing hormone Follicle-stimulating hormone Thyroid-stimulating hormone Adrenocorticotrophic hormone Glucagon Oxytocin Antidiuretic hormone Calcitonin Parathyroid hormone	Activate G proteins Stimulate synthesis of cAMP
		Epinephrine Insulin Growth hormone Prolactin	Open ion channels Phosphorylate intracellular proteins

*Hormones often exhibit more than one mechanism of action. For simplicity, hormones are listed in only one category.

FIGURE 17.12 General Comparison of Nuclear and Membrane-Bound Receptors

(a) Lipid-soluble hormones diffuse through the plasma membrane of their target cell and bind to a cytoplasmic receptor or a nuclear receptor. In the nucleus, the combination of the hormone and the receptor initiates protein synthesis, described later in this chapter. (b) Water-soluble hormones bind to the external portion of membrane-bound receptors, which are integral membrane proteins on their target cell.

ASSESS YOUR PROGRESS

17. What characteristics of a hormone receptor make it specific for one type of hormone?

18. What is down-regulation, and what may cause it to occur? Give an example of down-regulation in the body.
19. What is up-regulation, and what may cause it to occur? Give an example of up-regulation in the body.
20. What are the two classes of hormone receptors? How do they differ in the chemical category of hormones that will bind to them? Give examples of the types of hormones that bind to each type of receptor.

Action of Nuclear Receptors

Lipid-soluble hormones stimulate synthesis of new proteins. Recall from chapter 3 that protein synthesis relies on information stored in DNA. Therefore, after lipid-soluble hormones diffuse across the plasma membrane and bind to their receptors, the hormone-receptor complex binds to DNA to produce a response (figure 17.13). The receptors that bind to DNA have fingerlike projections that recognize and bind to specific nucleotide sequences in the DNA called **hormone-response elements**. The combination of the hormone and its receptor forms a **transcription factor**, because when the hormone-receptor complex binds to the hormone-response element, it activates the transcription of specific **messenger ribonucleic acid (mRNA)** molecules. The mRNA molecules then move to the cytoplasm to be translated into specific proteins at the ribosomes. The newly synthesized proteins produce the cell's response to the hormone. For example, testosterone stimulates the synthesis of the proteins that are responsible for male secondary sex characteristics, such as the formation of muscle mass and the typical male body structure. The steroid hormone aldosterone affects its target cells in the kidneys by stimulating the synthesis of proteins that increase the rate of Na^+ and K^+ transport. The result is a reduction in the amount of Na^+ and an increase in the amount of K^+ lost in the urine. Other hormones that produce responses through nuclear receptor mechanisms include thyroid hormones and vitamin D.

Target cells that synthesize new protein molecules in response to hormonal stimuli normally have a latent period of several hours between the time the hormones bind to their receptors and the time responses are observed. During this latent period, mRNA and new proteins are synthesized. Hormone-receptor complexes are eventually degraded within the cell, limiting the length of time hormones influence the cells' activities, and the cells slowly return to their previous functional states.

ASSESS YOUR PROGRESS

21. Describe how a hormone that crosses the plasma membrane interacts with its receptor and how it affects protein synthesis.
22. Why is there normally a latent period between the time a hormone binds to its receptor and the time responses are observed?
23. What eventually limits the processes activated by the nuclear receptor mechanism?

- 1 Lipid-soluble hormones diffuse through the plasma membrane.
- 2 Lipid-soluble hormones bind to cytoplasmic receptors and travel to the nucleus or bind to nuclear receptors.
- 3 The hormone-receptor complex functions as a transcription factor by binding to a hormone response element on the DNA.
- 4 The binding of the hormone-receptor complex to DNA stimulates the synthesis of messenger RNA (mRNA), which codes for proteins.
- 5 The mRNA leaves the nucleus, passes into the cytoplasm of the cell, and binds to ribosomes, where it directs the synthesis of specific proteins.
- 6 The newly synthesized proteins produce the cell's response to the lipid-soluble hormones—for example, the secretion of a new protein.

PROCESS FIGURE 17.13 Nuclear Receptor Model **AP R**

Membrane-Bound Receptors and Signal Amplification

Membrane-bound receptors have peptide chains that are anchored in the phospholipid bilayer of the plasma membrane (see chapter 3). Membrane-bound receptors activate responses in two ways: (1) Some receptors alter the activity of G proteins at the inner surface of the plasma membrane. (2) Other receptors directly alter the activity of intracellular enzymes. These intracellular pathways elicit specific responses in cells, including the production of **intracellular mediators**. Some intracellular mediators are called *second messengers*. An intracellular mediator is a chemical

produced inside a cell once a hormone or another chemical messenger binds to certain membrane-bound receptors (table 17.4). The intracellular mediator then activates specific cellular processes inside the cell in response to the hormone. In some cases, this coordinated set of events is referred to as a **second-messenger system**. For example, in chapter 3 we discussed that cyclic adenosine monophosphate (cAMP) is a common second messenger produced when a ligand binds to its receptor. Rather than the ligand entering the cell to activate a cellular process, cAMP stimulates the cellular process. This mechanism is usually employed by water-soluble hormones that are unable to cross the target cell's membrane.

TABLE 17.4 Common Intracellular Mediators

Intracellular Mediator	Example of Cell Type	Example of Response
Cyclic guanine monophosphate (cGMP)	Kidney cells	Increased Na^+ and water excretion by the kidneys
Cyclic adenosine monophosphate (cAMP)	Liver cells	Increased breakdown of glycogen and release of glucose into the circulatory system
Calcium ions (Ca^{2+})	Smooth muscle cells	Contraction of smooth muscle cells
Inositol triphosphate (IP_3)	Smooth muscle cells	Contraction of certain smooth muscle cells in response to epinephrine
Diacylglycerol (DAG)	Smooth muscle cells	Contraction of certain smooth muscle cells in response to epinephrine
Nitric oxide (NO)	Smooth muscle cells	Relaxation of smooth muscle cells of blood vessels, resulting in vasodilation

Receptors That Activate G Proteins

Many membrane-bound receptors produce responses through the action of G proteins (see figures 3.9 and 17.12*b*). G proteins consist of three subunits; from largest to smallest, they are called alpha (α), beta (β), and gamma (γ ; figure 17.14*a*, *step 1*). The G proteins are so named because one of the subunits binds to guanine nucleotides. In the inactive state, a guanine diphosphate (GDP) molecule is bound to the α subunit of each G protein. In the active state, guanine triphosphate (GTP) is bound to the α subunit.

After a hormone binds to the receptor on the outside of a cell, the receptor changes shape (figure 17.14*a*, *step 2*). As a result, the receptor binds to a G protein on the inner surface of the plasma membrane, and GDP is released from the α subunit. Guanine triphosphate (GTP) binds to the α subunit, thereby activating it (figure 17.14*a*, *step 3*). As a result, G proteins separate from the receptor, and the activated α subunit separates from the β and γ

subunits. The activated α subunit can alter the activity of molecules within the plasma membrane or inside the cell, thus producing cellular responses. After a short time, the activated α subunit is turned off, because the G protein removes a phosphate group from GTP, which converts it to GDP (figure 17.14*a*, *step 4*). Thus, the α subunit is called a GTPase. The α subunit then recombines with the β and γ subunits.

G Proteins That Interact with Adenylate Cyclase

Activated α subunits of G proteins can alter the activity of enzymes inside the cell membrane. For example, activated α subunits can influence the rate of cAMP formation by activating or inhibiting **adenylate cyclase** (a-den'i-lāt sī'klās), an enzyme that converts ATP to cAMP (figure 17.14*b*). Cyclic AMP functions as a second messenger, an intracellular mediator that carries out cellular metabolic processes in response to hormonal

(a) Membrane-bound receptors activating G proteins

- 1 After a water-soluble hormone binds to its receptor, the G protein is activated.
- 2 The activated α subunit, with GTP bound to it, binds to and activates an adenylate cyclase enzyme, so that it converts ATP to cAMP.
- 3 The cAMP can activate protein kinase enzymes, which phosphorylate specific enzymes activating them. The chemical reactions catalyzed by the activated enzymes produce the cell's response.
- 4 Phosphodiesterase enzymes inactivate cAMP by converting cAMP to AMP.

(b) Membrane-bound receptors that interact with adenylate cyclase

PROCESS FIGURE 17.14 (continued)

activation. For example, cAMP binds to protein kinases and activates them. **Protein kinases** are enzymes that regulate the activity of other enzymes by attaching phosphates to them, a process called **phosphorylation**. Depending on the enzyme, phosphorylation increases or decreases the enzyme's activity. The amount of time cAMP is present to produce a response in a cell is limited. An enzyme in the cytoplasm, called **phosphodiesterase** (fos'fō-dī-es'ter-ās), breaks down cAMP to AMP. Once cAMP levels drop, the enzymes in the cell are no longer stimulated.

Cyclic AMP can elicit many different responses in the body, because each cell type possesses a unique set of enzymes. For example, the hormone glucagon increases blood glucose levels when it binds to receptors on the surface of liver cells. Binding to the receptor activates G proteins and causes an increase in cAMP synthesis. Cyclic AMP then stimulates the activity of enzymes that break down glycogen into glucose for release from liver cells (figure 17.14b).

G Proteins That Activate Other Intracellular Mediators

G proteins can also alter the concentration of intracellular mediators other than cAMP (table 17.4). For example, **diacylglycerol** (dī-as-il-glis'er-ol; **DAG**) and **inositol** (in-ō'si-tōl, in-ō'si-tol) **triphosphate** (**IP₃**) are intracellular mediators that are influenced by G proteins (figure 17.15). Epinephrine binds to certain membrane-bound receptors in some types of smooth muscle. The combination activates a G protein mechanism, which in turn increases the activity of the enzyme phospholipase C. Phospholipase C

converts phosphoinositol diphosphate (**PIP₂**), a constituent of the plasma membrane, to DAG and **IP₃**, which are released into the cytosol. DAG activates enzymes that synthesize prostaglandins, which increase smooth muscle contraction. **IP₃** releases Ca^{2+} from the endoplasmic reticulum or opens Ca^{2+} channels in the plasma membrane, allowing the ions to enter the cytoplasm and increase the contraction of the smooth muscle cells.

Predict 4

As long as the smooth muscle cells in the airways of the lungs are relaxed, breathing is easy. However, during asthma attacks, these smooth muscle cells contract, and breathing becomes very difficult. Some of the drugs used to treat asthma increase cAMP in smooth muscle cells. Explain some of the different ways in which these drugs work.

G Proteins That Open Ion Channels

Some activated α subunits of G proteins can combine with ion channels, causing them to open or close (figure 17.16). For example, epinephrine activates α subunits to open Ca^{2+} channels in smooth muscle cells, allowing Ca^{2+} to move into those cells. The Ca^{2+} ions combine with calmodulin (kal-mod'ū-lin) proteins, and the calcium-calmodulin complexes activate enzymes that cause the smooth muscle cells to contract (figure 17.16, *steps 1 and 2*; see figure 9.25). After a short time, the activated α subunit is inactivated, because GTP is converted to GDP, and muscle contraction ceases. The α subunit then recombines with the β and γ subunits (figure 17.16, *steps 3 and 4*).

- 1 Epinephrine binds to its receptor in the smooth muscle plasma membrane.
- 2 The G protein is activated. The activated α subunit with GTP bound to it separates from the γ and β subunits.
- 3 The activated subunit then binds with phospholipase C, which acts on phosphoinositol diphosphate (PIP_2) and produces inositol triphosphate (IP_3) and diacylglycerol (DAG).
- 4 IP_3 releases Ca^{2+} from the endoplasmic reticulum or opens Ca^{2+} channels in the plasma membrane. Calcium ions then regulate enzyme activity.
- 5 DAG regulates enzymes such as protein kinases and those that synthesize prostaglandin. These responses increase smooth muscle contraction.

PROCESS FIGURE 17.15 Membrane-Bound Receptors Activating G Proteins to Increase the Synthesis of DAG and IP_3

Epinephrine receptors in some smooth muscle cells are associated with G proteins. **APR**

Receptors That Directly Activate Intracellular Mediators

Cyclic guanine (gwahn'ēn) monophosphate (cGMP), an intracellular mediator, is synthesized in response to a hormone binding to a membrane-bound receptor (figure 17.17). The hormone binds to its receptor, and the combination activates an enzyme called **guanylate cyclase** (gwahn'i-lāt sī'klās) located at the inner surface of the plasma membrane. The guanylate cyclase converts guanine triphosphate (GTP) to cGMP and two inorganic phosphate groups. The cGMP molecules then combine with specific enzymes in the cytoplasm of the cell and activate them. In turn, the activated enzymes produce the cell's response to the hormone. For example, atrial natriuretic hormone, secreted by the heart atria, binds with its receptor in the plasma membrane of kidney cells. The result is an increase in the rate of cGMP synthesis at the inner surface of the plasma membrane (figure 17.17). Cyclic GMP influences the action of enzymes in the kidney cells, which increases the kidneys' rate of Na^+ and water excretion (see chapter 26). The cGMP is present in the cell for only a limited amount of time, because phosphodiesterase breaks down cGMP to GMP. Consequently, the length of time a hormone increases cGMP synthesis and has an effect on a cell is brief, once the hormone is no longer present.

Receptors That Phosphorylate Intracellular Proteins

Some hormones bind to membrane-bound receptors, and the portion of the receptor on the inner surface of the plasma membrane acts as a kinase enzyme that phosphorylates several specific proteins (figure 17.18). Some of the phosphorylated proteins are part of the membrane-bound receptor; others are in the cytoplasm of the cell. The phosphorylated proteins influence the activity of other enzymes in the cytoplasm. For example, insulin binds to its membrane-bound receptor, resulting in the phosphorylation of parts of the receptor on the inner surface of the plasma membrane and the phosphorylation of certain other intracellular proteins. The phosphorylated proteins enable the very powerful effect of insulin to allow glucose entry into cells.

Receptors That Directly Alter the Activity of Intracellular Enzymes

Some hormones bind to membrane-bound receptors and directly change the activity of an intracellular enzyme. The altered enzyme activity regulates the synthesis of intracellular mediators or results in the phosphorylation of intracellular proteins. The intracellular mediators or phosphorylated proteins activate processes that

- 1 After a hormone binds to its receptor, the G protein is activated. The activated α subunit with GTP bound to it separates from the γ and β subunits.

- 2 The α subunit, with GTP bound to it, binds to the Ca²⁺ channel, and the combination causes the Ca²⁺ channel to open. The Ca²⁺ diffuses into the cell and combines with calmodulin. The combination of Ca²⁺ with calmodulin produces the cell's response to the hormone.

- 3 Phosphate is removed from the GTP bound to the α subunit, leaving GDP bound to the α subunit. The α subunit can no longer stimulate a cellular response; it separates from the Ca²⁺ channel, and the channel closes.

- 4 The α subunit recombines with the γ and β subunits.

FIGURE 17.16 G Proteins Opening Ion Channels

produce the cells' response to the chemical signals. Intracellular enzymes controlled by membrane-bound receptors can be part of the receptor, or they can be separate molecules. The intracellular mediators act as chemical signals that move from the enzymes that produce them into the cytoplasm of the cell, where they activate the processes that produce the cell's response. For example, the hormone glucagon activates enzymes that release glucose into the circulation from cells within the liver.

Signal Amplification

The rate and magnitude at which a hormone's response is elicited are determined by its mechanism of action at the receptor. Nuclear receptors work by activating protein synthesis, which for some hormones can take several hours (see "Action of Nuclear Receptors"). However, hormones that stimulate the synthesis of second messengers can produce an almost instantaneous response, because the second messenger influences existing enzymes. In

PROCESS FIGURE 17.17 Membrane-Bound Receptor Directly Activating an Intracellular Mediator

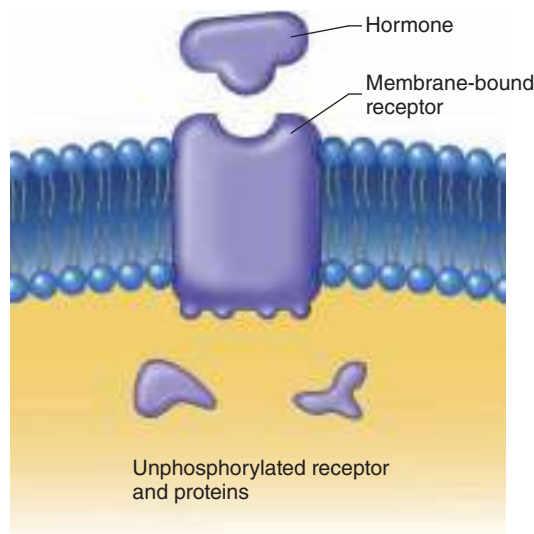

Some second messengers are produced when the hormone binds to its receptor, which activates the second messenger-producing enzyme.

other words, the response proteins are already present. Additionally, each receptor produces thousands of second messengers, leading to a cascade effect and ultimately **amplification** of the hormonal signal. With amplification, a single hormone activates many second messengers, each of which activates enzymes that

produce an enormous amount of final product (figure 17.19). The efficiency of this second-messenger amplification is virtually unparalleled in the body and can be thought of as an “army of molecules” launching an offensive. In a war, the general gives the signal to attack, and thousands of soldiers carry out the order. The general alone could not kill thousands of enemies. Likewise, one hormone could not single-handedly produce millions of final products within a few seconds. However, with amplification, one hormone has an army of molecules working simultaneously to produce the final products.

Both nuclear receptor and membrane-bound receptor hormone systems are effective, but each is more suited to one type of response than another. For example, the reason epinephrine (membrane-bound receptors) is effective in a fight-or-flight situation is that it can turn on the target cell responses within a few seconds. If running away from an immediate threat depended on producing new proteins (nuclear receptors), a process that can take several hours, many of us

would have already perished. On the other hand, pregnancy maintenance is mediated by steroids (nuclear receptors), long-acting hormones, which is reflected by the fact that pregnancy is a long-term process. Thus, it is important for our bodies to have hormones that can function over differing time scales.

1 The membrane-bound receptor and other proteins have sites that can be phosphorylated at the inner surface of the plasma membrane. When the receptor is not bound to a hormone, these sites remain unphosphorylated.

2 The hormone binds to its receptor site on the outside of the plasma membrane. The receptor acts as an enzyme that phosphorylates the sites on the receptor and associated proteins. These phosphorylated proteins produce a response inside the cell.

PROCESS FIGURE 17.18 Membrane-Bound Receptors That Phosphorylate Intracellular Proteins

FUNDAMENTAL Figure

FIGURE 17.19 Amplification

The combination of a hormone with a membrane-bound receptor initiates a cascade effect that activates several G proteins. The G proteins, in turn, activate many inactive adenylate cyclase enzymes, which cause the synthesis of a large number of cAMP molecules. The large number of cAMP molecules, in turn, activate many inactive protein kinase enzymes, which produce a rapid and amplified response.

Predict 5

Of membrane-bound receptors and nuclear receptors, which is better adapted for mediating a response that lasts a considerable length of time, and which is better for mediating a response with a rapid onset and short duration? Explain why.

ASSESS YOUR PROGRESS

- What two ways can a membrane-bound receptor use to activate cellular response?
- Explain how the hormone-receptor complex can alter the G proteins on the inner surface of the plasma membrane. Which subunit of the G protein alters the activity of molecules inside the plasma membrane or inside the cell?
- List four intracellular mediators affected by G proteins.
- Describe how G proteins can alter the permeability of the plasma membrane and how they can alter the synthesis of an intracellular mediator, such as cAMP. Give examples.
- Describe how a hormone can combine with a membrane-bound receptor, directly change enzyme activity inside the cell, and increase phosphorylation of intracellular proteins. Give examples.
- What limits the activity of intracellular mediators, such as cGMP, and phosphorylated proteins?
- Explain the cascade effect for the second-messenger model of hormone action. Does the second-messenger amplification produce a slow or rapid response?

Answer

Learn to Predict ◀ From page 575

After using anabolic steroids, Liu Dan's muscles increased in size, but he also experienced some unintended changes, including slight breast development, reduced testes size, and mood swings. We learned in this chapter that steroid hormones are all derived from cholesterol, a type of lipid, and are thus lipid-soluble. We also know that hormones, chemical messengers produced by the endocrine system, travel through the body via the bloodstream until they arrive at their target tissues. The cells of target tissues possess specific receptors that the hormones bind to and initiate changes in cellular metabolism or cell growth. Steroid hormones, because they are lipid-soluble, bind to intracellular receptors in the cell's cytoplasm or nucleus. Once the steroid hormone has bound to its receptor, the hormone-receptor complex stimulates increased gene expression

and therefore increased protein production. In muscle cells, this leads to the increased muscle mass that Liu Dan experienced.

However, other tissues of the body contain receptors that can also bind the anabolic steroids, so using anabolic steroids can cause some unintended effects. The anabolic steroids Liu Dan used also led to the abnormal breast tissue growth, decreased testes size, and behavioral changes. Thus, although it may be tempting to take anabolic steroids to increase muscle mass, the risk for side effects is simply too great.

Answers to the rest of this chapter's Predict questions are in appendix G.

Summary

17.1 Principles of Chemical Communication (p. 576)

Classes of Chemical Messengers

1. The four classes of chemical messengers are autocrine, paracrine, neurotransmitter, and endocrine.
2. Endocrine chemical messengers are called hormones.

Characteristics of the Endocrine System

1. The endocrine system includes glands and specialized endocrine cells that secrete hormones into the bloodstream.
2. A hormone is a chemical messenger that is secreted into the blood, travels to a distant target tissue, and binds to specific receptors to produce a coordinated set of events in that target tissue.

Comparison of the Nervous and Endocrine Systems

1. The endocrine system and the nervous system are closely related.
 - They share anatomical structures in the brain.
 - They share molecules that are both neurotransmitters and hormones.
 - They cooperate to regulate important processes.
 - They both have chemical messengers that bind to the same receptor type.
2. The endocrine system and the nervous system have important differences.
 - Neurotransmitters deliver their chemical messengers directly to their target, whereas hormones travel in the bloodstream.
 - The endocrine system is slower than the nervous system.
 - The endocrine system has longer-lasting effects than the nervous system.

17.2 Hormones (p. 579)

General Characteristics of Hormones

1. Hormones have several characteristics in common: stability, communication, and distribution.
 - The length of time a hormone is active in the circulation is termed its half-life.
 - The half-life of some hormones is prolonged because they circulate in the blood bound to binding proteins.
2. Hormones not bound to binding proteins are called free hormones, and they can interact with their receptor.

Chemical Nature of Hormones

1. There are two chemical categories of hormones: lipid-soluble and water-soluble.
2. Lipid-soluble hormones include steroids, thyroid hormones, and some fatty acid derivatives.
 - Most lipid-soluble hormones are transported bound to binding proteins. Thus, their half-life extends from minutes to weeks.
 - Lipid-soluble hormones are removed from the circulation by conjugation to sulfate or glucuronic acid, which then allows them to be excreted in the bile.
3. Water-soluble hormones include proteins, peptides, and amino acid derivatives.
 - Water-soluble hormones circulate freely in the blood.
 - Proteases degrade protein and peptide hormones in the circulation; the breakdown products are then excreted in the urine. However, some water-soluble hormones have chemical modifications,

such as the addition of a carbohydrate group, which prolongs their half-life.

Patterns of Hormone Secretion

The three main patterns of hormone secretions are chronic, acute, and episodic.

1. Chronic hormone secretion results in hormones whose circulating levels are relatively constant.
2. Acute hormone secretion results in hormone levels that can vary dramatically.
3. Episodic hormone secretion results in a cyclic pattern of hormone release.

17.3 Control of Hormone Secretion (p. 583)

Stimulation of Hormone Release

Three types of stimuli result in hormone secretion: humoral, neural, and hormonal.

1. Humoral stimulation is exhibited by hormones that are sensitive to circulating blood levels of certain molecules, such as glucose or calcium.
2. Neural stimuli cause hormone secretion in direct response to action potentials in neurons, as occurs during stress or exercise. Hormones from the hypothalamus that cause the release of other hormones are called releasing hormones.
3. Hormonal stimulation of other hormone secretion is common in the endocrine system. Hormones from the anterior pituitary that stimulate hormones from other endocrine glands are called tropic hormones.

Inhibition of Hormone Release

Although the stimulus of hormone secretion is important, inhibition is equally important.

1. Humoral substances can inhibit the secretion of hormones.
2. Neural stimuli can prevent hormone secretion.
3. Inhibiting hormones prevent hormone release.

Regulation of Hormone Levels in the Blood

Two processes regulate the overall blood levels of hormones: negative feedback and positive feedback.

1. Negative feedback prevents further hormone secretion once a set point is achieved.
2. Positive feedback is a self-promoting system whereby the stimulation of hormone secretion increases over time.

17.4 Hormone Receptors and Mechanisms of Action (p. 586)

Agonists and Antagonists

1. Agonists mimic the actions of a natural hormone.
2. Antagonists block the actions of a natural hormone.

Decrease in Receptor Number

1. Hormones stimulate their targets by binding to proteins in the target cell called receptors.
2. A target cell may decrease its sensitivity to a hormone through desensitization, which can occur through a decrease in receptor number, a process called down-regulation.

Increase in Receptor Number

A target cell may increase its sensitivity to a hormone through sensitization, which can occur through an increase in receptor number, a process called up-regulation.

Classes of Receptors

The two groups of hormones each have their own class of receptors.

1. Lipid-soluble hormones bind to nuclear receptors located inside the nucleus of the target cell.
2. Water-soluble hormones bind to membrane-bound receptors, which are integral membrane proteins.

Action of Nuclear Receptors

1. Nuclear receptors have portions that allow them to bind to the DNA in the nucleus once the hormone is bound.
 - The hormone-receptor complex activates genes, which in turn activate the DNA to produce mRNA.
 - The mRNA increases the synthesis of certain proteins that produce the target cell's response.

2. Nuclear receptors cannot respond immediately, because it takes time to produce the mRNA and the protein.

Membrane-Bound Receptors and Signal Amplification

1. Membrane-bound receptors activate a cascade of events once the hormone binds.
2. Some membrane-bound receptors are associated with membrane proteins called G proteins.
 - Hormone binds to a membrane-bound receptor, and G proteins are activated.
 - The α subunit of the G protein binds to ion channels and causes them to open or change the rate of synthesis of intracellular mediators, such as cAMP, cGMP, IP₃, and DAG.
3. Intracellular enzymes can be activated directly, which in turn causes the synthesis of intracellular mediators, such as cGMP, or adds a phosphate group to intracellular enzymes, which alters their activity.
4. Second-messenger systems act rapidly, because they act on already existing enzymes to amplify the signal.

REVIEW AND COMPREHENSION

1. When comparing the endocrine system and the nervous system, the endocrine system generally
 - a. is faster-acting than the nervous system.
 - b. produces effects that are of shorter duration.
 - c. uses blood-borne chemical messengers.
 - d. produces more localized effects.
 - e. relies less on chemical messengers.
2. Given this list of molecule types:
 - (1) nucleic acid derivatives
 - (2) fatty acid derivatives
 - (3) peptides
 - (4) proteins
 - (5) phospholipids

Which could be hormone molecules?

a. 1,2,3	c. 1,2,3,4	e. 1,2,3,4,5
b. 2,3,4	d. 2,3,4,5	
3. Which of these can regulate the secretion of a hormone from an endocrine tissue?
 - a. other hormones
 - b. negative-feedback mechanisms
 - c. humoral substances in the blood
 - d. the nervous system
 - e. All of these are correct.
4. Hormones are released into the blood
 - a. at relatively constant levels.
 - b. in large amounts in response to a stimulus.
 - c. in an episodic fashion.
 - d. All of these are correct.
5. Lipid-soluble hormones readily diffuse through capillary walls, whereas water-soluble hormones, such as proteins, must
 - a. pass through capillary cells.
 - b. pass through pores in the capillary endothelium.
 - c. be moved out of the capillary by active transport.
 - d. remain in the blood.
 - e. be broken down to amino acids before leaving the blood.
6. Concerning the half-life of hormones,
 - a. lipid-soluble hormones generally have a longer half-life.
 - b. hormones with a shorter half-life regulate activities with a slow onset and long duration.
 - c. hormones with a shorter half-life are maintained at more constant levels in the blood.
 - d. lipid-soluble hormones are degraded rapidly by enzymes in the circulatory system.
 - e. water-soluble hormones usually combine with plasma proteins.
7. Given these observations:
 - (1) A hormone affects only a specific tissue (not all tissues).
 - (2) A tissue can respond to more than one hormone.
 - (3) Some tissues respond rapidly to a hormone, whereas others take many hours to respond.

Which of these observations can be explained by the characteristics of hormone receptors?

a. 1	c. 2,3	e. 1,2,3
b. 1,2	d. 1,3	
8. Which of these is *not* a means by which hormones are eliminated from the circulatory system?
 - a. excreted into urine or bile
 - b. bound to binding proteins
 - c. enzymatically degraded in the blood (metabolism)
 - d. actively transported into cells
 - e. conjugated with sulfate or glucuronic acid
9. Down-regulation
 - a. produces a decrease in the number of receptors in the target cells.
 - b. produces an increase in target cells' sensitivity to a hormone.
 - c. is found in target cells that respond to hormones that are maintained at constant levels.
 - d. occurs partly because of an increase in receptor synthesis by the target cell.
 - e. All of these are correct.

10. Activated G proteins can
- cause ion channels to open or close.
 - activate adenylate cyclase.
 - inhibit the synthesis of cAMP.
 - alter the activity of IP_3 .
 - All of these are correct.
11. Given these events:
- GTP is converted to GDP.
 - The subunit separates from the β and γ units.
 - GDP is released from the α subunit.

List the order in which the events occur after a hormone binds to a membrane-bound receptor.

- 1,2,3
- 1,3,2
- 2,3,1
- 3,2,1
- 3,1,2

12. Which of these can limit a cell's response to a hormone?
- phosphodiesterase
 - converting GTP to GDP
 - decreasing the number of receptors
 - blocking binding sites
 - All of these are correct.

13. Given these events:
- The α subunit of a G protein interacts with Ca^{2+} channels.
 - Calcium ions diffuse into the cell.
 - The α subunit of a G protein is activated.

Choose the arrangement that lists the events in the order they occur after a hormone binds to a receptor on a smooth muscle cell.

- 1,2,3
- 1,3,2
- 2,1,3
- 3,1,2
- 3,2,1

14. Given these events:
- cAMP is synthesized.
 - The α subunit of G protein is activated.
 - Phosphodiesterase breaks down cAMP.

Choose the arrangement that lists the events in the order they occur after a hormone binds to a receptor.

- 1,2,3
- 1,3,2
- 2,1,3
- 2,3,1
- 3,2,1

15. When a hormone binds to a nuclear receptor,
- DNA produces mRNA.
 - G proteins are activated.
 - the hormone-receptor complex causes ion channels to open or close.
 - the cell's response is faster than when a hormone binds to a membrane-bound receptor.
 - the hormone is usually a large, water-soluble molecule.
16. Given these events:
- activation of cAMP
 - activation of genes
 - alteration of enzyme activity

Which of these events can occur when a hormone binds to a nuclear hormone receptor?

- 1
- 1,2
- 2,3
- 1,2,3

Answers in appendix E

CRITICAL THINKING

- Consider a hormone that is secreted in large amounts at a given interval, modified chemically by the liver, and excreted by the kidneys at a rapid rate, thus making the half-life of the hormone in the circulatory system very short. The hormone therefore rapidly increases in the blood and then decreases rapidly. Suppose that a patient has both liver and kidney disease, and predict the consequences on the blood levels of that hormone.
- Consider a hormone that increases the concentration of a substance in the circulatory system. If a tumor begins to produce that substance in large amounts in an uncontrolled fashion, predict the effect on the hormone's secretion rate.
- How could you determine whether a hormone-mediated response has resulted from the intracellular mediator mechanism or the nuclear receptor mechanism?
- If a hormone affects a target tissue through a membrane-bound receptor that has a G protein associated with it, predict the consequences if a genetic disease causes the α subunit of the G protein to have a structure that prevents it from binding to GTP.
- For a hormone that binds to a membrane-bound receptor and has cAMP as the intracellular mediator, predict and explain the consequences if a patient takes a drug that strongly inhibits phosphodiesterase.
- When an individual is confronted with a potentially harmful situation, the adrenal glands release epinephrine (adrenaline). Epinephrine prepares the body for action by increasing the heart rate and blood glucose levels. Explain the advantages or disadvantages associated with a shorter half-life for epinephrine, such as when it is released as a neurotransmitter, and those associated with a longer half-life, such as when it is secreted as a hormone.
- Thyroid hormones are important in regulating the body's basal metabolic rate. Thyroid hormones are lipid-soluble and have a long half-life. What are the advantages and disadvantages of a long half-life for thyroid hormones, compared with a short half-life?
- Predict the effect on LH and FSH secretion if a small tumor in the hypothalamus continuously secretes large concentrations of GnRH. Given that LH and FSH regulate the function of the male and female reproductive systems, state whether the condition will increase or decrease the activity of these systems.
- Predict some consequences of trying to use a skin patch to administer insulin, a protein hormone, to a person who has diabetes mellitus.

Answers in appendix F

18

Learn to Predict

Dylan, a 10-year-old boy, was constantly hungry and was losing weight rapidly in spite of his unusually large food intake. Dylan was also constantly thirsty and urinated frequently. In addition, he felt weak and lethargic, and his breath occasionally had a distinctive sweet, or acetone, odor. Dylan's parents tried to make sure he ate a healthy diet, but Dylan was sneaking candy and soft drinks when his parents were not around. **After reading this chapter and learning about the body's hormones, what type of hormonal imbalance do you think is responsible for Dylan's symptoms? What effect would eating candy and drinking sugary soda have on Dylan's health?**

Endocrine Glands

As described in chapter 17, the nervous and endocrine systems work together to regulate and coordinate the activities of nearly all the other body structures. When either system fails to function properly, conditions can rapidly deviate from homeostasis, and disease may result. One of the most common endocrine system disorders is insulin-dependent diabetes mellitus. You may know someone who has this condition, but, as recently as the early 1900s, people who developed the disease died because no effective treatment was available. As physiologists learned more about the function of endocrine glands and the nature of their hormones, successful treatments were developed for diabetes mellitus, as well as for many other endocrine disorders. This chapter examines each of the organs of the endocrine system, describes the hormones they secrete, and explains how hormone secretion is regulated so that homeostasis is maintained.

Photo: The surgeon in this photo is transfusing donor islet cells into a diabetic patient. The islet cells may take residence in the pancreas and secrete insulin for the patient. Note the new islet cells in the right-hand photo. They are now functioning normally. This patient will never again need to inject insulin.

18.1 Overview of the Endocrine System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Explain the types of information that are necessary to understand endocrine function.**
- B. Describe the 10 regulatory functions of the endocrine system.**

The endocrine system is one of the two important control systems of the body. The nervous system is the body's other important control system. Recall from chapter 17 that the endocrine system is composed of glands and cells that secrete the chemical signals called hormones into the plasma of the blood (see figure 17.1). The hormones are secreted in response to humoral, neural, or hormonal stimuli and then travel in the blood plasma to target cells, where they regulate homeostasis. In order to understand completely how the endocrine system regulates body functions, you need to know the various endocrine glands, their hormones, and their mechanisms of action. In addition, many disorders of the body are caused by either hypersecretion or hyposecretion of hormones.

The main regulatory functions of the endocrine system are the following:

1. *Regulation of metabolism.* The endocrine system controls the rate of nutrient utilization and energy production.
2. *Control of food intake and digestion.* The endocrine system regulates the level of satiation (fullness) and the breakdown of food into individual nutrients.
3. *Modulation of tissue development.* The endocrine system influences the development of tissues, such as those of the nervous system.
4. *Regulation of ion levels.* The endocrine system helps monitor blood pH, as well as Na^+ , K^+ , and Ca^{2+} concentrations in the blood.
5. *Control of water balance.* The endocrine system regulates water balance by controlling the solute concentration of the blood.
6. *Changes in heart rate and blood pressure.* The endocrine system helps regulate the heart rate and blood pressure and prepare the body for physical activity.
7. *Control of blood glucose and other nutrients.* The endocrine system regulates the levels of glucose and other nutrients in the blood.
8. *Control of reproductive functions.* The endocrine system controls the development and functions of the reproductive systems in males and females.
9. *Stimulation of uterine contractions and milk release.* The endocrine system regulates uterine contractions during delivery and stimulates milk release from the breasts in lactating females.
10. *Modulation of immune system function.* The endocrine system helps control the production of immune cells.

ASSESS YOUR PROGRESS

1. What pieces of information are needed to understand how the endocrine system regulates body functions?
2. List 10 regulatory functions of the endocrine system.

18.2 Pituitary Gland and Hypothalamus

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the location and structure of the pituitary gland.**
- B. Explain the physical, neural, and vascular connections between the hypothalamus and the pituitary gland.**
- C. Describe how the hypothalamus regulates hormone secretion from the pituitary gland.**
- D. List the hormones produced by the hypothalamus and state their structural type, target tissues, and actions.**
- E. List the hormones produced by the anterior pituitary gland and state their structural type, target tissues, and actions.**
- F. Explain the nature of a tropic hormone.**
- G. Describe the conditions that result from over- and undersecretion of pituitary hormones.**

As you learned in chapter 17, the endocrine system works closely with the nervous system to regulate and maintain homeostasis. Two important structures for integrating the nervous system and the endocrine system are the **pituitary** (pi-too'i-tār-rē) **gland**, or *hypophysis* (hī-pof'i-sis; an undergrowth), and the **hypothalamus** (hī'pō-thal'ā-mūs; figure 18.1). The pituitary gland secretes nine major hormones that regulate numerous body functions and the secretory activity of several other endocrine glands. The hypothalamus regulates the secretory activity of the pituitary gland in response to other hormones, sensory information, and emotions.

Structure of the Pituitary Gland

The pituitary gland is connected to the base of the brain, just inferior to the hypothalamus. A stalk of tissue called the **infundibulum** (in-fūn-dib'u-lūm) connects the pituitary gland to the hypothalamus. The pituitary gland rests in the sella turcica of the sphenoid bone and is roughly the size of a pea—1 cm in diameter, weighing 0.5–1.0 g (figure 18.1a).

The pituitary gland is divided into two lobes: the **posterior pituitary gland**, or *neurohypophysis* (noor'ō-hī-pof'i-sis), and the **anterior pituitary gland**, or *adenohypophysis* (ad'ē-nō-hī-pof'i-sis; *adeno*, gland).

Posterior Pituitary

The posterior pituitary is called the neurohypophysis because it is continuous with the hypothalamus in the brain (*neuro-* refers to the nervous system). During embryonic development, the posterior pituitary forms from an outgrowth of the inferior part of the brain in

FIGURE 18.1 Subdivisions of the Pituitary Gland

(a) A midsagittal section of the head through the pituitary gland, showing the location of the hypothalamus of the brain and the pituitary gland. The pituitary gland is in a depression called the sella turcica in the floor of the skull. It is connected to the hypothalamus by the infundibulum. (b) The pituitary gland is divided into the anterior pituitary gland and the posterior pituitary gland. The posterior pituitary consists of the enlarged distal end of the infundibulum, which connects the posterior pituitary to the hypothalamus. (c,d) Histology of the pituitary gland: (c) The posterior pituitary consists of axon terminals, whereas (d) the anterior pituitary consists of groups of secretory cells. **APR**

the area of the hypothalamus (see chapter 29). The outgrowth of the brain forms the infundibulum, and the distal end of the infundibulum enlarges to form the posterior pituitary (figure 18.1b). Because the posterior pituitary is a part of the nervous system, its hormones are called **neuropeptides**, or **neurohormones** (noor-ō-hōr'mōnz).

Anterior Pituitary

The anterior pituitary develops as an outpocketing of the roof of the embryonic oral cavity called the pituitary diverticulum, or Rathke pouch. The pituitary diverticulum continues growing toward the posterior pituitary. As it nears the posterior pituitary, the pituitary diverticulum loses its connection with the oral cavity and becomes the anterior pituitary, which includes an area called the pars intermedia that is not functional in adult humans (figure 18.2). Because the anterior pituitary is derived from epithelial tissue of the embryonic oral cavity, not from neural tissue, the hormones secreted from the anterior pituitary are traditional hormones, not neurohormones.

Relationship of the Pituitary Gland to the Brain: The Hypothalamus

The pituitary is regulated, in part, by hormones produced and secreted by neurons in the hypothalamus. Some of these hypothalamic hormones are delivered to the anterior pituitary via a circulatory system called a portal system. Most blood vessels follow the prescribed pattern of artery to capillary network then to a vein. Portal system vessels directly connect a primary capillary network to a secondary capillary network. The **hypothalamohypophysial** (hī'pō-thal'ā-mō-hī'pō-fiz'ē-āl) **portal system** is one of the major portal systems in the body. The others include the hepatic portal system and the renal nephron portal systems (see chapters 21 and 26). The hypothalamohypophysial portal system extends from the floor of the hypothalamus to the anterior pituitary (figure 18.3). The primary capillary network in the hypothalamus is supplied with blood from arteries that deliver blood to the hypothalamus. From the primary capillary network, the hypothalamohypophysial portal vessels carry blood to a secondary capillary network in the anterior pituitary. Veins from the secondary capillary network eventually merge with the general circulation.

The hypothalamus controls the anterior pituitary through hormones that are delivered by the hypothalamohypophysial portal system. Remember that neurons of the hypothalamus produce neurohormones. These neurohormones enter the portal system capillaries in the hypothalamus and are transported directly to the anterior pituitary. There they exit the portal system and act on cells of the anterior pituitary. Hypothalamic hormones can either stimulate or inhibit release of anterior pituitary hormones. Hypothalamic hormones that stimulate anterior pituitary secretion are called **releasing hormones**. Hypothalamic hormones that decrease anterior pituitary hormone secretion are called **inhibiting hormones**. When a releasing hormone stimulates secretion of an anterior pituitary hormone, the secreted hormone enters the general circulation for transport to its target tissues. Thus, the hypothalamohypophysial portal system provides a means by which the hypothalamus, using neurohormones as chemical messengers, regulates the secretory activity of the anterior pituitary (figure 18.3).

FIGURE 18.2 Development of the Pituitary Gland

The posterior pituitary develops as a downward growth of the hypothalamus. The anterior pituitary develops as an outpocketing of the embryonic gut called the pituitary diverticulum; the pars intermedia is not shown in this figure.

Many releasing and inhibiting hormones are produced and secreted by hypothalamic neurons (table 18.1). **Growth hormone-releasing hormone (GHRH)** is a small peptide that stimulates the secretion of growth hormone from the anterior pituitary gland, and **growth hormone-inhibiting hormone (GHIH)**, also called *somatostatin* (sō'mă-tō-stat'in), is a small peptide that inhibits growth hormone secretion. **Thyrotropin-releasing hormone (TRH)** is a small peptide that stimulates the secretion of thyroid-stimulating hormone from the anterior pituitary gland. **Corticotropin-releasing hormone (CRH)** is a peptide that stimulates the secretion of adrenocorticotropic hormone from the anterior pituitary gland. **Gonadotropin-releasing hormone (GnRH)** is a small peptide that stimulates the secretion of both luteinizing hormone and follicle-stimulating hormone from the anterior pituitary gland. **Prolactin-releasing hormone (PRH)** and **prolactin-inhibiting hormone (PIH)** regulate the secretion of prolactin from the anterior pituitary gland. Secretions of the anterior pituitary gland are described later in this section.

Secretion of hormones by the posterior pituitary is very different from that of the anterior pituitary. There is no portal system to carry hypothalamic neuropeptides to the posterior pituitary. The posterior pituitary is simply a storage location for two

neurohormones. The neurohormones released from the posterior pituitary are produced by neurosecretory neurons whose cell bodies are in the hypothalamus. The axons of these neurons extend from the hypothalamus through the infundibulum into the posterior pituitary and form a tract called the **hypothalamohypophysial tract** (figure 18.4). Neurohormones produced in the hypothalamus pass down these axons in tiny vesicles and are stored in secretory vesicles in the ends of the axons. Action potentials originating in the neuron cell bodies in the hypothalamus are propagated along the axons to the axon terminals in the posterior pituitary. The action potentials cause the release of neurohormones from the axon terminals, and they enter the general circulation. Neurohormones of the posterior pituitary gland are described later in this section.

Predict 2

Surgical removal of the posterior pituitary in experimental animals results in clear symptoms of a hormone shortage, but they can be temporary. Surgical removal of the anterior pituitary, in contrast, results in many manifestations and a permanent shortage of several hormones. Explain these results.

ASSESS YOUR PROGRESS

- Where is the pituitary gland located? Contrast the embryonic origins of the anterior pituitary and the posterior pituitary.
- What is a portal system? Describe the hypothalamohypophysial portal system.
- How does the hypothalamus regulate the secretion of anterior pituitary hormones?
- List the releasing and inhibiting hormones that are produced and released from hypothalamic neurons.
- Describe the hypothalamohypophysial tract, including the production of neurohormones in the hypothalamus and their subsequent release from the posterior pituitary gland.

Hormones of the Pituitary Gland

The hormones secreted from the pituitary gland are separated into two categories: posterior pituitary hormones and anterior pituitary hormones (table 18.2). Hormones from the pituitary gland have many, varied effects on the body and exert these effects in several ways. In addition, there are major consequences of abnormal pituitary hormone secretion on the body.

Posterior Pituitary Hormones

Recall that the posterior pituitary is composed of neural tissue. Thus, the hormones stored and secreted by the posterior pituitary gland are the neurohormones, antidiuretic hormone and oxytocin. A separate population of neurons secretes each neurohormone.

- 1 Stimuli within the nervous system regulate the secretion of releasing hormones (*green circles*) and inhibiting hormones (*red circles*) from neurons of the hypothalamus.
- 2 Releasing hormones and inhibiting hormones pass through the hypothalamohypophysial portal system to the anterior pituitary.
- 3 Releasing hormones and inhibiting hormones (*green and red circles*) leave capillaries and stimulate or inhibit the release of hormones (*yellow squares*) from anterior pituitary cells.
- 4 In response to releasing hormones, anterior pituitary hormones (*yellow squares*) travel in the blood to their target tissues (*green arrow*), which in some cases, are other endocrine glands.

PROCESS FIGURE 18.3 Hypothalamic Control of the Anterior Pituitary

TABLE 18.1 Hormones of the Hypothalamus

Hormones	Structure	Target Tissue	Response
Growth hormone–releasing hormone (GHRH)	Peptide	Anterior pituitary cells that secrete growth hormone	Increased growth hormone secretion
Growth hormone–inhibiting hormone (GHIH), or somatostatin	Small peptide	Anterior pituitary cells that secrete growth hormone	Decreased growth hormone secretion
Thyrotropin-releasing hormone (TRH)	Small peptide	Anterior pituitary cells that secrete thyroid-stimulating hormone	Increased thyroid-stimulating hormone secretion
Corticotropin-releasing hormone (CRH)	Peptide	Anterior pituitary cells that secrete adrenocorticotropic hormone	Increased adrenocorticotropic hormone secretion
Gonadotropin-releasing hormone (GnRH)	Small peptide	Anterior pituitary cells that secrete luteinizing hormone and follicle-stimulating hormone	Increased secretion of luteinizing hormone and follicle-stimulating hormone
Prolactin-releasing hormone (PRH)	Unknown	Anterior pituitary cells that secrete prolactin	Increased prolactin secretion
Prolactin-inhibiting hormone (PIH)	Dopamine (amino acid derivative)	Anterior pituitary cells that secrete prolactin	Decreased prolactin secretion

- 1 Stimuli within the nervous system cause hypothalamic neurons to either increase or decrease their action potential frequency.
- 2 Action potentials are conducted by axons of the hypothalamic neurons through the hypothalamohypophysial tract to the posterior pituitary. The axon endings of neurons store neurohormones in the posterior pituitary.
- 3 In the posterior pituitary gland, action potentials cause the release of neurohormones (*blue circles*) from axon terminals into the blood.
- 4 The neurohormones pass through the blood and influence the activity of their target tissues.

PROCESS FIGURE 18.4 Secretion of Posterior Pituitary Hormones

Antidiuretic Hormone

Antidiuretic (an'tē-dī-ū-ret'ik) **hormone (ADH)** is a water-conservation hormone. ADH prevents (*anti-*) the output of large amounts of urine (*diuresis*). An alternate name for ADH is **vasopressin** (vā-sō-pres'in, vas-ō-pres'in) because it also constricts blood vessels and raises blood pressure when large amounts are released. ADH molecules are synthesized predominantly by neurosecretory neuron cell bodies in the supraoptic nuclei of the hypothalamus and are transported within the axons of the hypothalamohypophysial tract from the supraoptic nuclei to the posterior pituitary, where they are stored in axon terminals. Action potentials in these neurons stimulate the release of ADH into the blood, where it is carried to its primary target tissue, the kidney tubules. Kidney tubules are the sites of urine production in the kidneys. ADH promotes the reabsorption of water from kidney tubules, which reduces urine volume (see chapter 26).

The secretion rate for ADH changes in response to alterations in blood osmolality and blood volume (figure 18.5). The **osmolality** of a solution increases as the concentration of solutes in the solution increases. Specialized neurons, called **osmoreceptors** (os'mō-rē-sep'terz), synapse with the ADH neurosecretory neurons in the hypothalamus. Osmoreceptors are sensitive to changes in blood osmolality. When blood osmolality increases, the frequency of action potentials in the osmoreceptors increases, resulting in a greater frequency of

action potentials in the axons of ADH neurosecretory neurons. As a consequence, ADH secretion increases. ADH stimulates the kidney tubules to retain water, which reduces blood osmolality and resists any further increase in the osmolality of body fluids.

As the osmolality of the blood decreases, the action potential frequency in the osmoreceptors and the neurosecretory neurons decreases. Thus, less ADH is secreted from the posterior pituitary gland, and the decreased ADH secretion causes an increased volume of water to be eliminated in the form of urine.

Urine volume increases within minutes to a few hours in response to the consumption of a large volume of water. In contrast, urine volume decreases and urine concentration increases within hours if little water is consumed. ADH regulates these changes in urine formation by controlling the permeability of kidney tubules to water. Its effect is to maintain the osmolality and the volume of the extracellular fluid within a normal range of values.

Because ADH regulates blood volume, its secretion is also controlled by blood pressure changes. Sensory receptors that detect changes in blood pressure send action potentials through sensory nerve fibers of the vagus nerve that eventually communicate these changes to the ADH neurosecretory neurons. A decrease in blood pressure, which normally accompanies a decrease in blood volume, causes an increased action potential frequency in

TABLE 18.2 Hormones of the Pituitary Gland

Hormones	Structure	Target Tissue	Response
Posterior Pituitary (Neurohypophysis)			
Antidiuretic hormone (ADH)	Small peptide	Kidneys	Increased water reabsorption (less water is lost in the form of urine)
Oxytocin	Small peptide	Uterus; mammary glands	Increased uterine contractions; increased milk expulsion from mammary glands; unclear function in males
Anterior Pituitary (Adenohypophysis)			
Growth hormone (GH), or somatotropin	Protein	Most tissues	Increased growth in tissues; increased amino acid uptake and protein synthesis; increased breakdown of lipids and release of fatty acids from cells; increased glycogen synthesis and increased blood glucose levels; increased somatomedin production
Thyroid-stimulating hormone (TSH)	Glycoprotein	Thyroid gland	Increased thyroid hormone secretion
Adrenocorticotropic hormone (ACTH)	Peptide	Adrenal cortex	Increased glucocorticoid hormone secretion
Lipotropins	Peptides	Adipose tissues	Increased lipid breakdown
β endorphins	Peptides	Brain, but not all target tissues are known	Analgesia in the brain; inhibition of gonadotropin-releasing hormone secretion
Melanocyte-stimulating hormone (MSH)	Peptide	Melanocytes in the skin	Increased melanin production in melanocytes to make the skin darker in color
Luteinizing hormone (LH)	Glycoprotein	Ovaries in females; testes in males	Ovulation and progesterone production in ovaries; testosterone synthesis and support for sperm cell production in testes
Follicle-stimulating hormone (FSH)	Glycoprotein	Follicles in ovaries in females; seminiferous tubules in males	Follicle maturation and estrogen secretion in ovaries; sperm cell production in testes
Prolactin	Protein	Ovaries and mammary glands in females	Milk production in lactating women; increased response of follicle to LH and FSH; unclear function in males

the neurosecretory neurons and increased ADH secretion, which stimulates the kidneys to retain water. Because the water in urine is derived from blood as it passes through the kidneys, ADH slows any further reduction in blood volume.

An increase in blood pressure decreases the action potential frequency in the ADH neurosecretory neurons. This leads to the secretion of less ADH from the posterior pituitary. As a result, the volume of urine produced by the kidneys increases (figure 18.5). Even small changes in blood osmolality influence ADH secretion. Larger changes in blood pressure are required to influence ADH secretion. The effect of ADH on the kidney and its role in regulating extracellular osmolality and volume are described in greater detail in chapters 26 and 27.

➤ Predict 3

After his school's football team won the division championship, Luke went to a local bar with some friends and drank too much beer. Fortunately, one of his friends served as a designated driver. The next morning, Luke wondered why he was thirsty and felt somewhat dehydrated. His roommate, an anatomy and physiology student, pointed out that alcohol inhibits ADH secretion from the posterior pituitary. The roommate then explained why Luke was thirsty and dehydrated. What was the explanation?

Oxytocin

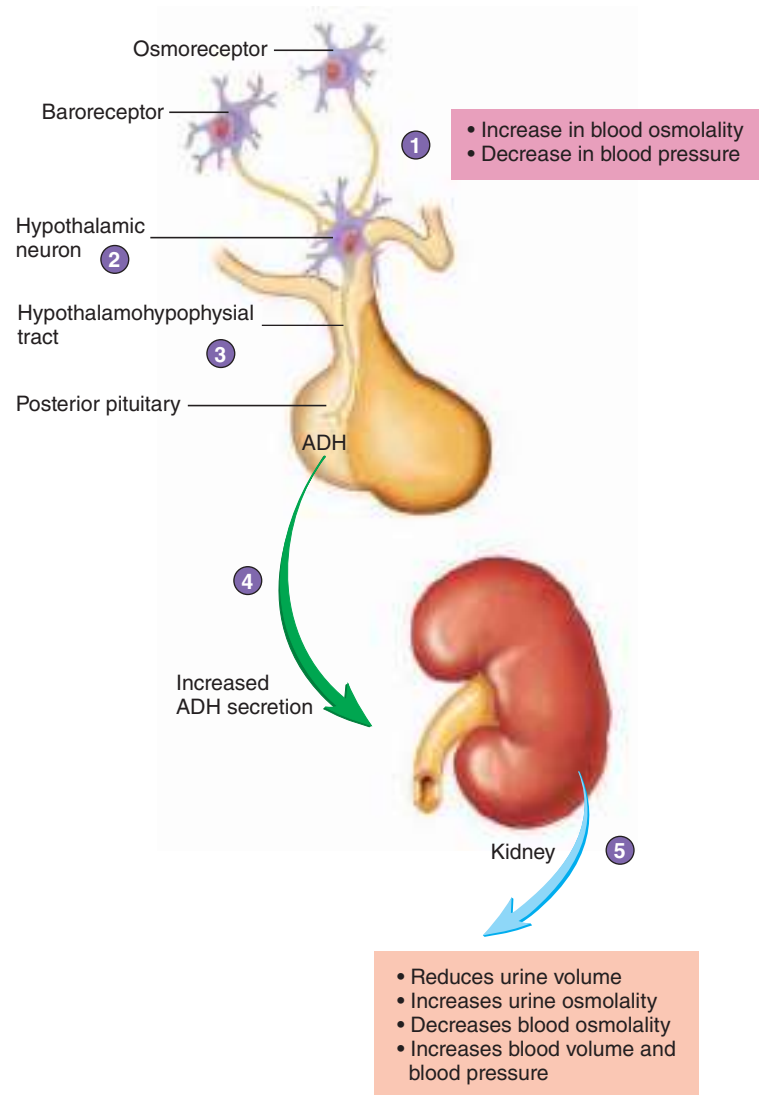

Oxytocin (ok-sē-tō'sin) is an important reproductive hormone, synthesized by the hypothalamic neurosecretory neuron cell bodies in

the paraventricular nuclei. Oxytocin is transported through axons to the posterior pituitary, where it is stored in the axon terminals.

Oxytocin stimulates labor in pregnant mammals. It does this by stimulating smooth muscle contraction in the uterus. This neurohormone plays an important role in the birth of a baby during delivery. It also causes contraction of uterine smooth muscle in nonpregnant women, primarily during menstruation and sexual intercourse. The uterine contractions help rid the uterus of its lining along with small amounts of blood during menstruation. Oxytocin can also facilitate the movement of sperm cells through the uterus after sexual intercourse. Oxytocin is responsible for milk letdown in breastfeeding moms and other lactating mammals. It promotes the contraction of smooth-muscle-like cells surrounding the milk ducts in the mammary glands. In addition, oxytocin is associated with maternal nurturing and bonding (see chapter 29). Although little is known about the specific effects of oxytocin in males, evidence suggests that it promotes sperm movement during ejaculation and pair bonding.

Stretch of the uterus, mechanical stimulation of the cervix, and stimulation of the nipples of the breast when a baby nurses activate nervous reflexes that stimulate oxytocin release. Action potentials are carried by sensory neurons from the uterus and from the nipples to the spinal cord. Action potentials then travel up the spinal cord to the hypothalamus, where they stimulate an increase in the action potential frequency in the axons of oxytocin-secreting neurons. The action potentials pass along the axons in the hypothalamohypophysial tract to the posterior pituitary, where they

- 1 Osmoreceptors in the hypothalamus detect changes in blood osmolality, and baroreceptors detect changes in blood pressure and change the frequency of action potentials in axons of the vagus nerve to the hypothalamus.
- 2 An increase in osmolality and a decrease in blood pressure increase action potentials in ADH-secreting neurons.
- 3 Action potentials are carried by axons of ADH-secreting neurons through the hypothalamohypophysial tract to the posterior pituitary.
- 4 In the posterior pituitary, action potentials cause the release of ADH from the axon terminals into the blood.
- 5 Increasing ADH acts on the kidney tubules to increase water reabsorption, resulting in reduced urine volume, increased urine osmolality, and decreased blood osmolality. This helps maintain blood osmolality and volume.

PROCESS FIGURE 18.5 Control of Antidiuretic Hormone (ADH) Secretion

Small changes in blood osmolality are important in regulating ADH secretion. Larger changes in blood pressure are required to influence ADH secretion.

cause the axon terminals to secrete oxytocin (figure 18.6). The role of oxytocin in the reproductive system is described in greater detail in chapter 29.

ASSESS YOUR PROGRESS

8. Where is ADH produced, from where is it secreted, and what is its target tissue?
9. When ADH levels increase, how are urine volume, blood osmolality, and blood volume affected?
10. What two factors will cause changes in ADH secretion rates? Name the types of sensory cells that respond to alterations in those factors.
11. Where is oxytocin produced, from where is it secreted, and what are its target tissues?
12. What effects does oxytocin have on its target tissues? What factors stimulate the secretion of oxytocin?

Anterior Pituitary Hormones

The anterior pituitary is different from the posterior pituitary because its hormones are synthesized by cells in the anterior pituitary. These anterior pituitary hormones are regulated by releasing and inhibiting hormones. These hormones pass from the hypothalamus through the hypothalamohypophysial portal system to the anterior pituitary and influence anterior pituitary secretions. For some anterior pituitary hormones, the hypothalamus produces both releasing hormones and inhibiting hormones. For others, regulation is primarily by releasing hormones (see table 18.1).

The hormones secreted from the anterior pituitary are proteins, glycoproteins, or polypeptides. They are transported in the plasma of the blood, have a half-life measured in minutes, and bind to membrane-bound receptor molecules on their target cells. For the most part, each hormone is secreted by a separate cell type. Adrenocorticotropic hormone and lipotropin are exceptions because these hormones are derived from the same precursor protein.

- 1 Stretch of the uterus and the uterine cervix or stimulation of the breasts' nipples increases action potentials in axons of oxytocin-secreting neurons.
- 2 Action potentials are conducted by sensory neurons from the uterus and breast to the spinal cord and up ascending tracts to the hypothalamus.
- 3 Action potentials are conducted by axons of oxytocin-secreting neurons in the hypothalamohypophysial tract to the posterior pituitary, where they increase oxytocin secretion.
- 4 Oxytocin enters the circulation, increasing contractions of the uterus and milk letdown from the lactating breast.

PROCESS FIGURE 18.6 Control of Oxytocin Secretion

Many hormones from the anterior pituitary gland are **tropic** (trō'pik) **hormones**, which stimulate the secretion of other hormones from the target tissues. Tropic hormones also control the growth of target tissues. The anterior pituitary hormones include the protein hormones, growth hormone, and prolactin; the peptide hormone adrenocorticotropic hormone and related substances; and the glycoprotein hormones, luteinizing hormone, follicle-stimulating hormone, and thyroid-stimulating hormone.

Growth Hormone

Growth hormone (GH), or *somatotropin*, stimulates growth in most tissues and plays an important role in determining how tall a person becomes. It also regulates metabolism. GH plays an important role in regulating blood nutrient levels after a meal and during periods of fasting. GH increases the movement of amino acids into cells, favors their incorporation into proteins, and slows protein breakdown. GH increases lipolysis (lipid breakdown) and the release of fatty acids from adipocytes into the blood. Fatty acids then can be used as energy sources to drive chemical reactions, including anabolic reactions, by other cells. GH also increases glucose synthesis by the liver, which releases glucose into the blood. The increased use of lipids as an energy source accompanies a decrease in glucose usage. Overall, GH activates the use of lipids to promote growth and protein synthesis.

GH binds directly to membrane-bound receptors on target cells (see chapter 17), such as adipocytes, to produce responses. These responses are called the direct effects of GH and include

the increased breakdown of lipids and the decreased use of glucose as an energy source.

GH also has indirect effects on some tissues. It increases the production of a number of polypeptides, primarily by the liver but also by skeletal muscle and other tissues. These polypeptides are called **somatomedins** (sō'mă-tō-mē'dinz). The best-known somatomedins are **insulin-like growth factors (IGFs)**. They are so named because of their structural resemblance to insulin and because the receptor molecules function through a mechanism similar to that of the insulin receptors. IGFs have paracrine effects and circulate in the blood until they bind to receptors on target tissues. IGFs stimulate growth in cartilage and bone and increase the synthesis of protein in skeletal muscles. Like IGFs, growth hormone and growth factors bind to membrane-bound receptors that phosphorylate intracellular proteins (see chapter 17).

Two neurohormones released from the hypothalamus regulate the secretion of GH (figure 18.7). One hormone, growth hormone-releasing hormone (GHRH), stimulates the secretion of GH, and the other, growth hormone-inhibiting hormone (GHIH), inhibits the secretion of GH. Stimuli that influence GH secretion act on the hypothalamus to increase or decrease the secretion of the releasing and inhibiting hormones. Low blood glucose levels and other stressors stimulate the secretion of GH, and high blood glucose levels inhibit the secretion of GH. Rising blood levels of certain amino acids also increase GH secretion.

- 1 Stress and decreased blood glucose levels increase the release of growth hormone–releasing hormone (GHRH), and decrease the release of growth hormone–inhibiting hormone (GHIH), from the hypothalamus.
- 2 GHRH and GHIH travel through the hypothalamohypophysial portal system to the anterior pituitary.
- 3 Increased GHRH and reduced GHIH act on the anterior pituitary and result in increased GH secretion.
- 4 GH acts on target tissues.
- 5 Increasing GH and somatomedins have a negative-feedback effect on the hypothalamus, resulting in decreased GHRH and increased GHIH release.

PROCESS FIGURE 18.7 Control of Growth Hormone (GH) Secretion

Secretion of GH is controlled by two neurohormones released from the hypothalamus: growth hormone–releasing hormone (GHRH), which stimulates GH secretion, and growth hormone–inhibiting hormone (GHIH), which inhibits GH secretion. Stress increases GHRH secretion and inhibits GHIH secretion. High levels of GH have a negative-feedback effect on the production of GHRH by the hypothalamus.

In most people, a rhythm of GH secretion occurs. Daily peak levels of GH are correlated with deep sleep. Surprisingly, rapidly growing children do not have chronically elevated blood GH levels. However, their levels tend to be higher than those of adults. In addition to GH, factors such as genetics, nutrition, and sex hormones influence growth.

Several pathological conditions are associated with abnormal GH secretion. In general, hypersecretion or hyposecretion of GH is caused by tumors in the hypothalamus or pituitary, the synthesis of structurally abnormal GH, the liver’s inability to produce somatomedins, or the lack of functional receptors in target tissues. The consequences of hypersecretion and hyposecretion of GH are described in the Clinical Impact, “Growth Hormone and Growth Disorders.”

Predict 4

Mr. Hoops has a son who wants to be a basketball player almost as much as Mr. Hoops wants him to be one. Mr. Hoops knows a little bit about growth hormone and asks his son’s doctor if she would prescribe some for his son, so that he can grow tall. What do you think the doctor tells Mr. Hoops?

Prolactin

Prolactin (prō-lak’tin) plays an important role in milk production by the mammary glands of lactating females. It binds to a membrane-bound receptor, which is linked to a kinase that phosphorylates intracellular proteins. The phosphorylated proteins produce the response in the cell. Prolactin also can enhance progesterone secretion by the ovaries after ovulation. No role for this hormone has been clearly established in males. Several hypothalamic neuropeptides can be involved in the complex regulation of prolactin secretion. One neurohormone is prolactin-releasing hormone (PRH), and another is prolactin-inhibiting hormone (PIH). The regulation of gonadotropin and prolactin secretion and their specific effects are explained more fully in chapter 28.

Thyroid-Stimulating Hormone

Thyroid-stimulating hormone (TSH), also called *thyrotropin* (thī-rot’rō-pin, thī-rō-trō’pin), stimulates the synthesis and secretion of thyroid hormones from the thyroid gland. TSH is a glycoprotein dimer consisting of two subunits, α and β , which bind to membrane-bound receptors of the thyroid gland. The α

Clinical IMPACT

Growth Hormone and Growth Disorders

Chronic hyposecretion, or insufficient secretion, of GH in infants and children leads to a condition called **pituitary dwarfism** (dwōrf'izm). Insufficient amounts of GH delay bone growth, resulting in short stature. However, the bones usually have a normal shape, and people with this condition exhibit normal intelligence, in contrast to those who have dwarfism caused by hyposecretion of thyroid hormones. Other symptoms resulting from the lack of GH include mild obesity and delayed development of adult reproductive functions.

There are two types of pituitary dwarfism: (1) In approximately two-thirds of the cases, GH and other anterior pituitary hormones are secreted in reduced amounts. The decrease in other anterior pituitary hormones can result in additional disorders caused by reduced secretion of thyroid hormones, adrenal cortex hormones, and reproductive hormones. (2) In the remaining approximately one-third of cases, GH secretion is reduced, and the secretion of other anterior pituitary hormones is closer to normal. Therefore, these individuals do not experience additional hormone-related disorders, and normal reproduction is possible for them. In adults, no obvious pathology is associated with hyposecretion of GH, although some evidence suggests that lack of GH can lead to reduced bone mineral content in adults.

The gene responsible for determining the structure of GH has been transferred successfully from human cells to bacterial cells, which can produce GH that is identical to human GH. GH produced in this fashion is available to treat patients who suffer from reduced GH secretion, especially children.

Chronic hypersecretion, or excessive secretion, of GH also leads to disorder, depending on whether the hypersecretion occurs before or after complete ossification of the epiphyseal plates in the skeletal system. Chronic hypersecretion of GH before the epiphyseal plates have ossified causes exaggerated and prolonged growth in long bones, a condition called **gigantism** (jī'gan-tizm). Some individuals thus affected have grown to be 8 feet tall or more (see figure 6.18).

In adults, chronically elevated GH levels result in **acromegaly** (ak-rō-meg'ā-lē). No height increase occurs because the epiphyseal plates have ossified. But the condition does result in an increased diameter of the fingers, toes, hands, and feet; the deposition of heavy bony ridges above the eyes; and a prominent jaw. The influence of GH on soft tissues results in a bulbous or broad nose, an enlarged tongue, thickened skin, and sparse subcutaneous adipose tissue. Nerves are frequently compressed as a result of the proliferation of connective tissue. Because GH spares glucose usage, chronic hyperglycemia results, frequently leading to diabetes mellitus and severe atherosclerosis. Treatment for chronic hypersecretion of GH often involves the surgical removal or irradiation of a GH-producing tumor.

subunit is common among the glycoprotein hormones, TSH, luteinizing hormone, and follicle-stimulating hormone. It is the β subunit that dictates the specificity of each of the glycoprotein hormones. Thyroid hormone receptors respond through a G protein mechanism that increases intracellular cAMP levels. cAMP then initiates a series of actions in the target tissue (see chapter 17).

TSH secretion is controlled by two mechanisms. The hypothalamic-releasing hormone, TRH, stimulates TSH secretion. In contrast, thyroid hormones inhibit TSH secretion; once thyroid hormone levels return to their set-point, they inhibit both TRH and TSH levels. Although TSH is secreted in an episodic fashion and its blood levels are highest at night, thyroid hormone levels are maintained within a narrow range of values. This tight regulation of hormone levels is possible because of this efficient feedback mechanism (see “Thyroid Hormones,” in section 18.3).

Adrenocorticotrophic Hormone and Related Substances

Adrenocorticotrophic (ă-drē'nō-kōr'ti-kō-trō'pik) **hormone (ACTH)** from the anterior pituitary stimulates secretion of the hormone cortisol from the adrenal cortex (see “Hormones of the Adrenal Cortex” in section 18.5). ACTH is one of four smaller molecules derived from a large precursor protein called **proopiomelanocortin** (prō-ō'pē-ō-mel'ā-nō-kōr'tin; **POMC**). POMC is synthesized in the anterior pituitary and is subsequently broken down into multiple, smaller peptides. Many of these peptides are also hormones, including ACTH, lipotropins, β endorphins, and melanocyte-stimulating hormone.

Environmental stress is a key stimulus for ACTH secretion. Once ACTH arrives at its target tissues, it activates a G protein-mediated cAMP mechanism. The primary action of ACTH is release of the principal hormone that regulates chronic stress. This hormone is cortisol from the adrenal cortex. In pathological conditions such as chronic adrenocortical insufficiency (Addison disease), the adrenal cortex degenerates, usually due to an autoimmune condition (see chapter 22). Blood levels of ACTH and related hormones are chronically elevated, and the skin becomes markedly darker. This is because ACTH and melanocyte-stimulating hormone bind to melanocytes in the skin and increase skin pigmentation (see chapter 5). Regulation of ACTH secretion and the effects of the hypersecretion and hyposecretion of ACTH are described in section 18.5.

The **lipotropins** (li-pō-trō'pinz) secreted from the anterior pituitary bind to membrane-bound receptor molecules on adipocytes. They cause lipid breakdown and the release of fatty acids into the blood.

The **β endorphins** (en'dōr-finz) have the same effects as opiate drugs, such as morphine, and they can play a role in analgesia (pain relief) in response to stress and exercise. Other functions have been proposed for the β endorphins, including the regulation of body temperature, food intake, and water balance. Both ACTH and β endorphin secretions increase in response to stress and exercise.

Melanocyte-stimulating hormone (MSH) binds to membrane-bound receptors on skin melanocytes and stimulates increased melanin deposition in the skin. The regulation of MSH secretion and its function in humans are not well understood, although studies have shown that MSH is also important in regulating appetite and sexual behavior.

Luteinizing Hormone and Follicle-Stimulating Hormone

Gonadotropins (gō'nad-ō-trō'pinz) are glycoprotein hormones capable of promoting the growth and function of the **gonads**, the ovaries and testes. The two major gonadotropins secreted from

the anterior pituitary are **luteinizing** (loo'tē-i-nīz-ing) **hormone (LH)** and **follicle-stimulating hormone (FSH)**. LH and FSH, along with prolactin, play important roles in regulating reproduction.

LH and FSH secreted into the blood bind to membrane-bound receptors, increase the intracellular synthesis of cAMP through G protein mechanisms, and stimulate the production of **gametes** (gam'ēts)—sperm cells in the testes and oocytes in the ovaries. LH and FSH also control the production of reproductive hormones—estrogens and progesterone in the ovaries and testosterone in the testes.

LH and FSH are released from anterior pituitary cells under the influence of the hypothalamic-releasing hormone gonadotropin-releasing hormone (GnRH). Gonadal steroid hormones are also critical regulators of the gonadotropins and exhibit a complex cycle of hormone interactions, which are further described in chapter 29.

ASSESS YOUR PROGRESS

13. Structurally, what kinds of hormones are released from the anterior pituitary gland? Do these hormones bind to plasma proteins? How long is their half-life, and how do they activate their target tissues?
14. What effects do stress, blood amino acid levels, and blood glucose levels have on GH secretion?
15. Describe the effects of GH on its target tissues.
16. What stimulates the release of somatomedins? Where are they produced, and what are their effects?
17. What pathological conditions are the result of hypersecretion of GH? Describe their symptoms.
18. What pathological conditions are the result of hyposecretion of GH? Describe their symptoms.
19. For each of the following hormones secreted by the anterior pituitary gland, name the target tissue and the hormone's effect on its target tissue: GH, prolactin, ACTH, LH, and FSH.
20. How are ACTH, lipotropins, β endorphins, and MSH related? What are the functions of these hormones?
21. What is a gonadotropin? Name two gonadotropins produced by the anterior pituitary gland, and explain their functions.

18.3 Thyroid Gland

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the structure of the thyroid gland.
- B. Explain the processes for the synthesis, secretion, and blood transport of T_3 and T_4 .
- C. Describe the mechanism of action and the effects of T_3 and T_4 in the body.
- D. Relate how thyroid hormone secretion is regulated.

- E. Describe the effects of hyposecretion and hypersecretion of thyroid hormones and the pathological conditions that cause the abnormalities.
- F. Describe the role of calcitonin in the maintenance of blood calcium levels and in bone health.

The **thyroid gland** synthesizes and secretes three hormones. It is composed of two lobes connected by a narrow band of thyroid tissue called the **isthmus**. The lobes are lateral to the upper portion of the trachea just inferior to the larynx, and the isthmus extends across the anterior aspect of the trachea (figure 18.8a). The thyroid gland is one of the largest endocrine glands, with a weight of approximately 20 g. Because it is highly vascular, it is a darker red than surrounding tissues.

The thyroid gland contains numerous **follicles**, which are small spheres whose walls are composed of a single layer of cuboidal epithelial cells (figure 18.8b,c). The center of each thyroid follicle is filled with a gelatinous material called colloid. Colloid is composed of a highly concentrated protein called **thyroglobulin** (thī-rō-glob'ū-lin), which is synthesized and secreted by cells of the thyroid follicle. Thyroglobulin is the precursor to thyroid hormones. It is a large collection of individual thyroid hormone molecules. Thus, thyroglobulin stores a huge amount of thyroid hormones. Storage of such a large amount of hormone is unique to the thyroid gland.

Between the follicles, a delicate network of loose connective tissue contains numerous capillaries. Scattered **parafollicular** (par-ă-fo-lik'ū-lār) **cells** lie between the follicles and among the cells that make up the walls of the follicle. The parafollicular cells secrete **calcitonin** (kal-si-tō'nin), which plays a role in reducing the concentration of calcium in the body fluids when calcium levels become elevated.

Thyroid Hormones

The thyroid hormones include **triiodothyronine** (trī-ī'ō-dō-thī'rō-nēn), commonly called T_3 , and **tetraiodothyronine** (tet'rā-ī'ō-dō-thī'rō-nēn). A more common name for tetraiodothyronine is **thyroxine** (thī-rok'sēn; thī-rok'sin), or even more commonly T_4 . T_4 is the precursor for T_3 , and both are major secretory products of the thyroid gland, consisting of 10% T_3 and 80% T_4 , respectively (table 18.3). Although calcitonin (10%) is secreted by the parafollicular cells of the thyroid gland, T_3 and T_4 are considered the thyroid hormones because they are more clinically important and because they are secreted from the thyroid follicles.

T_3 and T_4 Synthesis

Thyroid-stimulating hormone (TSH) from the anterior pituitary stimulates thyroid hormone synthesis and secretion. TSH causes an increase in the synthesis of T_3 and T_4 , which are then stored inside the thyroid follicles as part of thyroglobulin. TSH also causes T_3 and T_4 to be released from thyroglobulin and enter the plasma of the blood. Because iodine is an integral component of the T_3 and T_4 molecules, humans must consume an adequate amount of iodine in the diet to support thyroid hormone synthesis. In the United States, most of this dietary iodine is derived

FIGURE 18.8 Anatomy and Histology of the Thyroid Gland

Parafollicular cells are in the tissue between the thyroid follicles. (c) Low-power photomicrograph of thyroid follicles. **APR**

TABLE 18.3 Hormones of the Thyroid and Parathyroid Glands

Hormones	Structure	Target Tissue	Response
Thyroid Gland			
Secreted by <i>thyroid follicles</i>			
Thyroid hormones (T_3 and T_4)	Amino acid derivative	Most cells of the body	Increased metabolic rate; increased protein synthesis; essential for normal growth and maturation
Secreted by <i>parafollicular cells</i>			
Calcitonin	Polypeptide	Bone	Decreased rate of breakdown of bone by osteoclasts; prevention of a large increase in blood Ca^{2+} levels
Parathyroid Gland			
Parathyroid hormone (PTH)	Polypeptide	Bone, kidneys, small intestine	Increased rate of breakdown of bone by osteoclasts; increased reabsorption of Ca^{2+} in kidneys; increased absorption of Ca^{2+} from the small intestine; increased vitamin D synthesis; increased blood Ca^{2+} levels

PROCESS FIGURE 18.9 Biosynthesis of Thyroid Hormones

The numbered steps describe the synthesis and secretion of T_3 and T_4 from the thyroid gland.

from iodized salt. The following events in the thyroid follicles result in T_3 and T_4 synthesis and secretion (figure 18.9):

1. Iodide ions (I^-) are taken up by thyroid follicle cells via secondary active transport by a sodium-iodide symporter. The active transport of the I^- is against a concentration gradient of approximately 30-fold in healthy individuals.
2. Thyroglobulins, which contain numerous tyrosine molecules, are synthesized within the cells of the follicles.
3. Nearly simultaneously, the I^- are oxidized to form iodine (I), and either one or two iodine atoms are bound to some of the tyrosine molecules of thyroglobulin by the enzyme thyroid peroxidase.
4. This occurs close to the time the thyroglobulin molecules are secreted by exocytosis into the lumen of the follicle. As a result, the secreted thyroglobulin contains iodinated tyrosine amino acids with either one iodine atom (monoiodotyrosine) or two iodine atoms (diiodotyrosine).
5. Within the colloid in the lumen of the follicle, two diiodotyrosine molecules of thyroglobulin combine to form tetraiodothyronine (T_4), or one monoiodotyrosine and one diiodotyrosine molecule combine to form triiodothyronine (T_3). Large amounts of T_3 and T_4 are stored within the thyroid follicles as part of thyroglobulin. A reserve sufficient to supply thyroid hormones for approximately 2–4 months is stored in this form.

6. Thyroglobulin is taken into the thyroid follicle cells by endocytosis.
7. Lysosomes fuse with the endocytotic vesicles. Proteolytic enzymes break down thyroglobulin to release T_3 and T_4 . The remaining amino acids of thyroglobulin are recycled to synthesize more thyroglobulin.
8. T_3 and T_4 either diffuse through the plasma membranes or are carried by specific transporters of the follicular cells into the interstitial spaces and finally into the capillaries of the thyroid gland.

Transport in the Blood

T_3 and T_4 are transported in combination with plasma proteins in the blood. Approximately 75% of the circulating T_3 and T_4 are bound to **thyroxine-binding globulin (TBG)**, which is synthesized by the liver, and 20–30% are bound to other plasma proteins, including albumin. T_3 and T_4 , bound to these plasma proteins, form a large reservoir of circulating thyroid hormones, and the half-life of these hormones is greatly increased because of this binding. After thyroid gland removal in experimental animals, it takes approximately 1 week for T_3 and T_4 levels in the blood to decrease by 50%. As free T_3 and T_4 levels decrease in the interstitial spaces, additional T_3 and T_4 dissociate from the plasma proteins to maintain the levels in the tissue spaces. When sudden secretion of T_3 and T_4 occurs, the excess binds to the plasma

proteins. As a consequence, the concentration of thyroid hormones in the tissue spaces fluctuates very little.

Approximately 40% of the T_4 is converted to T_3 in the body tissues. This conversion is important for the action of thyroid hormones on their target tissues. T_3 is the major hormone that interacts with thyroid hormone target cells. T_3 is several times more potent than T_4 due to its higher affinity for the thyroid hormone receptor.

Much of the circulating T_4 is eliminated from the body by being converted to tetraiodothyroacetic acid, or by being modified, and then excreted in the urine or bile. In addition, a large amount is converted to an inactive form of T_3 , rapidly metabolized, and excreted.

Mechanism of Action of T_3 and T_4

Because T_3 and T_4 are lipid-soluble hormones, they can bind to nuclear receptors in their target tissues. This mechanism is similar to that of the steroid hormones. T_3 and T_4 diffuse through the plasma membrane into the cytoplasm of cells, migrate to the nucleus, and bind to their receptors. When thyroid hormones are bound to their receptors, they interact with DNA in the nucleus to influence genes and generally stimulate protein synthesis. The newly synthesized proteins within the target cells mediate the cells' response to thyroid hormones.

Effects of T_3 and T_4

T_3 and T_4 affect nearly every tissue in the body, but not all tissues respond identically. Metabolism is primarily affected in some tissues, and growth and maturation are influenced in others.

The normal rate of metabolism for an individual depends on an adequate supply of thyroid hormone, which increases the rate

at which glucose, lipids, and protein are metabolized. The metabolic rate can increase 60–100% when blood T_3 and T_4 are elevated, whereas low levels of T_3 and T_4 lead to the opposite effect. Because the increased rate of metabolism produces heat, normal body temperature is partly due to adequate thyroid hormones. Thyroid hormones increase the activity of Na^+K^+ pumps, which give off heat as a “by-product.” T_3 and T_4 also alter the number and activity of mitochondria, resulting in greater ATP synthesis and thus heat production.

In addition to metabolism, T_3 and T_4 regulate the normal growth and maturation of organs. For example, the growth of bone, hair, teeth, connective tissue, and nervous tissue requires thyroid hormone. One reason tissues require thyroid hormones for normal growth is that T_3 and T_4 play a permissive role for GH, which means that GH does not have its normal effect on target tissues if T_3 and T_4 are not present.

Failure to maintain homeostatic amounts of thyroid hormone dramatically affects the body's functions. Hypersecretion of T_3 and T_4 increases the rate of metabolism. High body temperature, weight loss, increased appetite, rapid heart rate, and an enlarged thyroid gland are major symptoms.

Hyposecretion of T_3 and T_4 decreases the rate of metabolism. Low body temperature, weight gain, reduced appetite, reduced heart rate, reduced blood pressure, weak skeletal muscles, and apathy are major symptoms. Hyposecretion of T_3 and T_4 that occurs during development causes a decreased metabolic rate, abnormal nervous system development, abnormal growth, and abnormal maturation of tissues. The consequence is neonatal hypothyroidism characterized by developmental delay, short stature, and specific physical deformities.

The specific effects of the hyposecretion and hypersecretion of thyroid hormones are outlined in table 18.4.

TABLE 18.4 Effects of Hyposecretion and Hypersecretion of Thyroid Hormones

Hypothyroidism	Hyperthyroidism
Decreased metabolic rate, low body temperature, cold intolerance	Increased metabolic rate, high body temperature, heat intolerance
Weight gain, reduced appetite	Weight loss, increased appetite
Reduced activity of sweat and sebaceous glands; dry, cold skin	Copious sweating; warm, flushed skin
Reduced heart rate, reduced blood pressure, dilated and enlarged heart	Rapid heart rate, elevated blood pressure, abnormal electrocardiogram
Weak, untoned skeletal muscles; sluggish movements	Weak skeletal muscles that exhibit tremors, quick movements with exaggerated reflexes
Constipation	Bouts of diarrhea
Myxedema (swelling of the face and body) as a result of subcutaneous mucoprotein deposits	Exophthalmos (protruding eyes) as a result of connective tissue proliferation and other deposits behind the eye
Apathy, somnolence	Hyperactivity, insomnia, restlessness, irritability, short attention span
Coarse hair; rough, dry skin	Soft, smooth hair and skin
Decreased iodide uptake	Increased iodide uptake
Possible goiter (enlargement of the thyroid gland) due to loss of negative feedback	Almost always a goiter

Regulation of Thyroid Hormone Secretion

Thyrotropin-releasing hormone (TRH) from the hypothalamus and TSH from the anterior pituitary function together to increase T_3 and T_4 secretion from the thyroid gland (figure 18.10). Stress and exposure to cold cause increased TRH secretion, and prolonged fasting decreases TRH secretion. TRH stimulates the secretion of TSH from the anterior pituitary. TSH travels to the thyroid gland, where it stimulates the synthesis and secretion of T_3 and T_4 . TSH also causes hypertrophy (increased cell size) and hyperplasia (increased cell number) of the thyroid gland. Decreased blood levels of TSH lead to decreased T_3 and T_4 secretion and to thyroid gland atrophy. T_3 and T_4 have a negative-feedback effect on the hypothalamus and anterior pituitary gland. As T_3 and T_4 levels increase in the blood, they inhibit TRH and TSH secretion. If the thyroid gland is removed or if T_3 and T_4 secretion declines, TSH levels in the blood increase dramatically. Conditions in which TSH is elevated can often be characterized by the abnormal thyroid gland overgrowth called goiter (table 18.5)

Hypothyroidism, or reduced secretion of thyroid hormones, can result from having an iodine deficiency, taking certain drugs, or being exposed to chemicals that inhibit T_3 and T_4 synthesis. It can also be caused by inadequate secretion of TSH, by an autoimmune disease that depresses thyroid hormone function, or by surgical removal of the thyroid gland. Hypersecretion of T_3 and T_4 can result from the synthesis of an immunoglobulin that stimulates TSH receptors and acts like TSH, from TSH-secreting tumors of the pituitary gland, and from thyroid tumors.

► Predict 5

Becky has lost 30 pounds over the past several months, even though her appetite has been good and she has been eating more than usual. She complains to her physician that she is nervous and restless, has a short attention span, becomes fatigued easily but cannot sleep well, moves compulsively, and sweats excessively. Her physician notes that she also exhibits tachycardia. Suspecting hyperthyroidism, he orders a blood test, which indicates elevated levels of T_3 and T_4 and low levels of TSH. Becky also has a TSH-like immunoglobulin in her plasma. Explain these results.

Calcitonin

Parafollicular cells, or C cells, are dispersed between the thyroid follicles throughout the thyroid gland. These cells secrete the hormone calcitonin in response to increased calcium levels in the blood.

The primary target tissue for calcitonin is bone (see chapter 6). Calcitonin binds to membrane-bound receptors, decreases osteoclast activity, and lengthens the life span of osteoblasts. The resulting bone deposition leads to decreases in blood calcium and phosphate levels.

Calcitonin's importance in regulating blood Ca^{2+} levels is unclear; it may be most important in juveniles in promoting bone growth. The rate of calcitonin secretion increases in response to elevated blood Ca^{2+} levels, and calcitonin may prevent large increases in blood Ca^{2+} levels following a meal. Blood levels of calcitonin decrease with age to a greater extent in females than in males. Also, the incidence of osteoporosis increases with age and occurs to a greater degree in females than in males.

Interestingly, complete thyroidectomy does not result in high blood Ca^{2+} levels, possibly because the regulation of blood Ca^{2+} levels by vitamin D and other hormones, such as parathyroid hormone (if the parathyroid glands are retained in the body), compensates for the loss of calcitonin in individuals who have undergone a thyroidectomy. No pathological condition is directly associated with a lack of calcitonin secretion. Some evidence suggests that calcitonin may play a role in regulating food intake by decreasing appetite. Clinically, calcitonin nasal sprays have been effective in the management of postmenopausal osteoporosis.

Clinical IMPACT

Goiter and Exophthalmos

An abnormal enlargement of the thyroid gland is called a **goiter**. Goiters can result from either hypothyroidism or hyperthyroidism. An **iodine-deficiency goiter** results when dietary iodine intake is so low that there is not enough iodine to synthesize T_3 and T_4 (table 18.5). As a result, blood levels of T_3 and T_4 decrease, and the person may exhibit symptoms of hypothyroidism. At the same time, the reduced negative feedback of T_3 and T_4 on the anterior pituitary and hypothalamus results in elevated TSH secretion. TSH causes hypertrophy and hyperplasia of the thyroid gland and increased thyroglobulin synthesis, even though there is not enough iodine to synthesize T_3 and T_4 . Consequently, the thyroid gland enlarges.

Historically, iodine-deficiency goiters were common in people inhabiting areas where the soil was depleted of iodine, called “goiter belts.” Consequently, plants grown in these areas had little iodine in them and caused iodine-deficient diets. In the United States, iodized salt has nearly eliminated iodine-deficiency goiters. However, iodine-deficiency diseases are still common throughout the world. The World Health Organization has called them the most common preventable cause of mental defects, and hypothyroidism may be the most common endemic disease on the planet.

A **toxic goiter** secretes excess T_3 and T_4 , and it can result from elevated TSH secretion or elevated TSH-like immunoglobulin (see Graves disease in table 18.5). Toxic goiter results in symptoms of hyperthyroidism. Protruding eyes, a condition called **exophthalmos**, often accompany hyperthyroidism. The deposition of excess connective tissue proteins behind the eyes makes the eyes move anteriorly; consequently, they appear to be larger than normal.

Graves disease is the most common cause of hyperthyroidism (see Systems Pathology, later in this chapter). Elevated T_3 and T_4 levels resulting from this condition suppress TSH and TRH, but the T_3 and T_4 levels remain elevated. Exophthalmos is common. Treatment often involves antithyroid drugs that reduce T_3 and T_4 secretion, partial destruction of the thyroid gland using radioactive iodine, and partial or complete surgical removal of the thyroid gland. These treatments are followed by the oral administration of the appropriate amount of T_3 and T_4 . Unfortunately, removal of the thyroid gland normally does not reverse exophthalmos.

**PROCESS FIGURE 18.10** Regulation of Thyroid Hormone (T_3 and T_4) Secretion**TABLE 18.5****Abnormal Thyroid Conditions**

Cause	Description
Hypothyroidism	
Iodine deficiency	Causes inadequate T_3 and T_4 synthesis, which results in elevated thyroid-stimulating hormone (TSH) secretion; thyroid gland enlarges (goiter) as a result of TSH stimulation; T_3 and T_4 frequently remain in the low to normal range
Goitrogenic (goiter-causing) substances	Inhibit T_3 and T_4 synthesis; found in certain drugs and in small amounts in certain plants, such as cabbage
Neonatal hypothyroidism	Caused by maternal iodine deficiency or congenital errors in thyroid hormone synthesis; results in developmental delay and a short, malformed appearance
Pituitary insufficiency	Results from lack of TSH secretion; often associated with inadequate secretion of other anterior pituitary hormones
Hashimoto disease	Autoimmune disease in which thyroid hormone secretion can be normal or depressed
Lack of thyroid gland	Partial or complete surgical removal or drug-induced destruction of the thyroid gland as a treatment for Graves disease (hyperthyroidism)
Hyperthyroidism	
Graves disease	Characterized by goiter and exophthalmos; apparently an autoimmune disease; most patients have a TSH-like immunoglobulin, called thyroid-stimulating immunoglobulin (TSI), in their plasma
Tumors—benign adenoma or cancer	Result in either normal secretion or hypersecretion of thyroid hormones (rarely hyposecretion)
Thyroiditis—a viral infection	Produces painful swelling of the thyroid gland with normal or slightly increased T_3 and T_4 production
Elevated TSH levels	Result from a pituitary tumor
Thyroid storm	Sudden release of large amounts of T_3 and T_4 ; caused by surgery, stress, infections, or other, unknown factors

ASSESS YOUR PROGRESS

22. Where is the thyroid gland located? Describe the follicles and the parafollicular cells within the thyroid. What hormones do they produce?
23. Starting with the uptake of iodide by the follicles, describe the production and secretion of thyroid hormones (T_3 and T_4).
24. How are the thyroid hormones transported in the blood? What effect does this transport have on their half-life?
25. What are the target tissues of thyroid hormones? By what mechanism do thyroid hormones alter the activities of their target tissues? What effects are produced?
26. Starting in the hypothalamus, explain how chronic exposure to cold, food deprivation, or stress can affect thyroid hormone production.
27. Diagram two negative-feedback mechanisms involving hormones that regulate the production of thyroid hormones.
28. What is a goiter? What can cause one to develop?
29. What conditions cause hypothyroidism? Describe the effects of hyposecretion of thyroid hormones.
30. What conditions cause hyperthyroidism? Describe the effects of hypersecretion of thyroid hormones.
31. What effect does calcitonin have on osteoclasts, osteoblasts, and blood calcium levels? What stimulus can cause an increase in calcitonin secretion?

18.4 Parathyroid Glands

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the location and structure of the parathyroid glands.
- B. Explain the mechanism of parathyroid hormone action and its effects.
- C. Describe the causes and symptoms of hypoparathyroidism and hyperparathyroidism.

The **parathyroid** (par-ă-thī'royd) **glands** are usually embedded in the posterior part of each lobe of the thyroid gland and are made up of two cell types: chief cells and oxyphils. The chief cells secrete parathyroid hormone, but the function of the oxyphils is unknown. Usually, four parathyroid glands are present, with their cells organized in densely packed masses, or cords, rather than in follicles (figure 18.11). In some cases, one or more of the parathyroid glands do not become embedded in the thyroid gland and remain in the nearby connective tissue.

Parathyroid hormone (PTH), also called *parathormone*, is a polypeptide hormone that is important in regulating calcium levels in body fluids (see table 18.3). The major target tissues for PTH are bone, the kidneys, and the small intestine. However, PTH targets the small intestine indirectly by stimulating vitamin D activation. Vitamin D acts directly on cells of the small intestine. PTH

(a)

Posterior view

(b)

FIGURE 18.11 Anatomy and Histology of the Parathyroid Glands

(a) The parathyroid glands are embedded in the posterior part of the thyroid gland. (b) The parathyroid glands are composed of densely packed cords of cells. **APR**

binds to membrane-bound receptors and activates a G protein mechanism that increases intracellular cAMP levels in target tissues. Without functional parathyroid glands, the ability to adequately regulate blood calcium levels is lost.

PTH stimulates osteoclast activity in bone and can cause the number of osteoclasts to increase. The increased osteoclast activity results in bone reabsorption and the release of calcium and phosphate, causing an increase in blood calcium levels. Osteoclasts have no PTH receptors, but osteoblasts and red bone marrow stem cells do. PTH binds to receptors on osteoblasts, which then promote an increase in osteoclast activity (see chapter 6).

PTH causes calcium reabsorption within the kidneys, so that less calcium leaves the body in urine. It also increases the enzymatic formation of active vitamin D in the kidneys. Calcium is actively absorbed by the epithelial cells of the small intestine, and the synthesis of transport proteins in the intestinal cells requires active vitamin D. PTH increases the rate of active vitamin D synthesis, which in turn increases the rate of calcium and phosphate absorption in the intestine, thereby elevating blood levels of calcium.

Although PTH increases the release of phosphate ions (PO_4^{3-}) from bone and indirectly stimulates PO_4^{3-} absorption in the small intestine, it increases PO_4^{3-} excretion in the kidney. The overall effect of PTH is to decrease blood phosphate levels. A simultaneous increase in both Ca^{2+} and PO_4^{3-} is undesirable because it allows calcium phosphate to precipitate in the body's soft tissues, where they cause irritation and inflammation.

The regulation of PTH secretion and the role of PTH and calcitonin in regulating blood Ca^{2+} levels are outlined in figure 18.12. The primary stimulus for the secretion of PTH is a decrease in blood Ca^{2+} levels, whereas elevated blood Ca^{2+} levels inhibit PTH secretion. This regulation keeps blood Ca^{2+} levels fluctuating within a normal range of values. Both hypersecretion and hyposecretion of PTH cause serious symptoms (table 18.6). The regulation of blood Ca^{2+} levels is discussed more thoroughly in chapter 27.

Inactive parathyroid glands result in **hypocalcemia**, abnormally low levels of calcium in the blood. Reduced extracellular calcium levels cause voltage-gated Na^+ channels in plasma membranes to open, which increases the permeability of plasma membranes to Na^+ . As a consequence, Na^+ diffuses into cells and causes depolarization (see chapter 11). Symptoms of hypocalcemia are nervousness, muscle spasms, cardiac arrhythmia, and convulsions. Extreme cases may lead to tetany of skeletal muscles, including the respiratory muscles, which can cause death.

Predict 6

A patient with a malignant tumor had his thyroid gland removed. What effect does this removal have on blood levels of Ca^{2+} ? If the parathyroid glands are inadvertently removed along with the thyroid gland, death can result because the muscles of respiration undergo sustained contractions. Explain.

ASSESS YOUR PROGRESS

32. Where are the parathyroid glands located, and what hormone do they produce?
33. What are the major target tissues for parathyroid hormone?
34. What effect does PTH have on osteoclasts, osteoblasts, the kidneys, the small intestine, and bone?
35. How are blood calcium and phosphate levels regulated by PTH?
36. What can cause hypoparathyroidism? Describe the symptoms.
37. What can cause hyperparathyroidism? Describe the symptoms.

18.5 Adrenal Glands

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Relate the location of the adrenal glands and explain the embryological origins of the two parts of the glands.
- B. Describe the mechanisms and actions of the hormones secreted by the adrenal medulla.
- C. Name the layers of the adrenal cortex, the type of product secreted by each layer, and the predominant hormone of each layer.
- D. Describe the individual target tissues and their responses to the hormones of the adrenal cortex.
- E. Explain the role of ACTH in the regulation of the adrenal cortex hormones.
- F. Discuss the causes and symptoms of hyposecretion and hypersecretion of adrenal cortex hormones.

The **adrenal** (ă-drē'năl) **glands** produce a diverse set of hormones. The adrenal glands, also called the *suprarenal* (soo'pră-rē'năl) *glands*, are near the superior poles of the kidneys. Like the kidneys, they are retroperitoneal, and they are surrounded by abundant adipose tissue. The adrenal glands are enclosed by a connective tissue capsule and have a well-developed blood supply (figure 18.13a).

The adrenal glands are composed of an inner **medulla** and an outer **cortex**, which are derived from two separate embryonic tissues. The adrenal medulla arises from neural crest cells, which also give rise to postganglionic neurons of the sympathetic division of the autonomic nervous system (see chapters 16 and 29). Unlike most glands of the body, which develop from invaginations of epithelial tissue, the adrenal cortex is derived from mesoderm.

Trabeculae of the connective tissue capsule penetrate the adrenal gland in several locations, and numerous small blood vessels course within the trabeculae to supply the gland. The adrenal medulla consists of closely packed polyhedral cells centrally located in the gland (figure 18.13b). The adrenal cortex is composed of smaller cells and forms three indistinct layers: the **zona glomerulosa** (glō-mār'ū-lōs-ă), the **zona fasciculata** (fa-sik'ū-lă-tă), and the **zona reticularis** (re-tik'ū-lăr'is). These three layers are functionally and structurally specialized. The zona glomerulosa, located immediately beneath the capsule, is composed of small clusters of cells and secretes aldosterone. Beneath the zona glomerulosa is the thickest part of the adrenal cortex, the zona fasciculata, which secretes cortisol. In this layer, the cells form long columns, or fascicles, that extend from the surface toward the medulla of the gland. The deepest layer of the adrenal cortex, the zona reticularis, secretes androgens and is a thin layer of irregularly arranged cords of cells.

Hormones of the Adrenal Medulla

The adrenal medulla is a modified sympathetic nervous system ganglion. It secretes two major hormones: **epinephrine** (ep'i-nef'rin; *adrenaline*; ă-dren'ă-lin), which accounts for 80% of adrenal medulla hormones, and **norepinephrine** (nōr'ep-i-nef'rin; *nor-adrenaline*; nor-ă-dren'ă-lin), which accounts for 20% (table 18.7). Epinephrine and norepinephrine are closely related. In fact, norepinephrine is a precursor to the formation of epinephrine.

HOMEOSTASIS FIGURE 18.12 Regulation of Blood Levels of Calcium Ions

(1) Blood Ca^{2+} is within its normal range. (2) Blood Ca^{2+} level increases outside the normal range. (3) The parafollicular cells and the parathyroid gland cells detect elevated blood Ca^{2+} . The parafollicular cells secrete calcitonin; the parathyroid gland cells decrease PTH secretion. (4) There is less bone reabsorption and less uptake of Ca^{2+} from both the kidney and the intestine. (5) Blood Ca^{2+} level drops back to its normal range. (6) Homeostasis is restored. Observe the response to a drop in blood Ca^{2+} by following the red arrows.

TABLE 18.6

Causes and Symptoms of Hyposecretion and Hypersecretion of Parathyroid Hormone

Cause	Symptoms
Hypoparathyroidism Accidental removal during thyroidectomy	Hypocalcemia Increased neuromuscular excitability; possible tetany, laryngospasm, and death from asphyxiation Flaccid heart muscle; possible cardiac arrhythmia Diarrhea
Hyperparathyroidism Primary hyperparathyroidism: a result of abnormal parathyroid function—adenomas of the parathyroid gland (90%), idiopathic (unknown cause) hyperplasia of parathyroid cells (9%), or carcinomas (1%) Secondary hyperparathyroidism: caused by conditions that reduce blood Ca^{2+} levels, such as inadequate Ca^{2+} in the diet, inadequate levels of vitamin D, pregnancy, or lactation	Hypercalcemia or normal blood Ca^{2+} levels; calcium carbonate salts may be deposited throughout the body, especially in the renal tubules (kidney stones), lungs, blood vessels, and gastric mucosa Bones weakened as a result of reabsorption; some cases are first diagnosed when a radiograph is taken of a broken bone Neuromuscular system less excitable; possible muscular weakness Increased force of contraction of cardiac muscle; at very high blood Ca^{2+} levels, possible cardiac arrest during contraction Constipation

**FIGURE 18.13** Anatomy and Histology of Adrenal Glands

(a) An adrenal gland is at the superior pole of each kidney. (b) The adrenal glands have an outer cortex and an inner medulla. The cortex is surrounded by a connective tissue capsule and consists of three layers: the zona glomerulosa, the zona fasciculata, and the zona reticularis. **APR**

TABLE 18.7 Hormones of the Adrenal Gland

Hormones	Structure	Target Tissue	Response
Adrenal Medulla			
Epinephrine primarily; norepinephrine	Amino acid derivatives	Heart, blood vessels, liver, adipose cells	Increased cardiac output; increased blood flow to skeletal muscles and to the heart (see chapter 20); vasoconstriction of blood vessels, especially in the viscera and skin; increased release of glucose and fatty acids into the blood; in general, preparation for physical activity
Adrenal Cortex			
Mineralocorticoids (aldosterone)	Steroids	Kidney	Increased Na ⁺ reabsorption and K ⁺ and H ⁺ excretion; enhanced water reabsorption
Glucocorticoids (cortisol)	Steroids	Most tissues	Increased protein and lipid breakdown; increased glucose production; inhibition of immune response and decreased inflammation
Androgens	Steroids	Many tissues	Of minor importance in males; in females, development of some secondary sex characteristics, such as axillary and pubic hair

Epinephrine and norepinephrine combine with adrenergic receptors, which are membrane-bound receptors in target cells. They are classified as either α -adrenergic or β -adrenergic receptors, and each of these categories has subcategories that affect target tissues differently. All of the adrenergic receptors function through G protein mechanisms. In general, the α -adrenergic receptors cause Ca²⁺ channels to open, cause the release of Ca²⁺ from the endoplasmic reticulum by activating phospholipase enzymes, open K⁺ channels, decrease cAMP synthesis, or stimulate the synthesis of eicosanoid molecules, such as prostaglandins. The β -adrenergic receptors all increase cAMP synthesis. A complete description of epinephrine and norepinephrine is not included in this chapter; rather, the effects of these hormones are described in the context of the body systems (see chapters 16, 20, 21, 24, and 26).

Epinephrine increases blood glucose levels. It binds to membrane-bound receptors in liver cells. Cyclic AMP, in turn, activates enzymes that catalyze the breakdown of glycogen to glucose and the release of glucose from the liver cells into the blood. Epinephrine also increases the breakdown of glycogen in muscle cells, but muscle cells do not release glucose into the blood because glucose is utilized in muscle cells. Epinephrine also increases lipid breakdown in adipose tissue, releasing fatty acids into the blood. The fatty acids can be taken up and metabolized by tissues such as skeletal and cardiac muscle. Epinephrine and norepinephrine increase the heart's rate and force of contraction and cause blood vessels to constrict in the skin, kidneys, gastrointestinal tract, and other viscera. Also, epinephrine causes dilation of blood vessels in skeletal muscles and cardiac muscle.

Secretion of adrenal medullary hormones prepares the individual for physical activity and is a major component of the fight-or-flight response (see chapter 16). This response results in reduced activity in organs not essential for physical activity, as well as increased blood flow and metabolic activity in organs that participate in physical activity. In addition, it mobilizes nutrients that can be used to sustain physical exercise.

The effects of epinephrine and norepinephrine are short-lived because they are rapidly metabolized, excreted, or taken up by tissues. Their half-life in the blood is measured in minutes.

The release of adrenal medullary hormones primarily occurs in response to stimulation by sympathetic neurons because the adrenal medulla is a specialized part of the autonomic nervous system. Several conditions, including emotional excitement, injury, stress, exercise, and low blood glucose levels, promote the release of adrenal medullary neuropeptides (figure 18.14).

ASSESS YOUR PROGRESS

- Where are the adrenal glands located? Describe the embryonic origins of the adrenal medulla and the adrenal cortex.
- Name two hormones secreted by the adrenal medulla, and list the effects of these hormones.
- List several conditions that can stimulate the production of adrenal medullary hormones. What role does the nervous system play in the release of these hormones? How does this role relate to the embryonic origin of the adrenal medulla?

Hormones of the Adrenal Cortex

The adrenal cortex secretes three types of steroid hormone: **mineralocorticoids** (min'er-al-ō-kōr'ti-koydz), **glucocorticoids** (gloo-kō-kōr'ti-koydz), and **androgens** (an'drō-jenz; table 18.7). All adrenal cortex hormones have a similar structure in that they are steroids, which are highly specialized lipids derived from cholesterol. Because these hormones are lipid-soluble, they are not stored in the adrenal gland cells but diffuse from the cells as they are synthesized. Adrenal cortical hormones are transported in the blood bound to specific plasma proteins; they are metabolized in the liver and excreted in the bile and urine. The hormones of the adrenal cortex bind to nuclear receptors and stimulate the synthesis of specific proteins responsible for producing the target cell's responses.

Mineralocorticoids

As their name suggests, the mineralocorticoids regulate ion balance in the blood. The mineralocorticoids are the major secretory products of the zona glomerulosa of the adrenal cortex. **Aldosterone**

- 1 Stress, physical activity, and low blood glucose levels act as stimuli to the hypothalamus, resulting in increased sympathetic nervous system activity.
- 2 An increased frequency of action potentials conducted through the sympathetic division of the autonomic nervous system stimulates the adrenal medulla to secrete epinephrine and some norepinephrine into the blood.
- 3 Epinephrine and norepinephrine act on their target tissues to produce responses.

- Physical activity
- Low blood glucose
- Other stressors

Epinephrine and norepinephrine in the target tissues:

- Increase the release of glucose from the liver into the blood
- Increase the release of fatty acids from adipose tissue into the blood
- Increase heart rate
- Decrease blood flow through blood vessels of most internal organs
- Increase blood flow through blood vessels of skeletal muscle and the heart
- Increase blood pressure
- Decrease the function of visceral organs
- Increase the metabolic rate of skeletal muscles

PROCESS FIGURE 18.14 Regulation of Adrenal Medulla Secretions

Stress, physical exercise, and low blood glucose levels cause increased activity of the sympathetic nervous system, which increases epinephrine and norepinephrine secretion from the adrenal medulla.

(al-dos'ter-ōn) is produced in the greatest amounts, although other, closely related mineralocorticoids are also secreted. Aldosterone is secreted under low blood pressure conditions. It returns blood pressure to its normal range through modulation of kidney function. Aldosterone increases the rate of sodium reabsorption by the kidneys, which increases blood levels of sodium. The higher blood sodium levels enhance water reabsorption through osmosis. Recall from chapter 3 that osmosis is the diffusion of water toward higher solute areas. This reabsorption of water increases blood volume and thereby increases blood pressure. Aldosterone also stimulates K^+ excretion into the urine by the kidneys, which lowers blood levels of K^+ . In addition, aldosterone increases the rate of H^+ excretion into the urine. When aldosterone is secreted in high concentrations, reduced blood K^+ levels and alkalosis (elevated pH of body fluids) may result. The specific effects of aldosterone and the mechanisms controlling aldosterone secretion are discussed along with kidney functions in chapters 26 and 27 and with cardiovascular system functions in chapter 21.

Glucocorticoids

Glucocorticoids help to provide energy for cells by stimulating the increased use of lipids and proteins. It is the zona fasciculata of the

adrenal cortex that secretes the **glucocorticoid hormones**, primarily **cortisol** (kōr'ti-sol). The numerous target tissues and responses to the glucocorticoids are listed in table 18.8. The responses are classified as metabolic, developmental, or anti-inflammatory. Glucocorticoids cause lipid breakdown, reduce glucose and amino acid uptake in skeletal muscle, stimulate **gluconeogenesis** (gloo'kō-nē-ō-jen'ē-sis; the synthesis of new glucose from precursor molecules, such as amino acids in the liver), and increase protein degradation. Glucocorticoids also increase blood glucose levels and glycogen deposits in cells. The glucose and glycogen are a reservoir of molecules that can be metabolized rapidly.

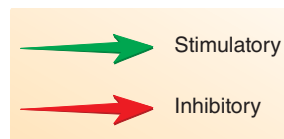

Glucocorticoids are also required for the maturation of tissues, such as fetal lungs, and for the development of receptor molecules in target tissues for epinephrine and norepinephrine. In addition, glucocorticoids decrease the intensity of the inflammatory and immune responses by decreasing both the number of white blood cells and the secretion of inflammatory chemicals from tissues. This anti-inflammatory effect is important under conditions of stress, when the rate of glucocorticoid secretion is relatively high. Synthetic glucocorticoids are often used to suppress the immune response in people suffering from autoimmune conditions and in transplant recipients (see chapter 22).

TABLE 18.8 Target Tissues and Their Responses to Glucocorticoid Hormones

Target Tissues	Responses
Peripheral tissues, such as skeletal muscle, liver, and adipose tissue	Inhibit glucose use; stimulate the formation of glucose from amino acids and, to some degree, from lipids (gluconeogenesis) in the liver, which results in elevated blood glucose levels; stimulate glycogen synthesis in cells; mobilize lipids by increasing lipolysis, which results in the release of fatty acids into the blood and an increased rate of fatty acid metabolism; increase protein breakdown and decrease protein synthesis
Immune tissues	Anti-inflammatory; depress antibody production, white blood cell production, and the release of inflammatory components in response to injury; suppress the immune system
Target cells for epinephrine	Receptor molecules for epinephrine and norepinephrine decrease without adequate amounts of glucocorticoid hormone

- 1 Corticotropin-releasing hormone (CRH) is released from hypothalamic neurons in response to stress or low blood glucose and passes, by way of the hypothalamohypophysial portal system, to the anterior pituitary.
- 2 In the anterior pituitary, CRH binds to and stimulates cells that secrete adrenocorticotropic hormone (ACTH).
- 3 ACTH binds to membrane-bound receptors on cells of the adrenal cortex and stimulates the secretion of glucocorticoids, primarily cortisol.
- 4 Cortisol acts on target tissues, resulting in increased lipid and protein breakdown, increased glucose levels, and anti-inflammatory effects.
- 5 Cortisol has a negative-feedback effect because it inhibits CRH release from the hypothalamus and ACTH secretion from the anterior pituitary.

PROCESS FIGURE 18.15 Regulation of Cortisol Secretion

ACTH is necessary to maintain the secretory activity of the adrenal cortex, which rapidly atrophies without this hormone. Corticotropin-releasing hormone (CRH) released from the hypothalamus stimulates the anterior pituitary to secrete ACTH. The zona fasciculata is very sensitive to ACTH, and it responds by increasing cortisol secretion. The regulation of ACTH and cortisol secretion is outlined in figure 18.15. Both ACTH and cortisol inhibit CRH secretion from the hypothalamus by negative feedback. In addition, high concentrations of cortisol in the blood inhibit ACTH secretion from the anterior pituitary, and low concentrations stimulate it. This negative-feedback loop is important in maintaining blood cortisol levels within a controlled range of concentration. Stress and hypoglycemia (low levels of glucose in the blood) trigger a large increase in CRH release from the hypothalamus by causing a rapid increase in blood levels of cortisol. In addition, CRH levels vary significantly throughout the day. Table 18.9 outlines several abnormalities associated with the hyposecretion or hypersecretion of adrenal hormones.

Predict 7

Cortisone, a drug similar to cortisol, is sometimes given to people who have severe allergies or extensive inflammation or to those who suffer from autoimmune diseases. Taking this substance chronically can damage the adrenal cortex. Explain how this damage can occur.

Adrenal Androgens

Some adrenal steroids function as weak androgens. *Androgen* is a generic term for steroid hormones that cause the development of

male secondary sex characteristics (see chapter 28). Most androgens are secreted by the reproductive system (see chapter 28). However, there are adrenal androgens secreted by the zona reticularis. Some adrenal androgens are converted by peripheral tissues to the potent androgen testosterone, while other adrenal androgens are weak androgens such as androstenedione (an-drō-stēn'dī-ōn). Adrenal androgens stimulate pubic and axillary hair growth and sex drive in females. However, the effects of adrenal androgens in males are negligible, in comparison with testosterone secreted by the testes.

ASSESS YOUR PROGRESS

41. Describe the three layers of the adrenal cortex, and name the hormones produced by each layer.
42. Name the target tissue of aldosterone, and list the effects of an increase in aldosterone secretion on the concentration of ions in the blood.
43. Describe the effects produced by an increase in cortisol secretion. Starting with the hypothalamus, describe how stress or low blood glucose levels can stimulate cortisol release.
44. List the possible causes of hyposecretion of adrenal cortex hormones, and describe the symptoms.
45. List the possible causes of hypersecretion of adrenal cortex hormones, and describe the symptoms.
46. What effects do adrenal androgens have on males and on females?

TABLE 18.9 Symptoms of Hyposecretion and Hypersecretion of Adrenal Cortex Hormones

	Cause	Symptoms
Hyposecretion		
Mineralocorticoids (aldosterone)	Removal of gland or loss of function or Addison disease (low levels of aldosterone <i>and</i> cortisol)	Hyponatremia (low blood levels of sodium) Hyperkalemia (high blood levels of potassium) Acidosis Low blood pressure Tremors and tetany of skeletal muscles Polyuria
Glucocorticoids (cortisol)	Removal of gland or loss of function	Hypoglycemia (low blood glucose levels) Depressed immune system Unused proteins and lipids from diet, resulting in weight loss Loss of appetite, nausea, vomiting Bronzing of skin due to increased pigmentation (if ACTH levels are elevated)
Androgens		In women, reduction of pubic and axillary hair
Hypersecretion		
Mineralocorticoids (aldosterone)	Tumor in gland or aldosteronism	Slight hypernatremia (high blood levels of sodium) Hypokalemia (low blood levels of potassium) Alkalosis High blood pressure Weakness of skeletal muscles Acidic urine
Glucocorticoids (cortisol)	Tumor in gland or Cushing syndrome (high cortisol <i>and</i> androgens)	Hyperglycemia (high blood glucose levels; adrenal diabetes; leads to diabetes mellitus) Depressed immune system Destruction of tissue proteins, causing muscle atrophy and weakness, osteoporosis, weak capillaries (easy bruising), thin skin, and impaired wound healing; mobilization and redistribution of lipids, causing depletion of adipose tissue from limbs and deposition in face (moon face), neck (buffalo hump), and abdomen (Cushing syndrome) Emotional effects, including euphoria and depression
Androgens	Tumor in gland or adrenogenital syndrome	In women, hirsutism (excessive facial and body hair), acne, increased sex drive, regression of breast tissue, and loss of regular menstruation

18.6 Pancreas

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the location and structure of the pancreas.
- Name the hormones secreted by the pancreatic islets and describe their effects on their target tissues.
- Explain how pancreatic hormones are regulated.
- Compare and contrast the causes and symptoms of type 1 and type 2 diabetes mellitus.

The **pancreas** (pan/'krē-us) is both an exocrine gland and an endocrine gland. The exocrine portion consists of acini (as/'i-nī), which produce pancreatic juice, and a duct system, which carries the pancreatic juice to the small intestine (see chapter 24). The

endocrine part, consisting of pancreatic islets (islets of Langerhans; figure 18.16), secretes hormones that enter the plasma of the blood. The pancreas lies behind the peritoneum between the greater curvature of the stomach and the duodenum. It is an elongated structure approximately 15 cm long, weighing approximately 85–100 g. The head of the pancreas lies near the duodenum, and its body and tail extend toward the spleen.

Between 500,000 and 1 million pancreatic islets are dispersed among the ducts and acini of the pancreas. Each islet is composed of **alpha (α) cells** (20%), which secrete **glucagon**, a small polypeptide hormone, and **beta (β) cells** (75%), which secrete **insulin**, a small protein hormone consisting of two polypeptide chains bound together. The remaining 5% of cell types are either immature cells that produce secretions with digestive functions or **delta (δ) cells**, which secrete somatostatin, a small polypeptide hormone. Nerves from both divisions of the autonomic nervous system innervate the pancreatic islets, and a well-developed capillary network surrounds each islet.

FIGURE 18.16 Histology of the Pancreatic Islets

A pancreatic islet consists of clusters of specialized cells among the acini of the exocrine portion of the pancreas. The stain used for this slide does not distinguish between alpha and beta cells. **APR**

Effect of Insulin and Glucagon on Their Target Tissues

The pancreatic hormones play an important role in regulating the concentration of critical nutrients in the blood, especially glucose and amino acids (table 18.10). The major target tissues of insulin are the liver, adipose tissue, the skeletal muscles, and the satiety center within the hypothalamus of the brain. The **satiety center** (sa'tī-ě-tē) is a collection of neurons in the hypothalamus that controls appetite. However, insulin does not directly affect most other areas of the nervous system. The specific effects of insulin on these target tissues are listed in table 18.11.

Insulin

Insulin's primary function is to lower blood glucose levels by stimulating glucose transport into body cells. Insulin is secreted when blood glucose is elevated, such as after a meal. Insulin binds to membrane-bound receptors on target cells. Once insulin binds to its receptor, the receptor causes specific proteins in the membrane to become phosphorylated. Part of the cells' response to insulin is to increase the number of transport proteins in the plasma membrane for glucose and amino acids. Finally, insulin and its receptor enter the cell by endocytosis. The insulin is released from the insulin receptor and broken

TABLE 18.10 Pancreatic Hormones

Cells in Islets	Hormone	Structure	Target Tissue	Response
Alpha (α)	Glucagon	Polypeptide	Primarily liver	Increased breakdown of glycogen; release of glucose into the blood
Beta (β)	Insulin	Protein	Especially liver, skeletal muscle, adipose tissue	Increased uptake and use of glucose and amino acids
Delta (δ)	Somatostatin	Peptide	Alpha and beta cells (some somatostatin is produced in the hypothalamus)	Inhibition of insulin and glucagon secretion

TABLE 18.11 Effect of Insulin and Glucagon on Target Tissues

Target Tissue	Response to Insulin	Response to Glucagon
Skeletal muscle, cardiac muscle, cartilage, bone, fibroblasts, leukocytes, and mammary glands	Increased glucose uptake and glycogen synthesis; increased uptake of certain amino acids	Little effect
Liver	Increased glycogen synthesis; increased use of glucose for energy (glycolysis)	Rapid increase in the breakdown of glycogen to glucose (glycogenolysis) and release of glucose into the blood; increased formation of glucose (gluconeogenesis) from amino acids and, to some degree, from lipids; increased metabolism of fatty acids, resulting in more ketones in the blood
Adipose cells	Increased glucose uptake, glycogen synthesis, lipid synthesis, and fatty acid uptake; increased glycolysis	High concentrations cause breakdown of lipids (lipolysis); probably unimportant under most conditions
Nervous system	Little effect, except increased glucose uptake in the satiety center	No effect

down within the cell, and the insulin receptor returns to the plasma membrane.

In general, the target tissue responds to insulin by increasing its ability to take up and use glucose and amino acids. Glucose molecules that are not needed immediately as an energy source to maintain cell metabolism are stored as glycogen in skeletal muscle, the liver, and other tissues and are converted to lipids in adipose tissue. Amino acids can be broken down and used as an energy source, or they can be converted to protein. Without insulin, the ability of these tissues to take up and use glucose and amino acids is minimal.

The normal regulation of blood glucose levels requires insulin. Blood glucose levels can increase dramatically when too little insulin is secreted or when insulin receptors do not respond to it (see Clinical Impact, “Diabetes Mellitus”). In the absence of insulin, the movement of glucose and amino acids into cells declines

dramatically, even though blood levels of these molecules may increase to very high levels. The hypothalamic satiety center requires insulin in order to take up glucose. In the absence of insulin, the satiety center cannot detect the presence of glucose in the extracellular fluid, even when glucose levels are high. The result is an intense sensation of hunger in spite of high blood glucose levels, a condition called *polyphagia* (pol-ē-fā’jē-ă). High blood glucose levels also cause increased urine volume (*polyuria*; pol-ē-ū’rē-ă) and loss of water in the urine. Glucose is filtered from the blood into the kidney tubules. There, the glucose creates an osmotic gradient favoring the movement of water into the tubules and its subsequent loss in urine (see chapter 26). Elevated blood glucose levels also increase blood osmolality, resulting in an increased sensation of thirst (*polydipsia*; pol-ē-dip’sē-ă; see chapter 27).

When too much insulin is secreted, blood glucose levels can fall very low because too much insulin causes target tissues to

Case STUDY

Cushing Syndrome

Ethan noticed that he had gained a substantial amount of weight over the past few months and that he was feeling weak. His physician observed that the adipose tissue distribution was mainly in his trunk, face, and neck. There was also evidence of decreased muscle mass, and Ethan had several bruises on his upper and lower limbs. Results of a routine blood test showed elevated blood glucose levels and low blood K^+ levels. There was no observable evidence that Ethan had cancer. His physician suspected that he was suffering from Cushing syndrome.

A second blood sample was taken. Ethan’s blood cortisol levels were very high, and his blood ACTH levels were very low. Based on these data, Ethan’s physician explained that he was probably suffering from an adrenal gland tumor, which was secreting large amounts of cortisol, and that the tumor was not responding to the negative-feedback mechanisms that normally control cortisol secretion. Subsequently, imaging techniques revealed a tumor in Ethan’s left adrenal gland. After his left adrenal gland was surgically removed, Ethan’s symptoms decreased dramatically over the next few weeks.

Predict 8

- Why did the physician suspect Cushing syndrome?
- Explain why Ethan’s physician concluded that a hormone-secreting tumor in one of Ethan’s adrenal glands was responsible for his symptoms.
- After surgical removal of his left adrenal gland, how did Ethan’s blood cortisol and ACTH levels change?
- How would the data from the second blood sample have been different if Ethan’s condition had been due to a hormone-secreting tumor in his anterior pituitary gland?

Clinical IMPACT

Diabetes Mellitus

Diabetes mellitus results primarily from the inadequate secretion of insulin or the inability of tissues to respond to insulin. **Type 1 diabetes mellitus**, also called *insulin-dependent diabetes mellitus (IDDM)*, affects approximately 5–10% of people with diabetes mellitus and results from diminished insulin secretion. It develops as a result of autoimmune destruction of the pancreatic islets, and symptoms appear after approximately 90% of the islets have been destroyed. Type 1 diabetes mellitus most commonly develops in young people. Heredity may play a role in the condition, although the initiation of pancreatic islet destruction may involve a viral infection of the pancreas.

Type 2 diabetes mellitus, also called *noninsulin-dependent diabetes mellitus (NIDDM)*, results from the inability of tissues to respond to insulin. Type 2 diabetes mellitus usually develops in people older than 40–45 years of age, although it is being observed more frequently in much younger patients.

Type 2 diabetes mellitus is more common than type 1 diabetes mellitus. Approximately 90–95% of people who have diabetes mellitus have type 2. People with type 2 diabetes mellitus have a reduced number of functional receptors for insulin, or one or more of the enzymes activated by the insulin receptor are defective. Thus, glucose uptake by cells is very slow, which results in elevated blood glucose after a meal. Obesity is common, although not universal, in patients with type 2 diabetes mellitus. Elevated blood glucose levels cause adipose cells to convert glucose to lipid, even though the rate at which adipose cells take up glucose is impaired. Increased blood glucose and increased urine production lead to hyperosmolality of blood and dehydration of cells. The poor use of nutrients and dehydration of cells lead to lethargy, fatigue, and periods of irritability. Elevated blood glucose levels affect the endothelial tissue of blood vessels, as well as the nervous system's ability to respond to tactile sensation. The combination of these effects results in recurrent injury and infection, especially in distal tissues, such as the feet.

Patients with type 2 diabetes mellitus do not experience sudden, large increases in blood glucose and severe tissue wasting, as occurs with type 1 diabetes mellitus, because a slow rate of glucose uptake does occur, even though the insulin receptors are defective. In some

Clinical GENETICS

Type 2 Diabetes Mellitus

Most people with diabetes mellitus have type 2. Type 2 diabetes mellitus has a genetic basis, and it appears that several genes can make people more susceptible to developing the condition. For example, individuals whose close relatives have type 2 diabetes mellitus have an increased risk of developing it. In addition, type 2 diabetes mellitus is more prevalent among certain populations. For example, it is more common in Native Americans than in Caucasians, African-Americans, and Latinos.

The pathways activated by the insulin receptor are complex, and genes on 10 different chromosomes that code for proteins in those pathways have been associated with the development of type 2 diabetes mellitus. Antibodies that bind to insulin receptors and make them nonfunctional or reduced numbers of functional insulin receptors can cause type 2 diabetes mellitus. In most cases, however, the insulin receptor is normal, but mutations in the genes that code for enzymes activated by the combination of insulin and its receptors result in a reduced response to insulin.

people with type 2 diabetes mellitus, insulin production eventually decreases because pancreatic islet cells atrophy; then type 1 diabetes mellitus develops. Approximately 25–30% of patients with type 2 diabetes mellitus take insulin, 50% take oral medication to increase insulin secretion and improve the efficiency of glucose utilization, and the remainder control blood glucose levels with exercise and diet alone.

Glucose tolerance tests are used to diagnose diabetes mellitus. In general, the test involves feeding the patient a large amount of glucose after a period of fasting and then collecting blood samples for a few hours afterward. A sustained increase in blood glucose levels strongly indicates that the person has diabetes mellitus.

Too much insulin relative to the amount of glucose ingested leads to insulin shock. The high levels of insulin cause target tissues to

Type 2 diabetes mellitus involves a gradual failure of cells to respond to insulin and to take up glucose. Therefore, people who inherit genes that make them susceptible to type 2 diabetes mellitus are likely to develop the condition later in life. Also, symptoms are more likely to develop in people with an unhealthy lifestyle, which includes a diet high in calories and simple sugars and a sedentary tendency. A high percentage of people who have type 2 diabetes mellitus are obese. The severity of the condition may decrease in response to weight loss. An unhealthy lifestyle is also associated with a recent trend toward the development of diabetes mellitus in younger people.

The “thrifty genotype” hypothesis suggests that type 2 diabetes mellitus may be more common today because the genes that make people susceptible to the condition were once beneficial. For example, during periods of famine, the ability to store adipose tissue and to have altered glucose metabolism may have been advantageous, but today, when food is abundant, having these genes increases the likelihood of developing type 2 diabetes mellitus.

take up glucose at a very high rate. As a result, the concentration of blood glucose rapidly falls to a low level. Because the nervous system depends on glucose as its major source of energy, neurons malfunction, leading to nervous system responses, such as disorientation, confusion, and convulsions. Too much insulin, too little food intake after an insulin injection, or increased metabolism of glucose due to excess physical exercise can cause insulin shock in a diabetic patient.

Keeping blood glucose within normal levels at all times can prevent damage to blood vessels and reduced nerve function in patients with either type of diabetes mellitus. However, doing so requires increased attention to diet and frequent blood glucose testing to ensure that blood glucose levels do not fall too low and lead to insulin shock.

rapidly take up glucose from the blood. Although the nervous system, except for cells of the satiety center, is not a target tissue for insulin, the nervous system depends primarily on blood glucose as an energy source. Consequently, low blood glucose levels cause changes in the function of the CNS, including dizziness, loss of cognitive function, and in extreme cases, loss of consciousness.

Glucagon

Glucagon is the companion hormone to insulin (see chapter 17). Its secretion is stimulated when blood glucose levels decline. Glucagon promotes the release of glucose from intracellular stores. For example, glucagon primarily influences the liver, although it has some effect on skeletal muscle and adipose tissue (table 18.11). Glucagon binds to membrane-bound receptors, activates G proteins, and increases cAMP synthesis. In general, glucagon causes the breakdown of glycogen and increases glucose synthesis in the liver. It also increases the breakdown of lipids. The amount of glucose released from the liver into the blood increases dramatically after glucagon secretion increases. Because glucagon is secreted into the hepatic portal circulation, which carries blood from the intestines and pancreas to the liver, glucagon is delivered in a relatively high concentration to the liver, where it has its major effect. The liver also rapidly breaks down glucagon. Thus, glucagon has less effect on skeletal muscles and adipose tissue than on the liver.

Regulation of Pancreatic Hormone Secretion

Pancreatic hormone secretion is partially under humoral control. The hormone-secreting cells can directly respond to low blood glucose levels. In addition, blood levels of other nutrients, neural stimulation, and hormones control the secretion of insulin. *Hyperglycemia*, or elevated blood levels of glucose, directly stimulates insulin secretion from β cells. *Hypoglycemia*, or low blood levels of glucose, directly slows insulin secretion. In addition, the sympathetic nervous system can directly reduce insulin secretion. Conversely, certain amino acids stimulate insulin secretion by acting directly on the β cells. Thus, after a meal, when glucose and amino acid levels in the blood are their highest, insulin secretion increases. During periods of fasting, when blood glucose levels are low, the rate of insulin secretion declines (figure 18.17).

The autonomic nervous system also controls insulin secretion. Parasympathetic stimulation associated with food intake acts with the elevated blood glucose levels to increase insulin secretion. Sympathetic innervation inhibits insulin secretion and helps prevent a rapid fall in blood glucose levels. Because most tissues, except nervous tissue, require insulin to take up glucose, sympathetic stimulation maintains blood glucose levels in a normal range during periods of physical activity or excitement. This response is important for maintaining normal nervous system function.

Gastrointestinal hormones involved with regulating digestion, such as gastrin, secretin, and cholecystokinin (see chapter 24), increase insulin secretion. Somatostatin inhibits insulin and glucagon secretion, but the factors that regulate somatostatin secretion are not clear. It can be released in response to food intake, in which case somatostatin may prevent the oversecretion of insulin.

Predict 9

Explain why the increase in insulin secretion in response to parasympathetic stimulation and gastrointestinal hormones is consistent with the maintenance of blood glucose levels in the blood.

Low blood glucose levels stimulate glucagon secretion, and high blood glucose levels inhibit it. Certain amino acids and sympathetic stimulation also increase glucagon secretion. After a high-protein meal, amino acids increase both insulin and glucagon secretion. Insulin causes target tissue uptake of amino acids for protein synthesis, and glucagon increases the process of glucose synthesis from amino acids in the liver (gluconeogenesis). Both protein synthesis and the use of amino acids to maintain blood glucose levels result from the low, but simultaneous, secretion of insulin and glucagon induced by meals high in protein.

Predict 10

Compare the regulation of glucagon and insulin secretion after a meal high in carbohydrates, after a meal low in carbohydrates but high in proteins, and during physical exercise.

ASSESS YOUR PROGRESS

47. Where is the pancreas located? Describe the exocrine and endocrine parts of this gland and the secretions produced by each portion.
48. Name the target tissues for insulin and glucagon, and list their effects on the target tissues.
49. How does insulin affect the satiety center of the hypothalamus?
50. What effect do blood glucose levels, blood amino acid levels, the autonomic nervous system, and somatostatin have on insulin and glucagon secretion?
51. Describe the causes and symptoms of type 1 diabetes mellitus and type 2 diabetes mellitus.

18.7 Hormonal Regulation of Nutrient Utilization

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Explain the interactions of insulin, glucagon, cortisol, GH, and epinephrine immediately after a meal and 1–2 hours after a meal.
- B. Describe the nervous and hormonal interactions during exercise that will provide enough energy to cells.

Several hormones function together to regulate blood nutrient levels. The interactions of these hormones is illustrated in two situations—after a meal and during exercise. After a meal and under resting conditions, secretion of glucagon, cortisol, GH, and epinephrine is reduced (figure 18.18). Both increasing blood glucose levels and parasympathetic stimulation elevate insulin secretion to increase the uptake of glucose, amino acids, and lipids by target

HOMEOSTASIS FIGURE 18.17 Regulation of Insulin Secretion

(1) Blood glucose is within its normal range. (2) Blood glucose level increases outside the normal range. (3) Pancreatic islets secrete insulin in direct response to elevated blood glucose. Digestive hormones and parasympathetic activity also stimulate insulin secretion. (4) Most tissues take up glucose when insulin binds to its receptors on the tissue. Liver and skeletal muscle cells convert glucose to glycogen. (5) Blood glucose level drops back to the normal range. (6) Homeostasis is restored. Observe the response to a drop in blood glucose by following the red arrows.

Soon after a meal, blood levels of nutrients, such as glucose, amino acids, and fatty acids, increase.

Parasympathetic stimulation and increasing blood glucose levels cause elevated insulin secretion from the pancreas.

Nutrients move into cells.

Within 1–2 hours after a meal, nutrient levels decline.

Lowered blood glucose levels and increasing sympathetic stimulation cause insulin secretion to decline.

Lowered blood glucose levels and increasing sympathetic stimulation cause elevated glucagon secretion.

Lowered blood nutrient levels promote GH secretion.

Lowered blood nutrient levels promote cortisol secretion.

Most cells

Glucose uptake decreases and switches to lipid and protein metabolism.

Liver

Releases glucose, ketones, and triglycerides into the blood

Adipose tissue

Releases fatty acids into the blood

FIGURE 18.18 Regulation of Blood Nutrient Levels After a Meal

Blood nutrient levels are maintained immediately after a meal and for several hours afterward.

Exercise

Muscle

**Short-term exercise**

Sympathetic stimulation increases epinephrine secretion from the adrenal medulla and glucagon secretion from the pancreas. It also inhibits insulin secretion from the pancreas.

Epinephrine increases the rate at which glycogen in **muscle cells** is broken down to glucose. Because muscle cells use glucose as an energy source, the muscle cells take up less glucose from the blood and increase their rate of fatty acid metabolism.

Epinephrine and glucagon increase glycogen breakdown to glucose molecules in the **liver**. The glucose molecules are released into the blood.

Epinephrine and sympathetic stimulation also increase the breakdown of **lipid** and the release of fatty acids from adipose tissue.

Blood glucose levels are maintained for normal nervous system function.

Liver

Adipose tissue

Blood nutrients

**Prolonged exercise**

Increased ACTH and GH are released from the anterior pituitary. ACTH stimulates increased cortisol secretion from the adrenal cortex.

Cortisol increases protein breakdown in **muscle** and the **liver** to amino acids and increases glucose synthesis from amino acids and from some components from adipose tissue, such as glycerol.

Cortisol increases the breakdown of **lipids** and the use of fatty acids by **muscle cells** as an energy source.

GH slows the breakdown of proteins and helps conserve them, thus increasing the dependence on lipids as an energy source.

Blood glucose levels are maintained for normal nervous system function and the body is increasingly dependent on lipids and proteins for energy sources.

FIGURE 18.19 Regulation of Blood Nutrient Levels During Exercise

tissues. Substances not immediately used for cell metabolism are stored. Glucose is converted to glycogen in skeletal muscle and the liver, and it is used for lipid synthesis in adipose tissue and the liver. The rapid uptake and storage of glucose prevent too large an increase in blood glucose levels. Amino acids are incorporated into proteins, and lipids that were ingested as part of the meal are stored in adipose tissue and the liver. If the meal is high in protein, a small amount of glucagon is secreted, thereby increasing the rate at which the liver uses amino acids to form glucose.

Within 1–2 hours after the meal, absorption of digested materials from the digestive tract decreases, and blood glucose levels decline. As a result of the lowered blood glucose, secretion of glucagon, GH, cortisol, and epinephrine increases. As blood glucose declines, insulin secretion decreases, and the rate of glucose entry into insulin target tissues slows. Glycogen, stored in cells, is converted back to glucose and used as an energy source. The liver releases glucose into the blood. The reduced uptake of glucose by most tissues, combined with its release from the liver, helps maintain blood glucose at levels critical for normal brain function. Cells that

use less glucose start using more lipids and proteins. Adipose tissue releases fatty acids, and the liver releases triglycerides (in lipoproteins) and ketones into the blood. Tissues take up these substances from the blood and use them for energy. Lipid molecules are a major source of energy for most tissues when blood glucose levels are low.

The interactions of insulin, GH, glucagon, epinephrine, and cortisol are excellent examples of negative-feedback mechanisms. When blood glucose levels are high, these hormones cause the rapid uptake and storage of glucose, amino acids, and lipids. When blood glucose levels are low, they cause the release of glucose and a switch to lipid and protein metabolism as a source of energy for most tissues.

During exercise, skeletal muscles require energy to support the contraction process (see chapter 9). Although metabolism of intracellular nutrients can sustain muscle contraction for a short time, additional energy sources are required during prolonged activity. Sympathetic nervous system activity, which increases during exercise, stimulates the release of epinephrine from the adrenal medulla and the release of glucagon from the pancreas (figure 18.19). These hormones induce the conversion of

glycogen to glucose in the liver and the release of glucose into the blood, thus providing skeletal muscles with a source of energy. Because epinephrine and glucagon have short half-lives, they can rapidly adjust blood glucose levels for varying conditions of activity.

During sustained activity, glucose released from the liver and other tissues is not adequate to support muscle activity, and the danger exists that blood glucose levels will become too low to support brain function. A decrease in insulin prevents the uptake of glucose by most tissues, thus conserving glucose for the brain. In addition to other functions, epinephrine, glucagon, cortisol, and GH cause an increase in fatty acids, triglycerides, and ketones in the blood. Because GH increases protein synthesis and slows the breakdown of proteins, muscle proteins are not used as an energy source. Consequently, glucose metabolism decreases, and lipid metabolism in skeletal muscles increases. At the end of a long race, for example, muscles rely to a large extent on lipid metabolism for energy.

Predict 11

Explain why long-distance runners may not have much of a “kick” left when they try to sprint to the finish line.

ASSESS YOUR PROGRESS

52. Describe the hormonal effects that occur immediately after a meal to cause nutrients to move into cells and be stored.
53. What occurs hormonally 1–2 hours after a meal that causes stored materials to be released and used for energy?
54. During exercise, how does sympathetic nervous system activity regulate blood glucose levels? Name five hormones that interact to ensure that the brain and the muscles have adequate energy sources during exercise, and explain the role of each.

18.8 Hormones of the Reproductive System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List and describe the functions of the hormones secreted by the testes and ovaries.
- B. Explain how the anterior pituitary regulates secretion by the testes and ovaries.
- C. Explain how the placenta acts as a temporary endocrine gland.

All aspects of reproduction, including puberty, menstruation, gamete formation, and pregnancy, are under control of reproductive hormones. Reproductive hormones are secreted primarily from the ovaries, testes, placenta, and pituitary gland (table 18.12). These hormones are discussed in chapter 28. The main endocrine glands of the male reproductive system are the testes. The functions of the testes depend on the secretion of FSH and LH from the anterior pituitary gland. The main hormone secreted by the testes is testosterone, an androgen. **Testosterone** regulates the production of sperm cells by the testes and the development and maintenance of male reproductive organs and secondary sexual characteristics. The testes secrete another hormone, called **inhibin**, which inhibits the secretion of FSH from the anterior pituitary gland.

The main endocrine glands of the female reproductive system are the ovaries. Like the testes, the functions of the ovaries depend on the secretion of FSH and LH from the anterior pituitary gland. The main hormones secreted by the ovaries are **estrogen** and **progesterone**. These hormones, along with FSH and LH, control the female reproductive cycle, prepare the mammary glands for lactation, and maintain pregnancy. Estrogen and progesterone are also responsible for the development of the female

TABLE 18.12

Hormones of the Reproductive Organs

Hormones	Structure	Target Tissue	Response
Testes			
Testosterone	Steroid	Most cells	Aids in spermatogenesis, development of genitalia, maintenance of functional reproductive organs, secondary sexual characteristics, and sexual behavior
Inhibin	Polypeptide	Anterior pituitary gland	Inhibits FSH secretion
Ovaries			
Estrogen	Steroid	Most cells	Aids in uterine and mammary gland development and function, maturation of genitalia, secondary sex characteristics, sexual behavior, and menstrual cycle
Progesterone	Steroid	Most cells	Aids in uterine and mammary gland development and function, maturation of genitalia, secondary sex characteristics, and menstrual cycle
Inhibin	Polypeptide	Anterior pituitary gland	Inhibits FSH secretion
Relaxin	Polypeptide	Connective tissue cells	Increases the flexibility of connective tissue in the pelvic area, especially the symphysis pubis

MICROBES In Your Body

Do our bacteria make us fat?

Obesity has increased at an alarming rate over the last three decades. It is estimated that over 150 billion adults worldwide are overweight or obese. In the United States, one-third of adults are obese. As obesity rates have increased, so have the rates of obesity-related health conditions such as insulin resistance, diabetes, and cardiovascular disease. Why this dramatic increase? There are two main reasons for obesity, diet/lifestyle and gut bacteria, and it seems these two may be related.

The most familiar cause of obesity is diet and lifestyle. The “typical” Western diet consists of frequent large meals high in refined grains, red meat, saturated fats, and sugary drinks. This is in sharp contrast to healthier diets rich in whole grains, vegetables, fruits, and nuts that help with weight control and prevention of chronic disease. From an evolutionary perspective, our bodies are adapted to conserve energy because food sources were scarce for ancient humans. Many of us now have easy access to energy-rich foods. Combined with a reduction in physical activity and less sleep for many Americans, the Western diet and lifestyle can lead to obesity and poor health.

However, could humans’ gut microbiota be just as responsible (or even more responsible) for obesity? Comparisons between the gut microbiota of lean versus obese individuals seem to suggest the possibility of an important link between gut microbiota and our weight. The human gut, like other animals, is densely populated with microbiota consisting of at least 100 trillion microbial cells divided into approximately 1000 different species. The majority (90%) of human gut bacteria fall into two groups: Firmicutes and Bacteroidetes. Lean people have more Bacteroidetes than Firmicutes, while the opposite is true for obese people.

We now know that gut microbiota affect nutrient processing and absorption, hormonal regulation of nutrient use by body cells, and

even our hunger level. In addition, our diet can influence the type of bacteria in our GI system. Studies of humans on carbohydrate-restricted or fat-restricted diets demonstrated that after weight loss, the number of Bacteroidetes (“lean person” bacteria) increased, while the number of Firmicutes (“obese person” bacteria) decreased. This makes sense in light of the fact that Firmicutes bacteria break down ingested food more completely than Bacteroidetes, which makes the food’s energy easier to absorb by the human gut. Obese individuals store the absorbed energy in adipose tissue, which contributes to weight gain.

Furthermore, experiments with germ-free mice—mice lacking normal gut microbiota—have demonstrated just how important normal gut bacteria are for homeostasis. In the absence of normal gut microbiota, malfunctions in germ-free mice are widespread and significant. For example, when germ-free mice received gut microbiota transplants from normal mice, their body fat increased significantly to normal levels within 2 weeks, even though their diet and exercise level did not change. Studies have also shown that germ-free mice lack normal gastric immunity, but upon transplantation, their gastric immune system becomes functional. Germ-free mice also lack cell membrane proteins important for tight junction formation between the cells of the intestinal lining (see chapter 4). Without the normal microbiota, germ-free mice intestines are “leaky,” meaning they could easily be penetrated by pathogens. Finally, germ-free mice display an enhanced stress response, which is substantially reduced upon implantation of gut microbiota. Overall, these experiments demonstrate that there is a much greater correlation among bacteria, gut health, obesity, and anxiety than ever before realized.

Changes in gut microbiota also alter the hormonal regulation of nutrient use. Inflammation-promoting effects of an imbalanced gut microbiota are thought to induce

obesity via promoting insulin resistance, a known autoimmune malfunction. This observation is supported by the reduction in diabetes symptoms after gastric bypass surgery when patients exhibit a major shift in gut microbiota populations. Finally, it is well documented that normal gut microbiota metabolism is critical for secretion of several anti-hunger hormones, and anti-depressive neurotransmitters and neurochemicals. Shifts in normal gut microbiota, as related to diet, may very well disrupt normal anti-hunger signals and gut permeability, leading to the over-eating and inflammation related to obesity.

These observations beg the question: can we manipulate gut microbiota in obese people to cause them to become lean? Several possibilities exist, including the distinct possibility that prescribing antibiotics against bacteria associated with obesity could shift the metabolism of an obese person to become leaner. Another possibility is the use of prebiotics—non-digestible sugars that enhance the growth of beneficial microbiota. Finally, probiotic use is another possible intervention for obesity. Probiotics are non-pathogenic live bacteria that confer a health benefit to the host. This is a rapidly expanding field that holds much promise, but it is still in its beginning stages of our understanding.

Predict 12

Using section 18.7 in this chapter and knowledge you gained about how levels of growth hormone (GH) and cortisol determine nutrient use and metabolic reactions, predict the following relationship. Predict whether GH and cortisol levels are higher or lower in a person whose gut microbiota population has more *Firmicutes* than *Bacteroidetes* bacteria. Would this person experience hunger more or less often than an individual with more *Bacteroidetes* bacteria in his or her gut?

reproductive organs and female secondary sexual characteristics. Like the testes, the ovaries secrete inhibin, which inhibits FSH secretion.

During the first one-third of pregnancy, the placenta secretes an LH-like substance that is necessary to maintain pregnancy (see chapter 28). Throughout most of pregnancy, the ovaries and placenta secrete increasing amounts of estrogen and progesterone, which are also necessary to maintain pregnancy. In addition, the ovaries secrete **relaxin**, which increases the flexibility of the connective tissue of the

symphysis pubis and helps dilate the cervix of the uterus. This facilitates delivery by making the birth canal larger.

ASSESS YOUR PROGRESS

- List the hormones secreted by the testes, and describe their functions.
- List the hormones secreted by the ovaries, and describe their functions.

57. What hormones from the anterior pituitary gland regulate secretion by the testes and ovaries? Explain how these hormones function.
58. What hormones are secreted by the placenta to help maintain pregnancy and facilitate birth?

18.9 Hormones of the Pineal Gland

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the hormones secreted by the pineal gland and describe their possible functions.**
- B. Explain the photoperiod and its relationship to pineal gland secretion.**

The **pineal** (pin'ē-āl) **gland** in the epithalamus of the brain secretes hormones that act on the hypothalamus and the gonads to inhibit reproductive functions, such as by inhibiting the secretion of certain reproductive hormones. Two substances have been proposed as secretory products: **melatonin** (mel-ă-tōn'in) and **arginine vasotocin** (ar'ji-nēn vā-sō-tō'sin; table 18.13). Melatonin can decrease hypothalamic GnRH secretion. This mechanism may inhibit reproductive functions. It may also help regulate sleep cycles by increasing the tendency to sleep.

Arginine vasotocin works with melatonin to regulate the function of the reproductive system in some animals. Evidence for the role of melatonin is more extensive, however.

In some animals, pineal secretions are regulated by the **photoperiod**, the amount of daylight and darkness that occurs each day and changes with the seasons of the year (figure 18.20). For example, increased daylight initiates action potentials in the retina of the eye, which are propagated to the brain and cause a decrease in the action potentials sent first to the spinal cord and then through sympathetic neurons to the pineal gland, resulting in decreased secretions. In the dark, action potentials delivered by sympathetic neurons to the pineal gland increase, stimulating the secretion of pineal hormones. Thus, humans secrete larger amounts of melatonin at night than during the day. In animals that breed in the spring, the increasingly longer days as summer approaches reduce pineal secretions. Because pineal secretions inhibit reproductive functions in these species, they experience hypertrophy of the reproductive structures in the summer.

Melatonin's role in regulating reproductive functions in humans is not clear, but some researchers recommend its use to enhance sleep. However, because melatonin causes atrophy of reproductive structures in some species, undesirable side effects on the reproductive system may be possible for people who take supplemental melatonin.

The function of the pineal gland in humans is not clear, but tumors that destroy the pineal gland correlate with early sexual

TABLE 18.13

Other Hormones and Hormonelike Substances

Chemical Messenger	Structure	Target Tissue	Response
Pineal Gland			
Melatonin	Amino acid derivative	At least the hypothalamus	Inhibition of gonadotropin-releasing hormone secretion, thereby inhibiting reproduction; significance is not clear in humans; may help regulate sleep-wake cycles
Arginine vasotocin	Peptide	Possibly the hypothalamus	Possible inhibition of gonadotropin-releasing hormone secretion
Thymus			
Thymosin	Peptide	Immune tissues	Development and function of the immune system
Several Tissues (autocrine and paracrine chemical messengers)			
Eicosanoids			
Prostaglandins	Modified fatty acid	Most tissues	Mediation of the inflammatory response; increased uterine contractions; involved in ovulation, possible inhibition of progesterone synthesis; blood coagulation; other functions
Thromboxanes	Modified fatty acid	Most tissues	Mediation of the inflammatory response; other functions, including blood clotting
Prostacyclins	Modified fatty acid	Most tissues	Mediation of the inflammatory response; other functions, including blood clotting
Leukotrienes	Modified fatty acid	Most tissues	Mediation of the inflammatory response; other functions, including blood clotting
Enkephalins and endorphins	Peptides	Nervous system	Reduction of pain sensation; other functions
Epidermal growth factor	Protein	Many tissues	Stimulation of division in many cell types; embryonic development
Fibroblast growth factor	Protein	Many tissues	Stimulation of cell division in many cell types; embryonic development
Interleukin-2	Protein	Certain immune-competent cells	Stimulation of cell division of T lymphocytes

- 1 Light entering the eye stimulates neurons in the retina to initiate action potentials.
- 2 Action potentials are transmitted to the hypothalamus.
- 3 Action potentials from the hypothalamus are transmitted through the sympathetic division to the pineal gland.
- 4 A decrease in light (an increase in darkness) results in increased sympathetic stimulation of the pineal gland and increased melatonin secretion. An increase in light results in decreased sympathetic stimulation of the pineal gland and decreased melatonin secretion.
- 5 Melatonin inhibits GnRH secretion from the hypothalamus and may help regulate sleep cycles.

PROCESS FIGURE 18.20 Regulation of Melatonin Secretion from the Pineal Gland

Light entering the eye inhibits the release of melatonin from the pineal gland, and dark stimulates the release of melatonin.

development, and tumors that result in pineal hormone secretion correlate with delayed development of the reproductive system. It is not clear, however, if the pineal gland controls the onset of puberty.

ASSESS YOUR PROGRESS

59. Where is the pineal gland located? Name the hormones it produces and their possible effects.
60. Explain the relationship between the photoperiod and pineal gland secretion.

18.10 Other Hormones and Chemical Messengers

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the functions of the hormones secreted by the thymus, digestive system, heart, and kidneys.
- B. Differentiate between autocrine and paracrine chemical messengers.
- C. Give examples of both autocrine and paracrine chemical messengers and describe their functions.

Hormones of the Thymus

The **thymus** (thī'mūs) is important for immune function. It is in the neck and superior to the heart in the thorax. The thymus secretes the hormone **thymosin** (thī'mō-sin; table 18.13). Both the thymus and thymosin play a role in the development and maturation of the immune system (see chapter 22).

Hormones of the Digestive Tract

Several hormones are released from the digestive tract. They regulate digestive functions by influencing the activity of the stomach, intestines, liver, and pancreas (see chapter 24).

Hormonelike Chemicals

Recall from chapter 17 that some chemical messengers differ from hormones in that they are not secreted from discrete endocrine glands (see table 17.1). The effects of these chemicals are often local rather than systemic, or their functions are not understood adequately to explain their role in the body. **Autocrine chemical messengers** are released from cells that influence the same cell from which they are released. **Paracrine chemical messengers** are released from one cell type, diffuse short distances, and influence the activity of another cell type, which is the target tissue. Certain molecules sometimes function in an autocrine fashion and

Systems PATHOLOGY

Graves Disease (Hyperthyroidism)

Background Information

Graves disease is caused by altered regulation of hormone secretion—specifically, the elevated secretion of thyroid hormones from the thyroid gland. In approximately 95% of Graves disease cases, the immune system produces an unusual antibody type, which binds to receptors on the cells of the thyroid follicle and stimulates them to secrete increased amounts of thyroid hormone. The secretion of the releasing hormone and thyroid-stimulating hormone is inhibited by elevated thyroid hormones. However, the antibody is produced in large amounts and is not inhibited by thyroid hormones. A very elevated rate of thyroid hormone secretion is therefore maintained. In addition, the size of the thyroid gland increases. Enlargement of the thyroid gland is called a goiter. Connective tissue components are deposited behind the eyes, causing them to bulge (figure 18A).

Grace was treated with radioactive iodine (^{131}I) atoms that were actively transported into thyroid cells, where they destroyed a substantial portion of the thyroid gland. Data indicate that this treatment has few side effects and is effective in treating most cases of Graves disease. Other options include (1) drugs that inhibit the synthesis and secretion of thyroid hormones and (2) surgery to remove part of the thyroid gland.

► Predict 13

Explain why removal of part of the thyroid gland is an effective treatment for Graves disease.

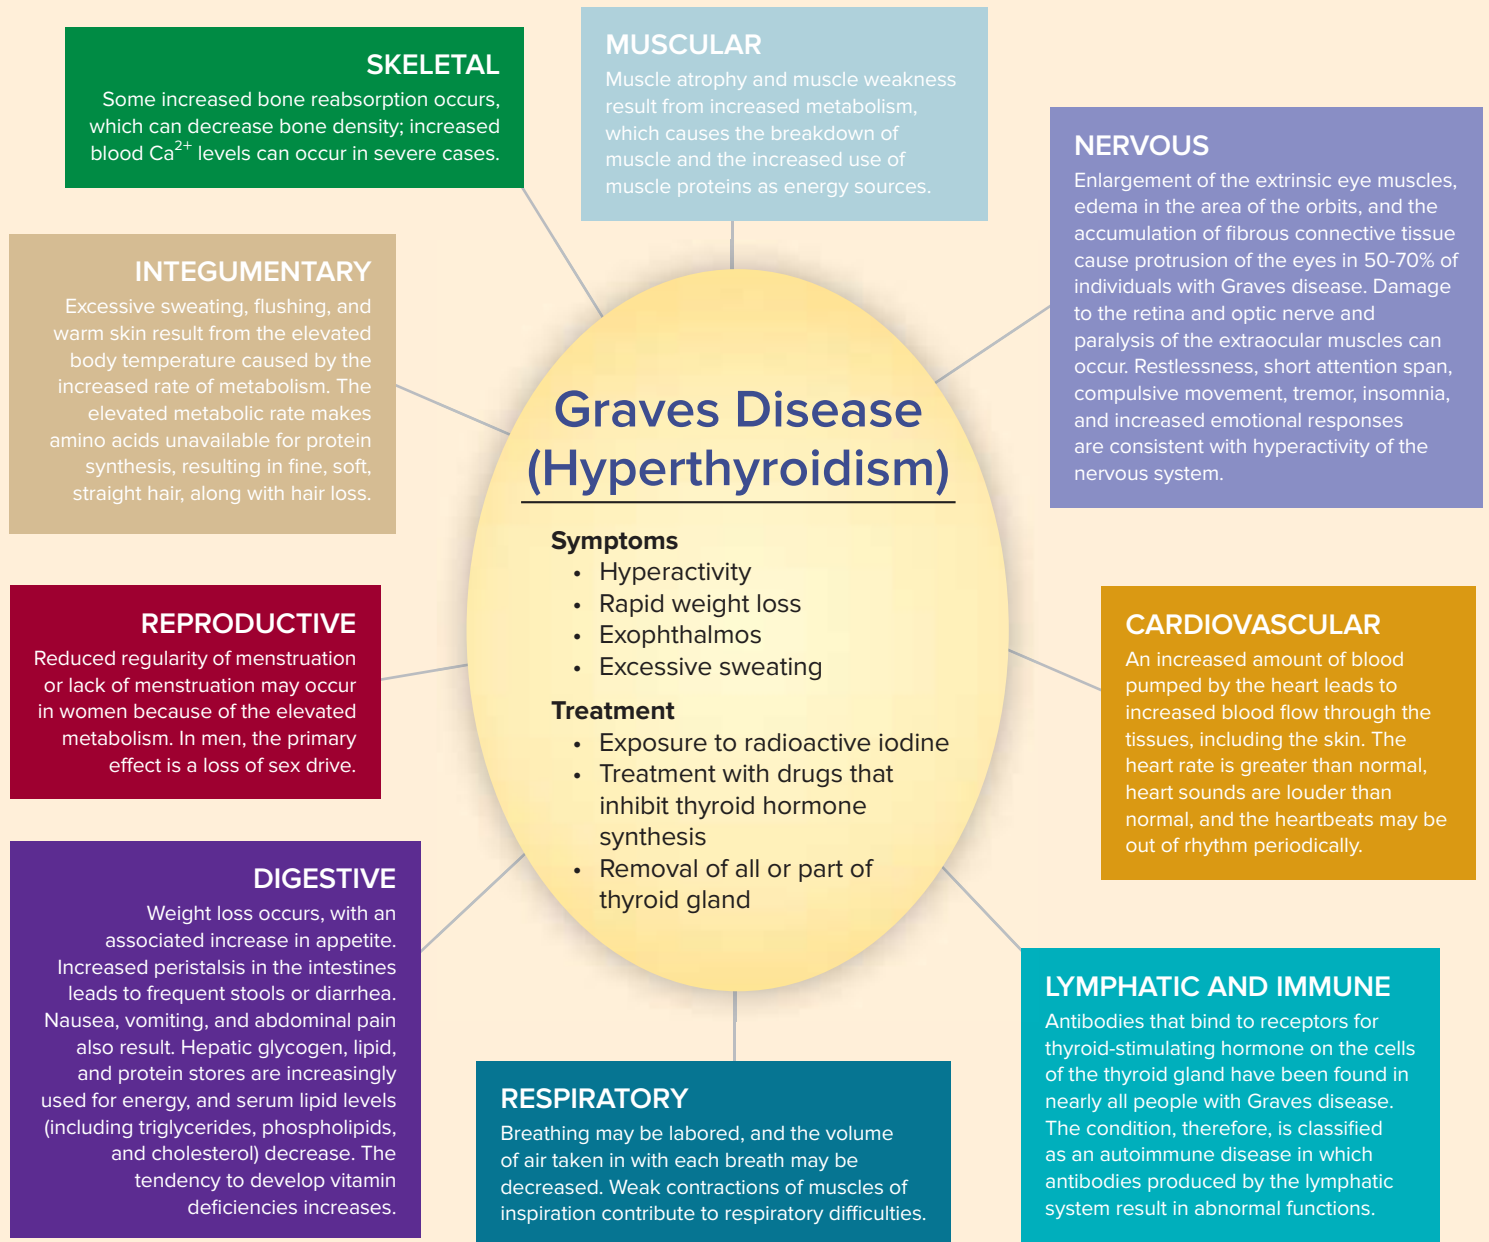

(a)

(b)

Figure 18A

(a) A goiter and (b) protruding eyes are symptoms of hyperthyroidism.

sometimes in a paracrine fashion. This distinction is similar to that for differentiating when a particular molecule is acting as a neurotransmitter and when it is acting as a hormone. The difference lies in the mode of transport (see chapter 17).

Examples of autocrine chemical messengers include chemical mediators of inflammation derived from the fatty acid arachidonic (ă-rak-i-don'ik) acid, such as eicosanoids and modified phospholipids. The eicosanoids include prostaglandins (pros'tă-glan-dinz), thromboxanes (throm'bok-zānz), prostacyclins (pros-tă-sī'klinz), and leukotrienes (loo'kō-trī'enz). An example of a modified phospholipid is platelet-activating factor (see

chapter 19). Paracrine chemical messengers include substances that play a role in modulating the sensation of pain, such as **endorphins** (en'dör-finz), **enkephalins** (en-kef'ă-linz), prostaglandins, and several peptide growth factors, such as **epidermal growth factor**, **fibroblast growth factor**, and **interleukin-2** (in-ter-loo'kin; table 18.13).

Prostaglandins, thromboxanes, prostacyclins, and leukotrienes are released from injured cells and are responsible for initiating some of the symptoms of inflammation (see chapter 22), in addition to being released from certain healthy cells. For example, prostaglandins are involved in the regulation of

uterine contractions during menstruation and childbirth, the process of ovulation, the inhibition of progesterone synthesis by the corpus luteum, the regulation of coagulation, kidney function, and the modification of the effect of other hormones on their target tissues. Pain receptors are stimulated directly by prostaglandins and other inflammatory compounds, or prostaglandins cause vasodilation of blood vessels, which is associated with headaches. Anti-inflammatory drugs, such as aspirin, inhibit prostaglandin synthesis and, as a result, reduce inflammation and pain. These examples are paracrine chemical messengers because they are synthesized and secreted by the cells near their target cells. Once prostaglandins enter the blood, they are metabolized rapidly.

Three classes of peptide molecules, which are endogenously produced analgesics, bind to the same receptors as morphine. They include enkephalins, endorphins, and **dynorphins** (dī'nōr-finz). They are produced in several body sites, such as in parts of the brain, pituitary gland, spinal cord, and intestines. They act as neurotransmitters in some neurons of both the central and the peripheral nervous systems and as hormones or paracrine regulatory substances. In general, they moderate the sensation of pain (see chapter 14). Decreased sensitivity to painful stimuli during exercise and stress may result from the increased secretion of these substances.

Several proteins can be classified as growth factors. They generally function as paracrine chemical messengers because they are secreted near their target tissues. Epidermal growth factor stimulates cell divisions in a number of tissues and plays an important role in embryonic development. Interleukin-2 stimulates the proliferation of T lymphocytes and plays a very important role in immune responses (see chapter 22).

The number of hormonelike substances in the body is large, and only a few of them have been mentioned here. Chemical communication among body cells is complex, well developed, and necessary to maintain homeostasis. Investigations into chemical regulation increase our knowledge of body functions—knowledge that can be used to develop new treatments for pathological conditions.

ASSESS YOUR PROGRESS

61. What hormone is secreted by the thymus? What is its function?
62. What function do the hormones secreted by the stomach and small intestine perform?
63. What is the difference between an autocrine and a paracrine chemical messenger?
64. List eicosanoids and modified phospholipids that function as autocrine chemical messengers, and explain how they work.
65. List examples of paracrine chemical messengers that play a role in modulating pain or are peptide growth factors.
66. Describe the paracrine functions of prostaglandins and how anti-inflammatory drugs can reduce pain and inflammation.

18.11 Effects of Aging on the Endocrine System

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe major age-related changes that occur in the endocrine system.

Age-related changes in the endocrine system are not the same for all of the endocrine glands. Some, but not all, undergo a gradual decrease in secretory activity. In addition, some decreases in the secretory activity of endocrine glands appear to be secondary to a decrease in physical activity as people age.

GH secretion decreases as people grow older. The decrease is greater in people who do not exercise, and it may not occur at all in those who exercise regularly. Decreasing GH secretion may explain the gradual decrease in lean body mass. For example, bone mass and muscle mass decrease as GH levels decline. At the same time, the proportion of adipose tissue increases.

Melatonin secretion decreases in aging people. This decrease may influence age-related changes in sleep patterns and the secretory patterns of other hormones, such as GH and testosterone.

The secretion of thyroid hormones decreases slightly with increasing age, and the $T_3:T_4$ ratio decreases. However, this may be less of a decrease in the secretory activity of the thyroid gland than a compensation for the decreased lean body mass in aging people. Age-related damage to the thyroid gland by the immune system can occur and is more common in women than in men. As a result, approximately 10% of elderly women's thyroid glands do not produce enough T_3 and T_4 .

Parathyroid hormone secretion does not appear to decrease with age. Blood levels of Ca^{2+} may decline slightly because of reduced dietary calcium intake and vitamin D levels. The greatest risk is loss of bone matrix as parathyroid hormone increases to maintain blood levels of Ca^{2+} within their normal range.

Reproductive hormone secretion gradually declines in elderly men, and women experience menopause, as described in chapter 28.

The ability to regulate blood glucose levels does not decline with age. However, there is an age-related probability of developing type 2 diabetes mellitus for those who have the familial tendency, and the incidence of the condition is correlated with age-related increases in body weight.

Secretion of thymosin from the thymus decreases with age. Fewer immature lymphocytes are able to mature and become functional, and the immune system becomes less effective in protecting the body. Thus, people's susceptibility to infection and to cancer increases.

ASSESS YOUR PROGRESS

67. Describe age-related changes in the secretion of the following hormones and the consequences of each: GH, melatonin, thyroid hormones, reproductive hormones, and thymosin.
68. Which hormone does not appear to decrease with age?

Answer

Learn to Predict ◀ From page 600

The first piece of information is that, although Dylan is always hungry and eating, he is losing weight. You learned in this chapter that two of the most important hormones for metabolism and blood glucose regulation are insulin and glucagon. The disease most often affiliated with disruptions in insulin regulation is diabetes mellitus. Normally, insulin allows for glucose to enter the body's cells for energy production, but in cases of diabetes mellitus, insufficient insulin causes excessive circulating blood glucose. When coupled with Dylan's other symptoms, chronic thirst and urination, there is a clear link to diabetes mellitus. Recall from chapter 3 that membrane transport proteins can be saturated by their transport molecule. The reason Dylan is always thirsty is that too much glucose is filtered out of his blood in his kidneys to be reabsorbed; the excess filtered glucose saturates its transport molecule. In the filtrate, the glucose has an osmotic effect and prevents the kidneys from

conserving water. The sweet, or acetone, breath is derived from the fact that, when starved from glucose, cells begin to catalyze lipids, and the by-products of this metabolism are acetone and other molecules chemically related to acetone. Dylan was treated with injectable insulin and began to feel much better. However, if Dylan keeps eating candy and drinking sugary soda, elevated blood glucose levels will continue to dehydrate Dylan and his neurons can become dehydrated. This would cause him to feel irritable and unwell. Dylan may also experience a sudden weight gain because of sugar intake while injecting insulin. His cells will be able to use the extra glucose and may convert it to adipose tissue. Dylan should eat a healthy diet and avoid sugary foods.

Answers to the rest of this chapter's Predict questions are in appendix G.

18.1 Overview of the Endocrine System (p. 601)

The main regulatory functions of the endocrine system are metabolism, control of food intake and digestion, tissue maturation, ion regulation, water balance, heart rate and blood pressure regulation, control of blood glucose and other nutrients, control of reproductive functions, uterine contractions and milk letdown and immune system regulation.

18.2 Pituitary Gland and Hypothalamus (p. 601)

1. The pituitary gland secretes at least nine hormones that regulate numerous body functions as well as other endocrine glands.
2. The hypothalamus regulates pituitary gland activity through neurohormones and action potentials.

Structure of the Pituitary Gland

1. The posterior pituitary develops from the floor of the brain and consists of the infundibulum and the neurohypophysis.
2. The anterior pituitary develops from the roof of the mouth.

Relationship of the Pituitary Gland to the Brain: The Hypothalamus

1. The hypothalamohypophysial portal system connects the hypothalamus and the anterior pituitary.
 - Neurohormones are produced in hypothalamic neurons.
 - Through the portal system, the neurohormones inhibit or stimulate hormone production in the anterior pituitary.
2. The hypothalamohypophysial tract connects the hypothalamus and the posterior pituitary.
 - Neurohormones are produced in hypothalamic neurons.
 - The neurohormones move down the axons of the tract and are secreted from the posterior pituitary.

Summary

Hormones of the Pituitary Gland

1. ADH promotes water retention by the kidneys.
2. Oxytocin promotes uterine contractions during delivery and causes milk letdown in lactating women.
3. GH is sometimes called somatotropin.
 - GH stimulates growth in most tissues and regulates metabolism.
 - GH stimulates the uptake of amino acids and their conversion into proteins and stimulates the breakdown of lipids and the synthesis of glucose.
 - GH stimulates the production of somatomedins; together, they promote bone and cartilage growth.
 - GH secretion increases in response to an increase in blood amino acids, low blood glucose, or stress.
 - GH is regulated by GHRH and GHIH or by somatostatin.
4. TSH, or thyrotropin, causes the release of thyroid hormones.
5. ACTH is derived from proopiomelanocortin; it stimulates cortisol secretion from the adrenal cortex and increases skin pigmentation.
6. Several hormones in addition to ACTH are derived from proopiomelanocortin.
 - Lipotropins cause lipid breakdown.
 - β endorphins play a role in analgesia.
 - MSH increases skin pigmentation.
7. LH and FSH are major gonadotropins.
 - Both hormones regulate the production of gametes and reproductive hormones (testosterone in males, estrogen and progesterone in females).
 - GnRH from the hypothalamus stimulates LH and FSH secretion.
8. Prolactin stimulates milk production in lactating females. Prolactin-releasing hormone (PRH) and prolactin-inhibiting hormone (PIH) from the hypothalamus affect prolactin secretion.

18.3 Thyroid Gland (p. 611)

1. The thyroid gland is just inferior to the larynx.
2. The thyroid gland is composed of small, hollow balls of cells called follicles, which contain thyroglobulin.
3. Parafollicular cells are scattered throughout the thyroid gland.

Thyroid Hormones

1. T_3 and T_4 synthesis occurs in thyroid follicles.
 - Iodide ions are taken into the follicles by active transport, oxidized, and bound to tyrosine molecules in thyroglobulin.
 - Thyroglobulin is secreted into the follicle lumen. Tyrosine molecules with iodine combine to form T_3 and T_4 thyroid hormones.
 - Thyroglobulin is taken into the follicular cells and broken down; T_3 and T_4 diffuse from the follicles to the blood.
2. T_3 and T_4 are transported in the blood.
 - T_3 and T_4 bind to thyroxine-binding globulin and other plasma proteins.
 - The plasma proteins prolong the half-life of T_3 and T_4 and regulate the levels of T_3 and T_4 in the blood.
 - Approximately one-third of the T_4 is converted into functional T_3 .
3. T_3 and T_4 bind with nuclear receptor molecules and initiate new protein synthesis.
4. T_3 and T_4 affect nearly every tissue in the body.
 - T_3 and T_4 increase the rate of glucose, lipid, and protein metabolism in many tissues, thus increasing body temperature.
 - Normal growth of many tissues is dependent on T_3 and T_4 .
5. TRH and TSH regulate T_3 and T_4 secretion.
 - Increased TSH from the anterior pituitary increases T_3 and T_4 secretion.
 - TRH from the hypothalamus increases TSH secretion. TRH increases as a result of chronic exposure to cold, food deprivation, and stress.
 - T_3 and T_4 inhibit TSH and TRH secretion.

Calcitonin

1. An increase in blood calcium levels stimulates calcitonin secretion by the parafollicular cells.
2. Calcitonin decreases blood calcium and phosphate levels by inhibiting osteoclasts.

18.4 Parathyroid Glands (p. 617)

1. The parathyroid glands are embedded in the thyroid gland.
2. PTH increases blood calcium levels.
 - PTH stimulates osteoclasts.
 - PTH promotes calcium reabsorption by the kidneys and the formation of active vitamin D by the kidneys.
 - Active vitamin D increases calcium absorption by the intestine.
3. A decrease in blood calcium stimulates PTH secretion.

18.5 Adrenal Glands (p. 618)

1. The adrenal glands are near the superior poles of the kidneys.
2. The adrenal medulla arises from neural crest cells and functions as part of the sympathetic nervous system. The adrenal cortex is derived from mesoderm.
3. The adrenal medulla is composed of closely packed cells.
4. The adrenal cortex is divided into three layers: the zona glomerulosa, the zona fasciculata, and the zona reticularis.

Hormones of the Adrenal Medulla

1. Epinephrine accounts for 80% and norepinephrine for 20% of the adrenal medulla hormones.
 - Epinephrine increases blood glucose levels, the use of glycogen and glucose by skeletal muscle, and heart rate and force of contraction. It also causes vasoconstriction in the skin and viscera and vasodilation in skeletal and cardiac muscle.
 - Norepinephrine and epinephrine stimulate cardiac muscle and cause the constriction of most peripheral blood vessels.
2. The adrenal medulla hormones prepare the body for physical activity.
3. Release of adrenal medulla hormones is mediated by the sympathetic nervous system in response to emotions, injury, stress, exercise, and low blood glucose.

Hormones of the Adrenal Cortex

1. The zona glomerulosa secretes the mineralocorticoids, especially aldosterone. Aldosterone acts on the kidneys to increase sodium and to decrease potassium and hydrogen levels in the blood.
2. The zona fasciculata secretes glucocorticoids, especially cortisol.
 - Cortisol increases lipid and protein breakdown, increases glucose synthesis from amino acids, decreases the inflammatory response, and is necessary for the development of some tissues.
 - ACTH from the anterior pituitary stimulates cortisol secretion. CRH from the hypothalamus stimulates ACTH release. Low blood glucose levels and stress stimulate CRH secretion.
3. The zona reticularis secretes androgens. In females, androgens stimulate axillary and pubic hair growth and sex drive.

18.6 Pancreas (p. 624)

1. The pancreas, located along the small intestine and the stomach, is both an exocrine and an endocrine gland.
2. The exocrine portion of the pancreas consists of a complex duct system, which ends in small sacs, called acini, that produce pancreatic digestive juices.
3. The endocrine portion consists of the pancreatic islets. Each islet is composed of alpha cells, which secrete glucagon; beta cells, which secrete insulin; and delta cells, which secrete somatostatin.

Effect of Insulin and Glucagon on Their Target Tissues

1. Insulin's target tissues are the liver, adipose tissue, muscle, and the satiety center in the hypothalamus. The nervous system is not a target tissue, but it does rely on blood glucose levels maintained by insulin.
2. Insulin increases the uptake of glucose and amino acids by cells. Glucose is used for energy or is stored as glycogen. Amino acids are used for energy or are converted to glucose or proteins.
3. Glucagon's target tissue is mainly the liver.
4. Glucagon causes the breakdown of glycogen and lipids for use as an energy source.

Regulation of Pancreatic Hormone Secretion

1. Insulin secretion increases because of elevated blood glucose levels, an increase in some amino acids, parasympathetic stimulation, and gastrointestinal hormones. Sympathetic stimulation decreases insulin secretion.

- Glucagon secretion is stimulated by low blood glucose levels, certain amino acids, and sympathetic stimulation.
- Somatostatin inhibits insulin and glucagon secretion.

18.7 Hormonal Regulation of Nutrient Utilization (p. 628)

- After a meal, the following events take place:
 - High glucose levels inhibit glucagon, cortisol, GH, and epinephrine, which reduces the release of glucose from tissues.
 - Insulin secretion increases as a result of the high blood glucose levels, thereby increasing the uptake of glucose, amino acids, and lipids, which are used for energy or stored.
 - Sometime after the meal, blood glucose levels drop. Glucagon, GH, cortisol, and epinephrine levels increase, insulin levels decrease, and glucose is released from tissues.
 - Adipose tissue releases fatty acids, triglycerides, and ketones, which most tissues use for energy.
- During exercise, the following events occur:
 - Sympathetic activity increases epinephrine and glucagon secretion, causing a release of glucose into the blood.
 - Low blood sugar levels, caused by the uptake of glucose by skeletal muscles, stimulate epinephrine, glucagon, GH, and cortisol secretion, causing an increase in fatty acids, triglycerides, and ketones in the blood, all of which are used for energy.

18.8 Hormones of the Reproductive System (p. 632)

The ovaries, testes, placenta, and pituitary gland secrete reproductive hormones.

18.9 Hormones of the Pineal Gland (p. 634)

The pineal gland produces melatonin and arginine vasotocin, which can inhibit reproductive maturation and may regulate sleep-wake cycles.

18.10 Other Hormones and Chemical Messengers (p. 635)

- The thymus produces thymosin, which is involved in the development of the immune system.
- The digestive tract produces several hormones that regulate digestive functions.
- Autocrine and paracrine chemical messengers are produced by many cells of the body and usually have a local effect on body functions.
- Eicosanoids, such as prostaglandins, prostacyclins, thromboxanes, and leukotrienes, are derived from fatty acids and mediate inflammation and other functions. Endorphins, enkephalins, and dynorphins are analgesic substances. Growth factors influence cell division and growth in many tissues, and interleukin-2 influences cell division in the T cells of the immune system.

18.11 Effects of Aging on the Endocrine System (p. 638)

A gradual decrease in the secretion rate occurs for most, but not all, hormones. Some of these decreases are related to gradual decreases in physical activity.

REVIEW AND COMPREHENSION

- The pituitary gland
 - develops from the floor of the brain.
 - develops from the roof of the mouth.
 - is stimulated by neurohormones produced in the midbrain.
 - secretes only three major hormones.
 - Both a and b are correct.
- The hypothalamohypophysial portal system
 - contains one capillary bed.
 - carries hormones from the anterior pituitary to the body.
 - carries hormones from the posterior pituitary to the body.
 - carries hormones from the hypothalamus to the anterior pituitary.
 - carries hormones from the hypothalamus to the posterior pituitary.
- Which of these hormones is *not* secreted into the hypothalamohypophysial portal system?

a. GHRH	c. PIH	e. ACTH
b. TRH	d. GnRH	
- Which of these stimulates the secretion of ADH?
 - elevated blood osmolality
 - decreased blood osmolality
 - release of hormones from the hypothalamus
 - ACTH
 - increased blood pressure
- Oxytocin is responsible for
 - preventing milk letdown from the mammary glands.
 - preventing goiter.
 - causing contraction of the uterus.
 - maintaining normal calcium levels.
 - increasing the metabolic rate.
- Growth hormone
 - increases the usage of glucose.
 - increases the breakdown of lipids.
 - decreases the synthesis of proteins.
 - decreases the synthesis of glycogen.
 - All of these are correct.
- Which of these hormones stimulates somatomedin secretion?

a. FSH	d. prolactin
b. GH	e. TSH
c. LH	
- Hypersecretion of growth hormone
 - results in gigantism if it occurs in children.
 - causes acromegaly in adults.
 - increases the probability that a person will develop diabetes.
 - can lead to severe atherosclerosis.
 - All of these are correct.

9. LH and FSH
 - a. are produced in the hypothalamus.
 - b. production is increased by TSH.
 - c. promote the production of gametes and reproductive hormones.
 - d. inhibit the production of prolactin.
 - e. All of these are correct.
10. T_3 and T_4
 - a. require iodine for their production.
 - b. are made from the amino acid tyrosine.
 - c. are transported in the blood bound to thyroxine-binding globulin.
 - d. All of these are correct.
11. Which of these symptoms is associated with hyposecretion of thyroid hormones?
 - a. hypertension
 - b. nervousness
 - c. diarrhea
 - d. weight loss with either normal or increased food intake
 - e. decreased metabolic rate
12. Choose the statement that most accurately predicts the long-term effect of exposure to a substance that prevents the active transport of iodide by the thyroid gland.
 - a. Large amounts of T_3 and T_4 accumulate within the thyroid follicles, but little is released.
 - b. The person exhibits hypothyroidism.
 - c. The anterior pituitary secretes smaller amounts of TSH.
 - d. The circulating levels of T_3 and T_4 increase.
13. Calcitonin
 - a. is secreted by the parathyroid glands.
 - b. levels increase when blood calcium levels decrease.
 - c. causes blood calcium levels to decrease.
 - d. insufficiency results in weak bones and tetany.
14. Parathyroid hormone secretion increases in response to
 - a. a decrease in blood calcium levels.
 - b. increased production of parathyroid-stimulating hormone from the anterior pituitary.
 - c. increased secretion of parathyroid-releasing hormone from the hypothalamus.
 - d. increased secretion of calcitonin.
 - e. decreased secretion of ACTH.
15. If parathyroid hormone levels increase, which of these conditions is expected?
 - a. Osteoclast activity increases.
 - b. Calcium absorption from the small intestine is inhibited.
 - c. Calcium reabsorption from the urine is inhibited.
 - d. Less active vitamin D forms in the kidneys.
 - e. All of these are correct.
16. The adrenal medulla
 - a. produces steroids.
 - b. secretes cortisol as its major product.
 - c. decreases its secretions during exercise.
 - d. forms from a modified portion of the sympathetic division of the ANS.
 - e. All of these are correct.
17. In the condition in which a benign tumor results in hypersecretion of hormones from the adrenal medulla, expected symptoms include
 - a. hypotension.
 - b. bradycardia (slow heart rate).
 - c. pallor (decreased blood flow to the skin).
 - d. lethargy.
 - e. hypoglycemia.
18. Which of these is *not* a hormone secreted by the adrenal cortex?
 - a. aldosterone
 - b. androgens
 - c. cortisol
 - d. epinephrine
19. If aldosterone secretions increase,
 - a. blood potassium levels increase.
 - b. blood hydrogen levels increase.
 - c. acidosis results.
 - d. blood sodium levels decrease.
 - e. blood volume increases.
20. Glucocorticoids (cortisol)
 - a. increase the breakdown of lipids.
 - b. increase the breakdown of proteins.
 - c. increase blood glucose levels.
 - d. decrease inflammation.
 - e. All of these are correct.
21. Which of these is (are) expected in Cushing syndrome (hypersecretion of adrenal cortex hormones)?
 - a. loss of hair in women
 - b. deposition of adipose tissue in the face, neck, and abdomen
 - c. low blood glucose
 - d. low blood pressure
 - e. All of these are correct.
22. Within the pancreas, the pancreatic islets produce
 - a. insulin.
 - b. glucagon.
 - c. digestive enzymes.
 - d. Both a and b are correct.
 - e. All of these are correct.
23. Insulin increases
 - a. the uptake of glucose by its target tissues.
 - b. the breakdown of protein.
 - c. the breakdown of lipids.
 - d. glycogen breakdown in the liver.
 - e. All of these are correct.
24. Glucagon
 - a. primarily affects the liver.
 - b. causes glycogen to be stored.
 - c. causes blood glucose levels to decrease.
 - d. decreases lipid metabolism.
 - e. performs all of these functions.
25. When blood glucose levels increase, the secretion of which of these hormones increases?
 - a. glucagon
 - b. insulin
 - c. GH
 - d. cortisol
 - e. epinephrine
26. If a person who has diabetes mellitus has forgotten to take an insulin injection, the symptoms that may soon appear include
 - a. acidosis.
 - b. hyperglycemia.
 - c. increased urine production.
 - d. lethargy and fatigue.
 - e. All of these are correct.

27. Which of the following is *not* a hormone produced by the ovaries?
 a. estrogen c. prolactin e. relaxin
 b. progesterone d. inhibin
28. Melatonin
 a. is produced by the posterior pituitary.
 b. production increases as day length increases.
 c. inhibits the development of the reproductive system.
 d. increases GnRH secretion from the hypothalamus.
 e. decreases the tendency to sleep.
29. Which of these substances, produced by many body tissues, can promote inflammation, pain, and vasodilation of blood vessels?
 a. endorphins c. thymosin e. prostaglandins
 b. enkephalins d. epidermal growth factor
30. Which of these secretions does *not* decrease with aging of the endocrine system?
 a. GH secretion c. thyroid hormone secretion
 b. melatonin secretion d. parathyroid hormone secretion

Answers in appendix E

CRITICAL THINKING

- The hypothalamohypophysial portal system connects the hypothalamus with the anterior pituitary. Why is such a special circulatory system advantageous?
- A patient exhibits polydipsia (thirst), polyuria (excess urine production), and urine with a low specific gravity (contains few ions and no glucose). If you wanted to reverse the symptoms, would you administer insulin, glucagon, ADH, or aldosterone? Explain.
- A patient complains of headaches and visual disturbances. A casual glance reveals enlarged finger bones, a heavy deposition of bone over the eyes, and a prominent jaw. The doctor determines that the headaches and visual disturbances result from increased pressure within the skull and that the presence of a pituitary tumor is affecting hormone secretion. Name the hormone causing the problem, and explain why increased pressure exists within the skull.
- Most laboratories are able to determine blood levels of TSH, T₃, and T₄. Given that ability, design a method of determining whether hyperthyroidism in a patient results from a pituitary abnormality or from the production of a nonpituitary thyroid stimulatory substance.
- Over the past year, Julie has gradually gained weight. The increase in adipose tissue is distributed over her trunk, face, and neck, and her muscle mass appears to be decreased. Julie also feels weak and bruises easily. Her physician suspects Cushing syndrome and orders a series of blood tests. The results reveal elevated blood levels of cortisol and ACTH. There is no evidence of an extrapituitary source of ACTH. Predict the cause of Julie's condition and the treatments that are likely to be recommended.
- An anatomy and physiology instructor asks two students to predict a patient's response to chronic vitamin D deficiency. One student claims the person would suffer from hypocalcemia. The other student claims the calcium levels would remain within their normal range, although at the low end, and that bone reabsorption would occur to the point that advanced osteomalacia might occur. With whom do you agree, and why?
- A patient arrives at the emergency room in an unconscious condition. A medical emergency bracelet reveals that he has diabetes. The patient is in either diabetic coma or insulin shock. How can you tell which, and what treatment do you recommend for each condition?
- Predict some of the consequences of exposure to intense and prolonged stress.
- Katie was getting nervous. At 16, she was the only one in her group of friends who had not started menstruating. Katie had always dreamed of having three beautiful children someday and she was worried. Her mother took her to see Dr. Josephine, who ordered several blood tests. When the results came back, Dr. Josephine gently explained to Katie and her mother that Katie would never be able to have children and would never menstruate. Dr. Josephine then asked Katie to wait in the outer room while she spoke privately to her mother. She explained to Katie's mom that Katie has androgen insensitivity syndrome. Though Katie is genetically male and her gonads produce more of the male reproductive hormone, testosterone, than the female reproductive hormone, estrogen, Katie did not reflect the tissue changes expected. What malfunction in Katie's body would cause this? Why does Katie's body look feminine if she is genetically male?

Learn to Predict

Frankie didn't have time to be sick. So at first she attributed her extreme tiredness to the stress of being a 40-year-old single mother of two teenagers while working full-time and attending school part-time. However, when she started experiencing significant abdominal pain, she consulted her doctor, who ordered several tests. The results indicated a low red blood cell (RBC) count with microcytic RBCs, a high reticulocyte count, low hemoglobin and hematocrit levels, and evidence of hemoglobin in her feces. **After reading this chapter and recalling what you learned about the endocrine system in chapters 17 and 18, explain Frankie's symptoms and test results.**

Photo: Colorized scanning electron micrograph of a blood clot. The red discs are red blood cells, the purple particles are platelets, and the yellow strands are fibrin.

Cardiovascular System

BLOOD

Historically, many cultures around the world, both ancient and modern, have believed in the magical qualities of blood. Some societies consider blood the “essence of life” because the uncontrolled loss of it can result in death. Blood has also been thought to define character and emotions. For example, people from prominent families are sometimes described as “bluebloods,” whereas criminals are said to have “bad blood.” Common expressions allege that anger causes the blood to “boil” and that fear results in blood “curdling.” The scientific study of blood reveals characteristics as fascinating as any of these fantasies. Blood performs many functions essential to life and can often reveal much about our health.

Blood is one component of the **cardiovascular system**, which also consists of the heart and the blood vessels. The cardiovascular system connects the various tissues of the body. The heart pumps blood through vessels extending throughout the body (often referred to as the *circulatory system*), and the blood delivers nutrients and picks up waste products at the body tissues. This chapter focuses on the blood, whereas chapters 20 and 21 discuss the heart and the blood vessels, respectively.

19.1 Functions of Blood

LEARNING OUTCOME

After reading this section, you should be able to

- A. List and explain the ways blood helps maintain homeostasis in the body.**

Blood helps maintain homeostasis in several ways:

1. *Transport of gases, nutrients, and waste products.* Oxygen enters the blood in the lungs and is carried to the cells. Carbon dioxide, produced by the cells, is carried in the blood to the lungs, where it is exhaled. The blood transports ingested nutrients, ions, and water from the digestive tract to the cells, and the blood transports the cells' waste products to the kidneys for elimination.
2. *Transport of processed molecules.* Many substances are produced in one part of the body and transported in the blood to another part, where they are modified. For example, the precursor to vitamin D is produced in the skin (see chapter 5) and transported by the blood to the liver and then to the kidneys for processing into active vitamin D. The blood then transports active vitamin D to the small intestine, where it promotes the uptake of calcium. Another example involves lactate produced by skeletal muscles during anaerobic respiration (see chapter 9). The blood carries lactate to the liver, where it is converted into glucose.
3. *Transport of regulatory molecules.* The blood carries the hormones and many of the enzymes that regulate body processes from one part of the body to another.
4. *Regulation of pH and osmosis.* Buffers (see chapter 2), which help keep the blood's pH within its normal range of 7.35–7.45, are in the blood. The osmotic composition of blood is also critical for maintaining normal fluid and ion balance.
5. *Maintenance of body temperature.* Body temperature regulation involves several mechanisms, including the movement of warm blood from the interior of the body to its surface, where heat is released.
6. *Protection against foreign substances.* Certain cells and chemicals in the blood make up an important part of the immune system, protecting against foreign substances, such as microorganisms and toxins.
7. *Clot formation.* Blood clotting protects against excessive blood loss when blood vessels are damaged. The blood clot that forms in damaged tissue is also the first step in tissue repair and the restoration of normal function (see chapter 4).

ASSESS YOUR PROGRESS

1. List the ways that blood helps maintain homeostasis in the body.
2. What substances are transported by the blood?
3. What is the normal pH range of the blood?
4. How does the blood provide protection?

19.2 Composition of Blood

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the components of blood.**
B. Relate the average total blood volume for females and for males.

Blood is a type of connective tissue consisting of a liquid matrix containing cells and cell fragments. Plasma is the liquid matrix, and the formed elements are the cells and cell fragments. The plasma makes up 55% of the total blood volume, and the formed elements make up 45% (figure 19.1). The total blood volume in the average adult is about 4–5 L in females and 5–6 L in males. Blood makes up about 8% of the total weight of the body.

ASSESS YOUR PROGRESS

5. What are the two major components of blood? What portion of the total blood volume does each compose?
6. What is the average total blood volume for females and for males?

19.3 Plasma

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Name the components of blood plasma.**
B. List the three major plasma proteins and describe their functions.

Plasma (plaz'mă) is the liquid part of blood. It is a pale yellow fluid that consists of about 91% water and 9% other substances, such as proteins, ions, nutrients, gases, waste products, and regulatory substances (table 19.1). Plasma is a **colloid** (kol'oyd), which is a liquid containing suspended substances that do not settle out of solution. Most of the suspended substances are plasma proteins, which make up about 7% of the volume of plasma (figure 19.1). Based on molecular size and charge, the plasma proteins can be classified into three groups: (1) albumin, (2) globulins, and (3) fibrinogen. Almost all of the plasma proteins are produced by the liver or blood cells, a notable exception being protein hormones. **Albumin** (al-bū'min) makes up 58% of the plasma proteins and is important in regulating the movement of water between the tissues and the blood. Recall from chapter 3 that osmosis, the diffusion of water, occurs when solutes cannot easily move across a selectively permeable barrier and that osmotic pressure is the tendency for water to move across that barrier. Because albumin does not pass easily from the blood into tissues, it plays an important role in maintaining blood colloid osmotic pressure (see chapters 21 and 26). Albumins also bind and transport other molecules in the blood, such as fatty acids, bilirubin, and thyroid hormones. **Globulins** (glob'ū-linz) account for 38% of the plasma proteins. The globulins are subdivided into α , β , and γ

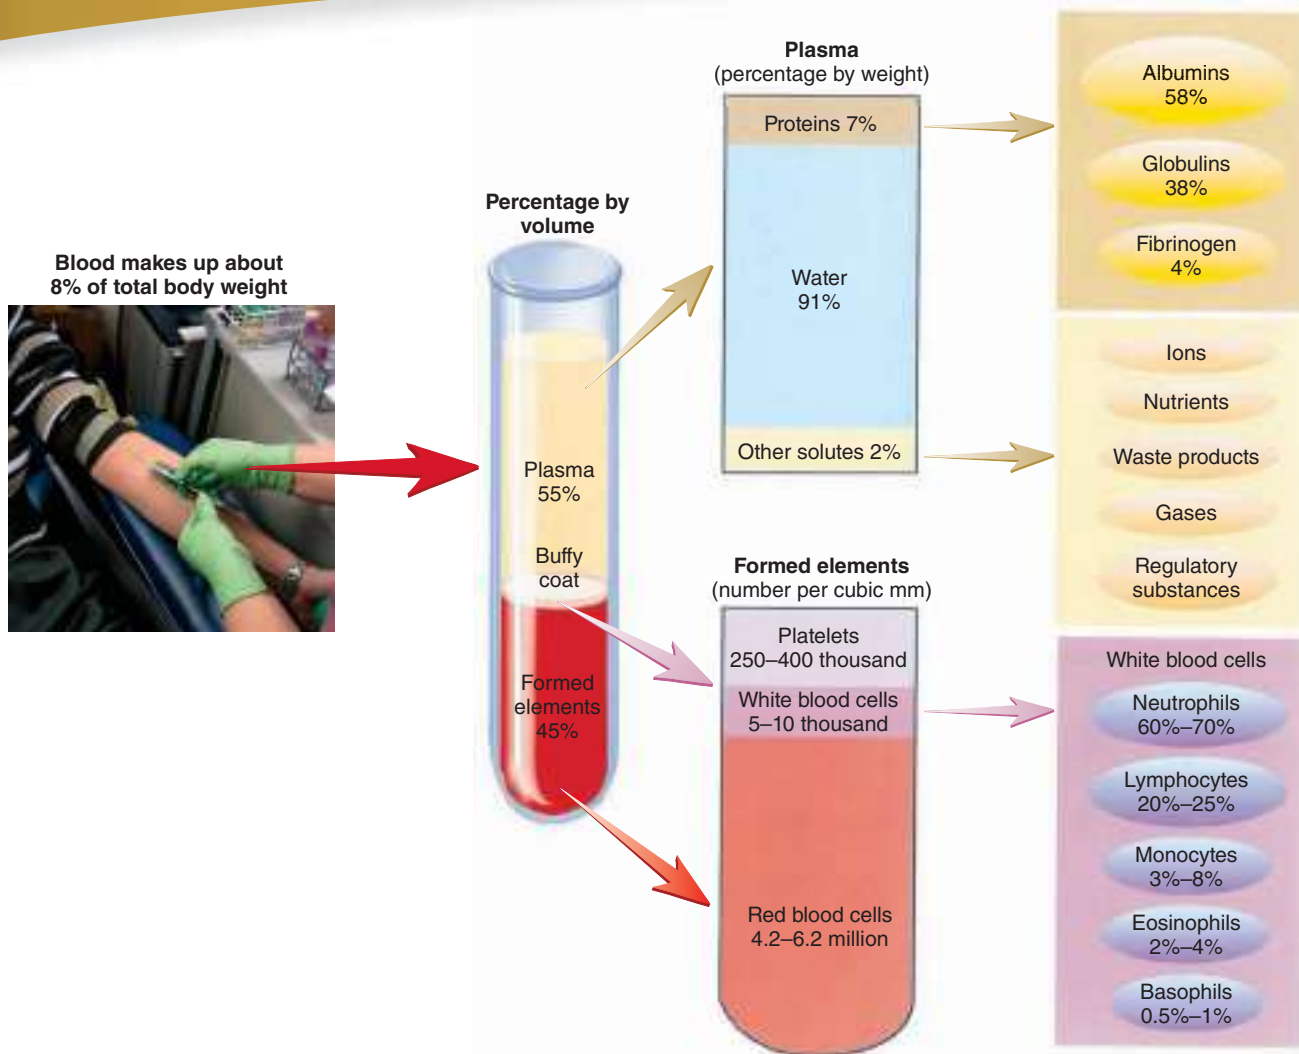

FIGURE 19.1 Composition of Blood

Approximate values for the components of blood in a normal adult. **AP R**

globulins. Globulins function in transporting many substances in the blood as well as protecting against microorganisms. (table 19.1; see chapter 22). **Fibrinogen** (fī-brin'ō-jen) constitutes 4% of the plasma proteins and is responsible for the formation of blood clots (see “Coagulation” in section 19.5). **Serum** (ser'um; whey) is plasma without the clotting factors.

The levels of water, proteins, and other substances in the blood, such as ions, nutrients, waste products, gases, and regulatory substances, are maintained within narrow limits. Normally, the amount of water taken in through the digestive tract closely matches the amount of water lost through the kidneys, lungs, digestive tract, and skin. Therefore, plasma volume remains relatively constant. Suspended or dissolved substances in the blood come from the liver, kidneys, intestines, endocrine glands, and immune tissues, such as the lymph nodes and spleen. Oxygen enters the blood in the lungs and leaves the blood as it flows through tissues. Carbon dioxide enters the blood from the tissues and leaves the blood as it flows through the lungs.

ASSESS YOUR PROGRESS

7. What is plasma, and what does it consist of? Why is plasma a colloid?
8. What are the three major plasma proteins, and what roles do they play in the blood?
9. Explain how plasma volume remains relatively constant.

19.4 Formed Elements

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the three kinds of formed elements using both their common and technical names.
- B. Describe the origin and production of the formed elements.

TABLE 19.1 Composition of Plasma

Components	Function
Water	Acts as a solvent and suspending medium for blood components
Plasma Proteins	
Albumin	Partly responsible for blood viscosity and osmotic pressure; acts as a buffer; transports fatty acids, free bilirubin, and thyroid hormones
Globulins	
α	Protect tissues from damage by inflammation (alpha-1 antitrypsin); transport thyroid hormones (thyroid-binding globulin), cortisol (transcortin), and testosterone and estrogen (sex hormone-binding globulin); transport lipids (e.g., cholesterol in high-density lipoproteins); convert ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}), which promotes iron transport by transferrin (ceruloplasmin); transport hemoglobin released from damaged red blood cells (haptoglobin)
β	Transport iron (transferrin); transport lipids (beta-lipoproteins), especially cholesterol in low-density lipoproteins; involved with immunity (complement); prevent blood loss (coagulation proteins)
γ	Involved in immunity (most antibodies are γ globulins, but some are β or α globulins)
Fibrinogen	Functions in blood clotting
Ions	
Sodium, potassium, calcium, magnesium, chloride, iron, phosphate, hydrogen, hydroxide, bicarbonate	Involved in osmosis, membrane potentials, and acid-base balance
Nutrients	
Glucose, amino acids, triglycerides, cholesterol	Source of energy and basic “building blocks” of more complex molecules
Vitamins	Promote enzyme activity
Waste Products	
Urea, uric acid, creatinine, ammonia salts	Breakdown products of protein metabolism; excreted by the kidneys
Bilirubin	Breakdown product of red blood cells; excreted as part of the bile from the liver into the small intestine
Lactate	End product of anaerobic respiration; converted to glucose by the liver
Gases	
Oxygen	Necessary for aerobic respiration; terminal electron acceptor in electron-transport chain
Carbon dioxide	Waste product of aerobic respiration; as bicarbonate, helps buffer blood
Nitrogen	Inert
Regulatory Substances	Enzymes catalyze chemical reactions; hormones stimulate or inhibit many body functions

- C. Describe the structure and function of hemoglobin and relate which gases associate with hemoglobin and how.**
- D. Compare fetal and adult hemoglobin as to structure and affinity for oxygen.**
- E. Discuss the life history of red blood cells.**
- F. Compare the structures and functions of the five types of white blood cells.**
- G. Describe the origin and structure of platelets.**
- H. Relate the functions of platelets in preventing blood loss.**

Red blood cells, or *erythrocytes* (ĕ-rith'rō-sītz), make up about 95% of the volume of the **formed elements**. The remaining 5% consists of white blood cells, or *leukocytes* (loo'kō-sītz), and cell fragments called platelets, or *thrombocytes* (throm'bō-sītz). Table 19.2 illustrates the formed elements of the blood. In healthy

adults, white blood cells are the only formed elements possessing nuclei; red blood cells and platelets lack nuclei.

Production of Formed Elements

The process of blood cell production is called **hematopoiesis** (hĕ'mă-tō-poy-ĕ'sis, hem'ă-to-poy-ĕ'sis), or *hemopoiesis* (hĕ'mō-poy-ĕ'sis). In the embryo and fetus, hematopoiesis occurs in tissues such as the yolk sac, liver, thymus, spleen, lymph nodes, and red bone marrow. After birth, hematopoiesis is confined primarily to red bone marrow, though some white blood cells (lymphocytes) complete their development in lymphatic tissue (see chapter 22). In young children, nearly all the marrow is red bone marrow. In adults, however, red marrow is confined to the ribs, sternum, vertebrae, pelvis, proximal femur, and proximal humerus. Yellow marrow replaces red marrow in other body locations (see chapter 6).

TABLE 19.2 Formed Elements of the Blood

Cell Type	Illustration	Description	Function
Red Blood Cell		Biconcave disc; no nucleus; contains hemoglobin, which colors the cell red; 7.5 μm in diameter	Transports oxygen and carbon dioxide
White Blood Cells		Spherical cells with a nucleus	Five types of white blood cells, each with specific functions
<i>Granulocytes</i>			
Neutrophil		Nucleus with two to five lobes connected by thin filaments; cytoplasmic granules stain a light pink or reddish-purple; 10–12 μm in diameter	Phagocytizes microorganisms and other substances
Eosinophil		Nucleus often bilobed; cytoplasmic granules stain orange-red or bright red; 11–14 μm in diameter	Attacks certain worm parasites; releases chemicals that modulate inflammation; negatively impacts airways during asthma attacks
Basophil		Nucleus with two indistinct lobes; cytoplasmic granules stain blue-purple; 10–12 μm in diameter	Releases histamine, which promotes inflammation, and heparin, which prevents clot formation
<i>Agranulocytes</i>			
Lymphocyte		Round nucleus; cytoplasm forms a thin ring around the nucleus; 6–14 μm in diameter	Produces antibodies and other chemicals responsible for destroying microorganisms; contributes to allergic reactions, graft rejection, tumor control, and regulation of the immune system
Monocyte		Nucleus round, kidney-shaped, or horseshoe-shaped; contains more cytoplasm than lymphocyte does; 12–20 μm in diameter	Phagocytic cell in the blood; leaves the blood and becomes a macrophage, which phagocytizes bacteria, dead cells, cell fragments, and other debris within tissues
Platelet		Cell fragment surrounded by plasma membrane and containing granules; 2–4 μm in diameter	Forms platelet plugs; releases chemicals necessary for blood clotting

All the formed elements of the blood are derived from a single population of stem cells called **hemocytoblasts**, located in the red bone marrow. Hemocytoblasts are precursor cells capable of dividing to produce daughter cells that can differentiate into various types of blood cells (figure 19.2). When a hemocytoblast divides, one daughter cell remains a hemocytoblast while the other daughter cell differentiates to form one of two types of intermediate stem cells: a **myeloid stem cell** or a **lymphoid stem cell**. Red blood cells, platelets, and most of the white blood cells develop from myeloid stem cells. Myeloid stem cells give rise to several intermediate cell types. These intermediates include **proerythroblasts** (prō-ě-rith'rō-blastz), which produce red blood cells; **myeloblasts** (mī'ě-lō-blastz), which produce basophils, eosinophils, and neutrophils; **monoblasts** (mon'ō-blastz), which produce monocytes; and **megakaryoblasts** (meg-ă-kar'ē-ō-blastz), which produce platelets. Lymphoid stem cells give rise to lymphocytes.

Chemical signals regulate the development of the different types of formed elements. These chemical signals include **colony-stimulating factors (CSFs)** and hormones transported to the bone marrow through the blood or substances released by bone marrow cells. **Erythropoietin (EPO)** is an example of a hormone,

secreted by endocrine cells of the kidneys, that stimulates myeloid stem cells to develop into red blood cells.

ASSESS YOUR PROGRESS

10. Name the three general types of formed elements in the blood, using both their common and technical names.
11. What is hematopoiesis? Where does the process occur before birth? After birth? What type of stem cell are all formed elements derived from? Distinguish between myeloid stem cells and lymphoid stem cells.
12. What types of formed elements develop from each of the following cells: proerythroblasts, myeloblasts, lymphoblasts, monoblasts, and megakaryocytes?

Red Blood Cells

Red blood cells (RBCs), or *erythrocytes*, are about 700 times more numerous than white blood cells and 17 times more numerous than platelets in the blood (figure 19.3a). Males, on average, have about 5.4 million red blood cells per microliter (μL ; 1 mm^3 , or 10^{-6} L) of blood, with a normal range of 4.6–6.2 million, whereas females

FIGURE 19.2 Hematopoiesis

Stem cells give rise to the cell lines that produce the formed elements. The production of red blood cells (far left column) is called erythropoiesis.

Clinical IMPACT

Stem Cells and Cancer Therapy

Many cancer therapies affect the type of rapidly dividing cells found in tumors. However, an undesirable side effect of such therapies can be the destruction of nontumor cells that are dividing, such as the stem cells and their derivatives in red bone marrow. After being treated for cancer, some patients are prescribed growth factors to stimulate the rapid regeneration of the red bone marrow. Although not a cure for cancer, the growth factors can speed recovery from the side effects of cancer therapy.

Some types of leukemia and genetic immune deficiency diseases can be treated with a bone marrow transplant that provides stem cells to the patient. To avoid tissue rejection, families with a history of these disorders can freeze the umbilical cord blood of their newborn children. The cord blood, which contains many stem cells, can be used instead of bone marrow.

have about 4.8 million/ μL with a normal range of 4.2–5.4 million. Red blood cells cannot move of their own accord; they are passively moved by forces that cause the blood to circulate.

Structure

Normal red blood cells are discs about 7.5 μm in diameter, and they are biconcave, meaning that their edges are thicker than their center (figure 19.3b). Red blood cell structure enhances its function. Researchers have long proposed that the biconcave shape of a red blood cell increases the cell's surface area, thereby allowing gases to move into and out of the red blood cell more rapidly as compared to a flat disc of the same size. However, recent evidence suggests that this may not be as important to red blood cell function. Gases enter and exit the red blood cells most often when the cells are in small blood vessels called capillaries. As the red blood cells move through these small vessels, they change shape, so the surface area to volume association is not as obvious. But the fact that the cells change shape is of interest. Because of its biconcave shape, the red blood cell can bend or fold around its thin center, thereby decreasing its size and enabling it to pass more easily through smaller blood vessels. Research has also shown that the biconcave disc shape of red blood cells may also improve blood flow in larger vessels as well.

Red blood cells are derived from specialized cells that lose their nuclei and nearly all their cellular organelles during maturation. The main component of the red blood cell is the pigmented protein **hemoglobin** (hē-mō-gl 'bin). Hemoglobin occupies about one-third of the total volume of a red blood cell and accounts for its red color. Other red blood cell contents include lipids, adenosine triphosphate (ATP), and the enzyme carbonic anhydrase.

Functions

The primary functions of red blood cells are to transport oxygen from the lungs to the various body tissues and to transport carbon dioxide from the tissues to the lungs. Approximately 98.5% of the

(a)

FIGURE 19.3 Formed Elements

(a) Color-enhanced scanning electron micrograph of formed elements: red blood cells (*red doughnut shapes*), white blood cells (*yellow*), and platelets (*red, irregular shapes*). (b) Shape and dimensions of a red blood cell. **APR**

oxygen in the blood is transported in combination with the hemoglobin in the red blood cells. The remaining 1.5% is dissolved in the plasma. **Hemolysis** (hē-mol'i-sis) occurs when red blood cells rupture and the hemoglobin is released into the plasma. Hemoglobin released into the plasma will denature as the molecule changes shape in this new environment (see chapter 2). Denatured hemoglobin is nonfunctional. Hemolysis occurs in hemolytic anemia (see Diseases and Disorders table, later in this chapter), transfusion reactions, hemolytic disease of the newborn, and malaria.

Carbon dioxide is transported in the blood in three major ways: (1) Approximately 7% is dissolved in the plasma; (2) approximately 23% is combined with hemoglobin; and (3) 70% is in the form of bicarbonate ions. The bicarbonate ions (HCO_3^-) are produced when carbon dioxide (CO_2) and water (H_2O) combine to form carbonic acid (H_2CO_3). Carbonic acid quickly dissociates to form hydrogen (H^+) and bicarbonate ions. The combination of carbon dioxide and water is catalyzed by an enzyme, **carbonic anhydrase**, which is located primarily within red blood cells.

**FIGURE 19.4 Hemoglobin**

(a) Hemoglobin consists of four subunits, each with a globin and a heme. There are two alpha (α) globins and two beta (β) globins. A heme is associated with each globin. (b) Each heme contains one iron atom.

Hemoglobin

Hemoglobin is a complex protein consisting of four subunits. Each subunit is composed of one polypeptide chain and one heme group. Each polypeptide chain, called a **globin** (glō'bin), is bound to one **heme** (hēm). Each heme is a red-pigment molecule containing one iron atom (figure 19.4). There are three forms of hemoglobin: (1) embryonic, (2) fetal, and (3) adult. Embryonic hemoglobin is the first type of hemoglobin produced during development. By the third month of development, embryonic hemoglobin has been replaced with fetal hemoglobin. At birth, 60–90% of the hemoglobin is adult hemoglobin. At 2 to 4 years of age, fetal hemoglobin makes up less than 2% of the hemoglobin, and in adulthood only traces of fetal hemoglobin can be found.

The different forms of hemoglobin have different affinities for, or abilities to bind with, oxygen. Embryonic and fetal hemoglobin have a higher affinity for oxygen than adult hemoglobin does. In the embryo and fetus, hemoglobin picks up oxygen from the mother's blood at the placenta. Even though placental blood contains less oxygen than does air in the mother's lungs, adequate amounts of oxygen are picked up because of the higher affinity of embryonic and fetal hemoglobin for oxygen. After birth, hemoglobin picks up oxygen from the air in the baby's lungs.

Predict 2

What would happen to a fetus if hemoglobin of the maternal blood had an affinity for oxygen that was equal to or greater than the hemoglobin of fetal blood?

Although embryonic, fetal, and adult hemoglobin each have four globins, the types of globins are different. There are nine types of globins, each with a slightly different amino acid composition. For example, there are two types of alpha globins, which differ from each other by one amino acid. Because they are so similar, they are usually referred to simply as alpha globins. There are also a beta globin, two kinds of gamma globins, a delta globin, and three kinds of embryonic globins. Most adult hemoglobin has

two alpha globins (one of each type) and two beta globins (figure 19.4). Fetal hemoglobin has two alpha globins (one of each type) and two gamma globins (one of each type).

There are nine globin genes, each of which codes for one of the globins. The globin genes are active during different stages of development. The embryonic globin genes are active first, but they become inactive as fetal globin genes become active. In a similar fashion, the fetal globin genes become inactive as the adult globin genes become active.

Oxygen molecules bind to the heme group. Specifically, each oxygen molecule that is transported by hemoglobin is associated with an iron atom at the center of a heme group; therefore, iron is necessary for normal hemoglobin function. The adult human body normally contains about 4 g of iron, two-thirds of which is associated with hemoglobin. Small amounts of iron are regularly lost from the body in waste products, such as urine and feces. Females lose additional iron as a result of menstrual bleeding and, therefore, require more dietary iron than males do. Dietary iron is absorbed into the blood from the upper part of the intestinal tract. Stomach acid and vitamin C in food increase iron absorption by converting ferric iron (Fe^{3+}) to ferrous iron (Fe^{2+}), which is more readily absorbed.

When hemoglobin is exposed to oxygen, one oxygen molecule can become associated with each heme group. So one hemoglobin molecule can carry up to four oxygen molecules. This oxygenated form of hemoglobin is called **oxyhemoglobin** (ok'sē-hēm-mō-glō'bin). The oxyhemoglobin in one red blood cell transports about 1 billion molecules of oxygen. This estimate becomes clear when we consider that a single red blood cell contains about 280 million hemoglobin molecules, each of which carries up to four oxygen molecules. Hemoglobin containing no oxygen is called **deoxyhemoglobin**. Interestingly, hemoglobin color changes depending on whether or not it is oxygenated. Oxyhemoglobin is bright red, whereas deoxyhemoglobin is a darker red color.

Hemoglobin also transports carbon dioxide; however, carbon dioxide does not combine with the iron atoms as oxygen molecules do. Instead, carbon dioxide attaches to the globin molecule.

Clinical GENETICS

Sickle-Cell Disease

Sickle-cell disease is a disorder in which red blood cells become sickle-shaped. It results from a mutation in the gene that codes for the beta globin chain of hemoglobin. The mutation is a change in one nucleotide in the DNA that leads to a change in one amino acid in beta globin. The single amino acid change in beta globin has a dramatic effect on hemoglobin. When blood oxygen levels decrease, as when oxygen diffuses away from hemoglobin in tissue capillaries, the abnormal hemoglobin molecules join together, causing a change in red blood cell shape (figure 19A). When blood oxygen levels increase, as in the lungs, the abnormal hemoglobin molecules separate, and red blood cells can resume their normal shape.

Sickle-shaped red blood cells are less able to squeeze through small capillaries. Consequently, they become lodged in capillaries, blocking blood flow through them. This causes a further decrease in oxygen levels, which promotes more sickling. As oxygen levels decrease further, more capillary blockage is promoted, and so on. After repeated cycles of sickling, red blood cells lose their ability to resume their normal shape. This increases the number of sickled cells.

The major consequence of sickle-cell disease is tissue damage resulting from reduced blood flow through tissues. As tissues are deprived of blood, the most common symptom is pain, which is often severe. In addition, spleen and liver enlargement, kidney and lung damage, and stroke can occur. Priapism (prī'ā-pizm), a prolonged, painful erection due to venous

FIGURE 19A Sickle-Cell Disease

Red blood cells in a person with sickle-cell disease appear normal in oxygenated blood. In deoxygenated blood, hemoglobin changes shape and causes the cells to become sickle-shaped and rigid.

blockage, can develop in men. Sickle-shaped red blood cells are also likely to rupture, which can result in hemolytic anemia (see the Diseases and Disorders table, later in this chapter).

Sickle-cell disease is an autosomal recessive disorder. Only individuals who have two mutated beta globin alleles express the disease. Individuals who are heterozygous have a normal beta globin allele and produce sufficient amounts of normal beta globin, so their red blood cells do not usually become sickle-shaped. Heterozygotes are carriers (see chapter 29) and are said to have **sickle-cell trait**.

Sickle-cell disease is an example of a genetic disorder in which the heterozygote has a better ability to survive under certain circumstances than homozygous individuals. Carriers (heterozygotes) with sickle-cell trait have increased resistance to malaria. Malaria is a disease caused by a parasitic protozoan that reproduces inside red blood cells. The parasite is usually transmitted from one person to another through the bite of a mosquito. The red blood cells of people with sickle-cell trait tend to rupture before the parasite successfully reproduces. Therefore, those people are less likely to contract malaria, and the disease is much milder if they do.

The highest percentage of people with sickle-cell trait occurs in populations exposed to malaria or whose ancestors were exposed to malaria. In certain parts of Africa where malaria is rampant, the percentage of sickle-cell carriers can be as high as 50%. In the United States, 8% of African-Americans are sickle-cell carriers, and 0.8% have sickle-cell disease. The mutant gene can also be found in other groups, but at lower frequencies.

Treatment for sickle-cell disease attempts to reduce the blockage of blood vessels, alleviate pain, and prevent infections. Hydroxyurea (hī-drok'sē-ū-rē'ā) stimulates the production of gamma (fetal) globins. When the gamma globins combine with defective beta globins, the formation of sickle-shaped cells slows. Bone marrow transplants can cure sickle-cell disease, but such transplants can be dangerous and even fatal. Gene therapy is under investigation.

This hemoglobin form is **carbaminohemoglobin** (kar-bam'i-nō-hē-mō-glō'bin). The transport of oxygen and carbon dioxide by the blood is discussed more fully in chapter 23.

Additionally, hemoglobin transports nitric oxide, which is produced by the endothelial cells lining the blood vessels. At the same time that hemoglobin picks up oxygen in the lungs, a sulfur-containing amino acid, cysteine, in each β -globin binds with a nitric oxide molecule to form *S*-nitrosothiol (nī-trōs'ō-thī-ol; SNO). When oxygen is released in tissues, so is the nitric oxide, where it functions as a chemical messenger that induces the relaxation of the smooth muscle of blood vessels. By affecting the amount of nitric oxide in tissues, hemoglobin may play a role in regulating blood pressure because the relaxation of blood vessels results in decreased blood pressure (see chapter 21).

Various types of poisons affect the hemoglobin molecule. Carbon monoxide (CO), which is produced by the incomplete combustion of gasoline, binds very strongly to the iron of hemoglobin to form the relatively stable compound **carboxyhemoglobin**

(kar-bok'sē-hē-mō-glō'bin). As a result of the stable binding of carbon monoxide, hemoglobin cannot transport oxygen. Nausea, headache, unconsciousness, and death are possible consequences of prolonged exposure to carbon monoxide. Interestingly, carbon monoxide is found in cigarette smoke, and the blood of smokers can contain 5–15% carboxyhemoglobin.

Life History of Red Blood Cells

Under normal conditions, about 2.5 million red blood cells are destroyed every second. This loss seems staggering, but it represents only 0.00001% of the total 25 trillion red blood cells contained in the normal adult circulation. Homeostasis is maintained by replacing the 2.5 million cells lost every second with an equal number of new red blood cells. Thus, approximately 1% of the total number of red blood cells is replaced each day.

The process by which new red blood cells are produced is called **erythropoiesis** (ē-rith'rō-poy-ē'sis; see figure 19.2). The time required to produce a single red blood cell is about 4 days. Myeloid stem cells,

derived from hemocytoblasts, give rise to **proerythroblasts**. After several mitotic divisions, proerythroblasts become **early erythroblasts**. These cells are also called *basophilic erythroblasts* because they stain with a basic dye. The dye binds to the large numbers of ribosomes necessary for the production of hemoglobin, giving the cytoplasm a purplish color. Early erythroblasts give rise to **intermediate erythroblasts**. These cells are also called *polychromatic erythroblasts* because they stain different colors with basic and acidic dyes. For example, when an acidic dye is used, intermediate erythroblasts stain a reddish color when it interacts with the hemoglobin accumulating in the cytoplasm. Intermediate erythroblasts continue to produce hemoglobin, and then most of their ribosomes and other organelles degenerate. The resulting **late erythroblasts** have a reddish color because about one-third of the cytoplasm is hemoglobin.

The late erythroblasts lose their nuclei to become immature red blood cells, called **reticulocytes** (re-tik'ū-lō-sītz). *Reticulocyte* refers to a reticulum, or network, that can be observed in the cytoplasm when a special staining technique is used. The reticulum is artificially produced by the reaction of the dye with the few remaining ribosomes in the reticulocyte. Reticulocytes are released from the bone marrow into the circulating blood. A normal reticulocyte level is 0.5–2% of circulating red blood cells. Reticulocyte counts are clinically useful to monitor red blood cell production, particularly when monitoring treatments for anemia. Also, reticulocyte counts can provide information about the health of the hemocytoblasts in the red bone marrow. Within 2 days, the ribosomes in the reticulocytes degenerate, and the reticulocytes become mature red blood cells.

► Predict 3

During a local Red Cross blood drive, Juan donated one unit of blood (about 500 mL). Predict how his reticulocyte count changed during the week after he donated blood, and explain why the change occurred.

Cell division requires the B vitamins folate and B₁₂, which are necessary for the synthesis of DNA (see chapter 3). Hemoglobin production requires iron. Consequently, adequate amounts of folate, vitamin B₁₂, and iron are necessary for normal red blood cell production.

Red blood cell production is stimulated by low blood oxygen levels, which result from several conditions: decreased numbers of red blood cells, decreased or defective hemoglobin, diseases of the lungs, high altitude, inability of the cardiovascular system to deliver blood to tissues, and increased tissue demands for oxygen—for example, during endurance exercises.

Red blood cell production is regulated by the glycoprotein **erythropoietin** (ě-rith-rō-poy'ě-tin), a hormone produced mostly by the kidneys (figure 19.5). Erythropoietin secretion increases when blood oxygen levels are low. This stimulates red bone marrow to produce more red blood cells by increasing the number of proerythroblasts formed and by decreasing the time required for red blood cells to mature. Thus, when blood oxygen levels decrease, erythropoietin production increases, which increases red blood cell production. The greater number of red blood cells increases the blood's ability to transport oxygen. This negative-feedback mechanism returns blood oxygen levels to normal and maintains homeostasis by increasing the delivery of oxygen to

FIGURE 19.5 Red Blood Cell Production

In response to decreased blood oxygen, the kidneys release erythropoietin into the bloodstream. The increased erythropoietin stimulates red blood cell production in the red bone marrow. This process increases blood oxygen levels, restoring homeostasis.

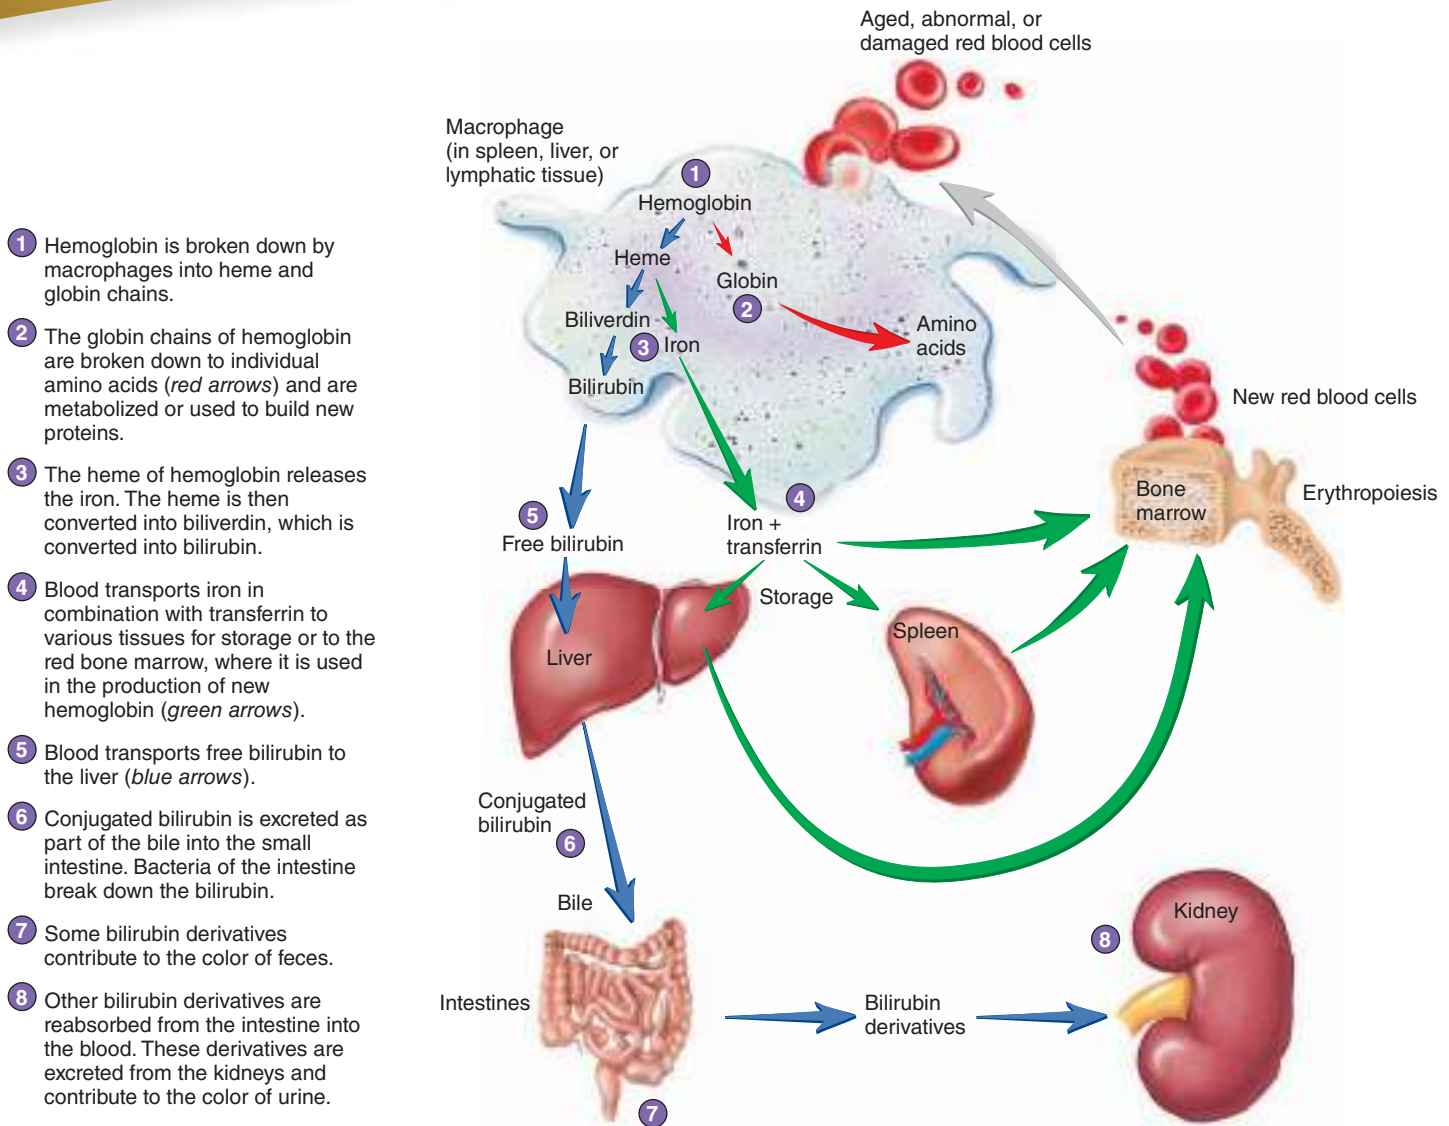

tissues. Conversely, if blood oxygen levels rise, less erythropoietin is released, and red blood cell production decreases.

► Predict 4

Cigarette smoke produces carbon monoxide. If a nonsmoker smoked a pack of cigarettes a day for a few weeks, what would happen to the number of red blood cells in the person's blood? Explain.

The normal lifespan of a red blood cell is about 120 days in males and 110 days in females. These cells have no nuclei and therefore cannot produce new proteins or divide. As their existing proteins, enzymes, plasma membrane components, and other structures degenerate, the red blood cells are less able to transport oxygen, and their plasma membranes become more fragile. Eventually, the red blood cells rupture as they squeeze through a tight spot in the circulation.

Macrophages located in the spleen, liver, and other lymphatic tissue take up the hemoglobin released from ruptured red blood cells (figure 19.6). Within a macrophage, lysosomal enzymes digest the hemoglobin to yield amino acids, iron, and bilirubin. The globin part of hemoglobin is broken down into its component amino acids. Most of the amino acids are reused to produce other proteins. Iron atoms released from heme are carried by the blood to red bone marrow, where they are incorporated into new hemoglobin molecules. After the removal of the iron atoms, the non-iron part of the heme groups is first converted to **biliverdin** (bil-i-ver'din) and then to **bilirubin** (bil-i-roo'bin). The bilirubin is then released into the plasma, where it binds to albumin and is transported to liver cells. This bilirubin, called **free bilirubin**, is taken up by the liver

PROCESS FIGURE 19.6 Hemoglobin Breakdown

Macrophages break down hemoglobin, and the breakdown products are used or excreted. **APR**

cells and conjugated, or joined, to glucuronic acid to form **conjugated bilirubin**, which is more water-soluble than free bilirubin. The conjugated bilirubin becomes part of the **bile**, which is the fluid secreted from the liver into the small intestine. In the intestine, bacteria convert bilirubin into the pigments that give feces its characteristic brownish color. Some of these pigments are absorbed from the intestine, modified in the kidneys, and excreted in the urine, thus contributing to the characteristic yellowish color of urine. **Jaundice** (jawn'dis) is a yellowish staining of the skin and the sclerae of the eyes caused by a buildup of bile pigments in the blood and some tissues. Any process that causes increased destruction of red blood cells can cause jaundice, such as damage by toxins, genetic defects in red blood cell plasma membranes, infections, and immune reactions. Other causes of jaundice are dysfunction or destruction of liver tissue and blockage of the duct system that drains bile from the liver (see chapter 24).

19. Describe the process of erythropoiesis, beginning with hemocytoblasts in the red bone marrow.
20. What is erythropoietin, where is it produced, what causes it to be produced, and what effect does it have on red blood cell production?
21. How long do red blood cells normally stay in circulation? Where are red blood cells removed from the blood? List the three breakdown products of hemoglobin, and explain what happens to them.

White Blood Cells

When the components of blood are separated from each other (see figure 19.1), **white blood cells (WBCs)**, or *leukocytes*, form a thin, white layer of cells between the plasma and the red blood cells. This layer is often referred to as the *buffy coat*. White blood cells lack hemoglobin but have a nucleus. In stained preparations, white blood cells attract stain, whereas red blood cells remain relatively unstained (figure 19.7; table 19.2).

White blood cells are grouped into two categories based on their appearance in stained preparations: granulocytes and agranulocytes. **Granulocytes** (gran'yū-lō-sītz) are white blood cells with large cytoplasmic granules and lobed nuclei (table 19.2). Their granules stain with dyes that make the cells more visible when viewed through a light microscope. The three types of granulocytes are named according to the staining characteristics of their granules: **Neutrophils** (nu'trō-fīlz) stain with acidic and basic dyes, **eosinophils** (ē-ō-sin'ō-fīlz) stain red with acidic dyes, and **basophils** (bā'sō-fīlz) stain dark purple with basic dyes. **Agranulocytes** (ă-gran'yū-lō-sītz) are white blood cells that appear to have no granules when viewed with a light microscope. Actually, agranulocytes have granules, but they are so small that they cannot be seen easily with the light microscope. The two types of agranulocytes are **lymphocytes** (lim'fō-sītz) and **monocytes** (mon'ō-sītz). They have nuclei that are not lobed.

FIGURE 19.7 Standard Blood Smear

A thin film of blood is spread on a microscope slide and stained. The white blood cells have pink-colored cytoplasm and purple-colored nuclei. The red blood cells do not have nuclei. The center of a red blood cell appears whitish because light more readily shines through the thin center of the disc than through the thicker edges. The platelets are purple cell fragments.

White blood cells protect the body against invading microorganisms and remove dead cells and debris from the body. Three characteristics—ameboid movement, diapedesis, and chemotaxis—allow white blood cells to carry out their function of protection. Most white blood cells are motile, exhibiting **ameboid movement**. This is the ability to move as an amoeba does, by putting out irregular cytoplasmic projections. Ameboid movement allows white blood cells to have more directed movement, instead of moving only with the flow of blood, like red blood cells. White blood cells also have the ability to leave the blood and enter other tissues. They accomplish this by the process of **diapedesis** (dī'ă-pē-dē'sis), in which they become thin and elongated and slip between or through the cells of blood vessel walls. The white blood cells can then be attracted to foreign materials or dead cells within the tissue by **chemotaxis** (kē-mō-tak'sis; see chapter 22). At the site of an infection, white blood cells accumulate and phagocytize bacteria, dirt, and dead cells; then they die. **Pus** is the accumulation of dead white blood cells and bacteria, along with fluid and cell debris.

Following are detailed descriptions of the five types of white blood cells: (1) neutrophils, (2) eosinophils, (3) basophils, (4) lymphocytes, and (5) monocytes.

Neutrophils

Neutrophils comprise 60–70% of white blood cells (table 19.2). They have small cytoplasmic granules that stain with both acidic and basic dyes. Commonly, their nuclei are lobed, with the number of lobes varying from two to five. Neutrophils are often called *polymorphonuclear* (pol'ē-mōr-fō-noo'klē-ăr) *neutrophils*, or *PMNs*, to indicate that their nuclei can occur in more than one (*poly*) form (*morph*). Neutrophils are usually the first of the white blood cells to respond to infection. They normally remain in the blood for about 10–12 hours and then move into other tissues. Once neutrophils leave the blood, they seek out and phagocytize bacteria, antigen-antibody complexes (antigens and antibodies bound together), and other foreign matter. Neutrophils also secrete a class of enzymes called **lysozymes** (lī'sō-zīzmz), which are capable of destroying certain bacteria. Neutrophils usually survive 1–2 days after leaving the blood.

Eosinophils

Eosinophils comprise 2–4% of white blood cells (table 19.2). They contain cytoplasmic granules that stain bright red with eosin, an acidic stain. They often have a two-lobed nucleus. Eosinophils are important in the defense against certain worm parasites. Although the eosinophils are not able to phagocytize the large parasites, they attach to the worms and release substances that kill the parasites. Eosinophils also increase in number in tissues experiencing inflammation, such as during allergic reactions. Eosinophils apparently modulate the inflammatory response by producing enzymes that destroy inflammatory chemicals, such as histamine. However, research has shown that eosinophils have harmful effects on respiratory airways in certain forms of asthma.

Basophils

Basophils comprise 0.5–1% of white blood cells (table 19.2). They contain large cytoplasmic granules that stain blue or purple with basic dyes. Basophils, like eosinophils and neutrophils, leave the blood and migrate through other tissues. They increase in number

in both allergic and inflammatory reactions. Basophils contain large amounts of **histamine** (see chapter 22), which they release within tissues to increase inflammation. They also release **heparin**, which inhibits blood clotting.

Lymphocytes

Lymphocytes comprise 20–25% of white blood cells (table 19.2). They are the smallest white blood cells, usually slightly larger in diameter than red blood cells. A lymphocyte's cytoplasm consists of only a thin, sometimes imperceptible, ring around the nucleus. Although lymphocytes originate in red bone marrow, they migrate through the blood to lymphatic tissues, where they can proliferate and produce more lymphocytes. The majority of the body's total lymphocyte population is in the lymphatic tissues: the lymph nodes, spleen, tonsils, lymphatic nodules, and thymus.

Some specific types of lymphocytes play important roles in immunity (see chapter 22). For example, **B cells** are a type of lymphocyte that can be stimulated by bacteria or toxins to divide and form cells that produce **antibodies**, a class of plasma proteins also called immunoglobulins. Antibodies can attach to bacteria and activate mechanisms that destroy the bacteria. **T cells** are another type of lymphocyte that protect against viruses and other intracellular microorganisms by attacking and destroying the cells in which they are found. In addition, T cells are involved in the destruction of tumor cells and in tissue graft rejections.

Monocytes

Monocytes comprise 3–8% of white blood cells (table 19.2). They are typically the largest of the white blood cells. Monocytes normally remain in the blood for about 3 days. Then they leave the blood and are transformed into macrophages. Macrophages migrate through various tissues, where they phagocytize bacteria, dead cells, cell fragments, and other debris. An increase in the number of monocytes in the blood is often associated with chronic infection. Macrophages also stimulate responses from other cells in two ways: (1) by releasing chemical messengers and (2) by phagocytizing and processing foreign substances, which are then presented to lymphocytes. The responses of these other cells help protect against microorganisms and other foreign substances (see chapter 22).

Predict 5

Based on their morphology, identify each of the white blood cells shown in figure 19.8.

22. What are the two major functions of white blood cells? Define amoeboid movement, diapedesis, and chemotaxis.
23. Describe the morphology of the five types of white blood cells.
24. Name the two white blood cells that function primarily as phagocytic cells. What are lysozymes?
25. Which white blood cell defends against parasitic worms?
26. Which white blood cell releases histamine and promotes inflammation?
27. B cells and T cells are examples of which type of white blood cell? How do these cells protect against bacteria and viruses?

Platelets

Platelets, or *thrombocytes* (table 19.2; see figure 19.7), are minute fragments of cells. They consist of a small amount of cytoplasm surrounded by a plasma membrane. Platelets are roughly disc-shaped and average about 3 μm in diameter. Glycoproteins and proteins on their surface allow platelets to attach to other molecules, such as collagen in connective tissue. Some of these surface molecules, as well as molecules released from granules in the platelet cytoplasm, play important roles in controlling blood loss. The platelet cytoplasm also contains actin and myosin, which can cause contraction of the platelet (see “Clot Retraction and Dissolution” in section 19.5).

The life expectancy of platelets is about 5–9 days. Platelets are derived from **megakaryocytes** (meg-ă-kar'ē-ō-sitz), which are extremely large cells found in the red bone marrow. Small fragments of these cells break off and enter the blood as platelets.

Platelets play an important role in preventing blood loss by (1) forming platelet plugs that seal holes in small vessels and (2) promoting the formation and contraction of clots that help seal off larger wounds in the vessels.

19.5 Hemostasis

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Explain the three processes that can lead to hemostasis: vascular spasm, platelet plug formation, and coagulation.**
- B. Describe how aspirin affects the action of platelets.**
- C. Describe the regulation of clot formation and how clots are removed.**

Hemostasis (hē'mō-stā-sis, hē-mos'tā-sis), the cessation of bleeding, is very important to the maintenance of homeostasis. If not stopped, excessive bleeding from a cut or torn blood vessel can result in a positive-feedback cycle, consisting of ever-decreasing blood volume and blood pressure that disrupts homeostasis and results in death. Fortunately, when a blood vessel is damaged, a series of events helps prevent excessive blood loss. Hemostasis involves three processes: (1) vascular spasm, (2) platelet plug formation, and (3) coagulation.

Vascular Spasm

Vascular spasm is the immediate but temporary constriction of a blood vessel. Vascular spasm occurs when smooth muscle within the wall of the vessel contracts. This constriction can close small vessels completely and stop the flow of blood through them. Damage to blood vessels can activate nervous system reflexes that cause vascular spasms. Chemicals released by cells of the damaged vessel as well as platelets also stimulate vascular spasms. For example, during the formation of a platelet plug, platelets release **thromboxanes** (throm'bok-zānz), which are derived from certain

prostaglandins, and endothelial cells release the peptide **endothelin** (en-dō'thē-lin), both of which lead to constriction of the vessel.

Platelet Plug Formation

A **platelet plug** is an accumulation of platelets that can seal small breaks in blood vessels. A platelet plug is not the same thing as a blood clot, but the formation of the platelet plug is an important step in blood clot formation. Platelet plug formation is very important in maintaining the integrity of the circulatory system. Small tears occur in the smaller vessels and capillaries many times each day, and platelet plug formation quickly closes them. People who lack the normal number of platelets tend to develop numerous small hemorrhages in their skin and internal organs.

The formation of a platelet plug can be described as a series of steps, but in actuality many of the steps take place simultaneously (figure 19.9):

1. **Platelet adhesion** occurs when platelets bind to collagen that is exposed when a blood vessel is damaged. Most platelet adhesion is mediated through **von Willebrand factor (vWF)**, a protein produced and secreted by blood vessel endothelial cells. Platelets have surface receptors on their membrane. These surface receptors bind to von Willebrand factor released from damaged blood vessels. Von Willebrand factor also binds to the exposed collagen of the damaged vessel, thereby forming a bridge between exposed collagen and platelets. In addition, other platelet surface receptors can bind directly to collagen.
2. After platelets adhere to collagen, they become activated. These activated platelets then initiate the **platelet release reaction**, in which adenosine diphosphate (ADP), thromboxanes, and other chemicals are released from the activated platelets by exocytosis. The ADP and thromboxane bind to their respective receptors on the surfaces of other platelets,

- 1 Platelet adhesion occurs when von Willebrand factor connects exposed collagen to platelets.
- 2 During the platelet release reaction, ADP, thromboxanes, and other chemicals are released and activate other platelets.
- 3 Platelet aggregation occurs when fibrinogen receptors on activated platelets bind to fibrinogen, connecting the platelets to one another. The accumulating mass of platelets forms a platelet plug.

PROCESS FIGURE 19.9 Platelet Plug Formation

Clinical IMPACT

Clinical Importance of Taking Aspirin

Platelet activation results in platelet plug formation and the production of chemicals, such as phospholipids, that are important for blood clotting. Alternatively, the inhibition of platelet activation reduces the formation of blood clots. Understanding how this occurs requires knowledge of the chemical behavior of the **eicosanoids**, a group that includes prostaglandins, thromboxanes, and leukotrienes, the compounds involved in platelet activation. In humans, arachidonic acid is the most common precursor molecule for the eicosanoids. The enzyme cyclooxygenase (COX) converts arachidonic acid into a prostaglandin that can be converted into thromboxane. However, the actions of COX are inhibited by aspirin, which inhibits prostaglandin and thromboxane synthesis. As a result, aspirin reduces platelet activation.

Taking aspirin can have harmful or beneficial effects, depending on the circumstances. If an expectant mother ingests aspirin near the end of pregnancy, thromboxane synthesis is inhibited and several effects are possible. The mother can experience excessive bleeding after delivery because of decreased platelet function, and the baby can exhibit numerous localized hemorrhages called **petechiae** (pe-tē'kē-ē) over the surface of its body as a result of decreased platelet function. If the quantity of ingested aspirin is large, the infant, the mother, or both may die as a result of hemorrhage.

On the other hand, platelet plugs and blood clots can block blood vessels, producing heart attacks and strokes. Therefore, suspected heart attack victims are routinely given aspirin en

route to the emergency room to reduce further clotting. The United States Preventive Services Task Force (USPSTF) and the American Heart Association (AHA) recommend low-dose aspirin therapy (75–160 mg/day) for all men and women at high risk for cardiovascular disease. Determining risk involves analyzing many factors and should be done in consultation with a physician. The decreased risk for cardiovascular disease from aspirin therapy must be weighed against the increased risk for hemorrhagic stroke and gastrointestinal bleeding.

The drug Plavix (clopidogrel bisulfate) reduces the activation of platelets by blocking the ADP receptors on the surface of platelets. It is used to prevent clotting and, with other anticlotting drugs, to treat heart attacks.

activating them. These activated platelets release additional chemicals, thereby producing a cascade of chemical release by the platelets. Thus, more and more platelets become activated. This is an example of positive feedback.

- As platelets become activated, they change shape and express fibrinogen receptors that can bind to fibrinogen, a plasma protein. In **platelet aggregation**, fibrinogen forms a bridge between the fibrinogen receptors of different platelets, resulting in a platelet plug.

In addition to forming a platelet plug, activated platelets also release phospholipids (platelet factor III) and coagulation factor V, which are important in clot formation.

Coagulation

Vascular spasms and platelet plugs alone are not sufficient to close large tears or cuts. When a blood vessel is severely damaged, **coagulation** (kō-ag-ū-lā'shūn), or blood clotting, results in the formation of a clot. A **blood clot** is a network of threadlike protein fibers, called **fibrin**, that traps blood cells, platelets, and fluid (figure 19.10).

Blood clot formation depends on a number of **clotting factors**, or *coagulation factors*, which are proteins found within plasma (table 19.3). Normally, the clotting factors are in an inactive state and do not cause clotting. After injury, the clotting factors are activated. The activation of clotting factors is a complex process involving many chemical reactions, some of which require calcium ions (Ca^{2+}) and molecules on the surface of activated platelets, such as phospholipids and factor V.

Clotting factors are activated in two ways: the extrinsic pathway and the intrinsic pathway (figure 19.11). These two pathways converge to form the common pathway, which results in the formation of a fibrin clot.

Extrinsic Pathway

The extrinsic pathway is so named because it begins with chemicals that are outside of, or extrinsic to, the blood (figure 19.11). Damaged tissues release a mixture of lipoproteins and phospholipids

FIGURE 19.10 Blood Clot

A blood clot consists of fibrin, which traps red blood cells, platelets, and fluid.

➤ Predict 6

Why is it advantageous for clot formation to involve molecules on the surface of activated platelets?

TABLE 19.3 Clotting Factors

Factor Number	Name (Synonym)	Description and Function
I	Fibrinogen	Plasma protein synthesized in the liver; converted to fibrin in the common pathway
II	Prothrombin	Plasma protein synthesized in the liver (requires vitamin K); converted to thrombin in the common pathway
III	Thromboplastin (tissue factor)	Mixture of lipoproteins released from damaged tissue; required in the extrinsic pathway
IV	Calcium ion	Required throughout the clotting sequence
V	Proaccelerin (labile factor)	Plasma protein synthesized in the liver; activated form functions in the intrinsic and extrinsic pathways
VI		Once thought to be involved but no longer accepted as playing a role in clotting; apparently the same as activated factor V
VII	Serum prothrombin conversion accelerator (stable factor, proconvertin)	Plasma protein synthesized in the liver (requires vitamin K); functions in the extrinsic pathway
VIII	Antihemophilic factor (antihemophilic globulin)	Plasma protein synthesized in megakaryocytes and endothelial cells; required in the intrinsic pathway
IX	Plasma thromboplastin component (Christmas factor)	Plasma protein synthesized in the liver (requires vitamin K); required in the intrinsic pathway
X	Stuart factor (Stuart-Prower factor)	Plasma protein synthesized in the liver (requires vitamin K); required in the common pathway
XI	Plasma thromboplastin antecedent	Plasma protein synthesized in the liver; required in the intrinsic pathway
XII	Hageman factor	Plasma protein required in the intrinsic pathway
XIII	Fibrin-stabilizing factor	Protein found in plasma and platelets; required in the common pathway
Platelet Factors		
I	Platelet accelerator	Same as plasma factor V
II	Thrombin accelerator	Accelerates thrombin and fibrin production
III		Phospholipids necessary for the intrinsic and extrinsic pathways
IV		Binds heparin, which prevents clot formation

called **thromboplastin** (throm-bō-plas'tin), also known as *tissue factor* (*TF*) or factor III. Thromboplastin, in the presence of Ca^{2+} , forms a complex with factor VII that activates factor X, which is the clotting factor that initiates the common pathway.

Intrinsic Pathway

The intrinsic pathway is so named because it begins with chemicals that are inside, or intrinsic to, the blood (figure 19.11). Damage to blood vessels can expose collagen in the connective tissue beneath the epithelium lining the blood vessel. When plasma factor XII comes into contact with collagen, factor XII is activated. Subsequently, activated factor XII stimulates factor XI, which in turn activates factor IX. Activated factor IX joins with factor VIII, platelet phospholipids, and Ca^{2+} to activate factor X, which, as stated in the extrinsic pathway description, initiates the common pathway.

Although the extrinsic and intrinsic pathways were once considered distinct, we now know that the extrinsic pathway can activate the clotting factors in the intrinsic pathway. The thromboplastin/factor VII complex from the extrinsic pathway can stimulate the formation of activated factor IX in the intrinsic pathway.

Common Pathway

On the surface of platelets, activated factor X, factor V, platelet phospholipids, and Ca^{2+} combine to form **prothrombinase**, or *prothrombin activator*. Prothrombinase converts the soluble plasma protein **prothrombin** to the enzyme **thrombin**. A major function of thrombin is to convert the soluble plasma protein fibrinogen to the insoluble protein fibrin. Fibrin is the protein that forms the fibrous network of the blood clot (see figure 19.10). In addition, thrombin also stimulates factor XIII activation, which is necessary to stabilize the clot.

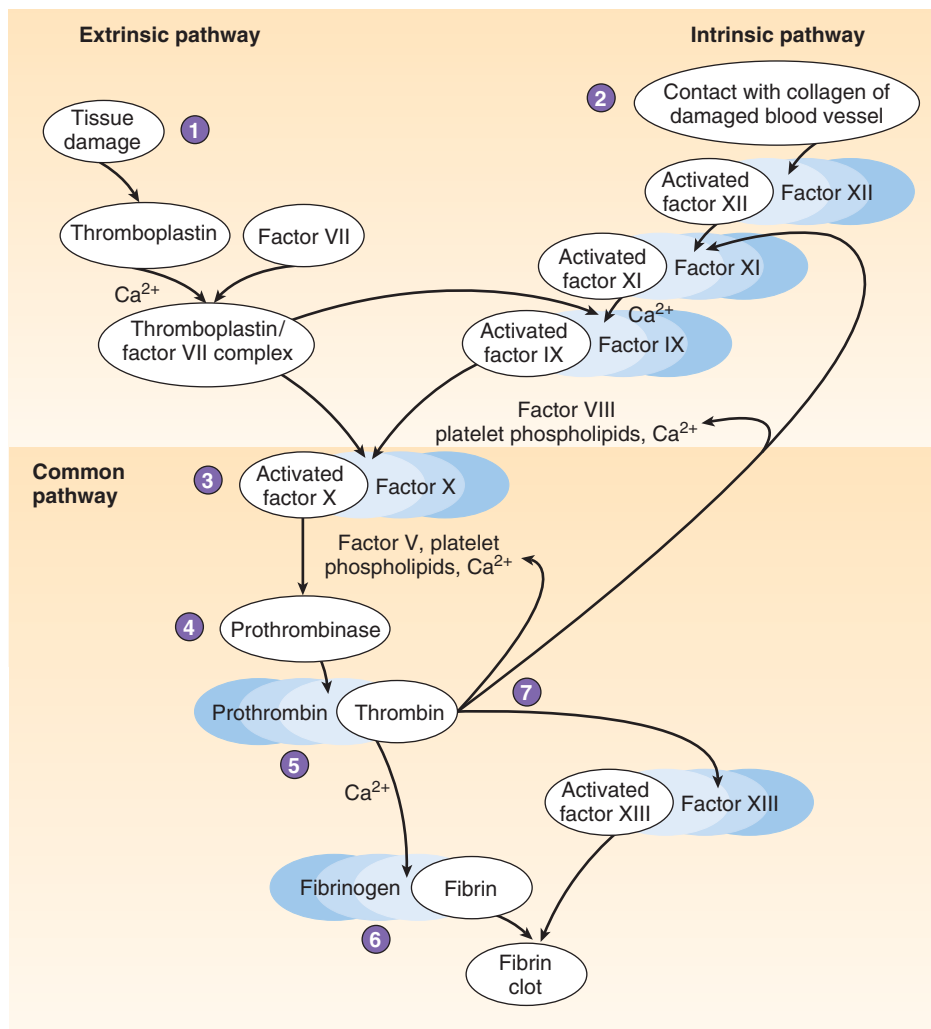

Thrombin can also activate many of the clotting proteins, such as factor XI and prothrombinase. Thus, a positive-feedback system operates whereby thrombin production stimulates the production of additional thrombin. Thrombin also has a positive-feedback effect on platelet aggregation by stimulating platelet activation.

Vitamin K is required for the formation of many of the factors involved in blood clot formation (table 19.3). Humans rely on two sources for vitamin K. About half comes from the diet, and half comes from bacteria within the large intestine. Antibiotics taken to fight bacterial infections sometimes kill these intestinal bacteria, thereby reducing vitamin K levels and causing bleeding. Vitamin K supplements may be necessary for patients on prolonged antibiotic therapy. Newborns lack these intestinal bacteria; thus,

FUNDAMENTAL Figure

- 1 The extrinsic pathway of clotting is stimulated by thromboplastin, released by damaged tissue.
- 2 The intrinsic pathway of clotting starts when inactive factor XII, which is in the blood, is activated by coming into contact with a damaged blood vessel.
- 3 Activation of the extrinsic or intrinsic pathway results in the production of activated factor X.
- 4 Activated factor X, factor V, phospholipids, and Ca^{2+} form prothrombinase.
- 5 Prothrombinase converts prothrombin to thrombin.
- 6 Thrombin converts fibrinogen to fibrin (the clot).
- 7 Thrombin activates clotting factors, promoting clot formation and stabilizing the fibrin clot.

PROCESS FIGURE 19.11 Clot Formation

In a sequence of chemical reactions, activated clotting factors (*white ovals*) activate inactive clotting factors (*blue ovals*). Clot formation begins through either the extrinsic or the intrinsic pathway. The common pathway starts with factor X and results in a fibrin clot.

they routinely receive a vitamin K injection at birth. Infants can also obtain vitamin K from food, such as milk.

The absorption of vitamin K from the large intestine requires the presence of bile because vitamin K is fat-soluble. Therefore, disorders involving an obstruction of bile flow to the intestine can interfere with vitamin K absorption and lead to insufficient blood clotting. Liver diseases that result in the decreased synthesis of clotting factors can also cause insufficient blood clotting.

Control of Clot Formation

Without control, clot formation would spread from the point of initiation through the entire circulatory system. Furthermore, blood vessels in a healthy person contain rough areas that can stimulate clot formation, and small amounts of prothrombin are constantly being converted into thrombin. To prevent unwanted clotting, the blood contains several **anticoagulants** (an'tē-kō-ag'ū-lantz). These anticoagulants prevent clotting factors from initiating clot formation under normal concentrations in the blood. Only when clotting factor concentrations exceed a given threshold in a local area does clot formation occur. At the site of injury, so many clotting factors are activated that the anticoagulants are unable to prevent clot formation. However, away from the injury site, the activated clotting factors are diluted in the blood, anticoagulants neutralize them, and clotting is prevented.

Examples of anticoagulants in the blood are antithrombin, heparin, and prostacyclin. **Antithrombin**, a plasma protein produced by the liver, slowly inactivates thrombin. Heparin, produced by basophils and endothelial cells, works with antithrombin to rapidly inactivate thrombin. **Prostacyclin** (pros-tā-sī'klin) is a prostaglandin derivative produced by endothelial cells. It counteracts the effects of thrombin by causing vasodilation and inhibiting the release of clotting factors from platelets.

Anticoagulants are also important when blood is outside the body. They prevent the clotting of blood used in transfusions and laboratory blood tests. Besides heparin, examples include **ethylenediaminetetraacetic acid (EDTA)** and sodium citrate. EDTA and sodium citrate prevent clot formation by binding to Ca^{2+} , thus making the ions inaccessible for clotting reactions.

Clot Retraction and Dissolution

The fibrin meshwork constituting a clot adheres to the walls of the blood vessel. Once a clot has formed, **clot retraction** occurs, a process whereby the blood clot condenses into a denser, compact structure. Platelets contain the contractile proteins actin and myosin, which operate in a similar fashion to actin and myosin in smooth muscle (see chapter 9). Platelets form extensions, which attach to fibrinogen through fibrinogen receptors (see figure 19.9). Contraction of the extensions pulls on the fibrinogen and leads to clot retraction. As the clot retracts, a fluid called **serum** (sēr'ŭm) is squeezed out of the clot. Serum is plasma from which fibrinogen and some of the clotting factors have been removed.

Clot retraction pulls the edges of the damaged blood vessel together, helping stop blood flow, reducing infection, and enhancing healing. The damaged vessel is repaired as fibroblasts move into the damaged area and new connective tissue forms. In addition, epithelial cells around the wound proliferate and fill in the torn area.

The Danger of Unwanted Clots

When platelets encounter damaged or diseased areas on the walls of blood vessels or the heart, an attached clot called a **thrombus** (throm'būs) may form. A thrombus that breaks loose and begins to float through the blood is called an **embolus** (em'bō-lūs). Both thrombi and emboli can cause death if they block vessels that supply blood to essential organs, such as the heart, brain, or lungs. Abnormal clotting can be prevented or hindered by administering an anticoagulant, such as heparin, which acts rapidly. Warfarin (war'fā-rin), commonly referred to by the brand name Coumadin® (koo'mă-din), acts more slowly than heparin. Coumadin prevents clot formation by suppressing the liver's production of vitamin K-dependent clotting factors (II, VII, IX, and X). Warfarin was first used as a rat poison by causing rats to bleed to death. In small doses, Coumadin is a proven, effective anticoagulant in humans. However, caution is necessary with anticoagulant treatment because the patient can hemorrhage internally or bleed excessively when cut.

The blood clot is usually dissolved within a few days after clot formation. The process that dissolves the blood clot is called **fibrinolysis** (fī-bri-nol'i-sis). During this process, an enzyme called **plasmin** (plaz'min) hydrolyzes, or breaks, fibrin, thereby dissolving the clot. Plasmin forms from inactive plasminogen, a normal blood protein produced by the liver. Plasmin becomes part of the clot as it forms. Plasmin is activated by many substances, including thrombin, factor XII, tissue plasminogen activator (t-PA), urokinase, and lysosomal enzymes released from damaged tissues (figure 19.12). Understanding how plasmin is activated has

- 1 Inactive plasminogen is converted to the active enzyme plasmin.
- 2 Plasmin breaks the fibrin molecules, and therefore the clot, into smaller pieces, which are washed away in the blood or phagocytized.

PROCESS FIGURE 19.12 Fibrinolysis

been useful for treating some clotting disorders. In disorders resulting from a blood clot blocking normal blood flow through a vessel, such as a heart attack, dissolving the clot can restore blood flow and reduce damage to tissues. For example, t-PA, urokinase, or streptokinase (a bacterial enzyme) can be injected into the blood or introduced at the clot site by means of a catheter. These substances activate plasmin, which breaks down the clot.

► Predict 7

Cedric's doctor recommended taking a small amount of aspirin each morning because Cedric has substantial atherosclerotic plaques in his coronary arteries. One morning, Cedric took his aspirin as usual, but that afternoon he was transported to the emergency room because of a coronary thrombosis. The ER team administered t-PA, and Cedric recovered quickly. What contributed to the rapid improvement in his condition?

ASSESS YOUR PROGRESS

30. What is a vascular spasm? Name two factors that produce it. What is the source of thromboxanes and endothelin?
31. What is the function of a platelet plug? Describe the process of platelet plug formation. How are platelets important to clot formation?
32. What is a clot, and what is its function?
33. What are clotting factors? What vitamin is required to produce many clotting factors?
34. What is the difference between extrinsic and intrinsic activation of clotting? What factor is activated by both pathways?
35. What are the three reactions that occur in the common pathway of clotting? What ion is a necessary part of the clotting process?
36. What is the function of anticoagulants in blood? Name three anticoagulants in blood, and explain how they prevent clot formation.
37. Describe the process of clot retraction. What is serum?
38. What is fibrinolysis? How does it occur?

19.6 Blood Grouping

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Explain the basis of the ABO blood group system and how incompatibilities occur.
- B. Describe the Rh blood group and its connection to hemolytic disease of the newborn (HDN).

If large quantities of blood are lost during surgery or due to injury, the patient can go into shock and die unless red blood cells are replaced to restore the blood's oxygen-carrying capacity. In this event, a transfusion or an infusion is required. A **transfusion** is the transfer of blood or blood components from one individual to another. An **infusion**, on the other hand, is the introduction of a fluid other than blood, such as a saline or glucose solution, into the

blood. It may be surprising that an infusion would be used to treat someone who has lost a large volume of blood, but in many cases the return of blood volume to normal levels is all that is necessary to prevent shock. Eventually, the body produces enough red blood cells to replace those that were lost.

Early attempts to transfuse blood from one person to another were often unsuccessful because they resulted in transfusion reactions, characterized by clotting within blood vessels, kidney damage, and death. We now know that transfusion reactions are caused by interactions between antigens and antibodies (see chapter 22). Recall from chapter 3 that cells have marker molecules on their membranes to identify them as normal cells of the body. The surfaces of red blood cells have marker molecules called **antigens** (an'ti-jenz), which identify the cells. The plasma contains proteins called **antibodies**, which bind to antigens. Antibodies are very specific, meaning that each antibody can bind only to a certain antigen. When the antibodies in the plasma bind to the antigens on the surfaces of the red blood cells, they form molecular bridges that connect the red blood cells. As a result, **agglutination** (ă-gloo-ti-nā'shŭn), or clumping, of the cells occurs. The combination of the antibodies with the antigens can also initiate reactions that cause hemolysis. Because the antigen-antibody combinations can cause agglutination, the antigens are often called **agglutinogens** (ă-gloo-tin'ō-jenz), and the antibodies are called **agglutinins** (ă-gloo'ti-ninz).

The antigens on the surface of red blood cells have been categorized into **blood groups**, and more than 35 blood groups, most of them rare, have been identified. For transfusions, the ABO and Rh blood groups are among the most important and are described in this text. Other well-known groups, not discussed in this text, are the Lewis, Duffy, MNSs, Kidd, Kell, and Lutheran groups.

ABO Blood Group

The **ABO blood group** system is used to categorize human blood based on the presence or absence of A and B antigens on the surface of red blood cells. Note that there are only two possible antigens associated with the ABO blood group: antigen A and antigen B. Type A blood has type A antigens, type B blood has type B antigens, type AB blood has both A and B antigens, and type O blood has neither A nor B antigens on the surface of red blood cells (figure 19.13). The ABO blood group is an example of codominance in that the A and B antigens can be expressed at the same time (see chapter 29).

In addition to the type A and type B antigens of the ABO group, there are two types of antibodies associated with this blood group: anti-A antibody and anti-B antibody. Anti-A antibodies act against type A antigens and anti-B antibodies act against type B antigens. Because the interaction between antigens and antibodies leads to the destruction of the red blood cells, we would not expect to find matching antigens and antibodies occurring naturally in the blood. Instead, we would expect to find antibodies for the antigens that are not present. Thus, plasma from type A blood contains anti-B antibodies, and plasma from type B blood contains anti-A antibodies. Type AB blood has neither type of antibody, and type O blood has both anti-A and anti-B antibodies.

The ABO blood types do not exist in equal numbers in a population. In Caucasians in the United States, the distribution is 47% type O, 41% type A, 9% type B, and 3% type AB. Among

	Antigen A 	Antigen B 	Antigens A and B 	Neither antigen A nor B 
Red blood cells				
	Anti-B antibody 	Anti-A antibody 	Neither anti-A nor anti-B antibodies	Anti-A and anti-B antibodies 
Plasma				
	Type A Red blood cells with type A surface antigens and plasma with anti-B antibodies	Type B Red blood cells with type B surface antigens and plasma with anti-A antibodies	Type AB Red blood cells with both type A and type B surface antigens and neither anti-A nor anti-B plasma antibodies	Type O Red blood cells with neither type A nor type B surface antigens but both anti-A and anti-B plasma antibodies

FIGURE 19.13 ABO Blood Groups

For simplicity, only parts of the anti-A and anti-B antibodies are illustrated. Each antibody has five identical, Y-shaped arms (see chapter 22).

African-Americans, the distribution is 46% type O, 27% type A, 20% type B, and 7% type AB.

Normally, antibodies do not develop against an antigen unless the body is exposed to that antigen. In the case of the antibodies associated with the ABO blood group, scientists are unsure exactly how this exposure occurs. One possible explanation for the production of anti-A and/or anti-B antibodies is that type A or B antigens on bacteria or food in the digestive tract stimulate the formation of antibodies against antigens that are different from the body's own antigens. In support of this explanation, anti-A and anti-B antibodies are not found in the blood until about 2 months after birth. It is possible that an infant with type A blood produces anti-B antibodies against the B antigens on bacteria or food. Meanwhile, an infant with A antigens does not produce antibodies against the A antigens on bacteria or food because mechanisms exist in the body to prevent the production of antibodies that react with the body's own antigens (see chapter 22).

In the event of a blood transfusion, it is very important to match the blood types of both the donor and the recipient to avoid transfusion reactions. When a blood transfusion is performed, the **donor** is the person who gives blood, and the **recipient** is the person who receives it. Usually, a recipient can successfully receive blood from a donor as long as they both have the same blood type. For example, a person with type A blood can receive blood from a person with type A blood. No ABO transfusion reaction occurs because the recipient has no anti-A antibodies against the type A antigen. On the other hand, if type A blood were donated to a person with type B blood, a transfusion reaction would occur because the person with type B blood has anti-A antibodies. These anti-A antibodies would act against the type A

antigens on the red blood cells in the donated blood, causing agglutination (figure 19.14).

Type O blood is characterized by the absence of either type A or type B antigens. Because the red blood cells lack the antigens, neither anti-A nor anti-B antibodies can react with these cells. People with type O blood are often called universal donors because they can usually give blood to the other ABO blood types without causing an ABO transfusion reaction. For example, if a person with type A blood receives type O blood, the type O red blood cells do not react with the anti-B antibodies in the recipient's blood.

The term *universal donor* is misleading, however. Transfusion of type O blood can still produce a transfusion reaction in one of two ways: First, other blood groups can cause a transfusion reaction. Second, antibodies in the donor's blood can react with antigens in the recipient's blood. For example, type O blood has anti-A and anti-B antibodies. If type O blood is transfused into a person with type A blood, the anti-A antibodies (in the type O blood) react against the A antigens (in the type A blood). Usually, such reactions are not serious because the antibodies in the donor's blood are diluted in the larger volume of the recipient's blood, and few reactions take place. Blood banks separate donated blood into several products, such as packed red blood cells, plasma, platelets, and cryoprecipitate, which contains von Willebrand factor, clotting factors, and fibrinogen. This process allows the donated blood to be used by multiple recipients, each of whom may need only one of the blood components. Type O packed red blood cells are unlikely to cause an ABO transfusion reaction when given to a person with a different blood type because the transfusion fluid contains concentrated red blood cells with very little plasma containing anti-A and anti-B antibodies.

(a) **No agglutination reaction.** Type A blood donated to a type A recipient does not cause an agglutination reaction because the anti-B antibodies in the recipient do not combine with the type A antigens on the red blood cells in the donated blood.

(b) **Agglutination reaction.** Type A blood donated to a type B recipient causes an agglutination reaction because the anti-A antibodies in the recipient combine with the type A antigens on the red blood cells in the donated blood.

FIGURE 19.14 Agglutination Reaction

For simplicity, only parts of the anti-A and anti-B antibodies are illustrated. Each antibody has five identical, Y-shaped arms (see chapter 22).

Rh Blood Group

A second clinically important blood group is the Rh blood group. The **Rh blood group** is so named because it was first studied in rhesus monkeys. The antigen involved in this blood group is the D antigen. People are Rh-positive if they have the D antigen on the surface of their red blood cells, and people are Rh-negative if they do not have the D antigen. About 85% of Caucasians in the United States and 88% of African-Americans are Rh-positive. The ABO blood type and the Rh blood type are usually expressed together. For example, a person designated type A in the ABO blood group and Rh-positive is said to be A-positive. The rarest combination in the United States is AB-negative, which occurs in less than 1% of the population.

Unlike the natural occurrence of anti-A and anti-B antibodies in the blood, antibodies against the Rh antigen do not develop unless an Rh-negative person is exposed to Rh-positive blood. This can occur either through a transfusion or when blood crosses the placenta to a mother from her fetus.

Rh incompatibility can pose a major problem in a pregnancy when the mother is Rh-negative and the fetus is Rh-positive. If fetal blood leaks through the placenta and mixes with the mother's blood, the mother becomes sensitized to the Rh antigen and produces anti-Rh antibodies. These antibodies can cross the placenta and enter the fetal blood. In the fetal blood, the Rh antibodies will act against the D antigens on the red blood cells and cause agglutination and hemolysis of fetal red blood cells. This disorder is called **hemolytic** (hē-mō-lit'ik) **disease of the newborn (HDN)**, or *erythroblastosis fetalis* (ē-rith'rō-blas-tō'sis fē-ta'lis; figure 19.15). In the

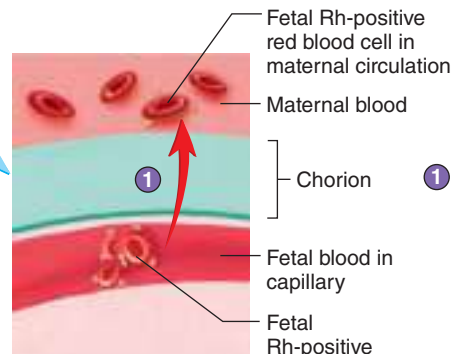

mother's first pregnancy, there is often no problem. The leakage of fetal blood is usually the result of a tear in the placenta that takes place either late in the pregnancy or during delivery. Thus, there is not sufficient time for the mother to produce enough anti-Rh antibodies to harm the fetus. However, if sensitization occurs, it can cause problems in a subsequent pregnancy. First, once a woman is sensitized and produces anti-Rh antibodies, she may continue to produce the antibodies throughout her life. Thus, in a subsequent pregnancy, anti-Rh antibodies may already be present. Second, and especially dangerous in a subsequent pregnancy with an Rh-positive fetus, if any fetal blood leaks into the mother's blood, she rapidly produces large amounts of anti-Rh antibodies, resulting in HDN. Because HDN can be fatal to the fetus, the levels of anti-Rh antibodies in the mother should be monitored. If they increase to unacceptable levels, the fetus should be tested to determine the severity of the HDN. In severe cases, a transfusion to replace lost red blood cells can be performed through the umbilical cord, or the baby can be delivered if mature enough.

Prevention of HDN is often possible if the Rh-negative mother is injected with a specific type of antibody preparation, called Rh₀(D) immune globulin (RhoGAM), which contains antibodies against Rh antigens. The injection can be given during the pregnancy, before delivery, or immediately after each delivery, miscarriage, or abortion. The injected antibodies bind to the Rh antigens of any fetal red blood cells that may have entered the mother's blood. This treatment inactivates the fetal Rh antigens and prevents sensitization of the mother. However, if sensitization has already occurred, the treatment is ineffective.

FUNDAMENTAL Figure

First Pregnancy

Maternal blood is separated from fetal blood by the chorion.

- 1 Before or during delivery, Rh-positive red blood cells from the fetus enter the blood of an Rh-negative woman through a tear in the placenta.

Anti-Rh antibodies

- 2 The mother is sensitized to the Rh antigen and produces anti-Rh antibodies. Because this usually happens after delivery, the fetus is not affected in the first pregnancy.

Subsequent Pregnancy

- 3 During a subsequent pregnancy with an Rh-positive fetus, if Rh-positive red blood cells cross the placenta and enter the maternal circulation, they can stimulate the mother to produce antibodies against the Rh antigen. Antibody production is rapid because the mother has been sensitized to the Rh antigen.

- 4 The anti-Rh antibodies from the mother cross the placenta, causing agglutination and hemolysis of fetal red blood cells, and hemolytic disease of the newborn (HDN) develops.

PROCESS FIGURE 19.15 Hemolytic Disease of the Newborn (HDN)

Case STUDY

Treatment of Hemolytic Disease of the Newborn

Billy was born with hemolytic disease of the newborn (HDN). He was treated with exchange transfusion, erythropoietin, and phototherapy. An exchange transfusion replaced Billy's blood with donor blood. In this procedure, as the donor's blood was transfused into Billy, his blood was withdrawn. During fetal development, the increased rate of red blood cell destruction caused by the mother's anti-Rh antibodies results in lower than normal numbers of red blood cells, a condition called **anemia** (ă-nĕ'mĕ-ă). It also results in increased levels of bilirubin. Although high levels of bilirubin can damage the brain by killing nerve cells, this is not usually a problem in the fetus because the bilirubin is removed by the placenta. Following birth,

bilirubin levels can increase because red blood cells continue to lyse, and the newborn's liver is unable to handle the large bilirubin load. However, in phototherapy, blood that passes through the skin is exposed to blue or white lights, which break down bilirubin to less toxic compounds that the newborn's liver can remove.

➤ Predict 8

Answer the following questions about Billy's treatment for HDN.

- What is the purpose of giving Billy a transfusion?
- What is the benefit of the exchange transfusion?
- Explain the reason for giving Billy erythropoietin.
- Just before birth, would Billy's erythropoietin levels have been higher or lower than those of a fetus without HDN?
- After birth, but before treatment, did Billy's erythropoietin levels increase or decrease?
- When treating HDN with an exchange transfusion, should the donor's blood be Rh-positive or Rh-negative? Explain.
- Does giving an Rh-positive newborn a transfusion of Rh-negative blood change the newborn's blood type? Explain.

ASSESS YOUR PROGRESS

- What are blood groups, and how do they cause transfusion reactions? What is agglutination?
- What kinds of antigens and antibodies are found in each of the four ABO blood types?
- Why is a person with type O blood considered a universal donor?
- What does it mean to be Rh-positive?
- What Rh blood types must the mother and the fetus have before HDN can occur?
- Why does HDN usually not develop in the first pregnancy?

19.7 Diagnostic Blood Tests

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe diagnostic blood tests and the normal values for the tests.
- Give examples of disorders that produce abnormal test values.

Type and Crossmatch

To prevent transfusion reactions, blood is typed. **Blood typing** determines the ABO and Rh blood groups of the blood sample. Typically, the cells are separated from the serum and then tested with known antibodies to determine the type of antigen on the cell surface. For example, if a patient's blood cells agglutinate when mixed with anti-A antibodies but do not

agglutinate when mixed with anti-B antibodies, the cells have type A antigen. In a similar fashion, the serum is mixed with known cell types (antigens) to determine the type of antibodies in the serum. Normally, donor blood must match the ABO and Rh type of the recipient.

The International Society of Blood Transfusion recognizes 29 important blood groups, including the ABO and Rh groups. Because any of these blood groups can cause a transfusion reaction, a crossmatch is performed. In a **crossmatch**, the donor's blood cells are mixed with the recipient's serum, and the donor's serum is mixed with the recipient's cells. The donor's blood is considered safe for transfusion only if no agglutination occurs in either match.

Complete Blood Count

A **complete blood count (CBC)** is an analysis of blood that provides much useful information. A CBC consists of a red blood count, hemoglobin and hematocrit measurements, a white blood count, and a differential white blood count.

Red Blood Count

Blood cell counts are usually performed with an electronic instrument, but they can also be done manually with a microscope. A **red blood count (RBC)** is the number (expressed in millions) of red blood cells per microliter of blood. A normal RBC for a male is 4.6–6.2 million/ μL of blood; for a female, a normal RBC is 4.2–5.4 million/ μL of blood. The condition called **erythrocytosis** (ĕ-rith'rō-sī-tō'sis) is an overabundance of red blood cells (see the Diseases and Disorders table, later in this chapter).

Hemoglobin Measurement

A **hemoglobin measurement** determines the amount of hemoglobin in a given volume of blood, usually expressed as grams of hemoglobin per 100 mL of blood. The normal hemoglobin count for a male

Diseases and Disorders

TABLE 19.4

Blood

Condition	Description
Erythrocytosis	
Relative erythrocytosis	Overabundance of red blood cells due to decreased blood volume, as may result from dehydration, diuretics, or burns
Primary erythrocytosis (polycythemia vera)	Stem cell defect of unknown cause; results in overproduction of red blood cells, granulocytes, and platelets; signs include low erythropoietin levels and enlarged spleen; increased blood viscosity and blood volume can cause clogging of the capillaries and hypertension
Secondary erythrocytosis	Overabundance of red blood cells resulting from decreased oxygen supply, as occurs at high altitudes, in chronic obstructive pulmonary disease, and in congestive heart failure; decreased oxygen delivery to the kidney stimulates the secretion of erythropoietin, resulting in increased blood viscosity and blood volume that can cause clogging of the capillaries and hypertension
Anemia	
Iron-deficiency anemia	Caused by insufficient intake or absorption of iron or by excessive iron loss; leads to reduced hemoglobin production
Folate-deficiency anemia	Folate is important in DNA synthesis; inadequate folate in the diet results in a reduction in cell division and therefore a reduced number of red blood cells
Pernicious anemia	Secondary folate-deficiency anemia caused by inadequate amounts of vitamin B ₁₂ , which is important for folate synthesis
Hemorrhagic anemia	Results from blood loss due to trauma, ulcers, or excessive menstrual bleeding
Hemolytic anemia	Occurs when red blood cells rupture or are destroyed at an excessive rate; causes include inherited defects, exposure to certain drugs or snake venom, response to artificial heart valves, autoimmune disease, and hemolytic disease of the newborn
Aplastic anemia	Caused by an inability of the red bone marrow to produce red blood cells, usually as a result of damage to stem cells after exposure to certain drugs, chemicals, or radiation
Thalassemia	Autosomal recessive disease that results in insufficient production of globin part of hemoglobin
Leukemia	
Cancers of the red bone marrow in which one or more white blood cell types is produced; cells are usually immature or abnormal and lack normal immunological functions	
Thrombocytopenia	
Reduction in the number of platelets that leads to chronic bleeding through small vessels and capillaries; causes include genetics, autoimmune disease, infections, and decreased platelet production resulting from pernicious anemia, drug therapy, radiation therapy, or leukemias	
Clotting Disorders	
Disseminated intravascular coagulation (DIC)	Clotting throughout the vascular system, followed by bleeding; may develop when normal regulation of clotting by anticoagulants is overwhelmed, as occurs due to massive tissue damage; also caused by alteration of the lining of the blood vessels resulting from infections or snakebites
Von Willebrand disease	Most common inherited bleeding disorder; platelet plug formation and the contribution of activated platelets to blood clotting are impaired; treatments are injection of von Willebrand factor or administration of drugs that increase von Willebrand factor levels in blood, which helps platelets adhere to collagen and become activated
Hemophilia	Genetic disorder in which clotting is abnormal or absent; each of the several types results from deficiency or dysfunction of a clotting factor; most often a sex-linked trait that occurs almost exclusively in males
Infectious Diseases of the Blood	
Septicemia (blood poisoning)	Spread of microorganisms and their toxins by the blood; often the result of a medical procedure, such as insertion of an intravenous tube; release of toxins by bacteria can cause septic shock, producing decreased blood pressure and possibly death
Malaria	Caused by a protozoan introduced into blood by <i>Anopheles</i> mosquito; symptoms include chills and fever produced by toxins released when the protozoan causes red blood cells to rupture
Infectious mononucleosis	Caused by Epstein-Barr virus, which infects salivary glands and lymphocytes; symptoms include fever, sore throat, and swollen lymph nodes, all probably produced by the immune system response to infected lymphocytes
Acquired immunodeficiency syndrome (AIDS)	Caused by human immunodeficiency virus (HIV), which infects lymphocytes and suppresses immune system

is 14–18 g/100 mL of blood, and for a female it is 12–16 g/100 mL of blood. Abnormally low hemoglobin is an indication of anemia (see the Diseases and Disorders table).

Hematocrit Measurement

The hematocrit (hē'mă-tō-krit, hem'ă-tō-krit) is the percentage of the total blood volume that is composed of red blood cells. One

way to determine hematocrit is to place blood in a tube and spin it in a centrifuge. The formed elements, which are heavier than the plasma, are forced to one end of the tube (figure 19.16). Of these, the white blood cells and platelets form a thin, whitish layer, called the buffy coat, between the plasma and the red blood cells. The red blood cells account for 40–54% of the total blood volume in males and 38–47% in females.

FIGURE 19.16 Hematocrit

Blood is withdrawn into a capillary tube and spun in a centrifuge. The blood is separated into plasma and red blood cells, with a narrow layer of white blood cells and platelets forming in between. The hematocrit is the percentage of the total blood volume that is composed of red blood cells. It does not include the white blood cells and platelets. Normal hematocrits for a male and a female are shown.

The number and size of red blood cells affect the hematocrit measurement. **Normocytes** (nōr'mō-sītz) are normal-sized red blood cells with a diameter of 7.5 μm . **Microcytes** (mī'krō-sītz) are smaller than normal, with a diameter of 6 μm or less, and **macrocytes** (mak'krō-sītz) are larger than normal, with a diameter of 9 μm or greater. Blood disorders can result in an abnormal hematocrit measurement because they cause red blood cell numbers to be abnormally high or low or cause the red blood cells themselves to be abnormally small or large (see the Diseases and Disorders table). A decreased hematocrit indicates that the volume of red blood cells is less than normal. This can result from a decreased number of normocytes or a normal number of microcytes. For example, inadequate iron in the diet can impair hemoglobin production. Consequently, during their formation, red blood cells do not fill with hemoglobin, and they remain smaller than normal.

White Blood Count

A **white blood count (WBC)** measures the total number of white blood cells in the blood. Normally, 5000–10,000 white blood cells are present in each microliter of blood. **Leukopenia** (loo-kō-pē'nē-ă) is a lower than normal WBC resulting from depression or destruction of the red marrow. Viral infections, radiation,

drugs, tumors, and vitamin deficiencies (B_{12} or folate) can cause leukopenia. **Leukocytosis** (loo'kō-sī-tō'sis) is an abnormally high WBC. **Leukemia** (loo-kē'mē-ă), a cancer of the red marrow, often results in leukocytosis, but the white blood cells have an abnormal structure and function as well. Bacterial infections can also cause leukocytosis by stimulating neutrophils to increase in number.

Differential White Blood Count

A **differential white blood count** determines the percentage of each of the five kinds of white blood cells. Normally, neutrophils account for 60–70%; lymphocytes, 20–30%; monocytes, 2–8%; eosinophils, 1–4%; and basophils, 0.5–1%. A differential WBC can provide insight into a patient's condition. For example, in patients with bacterial infections the neutrophil count is often greatly increased, whereas in patients with allergic reactions the eosinophil and basophil counts are elevated.

Clotting

The blood's ability to clot can be assessed by the platelet count and the prothrombin time measurement.

Platelet Count

A normal **platelet count** is 250,000–400,000 platelets per microliter of blood. In the condition called **thrombocytopenia** (throm'bō-sī-tō-pē'nē-ă), the platelet count is greatly reduced, resulting in chronic bleeding through small vessels and capillaries. It can be caused by decreased platelet production as a result of hereditary disorders, lack of vitamin B_{12} , drug therapy, or radiation therapy.

Prothrombin Time Measurement

Prothrombin time measurement expresses how long it takes for the blood to start clotting, which is normally 9–12 seconds. Prothrombin time is determined by adding thromboplastin to whole plasma. Thromboplastin is a chemical released from injured tissues that starts the process of clotting (see figure 19.11). Prothrombin time is officially reported as the International Normalized Ratio (INR), which standardizes the time blood takes to clot based on the slightly different thromboplastins used by different labs. Because many clotting factors must be activated to form fibrin, a deficiency of any one of them can cause the prothrombin time to be abnormal. Vitamin K deficiency, certain liver diseases, and drug therapy can increase prothrombin time.

Blood Chemistry

The composition of materials dissolved or suspended in the plasma can be used to assess the functioning of many of the body's systems. For example, high blood glucose levels can indicate that the pancreas is not producing enough insulin; high blood urea nitrogen (BUN) can be a sign of reduced kidney function; increased bilirubin can indicate liver dysfunction or hemolysis; and high cholesterol levels can signify an increased risk for cardiovascular disease. A number of blood chemistry tests are

routinely done when a blood sample is taken, and additional tests are available.

► Predict 9

When a patient complains of acute pain in the abdomen, the physician suspects appendicitis, which is often caused by a bacterial infection of the appendix. What blood test should be done to support the diagnosis?

ASSESS YOUR PROGRESS

45. What occurs in a type and crossmatch?
46. What tests are included in a CBC? Give the normal value, and name a disorder that would cause an abnormal test result for each.
47. What are the normal values for a platelet count and a prothrombin time measurement? Name a disorder that would cause an abnormal result for each test.
48. What are some examples of blood chemistry tests?

Answer

Learn to Predict ◀ From page 644

Frankie's feeling of fatigue and her blood test results are consistent with anemia. A low red blood cell count with microcytic cells, low hemoglobin, and a low hematocrit are all indicators of iron deficiency anemia.

The increased reticulocyte count indicated an increased rate of red blood cell production. But if red blood cell production was increased, why was Frankie's red blood cell count still low? We learned in this chapter that red blood cell production is regulated by the hormone erythropoietin. Specifically, reduced red blood cell numbers, as indicated by Frankie's blood test, caused less oxygen to be transported to her kidneys. Consequently, her kidneys secreted more erythropoietin, which resulted in increased

red blood cell production in the red bone marrow. Because of Frankie's iron deficiency, which caused hemoglobin synthesis to slow, the newly synthesized red blood cells were smaller than normal, or microcytic. Remember, Frankie also complained of intense abdominal pain. The evidence of hemoglobin in her feces suggested that Frankie is losing blood into her digestive tract, which, considering her abdominal pain, would be consistent with having an ulcer. Frankie's doctor would need to order additional tests to confirm the presence of ulcers before determining treatment.

Answers to the rest of this chapter's Predict questions are in appendix G.

19.1 Functions of Blood (p. 645)

1. Blood transports gases, nutrients, waste products, processed molecules, and regulatory molecules.
2. Blood is involved in the regulation of pH, osmosis, and body temperature.
3. Blood protects against disease and initiates tissue repair.

19.2 Composition of Blood (p. 645)

Blood is a type of connective tissue that consists of plasma and formed elements.

19.3 Plasma (p. 645)

1. Plasma is mostly water (91%) and contains proteins, such as albumin (maintains osmotic pressure), globulins (function in transport and immunity), fibrinogen (involved in clot formation), and hormones and enzymes (involved in regulation).
2. Plasma contains ions, nutrients, waste products, and gases.

19.4 Formed Elements (p. 646)

The formed elements are red blood cells (erythrocytes), white blood cells (leukocytes), and platelets (cell fragments).

Summary

Production of Formed Elements

1. In the embryo and fetus, the formed elements are produced in a number of locations.
2. After birth, red bone marrow becomes the source of the formed elements.
3. All formed elements are derived from hemocytoblast, which gives rise to two intermediate stem cells: myeloid stem cells and lymphoid stem cells. Myeloid stem cells give rise to red blood cells, platelets, and most of the white blood cells. Lymphoid stem cells give rise to lymphocytes.

Red Blood Cells

1. Red blood cells are biconcave discs containing hemoglobin and carbonic anhydrase.
 - A hemoglobin molecule consists of four heme and four globin molecules. The heme molecules transport oxygen, and the globin molecules transport carbon dioxide and nitric oxide. Iron is required for oxygen transport.
 - Carbonic anhydrase is involved with the transport of carbon dioxide.

- Erythropoiesis is the production of red blood cells.
 - Stem cells in red bone marrow eventually give rise to late erythroblasts, which lose their nuclei and are released into the blood as reticulocytes. Loss of the endoplasmic reticulum by a reticulocyte produces a red blood cell.
 - In response to low blood oxygen, the kidneys produce erythropoietin, which stimulates erythropoiesis.
- Hemoglobin from ruptured red blood cells is phagocytized by macrophages. The hemoglobin is broken down, and heme becomes bilirubin, which is secreted in bile.

White Blood Cells

- White blood cells protect the body against microorganisms and remove dead cells and debris.
- Five types of white blood cells exist.
 - Neutrophils are small, phagocytic cells.
 - Eosinophils attack certain worm parasites and modulate inflammation.
 - Basophils release histamine and are involved with increasing the inflammatory response.
 - Lymphocytes are important in immunity, including the production of antibodies.
 - Monocytes leave the blood, enter tissues, and become large, phagocytic cells called macrophages.

Platelets

Platelets, or thrombocytes, are cell fragments pinched off from megakaryocytes in the red bone marrow.

19.5 Hemostasis (p. 657)

Hemostasis, the cessation of bleeding, is very important to the maintenance of homeostasis.

Vascular Spasm

Vasoconstriction of damaged blood vessels reduces blood loss.

Platelet Plug Formation

- Platelets repair minor damage to blood vessels by forming platelet plugs.
 - In platelet adhesion, platelets bind to collagen in damaged tissues.
 - In the platelet release reaction, platelets release chemicals that activate additional platelets.
 - In platelet aggregation, platelets bind to one another to form a platelet plug.
- Platelets also release chemicals involved with coagulation.

Coagulation

- Coagulation is the formation of a blood clot.
- The first stage of coagulation occurs through the extrinsic or intrinsic pathway. Both pathways end with the production of activated factor X.
 - The extrinsic pathway begins with the release of thromboplastin from damaged tissues.
 - The intrinsic pathway begins with the activation of factor XII.
- Activated factor X, factor V, phospholipids, and Ca^{2+} form prothrombinase.
- Prothrombinase converts prothrombin to thrombin.
- Thrombin converts fibrinogen to fibrin. The insoluble fibrin forms the clot.

Control of Clot Formation

- Heparin and antithrombin inhibit thrombin activity. Therefore, fibrinogen is not converted to fibrin, and clot formation is inhibited.
- Prostacyclin counteracts the effects of thrombin.

Clot Retraction and Dissolution

- Clot retraction results from the contraction of platelets, which pull the edges of damaged tissue closer together.
- Serum, which is plasma minus fibrinogen and some clotting factors, is squeezed out of the clot.
- Factor XII, thrombin, tissue plasminogen activator, and urokinase activate plasmin, which dissolves fibrin (the clot).

19.6 Blood Grouping (p. 662)

- Blood groups are determined by antigens on the surface of red blood cells.
- Antibodies can bind to red blood cell antigens, resulting in agglutination or hemolysis of red blood cells.

ABO Blood Group

- Type A blood has A antigens, type B blood has B antigens, type AB blood has A and B antigens, and type O blood has neither A nor B antigens.
- Type A blood has anti-B antibodies, type B blood has anti-A antibodies, type AB blood has neither anti-A nor anti-B antibodies, and type O blood has both anti-A and anti-B antibodies.
- Mismatching the ABO blood group results in a transfusion reaction.

Rh Blood Group

- Rh-positive blood has the D antigen, whereas Rh-negative blood does not.
- Antibodies against the D antigen are produced by an Rh-negative person when the person is exposed to Rh-positive blood.
- The Rh blood group is responsible for hemolytic disease of the newborn.

19.7 Diagnostic Blood Tests (p. 666)

Type and Crossmatch

Blood typing determines the ABO and Rh blood groups of a blood sample. A crossmatch tests for agglutination reactions between donor and recipient blood.

Complete Blood Count

A complete blood count consists of the following: red blood count, hemoglobin measurement (grams of hemoglobin per 100 mL of blood), hematocrit measurement (percent volume of red blood cells), white blood count, and differential white blood count (the percentage of each type of white blood cell).

Clotting

Platelet count and prothrombin time measurement assess the blood's ability to clot.

Blood Chemistry

The composition of materials dissolved or suspended in plasma (e.g., glucose, urea nitrogen, bilirubin, and cholesterol) can be used to assess the functioning and status of the body's systems.

REVIEW AND COMPREHENSION

- Which of these is a function of blood?
 - clot formation
 - protection against foreign substances
 - maintenance of body temperature
 - regulation of pH and osmosis
 - All of these are correct.
- Which of these is *not* a component of plasma?
 - nitrogen
 - sodium ions
 - platelets
 - water
 - urea
- Which of these proteins is normally found in the plasma and plays an important role in maintaining the osmotic concentration of the blood?
 - albumin
 - fibrinogen
 - platelets
 - hemoglobin
 - globulins
- Red blood cells
 - are the least numerous formed element in the blood.
 - are phagocytic cells.
 - are produced in the yellow marrow.
 - do not have a nucleus.
 - All of these are correct.
- Given these ways of transporting carbon dioxide in the blood:
 - bicarbonate ions
 - combined with blood proteins
 - dissolved in plasma

Choose the arrangement that lists them in the correct order from largest to smallest percentage of carbon dioxide transported.

 - 1,2,3
 - 1,3,2
 - 2,3,1
 - 2,1,3
 - 3,1,2
- Each hemoglobin molecule can become associated with _____ oxygen molecule(s).
 - one
 - two
 - three
 - four
 - an unlimited number of
- Erythropoietin
 - is produced mainly by the heart.
 - inhibits the production of red blood cells.
 - production increases when blood oxygen decreases.
 - production is inhibited by testosterone.
 - All of these are correct.
- Which of these changes occur(s) in the blood in response to the initiation of a vigorous exercise program?
 - increased erythropoietin production
 - increased concentration of reticulocytes
 - decreased bilirubin formation
 - Both a and b are correct.
 - All of these are correct.
- Which of the components of hemoglobin is correctly matched with its fate following the destruction of a red blood cell?
 - heme—reused to form a new hemoglobin molecule
 - globin—broken down into amino acids
 - iron—mostly secreted in bile
 - All of these are correct.
- The blood cells that protect against worm parasites are
 - eosinophils.
 - basophils.
 - neutrophils.
 - monocytes.
 - lymphocytes.
- The most numerous type of white blood cell, whose primary function is phagocytosis, is
 - eosinophils.
 - basophils.
 - neutrophils.
 - monocytes.
 - lymphocytes.
- Monocytes
 - are the smallest white blood cells.
 - increase in number during chronic infections.
 - give rise to neutrophils.
 - produce antibodies.
- The smallest white blood cells, which include B cells and T cells, are
 - eosinophils.
 - basophils.
 - neutrophils.
 - monocytes.
 - lymphocytes.
- Platelets
 - are derived from megakaryocytes.
 - are cell fragments.
 - have surface molecules that attach to collagen.
 - play an important role in clot formation.
 - All of these are correct.
- Given these processes in platelet plug formation:
 - platelet adhesion
 - platelet aggregation
 - platelet release reaction

Choose the arrangement that lists the processes in the correct order after a blood vessel is damaged.

 - 1,2,3
 - 1,3,2
 - 3,1,2
 - 3,2,1
 - 2,3,1
- A constituent of plasma that forms the network of fibers in a clot is
 - fibrinogen.
 - tissue factor.
 - platelets.
 - thrombin.
 - prothrombinase.
- Given these chemicals:
 - activated factor XII
 - fibrinogen
 - prothrombinase
 - thrombin

Choose the arrangement that lists the chemicals in the order they are used during clot formation.

 - 1,3,4,2
 - 2,3,4,1

 - 3,1,2,4
 - 3,4,2,1
- The extrinsic pathway
 - begins with the release of thromboplastin (tissue factor).
 - leads to the production of activated factor X.
 - requires Ca^{2+} .
 - All of these are correct.
- The chemical involved in the breakdown of a clot (fibrinolysis) is
 - antithrombin.
 - fibrinogen.
 - heparin
 - plasmin.
 - sodium citrate.
- A person with type A blood
 - has anti-A antibodies.
 - has type B antigens.
 - will have a transfusion reaction if given type B blood.
 - All of these are correct.
- In the United States, the most common blood type is
 - A positive.
 - B positive.
 - O positive.
 - O negative.
 - AB negative.

CRITICAL THINKING

- In hereditary hemolytic anemia, massive destruction of red blood cells occurs. Would you expect the reticulocyte count to be above or below normal? Explain why one of the symptoms of the disease is jaundice. In 1910, physicians discovered that hereditary hemolytic anemia can be treated successfully by removing the spleen. Explain why this treatment is effective.
- Red Packer, a physical education major, wanted to improve his performance in an upcoming marathon race. About 6 weeks before the race, 500 mL of blood was removed from his body, and the formed elements were separated from the plasma. The formed elements were frozen, and the plasma was reinfused into his body. Just before the competition, the formed elements were thawed and injected into his body. Explain why this procedure, called blood doping or blood boosting, would help Red's performance. Suggest any possible bad effects.
- Ben has an infected prostate. His physician prescribed several antibiotics before finding one that was effective. Results of the most recent blood tests indicate that Ben is anemic. After analyzing the following measurements of Ben's blood, identify the type of anemia he has.

	Ben's Values	Normal Values
Red blood count	3.1 million RBCs/ mm ³	4.6–6.2 million RBCs/mm ³
Reticulocyte count	0.4%	1–3%
Red blood cells	Normocytic, 7.5 mm	Normocytic, 7.5 mm
White blood count	2800 WBCs/mm ³	5000–10,000 WBCs/mm ³
Hemoglobin	9.0 g/100 mL	14–16.5 g/100 mL
Hematocrit	27%	40–54%
Prothrombin time	20 seconds	11–15 seconds
Platelets	200,000/mm ³	250,000–400,000 platelets/mm ³

Which of the following conclusions is most consistent with the results? Explain.

- pernicious anemia
 - iron-deficiency anemia
 - aplastic anemia
 - hemorrhagic anemia
 - vitamin B₁₂ deficiency
- Some people habitually use barbiturates to depress feelings of anxiety. Barbiturates cause hypoventilation, a slower than normal rate of breathing, because they suppress the respiratory centers in the brain. What happens to the red blood count of a habitual user of barbiturates? Explain.
 - According to an old saying, “good food makes good blood.” Name three substances in the diet that are essential for “good blood.” What blood disorders develop if these substances are absent from the diet?
 - Grace has a plasma membrane defect in her red blood cells that makes them more susceptible to rupturing. Her red blood cells are destroyed faster than they can be replaced. Are her RBC, hemoglobin, hematocrit, and bilirubin levels below normal, normal, or above normal? Explain.
 - Pam lives in Los Angeles, not far from the beach. She traveled by plane with her fiancé, Alex, to Jackson Hole, which is approximately 6000 feet above sea level. They took hikes of increasing length for each of 4 days and rested on the fifth day. On the sixth day, she and Alex hiked to the top of Table Mountain, which is approximately 11,000 feet above sea level. Which of the following was (were) apparent in Pam on the day they climbed Table Mountain? Explain.
 - Pam's rate of erythropoietin secretion was increasing.
 - Pam's erythrocyte count was increasing.
 - Pam's reticulocyte count was increasing.
 - Pam's platelet count was increasing.

Cardiovascular System

THE HEART

Almost 400 years ago, scientists established that the heart's pumping action maintains the continuous circulation of blood throughout the body. Our current understanding of the detailed function of this amazing pump, its regulation, and modern treatments for heart disease is, in comparison, very recent.

The heart of a healthy 70 kg person pumps approximately 7200 L (approximately 1900 gallons) of blood each day at a rate of 5 L/min. For most people, the heart continues to pump for more than 75 years. During periods of vigorous exercise, the amount of blood pumped per minute increases dramatically, but the person's life is in danger if the heart loses its ability to pump blood for even a few minutes. **Cardiology** (kar-dē-ol'ō-jē) is the medical specialty concerned with diagnosing and treating heart disease.

Learn to Predict

Grandpa Stan never missed watching his grandson pitch. One day, while climbing into the bleachers, he had difficulty breathing and knew he'd better see a doctor. Using a stethoscope, Stan's regular physician could hear an irregular swooshing after the first heart sound, so he referred Stan to a cardiologist. The cardiologist conducted a series of exams and determined that Stan had an incompetent bicuspid valve. **By recalling some information from chapter 19 and reading chapter 20, identify the major functional changes in the heart that result from an incompetent valve, and explain how these changes led to Stan's symptoms.**

20.1 Functions of the Heart

LEARNING OUTCOME

After reading this section, you should be able to

A. List the major functions of the heart.

Though we may think of the heart as a single structure, it is actually two pumps in one. The right side of the heart pumps blood through the **pulmonary** (pŭl'mō-nār-ē) **circulation**, which carries blood to the lungs, where carbon dioxide diffuses from the blood into the lungs and oxygen diffuses from the lungs into the blood. The pulmonary circulation returns the blood to the left side of the heart. The left side of the heart then pumps blood through the **systemic circulation**, which delivers oxygen and nutrients to all the remaining tissues of the body. From those tissues, carbon dioxide and other waste products are carried back to the right side of the heart (figure 20.1).

The following are the functions of the heart:

1. *Generating blood pressure.* Contractions of the heart generate blood pressure, which is responsible for moving blood through the blood vessels.
2. *Routing blood.* The heart separates the pulmonary and systemic circulations and ensures better oxygenation of the blood flowing to the tissues.
3. *Ensuring one-way blood flow.* The valves of the heart ensure a one-way flow of blood through the heart and blood vessels.
4. *Regulating blood supply.* The rate and force of heart contractions change to meet the metabolic needs of the tissues, which vary depending on such conditions as rest, exercise, and changes in body position.

ASSESS YOUR PROGRESS

1. State the four functions of the heart.

FUNDAMENTAL Figure

FIGURE 20.1 Systemic and Pulmonary Circulation

The circulatory system consists of the pulmonary and systemic circulations. The right side of the heart pumps blood through vessels to the lungs and back to the left side of the heart through the pulmonary circulation. The left side of the heart pumps blood through vessels to the tissues of the body and back to the right side of the heart through the systemic circulation. **AP R**

20.2 Size, Shape, and Location of the Heart

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Cite the size, shape, and location of the heart.
- B. Explain why knowing the heart's location is important.

The adult heart is shaped like a blunt cone and is approximately the size of a closed fist, with an average mass of 250 g in females and 300 g in males. It is larger in physically active adults than in other healthy adults. The heart generally decreases in size after approximately age 65, especially in people who are not physically active. The blunt, rounded point of the heart is the **apex**; the larger, flat part at the opposite end of the heart is the **base**.

The heart is located in the **mediastinum** (me'dē-as-tī'nūm; see figure 1.14), a midline partition of the thoracic cavity that also contains the trachea, the esophagus, the thymus, and associated structures.

It is important for health professionals to know the location of the heart in the thoracic cavity. Positioning a stethoscope to hear the heart sounds and positioning electrodes to record an electrocardiogram from chest leads depend on this knowledge. Effective **cardiopulmonary resuscitation** (kar'dē-ō-pūl'mo-nār-ē rē-sūs'i-tā-shūn; **CPR**) also depends on a reasonable knowledge of the position of the heart.

Clinical IMPACT

Cardiopulmonary Resuscitation (CPR)

CPR is an emergency procedure that maintains blood flow in the body if a person's heart stops. CPR consists of firm and rhythmic compression of the chest combined with artificial ventilation of the lungs. This is a life-saving process, but it requires training for correct execution. The American Heart Association (AHA) has developed different guidelines for the specific CPR practice for infants, children or teens, and adults. Guidelines released in 2010 emphasize the importance of beginning with chest compressions. Individuals properly trained in CPR can then administer artificial ventilation. However, in an emergency situation involving a teen or an adult, an untrained individual may use the "hands-only" CPR method until emergency medical help arrives. The person firmly presses down on the sternum at a rate of at least 100 compressions per minute (about the tempo of the Bee Gees song "Staying Alive"). Applying pressure to the sternum compresses the chest wall, which also compresses the heart, causing it to pump blood. Hands-only CPR can provide an adequate blood supply to the heart wall and brain until emergency medical assistance arrives.

The heart lies obliquely in the mediastinum, with its base directed posteriorly and slightly superiorly and its apex directed anteriorly and slightly inferiorly. The apex is also directed to the left, so that approximately two-thirds of the heart's mass lies to the left of the midline of the sternum (figure 20.2). The base of the heart is located deep to the sternum and extends to the second intercostal space. The apex is located deep to the fifth intercostal space, approximately 7–9 centimeters (cm) to the left of the sternum and medial to the midclavicular line, a perpendicular line that extends down from the middle of the clavicle.

ASSESS YOUR PROGRESS

2. What is the approximate size and shape of the heart?
3. Where is the heart located? How does this knowledge assist in performing CPR?

20.3 Anatomy of the Heart

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the structure of the pericardium.
- B. List the layers of the heart wall and describe the structure and function of each.
- C. Relate the large veins and arteries that enter and exit the heart.

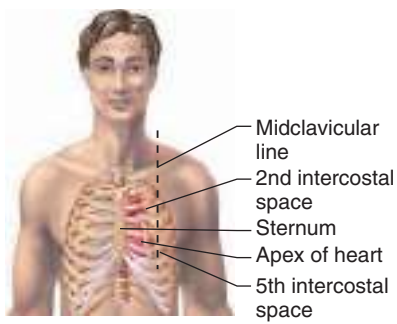

Clinical IMPACT

Pericarditis and Cardiac Tamponade

Pericarditis (per'i-kar-dī'tis) is an inflammation of the serous pericardium. The cause is frequently unknown, but it can result from infection, diseases of connective tissue, or damage due to radiation treatment for cancer. The condition can cause extremely painful sensations that are referred to the back and chest and can be confused with a myocardial infarction (heart attack). Pericarditis can lead to fluid accumulation within the pericardial sac.

Cardiac tamponade (tam-pō-nād') is a potentially fatal condition in which a large volume of fluid or blood accumulates in the pericardial cavity and compresses the heart from the outside. Although the heart is a powerful muscle, it relaxes passively. When it is compressed by fluid within the pericardial cavity, it cannot expand when the cardiac muscle relaxes. Consequently, it cannot fill with blood during relaxation; therefore, it cannot pump blood. Cardiac tamponade can cause a person to die quickly unless the fluid is removed. Causes of cardiac tamponade include rupture of the heart wall following a myocardial infarction, rupture of blood vessels in the pericardium after a malignant tumor has invaded the area, damage to the pericardium due to radiation therapy, and trauma, such as that resulting from a traffic accident.

D. Describe the location and blood flow through the coronary arteries and cardiac veins.

E. Review the structure and functions of the chambers of the heart.

F. Name the valves of the heart and state their locations and functions.

Pericardium

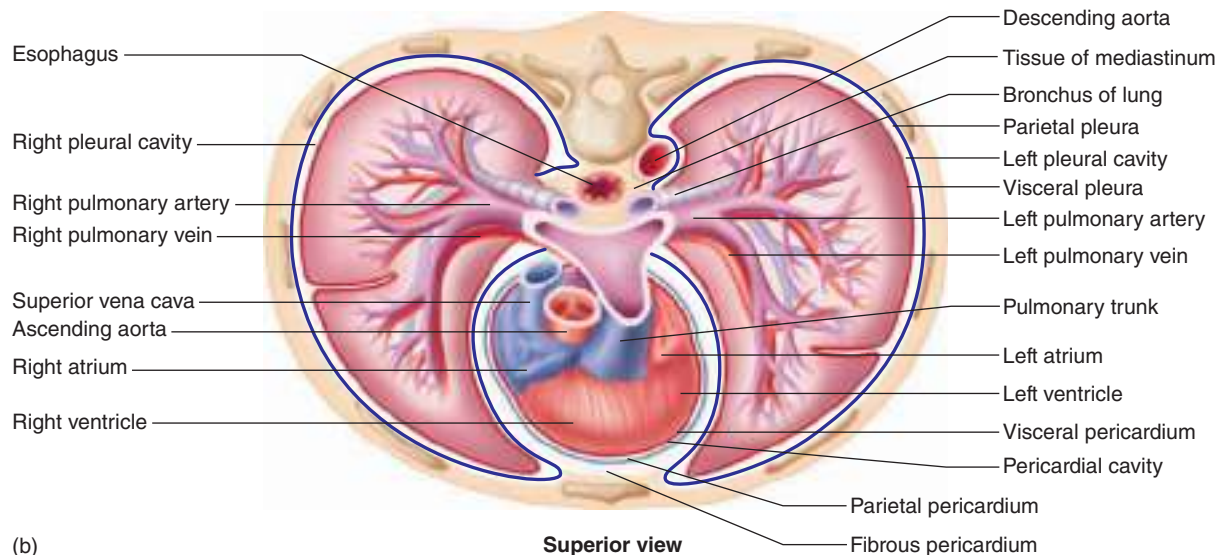

The **pericardium** (per-i-kar'dē-ŭm), or *pericardial sac*, is a double-layered, closed sac that surrounds the heart (figure 20.3). It consists of two layers: the outer **fibrous pericardium** and inner **serous pericardium**. The fibrous pericardium is a tough, fibrous connective tissue layer that prevents overdistension of the heart and anchors it within the mediastinum. Superiorly, the fibrous pericardium is continuous with the connective tissue coverings of the great vessels, and inferiorly it is attached to the surface of the diaphragm (see figure 20.2a). The serous pericardium is a layer of simple squamous epithelium.

The serous pericardium is further divided into two parts. The part of the serous pericardium lining the fibrous pericardium is the **parietal pericardium**, and the part covering the heart surface is the **visceral pericardium**, or *epicardium* (figure 20.3). The parietal and visceral portions of the serous pericardium are continuous with each other where the great vessels enter or leave the heart. The space between the visceral and parietal pericardia is the **pericardial cavity** and it is filled with a thin layer of serous **pericardial fluid**. This fluid helps reduce friction as the heart moves within the pericardial sac.

Even though the pericardium contains fibrous connective tissue, it can accommodate changes in heart size by gradually enlarging. The pericardial cavity can also increase in volume to hold a significant volume of pericardial fluid.

(a) **Anterior view**

(b)

Superior view

FIGURE 20.2 Location of the Heart in the Thorax

(a) The heart lies in the thoracic cavity between the lungs, deep to and slightly to the left of the sternum. The base of the heart, located deep to the sternum, extends to the second intercostal space, and the apex of the heart is deep to the fifth intercostal space, approximately 7–9 cm to the left of the sternum, or where the midclavicular line intersects with the fifth intercostal space (see inset). (b) Cross section of the thorax, showing the position of the heart in the mediastinum and its relationship to other structures. **APR**

FIGURE 20.3 Heart in the Pericardium

The heart is located in the pericardium, which consists of an outer fibrous pericardium and an inner serous pericardium. The serous pericardium has two parts: The parietal pericardium lines the fibrous pericardium, and the visceral pericardium (epicardium) covers the surface of the heart. The pericardial cavity, between the parietal and visceral pericardia, is filled with a small amount of pericardial fluid.

**Predict 2**

Over the weekend, Tony, 22 years old, developed severe chest pains that became worse with deep inhalations and when lying down. As his condition worsened over the next day, Tony became anxious and feared that he might be having a heart attack, so he had a friend drive him to the emergency room. The ER physician identified a low-grade fever, tachycardia (increased heart rate), and a weak and rapid pulse. A chest x-ray showed distension of the jugular veins and pericardial space. The ER physician diagnosed pericarditis, which was probably due to a viral infection, and performed pericardiocentesis to drain the excess fluid from the pericardium. Explain the manifestations that the physician observed, describe how she drained the excess fluid with a needle, and name the body layers the needle penetrated.

Heart Wall

The heart wall is composed of three layers of tissue: (1) the epicardium, (2) myocardium, and (3) endocardium (figure 20.4). The **epicardium** (ep-i-kar'dē-ŭm), or *visceral pericardium*, is the superficial layer of the heart wall. It is a thin serous membrane that constitutes the smooth, outer surface of the heart. The serous pericardium is called the epicardium when considered a part of the heart and the visceral pericardium when considered a part of the pericardium. The **myocardium** (mī-ō-kar'dē-ŭm) is the thick, middle layer of the heart. It is composed of cardiac muscle cells and is responsible for the heart's ability to contract. The **endocardium** (en-dō-kar'dē-ŭm) is deep to the myocardium. It consists of simple squamous epithelium over a layer of connective tissue. The endocardium forms the smooth, inner surface of the heart chambers, which allows blood to move easily through the heart. The endocardium also covers the surfaces of the heart valves.

Ridges formed by the myocardium can be seen on the internal surfaces of the heart chambers. The interior surfaces of the atria

**FIGURE 20.4 Heart Wall**

Part of the wall of the heart has been removed, enlarged, and rotated, so that its inner surface is visible. The enlarged section illustrates the epicardium (visceral pericardium), myocardium, and endocardium. **APR**

are mainly flat, but the interior of both auricles and a part of the right atrial wall contain muscular ridges called **pectinate** (pek'ti-nāt) **muscles**. The pectinate muscles of the right atrium are separated from the larger, smooth portions of the atrial wall by a ridge called the **crista terminalis** (kris'tā ter'mi-nal'is; terminal crest). The interior walls of the ventricles contain larger, muscular ridges and columns called **trabeculae** (tră-bek'ū-lē; beams) **carneae** (kar'nē-ē; flesh).

External Anatomy and Coronary Circulation

The heart consists of four chambers: two **atria** (ā'trē-ă; sing. *atrium*) and two **ventricles** (ven'tri-klz). The thin-walled atria form the superior and posterior parts of the heart, and the thick-walled ventricles form the anterior and inferior portions (figure 20.5). **Auricles** (aw'ri-klz; ears) are flaplike extensions of the atria that can be seen anteriorly between each atrium and ventricle. The entire atrium used to be called the auricle, and some medical personnel still refer to it as such.

Blood enters the atria of the heart through several large veins. The **superior vena cava** (vē'nā kā'vā) and the **inferior vena cava** carry blood from the body to the right atrium. In addition, the

smaller coronary sinus carries blood from the walls of the heart to the right atrium. Four **pulmonary veins** carry blood from the lungs to the left atrium.

Blood leaves the ventricles of the heart through two arteries: the **pulmonary trunk** and the **aorta**. The pulmonary trunk carries blood from the right ventricle to the lungs. The aorta carries blood from the left ventricle to the body. Because of their large size, the pulmonary trunk and aorta are often called the great arteries.

The coronary circulation consists of blood vessels that carry blood to and from the tissues of the heart wall. The major vessels of the coronary circulation lie in several grooves, or sulci, on the surface of the heart. A large **coronary** (kōr'o-nār-ē; circling like a crown) **sulcus** (sool'kūs; ditch) runs obliquely around the heart, separating the atria from the ventricles. Two more sulci extend inferiorly from the coronary sulcus, indicating the division between the right and left ventricles. The **anterior interventricular sulcus** (*groove*) is on the anterior surface of the heart, extending from the coronary sulcus toward the apex of the heart (figure 20.5*a,b*). The **posterior interventricular sulcus** (*groove*) is on the posterior surface of the heart, extending from the coronary sulcus toward the apex of the heart (figure 20.5*c*). In a healthy, intact heart, the sulci are covered by adipose tissue, and only after this tissue is removed can they be seen.

FIGURE 20.5 Surface View of the Heart

(a) The two atria (right and left) are located superiorly, and the two ventricles (right and left) are located inferiorly. The superior and inferior venae cavae enter the right atrium. The pulmonary veins enter the left atrium. The pulmonary trunk exits the right ventricle, and the aorta exits the left ventricle. **APR**

**FIGURE 20.5 (continued)**

(b) Photograph of the anterior surface of the heart. (c) The two atria (right and left) are located superiorly, and the two ventricles (right and left) are located inferiorly. The superior and inferior venae cavae enter the right atrium, and the four pulmonary veins enter the left atrium. The pulmonary trunk divides, forming the left and right pulmonary arteries.

The major arteries supplying blood to the tissue of the heart lie within the coronary sulcus and interventricular sulci on the surface of the heart. The **right and left coronary arteries** exit the aorta just above the point where the aorta leaves the heart. These vessels lie within the coronary sulcus (figure 20.6a). The right coronary artery is usually smaller in diameter than the left one, and it does not carry as much blood as the left coronary artery.

The left coronary artery has three major branches. The first major branch of the left coronary artery is the **anterior interventricular artery**, or the *left anterior descending artery*. It extends inferiorly in the anterior interventricular sulcus and supplies blood to most of the anterior part of the heart. The second major branch of the left coronary artery is the **left marginal artery**, which supplies blood to the lateral wall of the left ventricle. The third major branch of the left coronary artery is the **circumflex (ser'kūm-fleks) artery**, which extends around to the posterior side of the heart in the coronary sulcus. Branches of the circumflex artery supply blood to much of the posterior wall of the heart.

The right coronary artery lies within the coronary sulcus and extends from the aorta around to the posterior part of the heart. There are two major branches of the right coronary artery. A larger branch of the right coronary artery, called the **right marginal artery**, and other branches supply blood to the lateral wall of the right ventricle. A second branch of the right coronary artery, called the **posterior interventricular artery**, lies in the posterior

interventricular sulcus and supplies blood to the posterior and inferior part of the heart.

Most of the myocardium receives blood from more than one arterial branch. In addition, the coronary circulation includes many **anastomoses**, or direct connections between arteries. These anastomoses may form either between branches of a given artery or between branches of different arteries. As a result of these many connections among the coronary arteries, if one artery becomes blocked, the areas primarily supplied by that artery may still receive some blood through other arterial branches and anastomoses. The density of blood vessels supplying blood to the myocardium increases with aerobic exercise, as do the number and extent of the anastomoses. Consequently, aerobic exercise increases the chance that a person will survive the blockage of a small coronary artery. The blockage of larger coronary blood vessels still has the potential to permanently damage large areas of the heart wall.

The coronary circulation also includes veins that carry the blood from the heart walls to the right atrium. There are two major veins draining the blood from the heart wall tissue. The **great cardiac vein** drains blood from the left side of the heart. A **small cardiac vein** drains the right margin of the heart (figure 20.6b). These veins converge toward the posterior part of the coronary sulcus and empty into a large venous cavity called the **coronary sinus**, which in turn empties into the right atrium. A number of smaller veins empty into the cardiac veins, into the coronary sinus, or directly into the right atrium.

(b) Veins draining blood from the heart. The veins of the anterior surface are seen directly and are darker in color; the veins of the posterior surface are seen through the heart and are lighter in color. **APR**

Blood flow through the coronary blood circulation is not continuous. When the cardiac muscle contracts, blood vessels in the wall of the heart are compressed so blood does not readily flow through them. When the cardiac muscle relaxes, the blood vessels are not compressed, and blood flow through the coronary blood vessels resumes.

In a resting person, blood flowing through the coronary arteries gives up approximately 70% of its oxygen. In comparison, blood flowing through arteries to skeletal muscle gives up only about 25% of its oxygen. The percentage of oxygen the blood releases to skeletal muscle can increase to 70% or more during exercise. Because the percentage of oxygen delivered to cardiac muscle is near its maximum at rest, it cannot increase substantially during exercise. Therefore, cardiac muscle requires blood to flow through the coronary arteries at a higher rate than its resting level in order to provide an adequate oxygen supply during exercise.

ASSESS YOUR PROGRESS

- Describe the parts of the pericardium and their functions.
- Describe the three layers of the heart wall, and state their functions.
- Name the chambers of the heart, and describe their structures. What is an auricle?
- List the major blood vessels that enter and leave the heart. Which chambers do they enter or exit?
- Describe the flow of blood through the coronary arteries and their branches.
- Trace the flow of blood through the cardiac veins.

Heart Chambers and Valves

Right and Left Atria

The **right atrium** has three major openings: The openings from the superior vena cava and the inferior vena cava receive blood from the body, and the opening of the coronary sinus receives blood from the heart itself (figure 20.7). The **left atrium** has four relatively uniform openings from the four pulmonary veins that receive blood from the lungs.

The right and left atria are separated from each other by the wall of tissue called the **interatrial septum**. The **fossa ovalis** (fos'ă ō-va'lis) is a slight, oval depression on the right side of the interatrial septum marking the former location of the **foramen ovale** (ō-va'lē), an opening between the right and left atria in the embryo and the fetus. In the fetal heart, this opening allows blood to flow from the right to the left atrium and bypass the pulmonary circulation (see chapter 29).

Right and Left Ventricles

The atria open into the ventricles through **atrioventricular canals** (figure 20.7). Each ventricle has one large, superiorly placed out-flow route near the midline of the heart. Blood flows from the **right ventricle** into the pulmonary trunk and from the **left ventricle** into the aorta. The two ventricles are separated from each other by the **interventricular septum**, which has a thick, muscular part toward the apex and a thin, membranous part toward the atria. The wall of the left ventricle is much thicker than the wall of the right ventricle (figure 20.7). The thicker wall of the ventricle allows for stronger contractions to pump blood through the systemic circulation.

FIGURE 20.7 Internal Anatomy of the Heart

The heart is cut in a frontal plane to show the internal anatomy. **APR**

Atrioventricular Valves

An **atrioventricular valve** is in each atrioventricular canal and is composed of cusps, or flaps. Atrioventricular valves ensure blood flows from the atria into the ventricles, preventing blood from flowing back into the atria. The atrioventricular valve between the right atrium and the right ventricle is called the **tricuspid valve** (trī -kūs'pid) because it consists of three cusps (figures 20.7 and 20.8a). The atrioventricular valve between the left atrium and the left ventricle is called the **bicuspid valve** (bī-kūs'pid) because it has two cusps. Another common term for the bicuspid valve is the *mitral valve* (mī'trāl) valve (figures 20.7 and 20.8b).

Each ventricle contains cone-shaped, muscular pillars called **papillary muscles** (pap'i-lār-ē; nipple) muscles. These muscles are attached to the cusps of the atrioventricular valves by thin, strong connective tissue strings called **chordae tendineae** (kōr'dē ten'di-nē-ē; heart strings) (figures 20.7 and 20.8a). The papillary muscles contract when the ventricles contract and prevent the valves from opening into the atria by pulling on the chordae tendineae attached to the valve cusps. Blood flowing from the atrium into the ventricle pushes the valve open into the ventricle; however, when the ventricle contracts,

blood pushes the valve back toward the atrium. The atrioventricular canal is closed as the valve cusps meet (figure 20.9).

Semilunar Valves

A semilunar (sem-ē-loo'när; half-moon-shaped) valve is positioned between each ventricle and its associated great artery. The semilunar valves are identified by the great artery in which each is located and include the **aortic semilunar valve** and **pulmonary semilunar valve**. Each valve consists of three pocketlike, semilunar cusps, the free inner borders of which meet in the center of the artery to block blood flow (see figures 20.7 and 20.8b). Contraction of the ventricles pushes blood against the semilunar valves, forcing them to open. Blood can then enter the great arteries. However, when blood flows back from the aorta or pulmonary trunk toward the ventricles, it enters the pockets of the cusps, causing the cusps to meet in the center of the aorta or pulmonary trunk. This effectively closes the semilunar valves and prevents blood from flowing back into the ventricles (figure 20.9a).

20.4 Route of Blood Flow Through the Heart

LEARNING OUTCOME

After reading this section, you should be able to

A. Relate the flow of blood through the heart, naming the chambers, valves, and vessels in the correct order.

Blood flow through the heart is depicted in figure 20.10. Even though it is more convenient to discuss blood flow through the heart one side at a time, it is important to understand that blood flows through both sides simultaneously. Both atria contract at about the same time and both ventricles contract at about the same time, moving blood through the pulmonary and systemic circulations. This concept is particularly important when electrical activity, pressure changes, and heart sounds are discussed later in this chapter.

(a) Valve positions when blood is flowing into the left ventricle.

- 1 The bicuspid valve is open. The cusps of the valve are pushed by the blood into the ventricle.
- 2 The aortic semilunar valve is closed. The cusps of the valve overlap as they are pushed by the blood in the aorta toward the ventricle.

(b) Valve positions when blood is flowing out of the left ventricle.

- 1 The bicuspid valve is closed. The cusps of the valves overlap as they are pushed by the blood toward the left atrium.
- 2 The aortic semilunar valve is open. The cusps of the valve are pushed by the blood toward the aorta.

PROCESS FIGURE 20.9 Function of the Heart Valves

(a) Valve positions when blood is flowing into the left ventricle. (b) Valve positions when blood is flowing out of the left ventricle. Numbered steps show the functions of the bicuspid and aortic semilunar valves. The tricuspid and pulmonary semilunar valves (not shown) open and close in a similar pattern.

Blood enters the relaxed right atrium from the systemic circulation, which returns blood from all the tissues of the body. Most of the blood in the right atrium then passes into the relaxed right ventricle. The right atrium then contracts, pushing most of the remaining blood in the atrium into the right ventricle to complete right ventricular filling.

Contraction of the right ventricle pushes blood against the tricuspid valve, forcing it closed. Closing of the tricuspid valve prevents blood from moving back into the right atrium. Blood also pushes against the pulmonary semilunar valve, forcing it open. Blood then flows into the pulmonary trunk.

The pulmonary trunk branches to form the **pulmonary arteries** (see figure 20.5), which carry blood to the lungs, where carbon dioxide is released and oxygen is picked up (see chapters 21 and 23). Blood returning from the lungs enters the left atrium through the four pulmonary veins. Contraction of the left atrium completes left ventricular filling.

Contraction of the left ventricle pushes blood against the bicuspid valve, closing it and preventing blood from moving back into the left atrium. Blood is also pushed against the aortic semilunar valve, opening it and allowing blood to enter the aorta. Blood flowing through the aorta is distributed to all parts of the body, except to the parts of the lungs supplied by the pulmonary blood vessels (see chapter 23).

15. Starting at the *venae cavae* and ending at the *aorta*, trace the flow of blood through the heart.

20.5 Histology

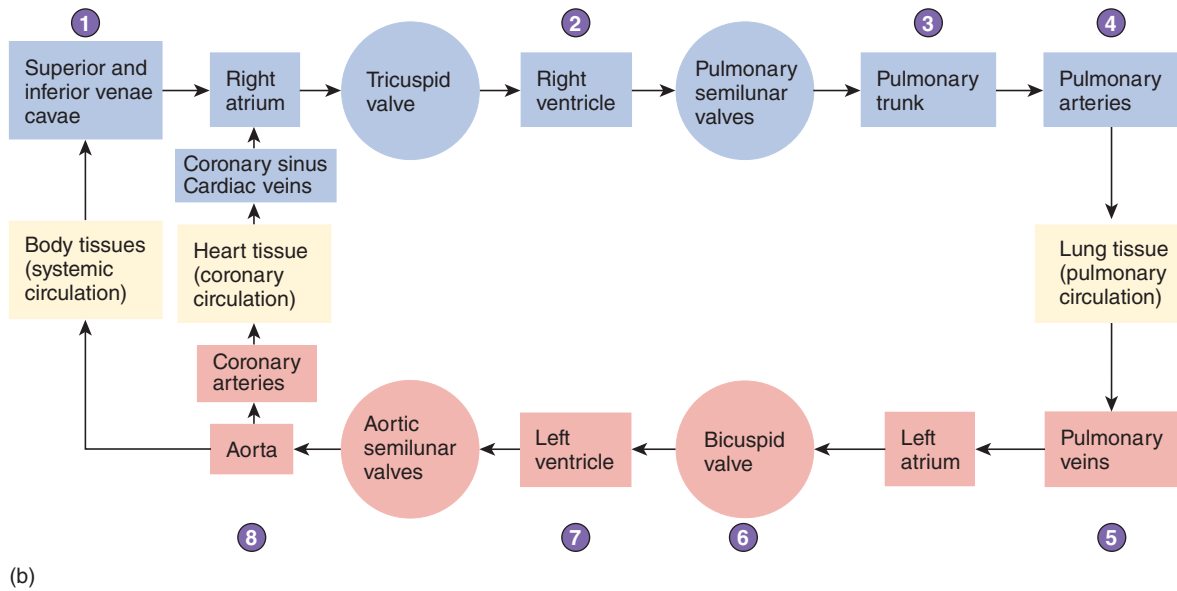

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the structure and functions of the heart skeleton.
- B. Relate the structural and functional characteristics of cardiac muscle cells.
- C. Compare and contrast cardiac muscle and skeletal muscle.
- D. Explain the structure and function of the conducting system of the heart.

Heart Skeleton

The **heart skeleton** consists of a plate of fibrous connective tissue between the atria and the ventricles. This connective tissue plate forms **fibrous rings** around the atrioventricular and semilunar valves and provides solid support for them, reinforcing the valve

PROCESS FIGURE 20.10 Blood Flow Through the Heart

The heart valves are indicated by circles; deoxygenated blood appears blue, and oxygenated blood appears red.

openings (figure 20.11). The fibrous connective tissue plate also serves as electrical insulation between the atria and the ventricles and provides a rigid site for attachment of the cardiac muscles.

Cardiac Muscle

Cardiac muscle cells are elongated, branching cells that have one, or occasionally two, centrally located nuclei. Cardiac muscle cells contain actin and myosin myofilaments organized to form

sarcomeres, which join end-to-end to form myofibrils (see chapter 9). The actin and myosin myofilaments are responsible for muscle contraction, and their organization gives cardiac muscle a striated (banded) appearance. The striations are less regularly arranged and less numerous than in skeletal muscle (figure 20.12).

Cardiac muscle cell contraction is very similar to that of skeletal muscle; however, the onset of contraction is longer and prolonged in cardiac muscle. These differences in contraction are partially due to differences in cell anatomy. Cardiac muscle has

FIGURE 20.11 Heart Skeleton

The skeleton of the heart consists of fibrous connective tissue rings, which surround the heart valves and separate the atria from the ventricles. Cardiac muscle attaches to the fibrous connective tissue. The muscle fibers are arranged so that contraction of the ventricles produces a wringing motion and the distance between the apex and the base of the heart shortens.

a smooth **sarcoplasmic reticulum**, which stores Ca^{2+} , similar to skeletal muscle. But the sarcoplasmic reticulum is not as regularly arranged as in skeletal muscle fibers, and there are no dilated cisternae, as in skeletal muscle. We learned in chapter 9 that stimulations of the skeletal muscle at the sarcolemma, or cell membrane, are carried deep into the cell by transverse tubules. Similarly, cardiac muscles have transverse tubules that are in close association with the sarcoplasmic reticulum. However, the T tubules in cardiac muscle are larger in diameter than in skeletal muscle, and extensions of T tubules are not as closely associated with the sarcoplasmic reticulum as in skeletal muscle. Also, the T tubules of cardiac muscle are found near the Z disks of the sarcomeres, instead of where the actin and myosin overlap, as in skeletal muscle. Given these structural differences, depolarizations of the cardiac muscle plasma membrane are not carried from the surface of the cell to the sarcoplasmic reticulum as efficiently as they are in skeletal muscle, and Ca^{2+} must diffuse a greater distance from the sarcoplasmic reticulum to the actin myofilaments. Another important difference between cardiac muscle and skeletal muscle is the sources for Ca^{2+} necessary for contraction. In skeletal muscle, adequate Ca^{2+} for contraction is stored in the sarcoplasmic reticulum, but cardiac muscle requires some Ca^{2+} from the extracellular fluid and from the T tubules.

Cardiac muscle is specialized to meet the high energy requirements needed for proper myocardial function. Adenosine triphosphate (ATP) provides the energy for cardiac muscle contraction. ATP production depends on oxygen availability. Because cardiac muscle must continue to contract and relax in a relatively steady rhythm to maintain life, it cannot develop a large oxygen deficit, which is often seen in skeletal muscle. Cardiac muscle cells are rich in mitochondria, which perform oxidative metabolism at a rate rapid enough to sustain normal myocardial energy requirements.

Also, the myocardium has an extensive capillary network that provides an adequate oxygen supply to the cardiac muscle cells.

Another unique characteristic of cardiac muscle is that cardiac muscle cells are organized in spiral bundles or sheets. Additionally, cardiac cells are bound to adjacent cells by specialized cell-to-cell contacts called **intercalated** (in-ter'kă-lā-ted) **disks** (figure 20.12). Intercalated disks are located at the ends of cells, connecting them end-to-end; however, intercalated disks can also connect cells laterally. At intercalated disks, the plasma membranes are folded, and the adjacent cells fit together, thus greatly increasing contact between them. In addition, specialized plasma membrane structures at the intercalated disks increase physical and electrical connections between cells. These plasma membrane structures include desmosomes and gap junctions. **Desmosomes** (dez'mō-sōmz) hold the cells together, and **gap junctions** allow cytoplasm to flow freely between cells, resulting in areas of low electrical resistance between the cells. This enables action potentials to pass easily from one cell to the next (see figure 4.2). Electrically, the cardiac muscle cells behave as a single unit, and the heart's highly coordinated contractions depend on this functional characteristic.

Conducting System

A conducting system relays action potentials through the heart. This system consists of modified cardiac muscle cells that form two nodes (knots or lumps) and a conducting bundle (figure 20.13). The two nodes are contained within the walls of the right atrium and are named according to their position in the atrium. The **sinoatrial (SA) node** is medial to the opening of the superior vena cava, and the **atrioventricular (AV) node** is medial to the right atrioventricular valve. The AV node gives rise to a conducting bundle of the heart, the **atrioventricular (AV) bundle** (bundle of His). This bundle passes through a small opening in the fibrous skeleton to reach the interventricular septum, where it divides to form the **right** and **left bundle branches**, which extend beneath the endocardium on each side of the interventricular septum to the apex of both the right and the left ventricles.

The inferior terminal branches of the bundles are called **Purkinje** (per-kin'jē) **fibers**. These fibers are large-diameter cardiac muscle fibers. They have fewer myofibrils than most cardiac muscle cells and do not contract as forcefully. Intercalated disks are well developed between the Purkinje fibers and contain numerous gap junctions. As a result of these structural modifications, action potentials travel along the Purkinje fibers much more rapidly than through other cardiac muscle tissue.

Unlike skeletal muscle cells that require neural stimulation for contraction, cardiac muscle cells have the intrinsic capacity to spontaneously generate action potentials for contraction. Because cells of the SA node spontaneously generate action potentials at a greater frequency than other cardiac muscle cells, these cells are called the **pacemaker** of the heart. The SA node is made up of specialized, small-diameter cardiac muscle cells that merge with the other cardiac muscle cells of the right atrium. Once action potentials are produced, they spread from the SA node to adjacent cardiac muscle fibers of the atrium. Preferential pathways conduct action potentials from the SA node to the AV node at a greater velocity than they are transmitted in the remainder of the atrial muscle fibers.

FIGURE 20.12 Histology of the Heart

(a) Cardiac muscle cells are branching cells with centrally located nuclei. The cells are joined to one another by intercalated disks. Gap junctions in the intercalated disks allow action potentials to pass from one cardiac muscle cell to the next. (b) A light micrograph of cardiac muscle tissue. The cardiac muscle fibers appear striated because of the arrangement of the individual myofilaments. (c) As in skeletal muscle, sarcomeres join end-to-end to form myofibrils, and mitochondria provide ATP for contraction. Sarcoplasmic reticulum and T tubules are visible but are not as numerous as they are in skeletal muscle. **APR**

However, such pathways cannot be distinguished structurally from the remainder of the atrium. It is the activity of the SA node that causes the heart to contract spontaneously and rhythmically.

When the heart beats under resting conditions, approximately 0.04 second is required for action potentials to travel from the SA node to the AV node. Action potentials are propagated slowly through the AV node, compared with the remainder of the conducting system. The slow rate of action potential conduction in the AV node is due, in part, to the smaller-diameter muscle fibers and fewer gap junctions in their intercalated disks. Like the other specialized conducting fibers in the heart, they have fewer myofibrils than most cardiac muscle cells. As a consequence, a delay of 0.11 second occurs from the time action potentials reach the AV node until they pass to the AV bundle. The delay of action potentials at the AV node allows for completion of the atrial contraction before ventricular contraction begins.

After action potentials pass from the AV node to the highly specialized conducting bundles, the velocity of conduction increases dramatically. The action potentials pass through the left and right

bundle branches and through the individual Purkinje fibers that penetrate the myocardium of the ventricles (figure 20.13).

Because of the arrangement of the conducting system in the ventricles, the first part of the ventricular myocardium that is stimulated is the inner wall of the ventricles near the apex. Thus, ventricular contraction begins at the apex and progresses throughout the ventricles toward the base of the heart. The spiral arrangement of muscle layers in the wall of the heart results in a wringing action. During the process, the distance between the apex and the base of the heart decreases and blood is forced upward from the apex toward the great vessels at the base of the heart (see figure 20.10).

► Predict 3

Because of a reduced blood supply to the AV node, the delay in the conduction of action potentials from the SA node to the AV node is increased slightly. All other areas of the conducting system of the heart are functioning normally. Predict how this affects the normal rhythm of the heart.

1 Action potentials originate in the sinoatrial (SA) node (the pacemaker) and travel across the wall of the atrium (arrows) from the SA node to the atrioventricular (AV) node.

2 Action potentials pass through the AV node and along the atrioventricular (AV) bundle, which extends from the AV node, through the fibrous skeleton, into the interventricular septum.

3 The AV bundle divides into right and left bundle branches, and action potentials descend to the apex of each ventricle along the bundle branches.

4 Action potentials are carried by the Purkinje fibers from the bundle branches to the ventricular walls and papillary muscles.

17. Compare and contrast cardiac muscle and skeletal muscle.
18. Why does cardiac muscle have slow onset of contraction and prolonged contraction?
19. What anatomical features are responsible for the ability of cardiac muscle cells to contract as a unit?
20. Identify the parts of the conducting system of the heart. Explain how the conducting system coordinates contraction of the atria and ventricles.
21. Explain why Purkinje fibers conduct action potentials more rapidly than other cardiac muscle cells.
22. Relate why the SA node is the pacemaker of the heart.

C. Explain the importance of a long refractory period in cardiac muscle.

D. Describe the waves and intervals of an electrocardiogram.

In chapter 3, we defined the membrane potential of a cell as the electrical charge difference across the plasma membrane. This charge difference is the result of a cell's regulation of ion movement into and out of the cell. Cardiac muscle cells—like other electrically excitable cells, such as neurons and skeletal muscle fibers—have a **resting membrane potential**, the membrane potential when the cell is relaxed. The resting membrane potential depends on a low permeability of the plasma membrane to Na^+ and Ca^{2+} and a higher permeability to K^+ . When neurons, skeletal muscle fibers, and cardiac muscle cells are depolarized to their threshold level, action potentials result (see chapter 11).

20.6 Electrical Properties

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Summarize the characteristics of action potentials in cardiac muscle.
- B. Explain what is meant by the autorhythmicity of cardiac muscle and relate it to the pacemaker potential.

Action Potentials

Like action potentials in skeletal muscle, those in cardiac muscle exhibit depolarization followed by repolarization of the resting membrane potential. Alterations in membrane channels are responsible for the changes in the permeability of the plasma membrane that produce the action potentials. Action potentials in cardiac muscle last longer than those in skeletal muscle, and the membrane channels differ somewhat from those in skeletal muscle. In contrast to action potentials in skeletal muscle, which take less than 2 milliseconds (ms) to complete, action potentials in

Clinical IMPACT

Angina, Infarctions, and the Treatment of Blocked Coronary Arteries

Angina pectoris (an'ji-nă, an-jī'nă pek'tō-ris) is chest pain that results from a reduced blood supply to cardiac muscle. The pain is temporary and, if blood flow is restored, little permanent change or damage results. Angina pectoris is characterized by chest discomfort deep to the sternum, often described as heaviness, pressure, or moderately severe pain. It is often mistaken for indigestion. The pain can also be referred to the neck, lower jaw, left arm, and left shoulder (see chapter 14).

Most often, angina pectoris results from narrowed and hardened coronary arterial walls. The reduced blood flow results in a reduced supply of oxygen to cardiac muscle cells. As a consequence, the limited anaerobic respiration of cardiac muscle results in a reduced pH in affected areas of the heart, which stimulates pain receptors. The pain is predictably associated with exercise because the increased pumping of the heart requires more oxygen, and the narrowed blood vessels cannot supply it.

Rest and drugs, such as nitroglycerin, frequently relieve angina pectoris. Nitroglycerin dilates the blood vessels, including the coronary arteries. Consequently, the drug increases the oxygen supply to cardiac muscle and reduces the heart's workload. Because peripheral arteries are dilated, the heart has to pump blood against a lower pressure, and the need for oxygen decreases. The heart also pumps less blood because blood tends to remain in the dilated blood vessels and less blood is returned to the heart.

Myocardial infarction (mī-ō-kar'dē-ăl in-fark'shūn) results when a prolonged lack of blood flow to a part of the cardiac muscle leads to a lack of oxygen and ultimately cellular

death. Symptoms of myocardial infarction include chest pain that radiates into the left shoulder and arm, shortness of breath, nausea, vomiting, and sweating. Interestingly, these symptoms are common in men, but women may experience very different symptoms. Over 40% of women who have suffered a myocardial infarction did not experience chest pain. Symptoms for women include sudden fatigue, dizziness, and abdominal pain.

Myocardial infarctions vary in severity, depending on the amount of cardiac muscle and the part of the heart that is affected. If blood supply to cardiac muscle is reestablished within 20 minutes, no permanent damage occurs. If the oxygen deficiency lasts longer, cell death results. However, within 30–60 seconds after blockage of a coronary blood vessel, functional changes are obvious. The electrical properties of the cardiac muscle are altered, and the heart's ability to function properly is lost.

The most common cause of myocardial infarction is thrombus formation that blocks a coronary artery. Coronary arteries narrowed by **atherosclerotic** (ath'er-ō-skler-ot'ik) **lesions** increase the risk for myocardial infarction. Atherosclerotic lesions partially block blood vessels, resulting in turbulent blood flow, and the surfaces of the lesions are rough. These changes increase the probability of thrombus formation.

Blocked blood vessels can be treated using various medical techniques. **Angioplasty** (an'jē-ō-plas-tē) is a process whereby a surgeon threads a small balloon, usually into the femoral artery (see chapter 21), through the aorta and into a coronary artery. After entering the partially occluded coronary artery, the balloon is inflated, flattening the atherosclerotic

deposits against the vessel walls and opening the occluded blood vessel. This technique improves the function of cardiac muscle in patients experiencing inadequate blood flow to the cardiac muscle through the coronary arteries. However, some controversy exists about its effectiveness. At least in some patients, dilation of the coronary arteries can reverse within a few weeks or months, and blood clots can form in coronary arteries following angioplasty. To help prevent future blockage, a metal-mesh tube called a **stent** is inserted into the vessel. Although the stent is better able to hold the vessel open, it, too, can eventually become blocked. Small, rotating blades and lasers are also used to remove lesions from coronary vessels.

Coronary bypass is a surgical procedure that relieves the effects of obstructed coronary arteries. This technique involves taking healthy segments of blood vessels from other parts of the patient's body and using them to bypass obstructions in the coronary arteries. The technique is common in cases of severe occlusion in specific parts of coronary arteries.

Enzymes are used to break down blood clots that form in the coronary arteries and cause myocardial infarctions. The major enzyme used is **tissue plasminogen** (plaz-min'ō-jen) **activator (t-PA)**. This enzyme activates plasminogen, an inactive form of an enzyme in the body that breaks down the fibrin of clots. The strategy calls for administering t-PA to people suffering from myocardial infarctions as soon as possible following the onset of symptoms. Removal of the occlusions produced by clots reestablishes blood flow to the cardiac muscle and reduces the amount of cardiac muscle permanently damaged by the occlusions.

cardiac muscle take approximately 200–500 ms to complete (figure 20.14).

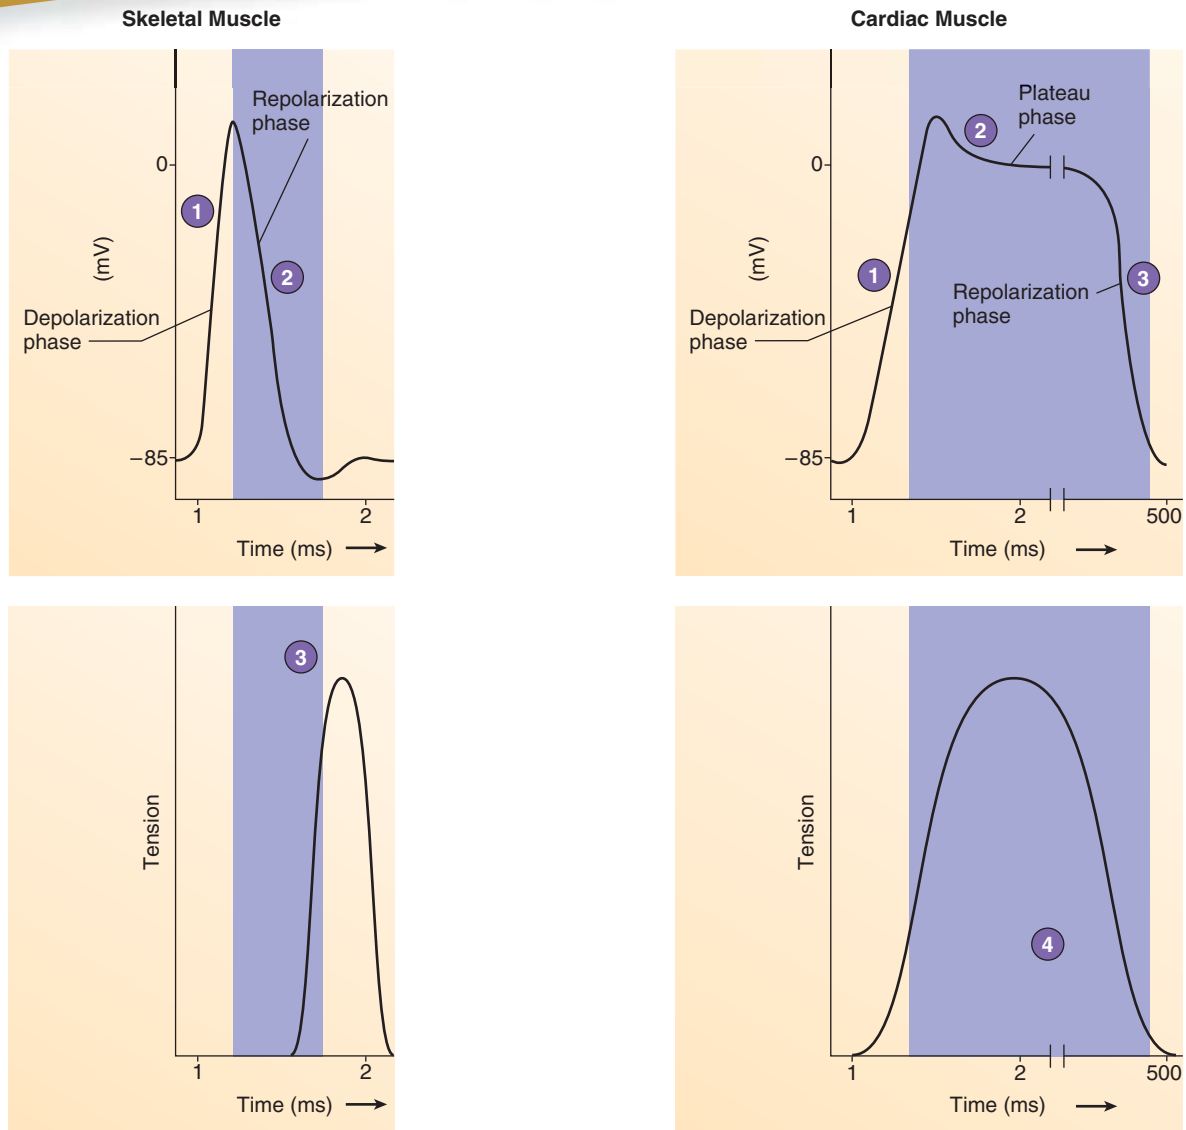

The longer action potentials in cardiac muscle can be divided into several phases, each associated with specific changes in ion movement across the membrane. In cardiac muscle, the action potential consists of a rapid **depolarization phase**, followed by a rapid but partial **early repolarization phase**. Then a prolonged period of slow repolarization occurs, called the **plateau phase**. At the end of the plateau phase, a more rapid **final repolarization phase** takes place, during which the membrane potential returns to its resting level (figure 20.14).

Rapid depolarization is the result of changes in membrane permeability to Na^+ , K^+ , and Ca^{2+} ; however, membrane permeability to Na^+ is the primary determinant of this phase. Membrane

channels, called **voltage-gated Na^+ channels**, open, bringing about the depolarization phase of the action potential. As the voltage-gated Na^+ channels open, Na^+ diffuses into the cell, causing rapid depolarization until the cell is depolarized to approximately +20 millivolts (mV).

The voltage change occurring during depolarization affects other ion channels in the plasma membrane. Several types of **voltage-gated K^+ channels** exist, each of which opens and closes at different membrane potentials, causing changes in membrane permeability to K^+ . For example, at rest, the movement of K^+ through open voltage-gated K^+ channels is primarily responsible for establishing the resting membrane potential in cardiac muscle cells. Depolarization causes these voltage-gated K^+ channels to close, thereby decreasing membrane permeability to K^+ .

FUNDAMENTAL Figure

- 2 Early repolarization and plateau phases**
- Voltage-gated Na^+ channels close.
 - Some voltage-gated K^+ channels open, causing early repolarization.
 - Voltage-gated Ca^{2+} channels are open, producing the plateau by slowing further repolarization.
- 3 Final repolarization phase**
- Voltage-gated Ca^{2+} channels close.
 - Many voltage-gated K^+ channels open.
- 4 Refractory period effect on tension**
- Cardiac muscle contracts and relaxes almost completely during the refractory period (purple shaded area).

PROCESS FIGURE 20.14 Comparison of Action Potentials in Skeletal and Cardiac Muscle

(a) An action potential in skeletal muscle consists of depolarization and repolarization phases. (b) An action potential in cardiac muscle consists of depolarization, early repolarization, plateau, and final repolarization phases. Cardiac muscle does not repolarize as rapidly as skeletal muscle (indicated by the *break in the curve*) because of the plateau phase.

Depolarization also causes **voltage-gated Ca^{2+}** channels to begin to open. These changes contribute to depolarization. Compared with Na^+ channels, the Ca^{2+} channels open and close slowly.

Repolarization is also the result of changes in membrane permeability to Na^+ , K^+ , and Ca^{2+} . Early repolarization occurs when the voltage-gated Na^+ channels and some voltage-gated Ca^{2+} channels close, and a small number of voltage-gated K^+ channels open. Sodium ion movement into the cell slows, and some K^+ moves out of the cell. At this point, repolarization begins, but in cardiac muscle early repolarization is slow due to the influx of Ca^{2+} , resulting in a plateau phase. The plateau phase occurs as voltage-gated Ca^{2+} channels remain open, and the movement of Ca^{2+} and some Na^+ through the voltage-gated Ca^{2+} channels into the cell counteracts the potential change produced by the movement of K^+ out of the cell. The plateau phase ends, and final repolarization begins as the voltage-gated Ca^{2+} channels close and many more voltage-gated K^+ channels open. Thus, Ca^{2+} and Na^+ stop diffusing into the cell, and the tendency for K^+ to diffuse out of the cell increases. These permeability changes cause the membrane potential to return to its resting level.

Action potential propagation in cardiac muscle differs from that in skeletal muscle. First, action potentials in cardiac muscle are conducted from cell to cell through the gap junctions of the intercalated disks, whereas action potentials in skeletal muscle fibers are conducted along the length of a single muscle fiber (cell), but not from fiber to fiber. Second, action potential propagation is slower in cardiac muscle than in skeletal muscle because cardiac muscle cells are smaller in diameter and much shorter than skeletal muscle fibers. Although the gap junctions allow the transfer of action potentials between cardiac muscle cells, they slow the rate of action potential conduction between the cardiac muscle cells.

Another interesting characteristic of cardiac muscle contraction is the need for extracellular Ca^{2+} for contraction to occur. The movement of Ca^{2+} through the plasma membrane, including the membranes of the T tubules, into cardiac muscle cells stimulates the release of Ca^{2+} from the sarcoplasmic reticulum, a process called **calcium-induced calcium release (CICR)**. When an action

potential occurs in a cardiac muscle cell, Ca^{2+} enters the cell and binds to receptors in the membranes of the sarcoplasmic reticulum, resulting in the opening of Ca^{2+} channels. Calcium ions then move out of the sarcoplasmic reticulum and activate the interaction between actin and myosin to produce contraction of the cardiac muscle cells. Skeletal muscle contraction does not depend on this mechanism and relies only on intracellular Ca^{2+} for contraction.

Autorhythmicity of Cardiac Muscle

The heart is said to be **autorhythmic** (aw'tō-rith'mik) because it stimulates itself (*auto*) to contract at regular intervals (*rhythmic*). If the heart is removed from the body and maintained under physiological conditions with the proper nutrients and temperature, it will continue to beat autorhythmically for a long time.

In the SA node, pacemaker cells generate action potentials spontaneously and at regular intervals. These action potentials spread through the conducting system of the heart to other cardiac muscle cells, causing voltage-gated Na^+ channels to open. As a result, action potentials are produced and the cardiac muscle cells contract.

Depolarization of pacemaker cells is dependent on Na^+ , K^+ , and Ca^{2+} ; however, the mechanisms are very different. When a spontaneously developing local potential, called the **pacemaker potential**, reaches threshold, then action potentials are generated in the SA node (figure 20.15). Changes in ion movement into and out of the pacemaker cells cause the pacemaker potential. Sodium ions cause depolarization by moving into the cells through specialized nongated Na^+ channels. A decreasing permeability to K^+ also causes depolarization as less K^+ moves out of the cells. The decreasing K^+ permeability occurs due to the voltage changes at the end of the previous action potential. As a result of the depolarization, voltage-gated Ca^{2+} channels open, and the movement of Ca^{2+} into the pacemaker cells causes further depolarization. When the pacemaker potential reaches threshold, many voltage-gated Ca^{2+} channels open. In pacemaker cells, the movement of Ca^{2+} into the cells is primarily responsible for the depolarization phase of the action potential. This is different from other cardiac muscle cells, where the movement of Na^+ into the cells is primarily responsible for depolarization. Repolarization occurs, as

Permeability changes in pacemaker cells

1 Pacemaker potential

- A small number of Na^+ channels are open.
- Voltage-gated K^+ channels that opened in the repolarization phase of the previous action potential are closing.
- Voltage-gated Ca^{2+} channels begin to open.

2 Depolarization phase

- Voltage-gated Ca^{2+} channels are open.
- Voltage-gated K^+ channels are closed.

3 Repolarization phase

- Voltage-gated Ca^{2+} channels close.
- Voltage-gated K^+ channels open.

PROCESS FIGURE 20.15 SA Node Action Potential

The production of action potentials by the SA node is responsible for the autorhythmicity of the heart.

Clinical IMPACT

Drugs That Block Calcium Channels

Various chemical agents, such as nifedipine and verapamil (ver-ap'ā-mil), block voltage-gated Ca^{2+} channels. Voltage-gated Ca^{2+} channel-blocking agents prevent the movement of Ca^{2+} through voltage-gated Ca^{2+} channels into the cell; for that reason, they are called **calcium channel blockers**. Some calcium channel blockers are widely used to treat various cardiac disorders, including tachycardia and certain arrhythmias (table 20.1). Calcium channel blockers slow the development of the pacemaker potential and thus reduce the heart rate. If action potentials arise prematurely within the SA node or other areas of the heart, calcium channel blockers reduce that tendency. Calcium channel blockers also reduce the amount of work performed by the heart because less Ca^{2+} enters cardiac muscle cells to activate the contractile mechanism. On the other hand, epinephrine and norepinephrine increase the heart rate and its force of contraction by opening voltage-gated Ca^{2+} channels.

in other cardiac muscle cells, when the voltage-gated Ca^{2+} channels close and the voltage-gated K^+ channels open. After the resting membrane potential is reestablished, production of another pacemaker potential starts the generation of the next action potential.

Although most cardiac muscle cells respond to action potentials produced by the SA node, some cardiac muscle cells in the conducting system can also generate spontaneous action potentials. Normally, the SA node controls the rhythm of the heart because its pacemaker cells generate action potentials at a faster rate than other potential pacemaker cells. The SA node produces a heart rate of 70–80 beats per minute (bpm). In some conditions, another area of the conducting system may generate a heartbeat. An **ectopic focus** (ek-top'ik fō'kūs; pl. *foci*, fō'sī) is any part of the heart other than the SA node that generates a heartbeat. For example, if the SA node does not function properly, the part of the heart that can produce action potentials at the next highest frequency is the AV node, which produces a heart rate of 40–60 bpm. Another cause of an ectopic focus is blockage of the conducting pathways between the SA node and other parts of the heart. For example, if action potentials do not pass through the AV node, an ectopic focus can develop in an AV bundle, resulting in a heart rate of only 30 bpm.

Ectopic foci can also appear when the rate of action potential generation in cardiac muscle cells outside the SA node becomes enhanced. For example, when cells are injured, their plasma membranes become more permeable, resulting in depolarization. Inflammation or lack of adequate blood flow to cardiac muscle tissue can injure cardiac muscle cells. These injured cells can be the source of ectopic action potentials. Also, alterations in blood levels of K^+ and Ca^{2+} can change the cardiac muscle membrane potential, and certain drugs, such as those that mimic the effect of epinephrine on the heart, can alter cardiac muscle membrane permeability. Changes in cardiac muscle cells' membrane potentials or permeability can produce ectopic foci.

Refractory Periods of Cardiac Muscle

Cardiac muscle, like skeletal muscle, has **refractory** (rē-frak'tōr-ē) **periods** associated with its action potentials. The refractory period can be subdivided into the absolute refractory period and the relative refractory period. During the **absolute refractory period**, the cardiac muscle cell is completely insensitive to further stimulation. During the **relative refractory period**, the cell is sensitive to stimulation, but a greater stimulation than normal is required to cause an action potential. Because the plateau phase of the action potential in cardiac muscle delays repolarization to the resting membrane potential, the refractory period is prolonged. The long refractory period ensures that contraction and most of relaxation are complete before another action potential can be initiated (see figure 20.14b, *step 4*). This prevents tetanic contractions in cardiac muscle and is responsible for rhythmic contractions.

Predict 4

Predict the consequences if cardiac muscle could undergo tetanic contraction.

Electrocardiogram

Action potentials conducted through the myocardium during the cardiac cycle produce electrical currents that can be measured at the body surface. Electrodes placed on the body surface and attached to an appropriate recording device can detect small voltage changes resulting from action potentials in the cardiac muscle. The electrodes do not detect individual action potentials; rather, they detect a summation of all the action potentials transmitted by the cardiac muscle cells through the heart at a given time. The summated record of the cardiac action potentials is an **electrocardiogram** (ECG or **EKG**; figure 20.16).

The ECG is a record of the electrical activity of the heart. It, however, is not a direct measurement of mechanical events in the heart, and neither the force of contraction nor blood pressure can be determined from it. However, each deflection in the ECG record indicates an electrical event within the heart that is correlated with a subsequent mechanical event. Consequently, electrocardiography is extremely valuable in diagnosing a number of abnormal cardiac rhythms (arrhythmias; table 20.1) and other abnormalities, particularly because it is painless, easy to record, and noninvasive (does not require surgery). In addition to abnormal heart rates and rhythms, ECG analysis can reveal abnormal conduction pathways, hypertrophy or atrophy of portions of the heart, and the approximate location of damaged cardiac muscle (table 20.1).

Figure 20.16 represents a typical ECG tracing of a single heartbeat. The normal ECG consists of a P wave, a QRS complex, and a T wave, each representing important electrical changes of the myocardium of the heart (figure 20.16). The **P wave**, which is the result of action potentials that cause depolarization of the atrial myocardium, signals the onset of atrial contraction. The **QRS complex**, composed of three individual waves—the Q, R, and S waves—results from ventricular depolarization and signals the onset of ventricular contraction. The **T wave** represents repolarization of the ventricles and precedes ventricular relaxation. A wave representing repolarization of the atria cannot be seen because it occurs during the QRS complex.

TABLE 20.1 Major Cardiac Arrhythmias

Conditions	Symptoms	Possible Causes
Abnormal Heart Rhythms		
Tachycardia	Heart rate in excess of 100 beats per minute (bpm)	Elevated body temperature; excessive sympathetic stimulation; toxic conditions
Paroxysmal atrial tachycardia	Sudden increase in heart rate to 95–150 bpm for a few seconds or even for several hours; P wave precedes every QRS complex; P wave inverted and superimposed on T wave	Excessive sympathetic stimulation; abnormally elevated permeability of slow channels
Ventricular tachycardia	Frequently causes fibrillation	Often associated with damage to AV node or ventricular muscle
Abnormal Rhythms Resulting from Ectopic Action Potentials		
Atrial flutter	300 P waves/min; 125 QRS complexes/min, resulting in two or three P waves (atrial contraction) for every QRS complex (ventricular contraction)	Ectopic action potentials in the atria
Atrial fibrillation	No P waves; normal QRS complexes; irregular timing; ventricles constantly stimulated by atria; reduced pumping effectiveness and filling time	Ectopic action potentials in the atria
Ventricular fibrillation	No QRS complexes; no rhythmic contraction of the myocardium; many patches of asynchronously contracting ventricular muscle	Ectopic action potentials in the ventricles
Bradycardia	Heart rate less than 60 bpm	Elevated stroke volume in athletes; excessive vagal stimulation; carotid sinus syndrome
Sinus Arrhythmia	Heart rate varies 5% during respiratory cycle and up to 30% during deep respiration	Cause not always known; occasionally caused by ischemia or inflammation or associated with cardiac failure
SA Node Block	Cessation of P wave; new low heart rate due to AV node acting as pacemaker; normal QRS complex and T wave	Ischemia; tissue damage due to infarction; causes unknown
AV Node Block		
First-degree	PR interval greater than 0.2 second	Inflammation of AV bundle
Second-degree	PR interval 0.25–0.45 second; some P waves trigger QRS complexes and others do not; 2:1, 3:1, and 3:2 P wave/QRS complex ratios may occur	Excessive vagal stimulation
Third-degree (complete heart block)	P wave dissociated from QRS complex; atrial rhythm approximately 100 bpm; ventricular rhythm less than 40 bpm	Ischemia of AV nodal fibers or compression of AV bundle
Premature Atrial Contractions	Occasional shortened intervals between contractions; frequently occurs in healthy people P wave superimposed on QRS complex	Excessive smoking; lack of sleep; too much caffeine; alcoholism
Premature Ventricular Contractions (PVCs)	Prolonged QRS complex; exaggerated voltage because only one ventricle may depolarize; inverted T wave; increased probability of fibrillation	Ectopic foci in ventricles; lack of sleep; too much caffeine, irritability; occasionally occurs with coronary thrombosis

Abbreviations: SA = sinoatrial; AV = atrioventricular.

In addition to the different waves that can be detected on an ECG, time intervals can also be determined. The time between the beginning of the P wave and the beginning of the QRS complex is the PQ interval, commonly called the PR interval because the Q wave is often very small. During the PR interval, which lasts approximately 0.16 second, the atria contract and begin to relax. The ventricles begin to depolarize at the end of the PR interval. The QT interval extends from the beginning of the QRS complex to the end of the T wave, lasting approximately 0.36 second. The QT interval represents the approximate length of time required for the ventricles to contract and begin to relax.

ASSESS YOUR PROGRESS

23. For cardiac muscle action potentials, describe ion movement during the depolarization, early repolarization, plateau, and final repolarization phases.
24. Why is cardiac muscle referred to as autorhythmic? What are ectopic foci?
25. How does the depolarization of pacemaker cells differ from the depolarization of other cardiac cells? What is the pacemaker potential?

MICROBES In Your Body

How Bacteria Affect Cardiac Muscle

You've learned that the majority of bacteria are either harmless or an integral part of our well-being. Unfortunately, there are a handful of pathogenic bacteria that can interfere with the body's homeostasis.

Most people associate bacterial pneumonia with the lungs only. However, in the medical community, it is well known that pneumonia can cause serious heart problems. In fact, cardiac problems cause 70% of the deaths in individuals with other types of severe bacterial infections. Most bacterial pneumonia is caused by the bacterium *Streptococcus pneumoniae*, but until recently the mechanism by which this pathogen damages the heart had not been well understood. It seems that these bacteria induce the cells lining blood vessels to endocytose them and deposit them in cardiac muscle tissue. There, the bacteria release a toxin, called

pneumolysin, which kills the cardiac muscle cells. These areas of dead cardiac muscle are called microlesions. In addition, during recovery from the infection, scars may form within the myocardium. Thus, the bacteria physically damage the heart, which interrupts the electrical signal necessary for cardiac muscle contraction. In addition, simply treating pneumonia with the traditional antibiotic, ampicillin, may actually worsen damage to the heart. Ampicillin causes the bacterial cell walls to burst, which releases a surge of pneumolysin, creating even more microlesions. Use of an antibiotic that does not destroy the bacterial cell walls will help reduce cardiac muscle death. Further, a vaccine against the bacterial molecule that induces the bacterial transport and against pneumolysin has shown great promise in minimizing the tissue damage caused by these bacteria.

Although pathogenic bacteria exist, modern medicine continues to make great strides to reduce their damaging effects on our bodies. In addition, the more we learn about our microbiome, the more effectively we may be able to prevent bacterial infections from occurring in the first place

Predict 5

Given that *Streptococcus pneumoniae* microlesions interrupt the electrical activity that flows between cardiac muscle cells, the heart can experience severe stress and may malfunction or stop contracting altogether. Using what you learned about skeletal muscle contraction, would microlesions in skeletal muscle cause the same type of reaction as in cardiac muscle?

FIGURE 20.16 Electrocardiogram

The major waves and intervals of an electrocardiogram. Each thin, horizontal line on the ECG recording represents 1 mV, and each thin, vertical line represents 0.04 second.

26. How is the prolonged refractory period generated in cardiac muscle? What is the advantage of a prolonged refractory period?

Clinical IMPACT

Alterations in the Electrocardiogram

Elongation of the PR interval can result from three events: (1) a delay in action potential conduction through the atrial muscle because of damage, such as that caused by **ischemia** (is-kē'mē-ă), which is obstruction of the blood supply to the walls of the heart; (2) a delay in action potential conduction through atrial muscle because of a dilated atrium; or (3) a delay in action potential conduction through the AV node and bundle because of ischemia, compression, or necrosis of the AV node or bundle. These conditions result in slow conduction of action potentials through the bundle branches. An unusually long QT interval reflects the abnormal conduction of action potentials through the ventricles, which can result from myocardial infarctions or from an abnormally enlarged left or right ventricle.

Altered forms of the electrocardiogram due to cardiac abnormalities include complete heart block, premature ventricular contraction, bundle branch block, atrial fibrillation, and ventricular fibrillation (figure 20.17).

27. What does an ECG measure? Name the waves and intervals produced by an ECG, and state what events occur during each wave and interval.

Complete heart block (P waves and QRS complexes are not coordinated)

Premature ventricular contraction (PVC) (no P waves precede PVCs)

Bundle branch block

Atrial fibrillation (no clear P waves and rapid QRS complexes)

Ventricular fibrillation (no P, QRS, or T waves)

FIGURE 20.17 Alterations in an Electrocardiogram

20.7 Cardiac Cycle

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the cardiac cycle and the relationship among the contraction of each of the chambers, the opening and closing of valves, the pressure in each of the chambers, the phases of the electrocardiogram, and the heart sounds.
- Discuss the heart sounds and their significance.

The right and left halves of the heart can be viewed as two separate pumps that work together. Each pump consists of a “primer pump” (the atrium) and a “power pump” (the ventricle). Both atrial primer pumps complete the filling of the ventricles with blood, and both ventricular power pumps produce the major force that causes blood to flow through the pulmonary and systemic arteries. The term **cardiac cycle** refers to the repetitive pumping process that begins with the onset of cardiac muscle contraction and ends with the beginning of the next contraction (figure 20.18; table 20.2). Blood moves from an area of higher pressure to an area of lower pressure. Pressure changes produced within the heart chambers as a result of cardiac muscle contraction and relaxation move blood along the previously described routes of the pulmonary and systemic circulations.

The duration of the cardiac cycle varies considerably among humans and during an individual’s lifetime. It can be as short as 0.25–0.3 second in a newborn or as long as 1 or more seconds in a well-trained athlete. The normal cardiac cycle of 0.7–0.8 second depends on the capability of cardiac muscle to contract and on the functional integrity of the conducting system.

The cardiac cycle involves a predictable pattern of contraction and relaxation of the heart chambers. As you study the events of the cardiac cycle listed in table 20.2, keep in mind that the term **systole** (sis’tō-lē) means to contract, and **diastole** (dī-as’tō-lē) means to dilate. Therefore, **atrial systole** is contraction of the atrial myocardium, and **atrial diastole** is relaxation of the atrial myocardium. Similarly, **ventricular systole** is contraction of the ventricular myocardium, and **ventricular diastole** is relaxation of the ventricular myocardium. When the terms *systole* and *diastole* are used alone, they refer to ventricular systole and diastole.

Before we begin our discussion of the cardiac cycle, it is important to have a clear image of the state of the heart. At the beginning of the cardiac cycle, the atria and ventricles are relaxed, the AV valves are open, and the semilunar valves are closed. During the cardiac cycle, changes in chamber pressure and the opening and closing of the heart valves determine the direction of blood movement. As the cardiac cycle is described, it is important to focus on these pressure changes and heart valve movements.

At rest, most of the blood movement into the chambers is a passive process resulting from the greater blood pressure in the veins than in the heart chambers. As the blood moves into the atria, much of it flows into the ventricles for two reasons: (1) The AV valves are open and (2) atrial pressure is slightly greater than ventricular pressure. This time period when blood is passively moving into the ventricles is called *passive ventricular filling*.

The SA node generates an action potential that stimulates atrial contraction and begins the cardiac cycle. As the atria contract, they carry out the primer pump function by forcing more blood into the ventricles. This period is referred to as *active ventricular filling* (figure 20.18, *step 1*).

The action potential passes to the AV node, down the AV bundle, bundle branches, and Purkinje fibers, stimulating ventricular systole. As the ventricles contract, ventricular pressures increase, causing blood to flow toward the atria and close the AV valves. Recall that the semilunar valves are closed at this point as well. Ventricular contraction continues and ventricular pressures

FUNDAMENTAL Figure

PROCESS FIGURE 20.18 Cardiac Cycle

The cardiac cycle is a repeating series of contraction and relaxation that moves blood through the heart (AV = atrioventricular).

TABLE 20.2 Summary of the Events of the Cardiac Cycle

	Atrial Systole	Atrial Diastole
	Ventricular Diastole	Ventricular Systole
	Active Ventricular Filling	Period of Isovolumetric Contraction
Time Period	Contraction of the atria pumps blood into the ventricles.	The ventricles begin to contract, but ventricular volume does not change.
Condition of Valves	The semilunar valves are closed; the AV valves are opened (figure 20.18, <i>step 1</i>).	The semilunar valves are closed; the AV valves are closed (figure 20.18, <i>step 2</i>).
ECG	<p>The P wave is completed and the atria are stimulated to contract. Action potentials are delayed in the AV node for 0.11 second, allowing time for the atria to contract.</p> <p>The QRS complex begins as action potentials are propagated from the AV node to the ventricles.</p>	<p>The QRS complex is completed, and the ventricles are depolarized. As a result, the ventricles begin to contract.</p> <p>Atrial repolarization is masked by the QRS complex. The atria are relaxed (atrial diastole).</p>
Atrial Pressure Graph	Atrial contraction (systole) causes an increase in atrial pressure, and blood is forced to flow from the atria into the ventricles.	<p>Atrial pressure decreases in the relaxed atria. When atrial pressure is less than venous pressure, blood flows into the atria.</p> <p>Atrial pressure increases briefly as the contracting ventricles push blood back toward the atria.</p>
Ventricular Pressure Graph	Atrial contraction (systole) and the movement of blood into the ventricles cause a slight increase in ventricular pressure.	<p>Ventricular contraction causes an increase in ventricular pressure, which causes blood to flow toward the atria, closing the AV valves.</p> <p>Ventricular pressure increases rapidly.</p>
Aortic Pressure Graph	Aortic pressure gradually decreases as blood runs out of the aorta into other systemic blood vessels.	Just before the semilunar valves open, pressure in the aorta decreases to its lowest value, called the diastolic pressure (approximately 80 mm Hg).
Volume Graph	Atrial contraction (systole) completes ventricular filling during the last one-third of diastole. The amount of blood in a ventricle at the end of ventricular diastole is called the end-diastolic volume .	During the period of isovolumetric contraction , ventricular volume does not change because the semilunar and AV valves are closed.
Sound Graph		Blood flowing from the ventricles toward the atria closes the AV valves. Vibrations of the valves and the turbulent flow of blood produce the first heart sound , which marks the beginning of ventricular systole.

Abbreviation: AV = atrioventricular.

rise; however, because all the valves are closed, no blood flows from the ventricles. This brief interval is called the *period of isovolumetric (iso, same) contraction* because the volume of blood in the ventricles does not change, even though the ventricles are contracting (figure 20.18, *step 2*). Ventricular contraction continues, and ventricular pressures become greater than the pressures in the pulmonary trunk and aorta. As a result, the semilunar valves are pushed open, and blood flows from the ventricles into those arteries. This time period, when blood moves from the

ventricles into the arteries, is called the *period of ejection* (figure 20.18, *step 3*).

As ventricular diastole begins, the ventricles relax, and ventricular pressures decrease below the pressures in the pulmonary trunk and aorta. Consequently, blood begins to flow back toward the ventricles, causing the semilunar valves to close (figure 20.18, *step 4*). With closure of the semilunar valves, all the heart valves are closed, and no blood flows into the relaxing ventricles during the *period of isovolumetric relaxation*.

Atrial Diastole		
Ventricular Systole	Ventricular Diastole	
Period of Ejection	Period of Isovolumetric Relaxation	Passive Ventricular Filling
The ventricles continue to contract, and blood is pumped out of the ventricles.	The ventricles relax, but ventricular volume does not change.	Blood flows into the ventricles because blood pressure is higher in the veins and atria than in the relaxed ventricles.
The semilunar valves are opened; the AV valves are closed (figure 20.18, <i>step 3</i>).	The semilunar valves are closed; the AV valves are closed (figure 20.18, <i>step 4</i>).	The semilunar valves are closed; the AV valves are opened (see figure 20.18, <i>step 5</i>).
The T wave results from ventricular repolarization.	The T wave is completed, and the ventricles are repolarized. The ventricles relax.	The P wave is produced when the SA node generates action potentials and a wave of depolarization begins to propagate across the atria.
Atrial pressure increases gradually as blood flows from the veins into the relaxed atria.	Atrial pressure continues to increase gradually as blood flows from the veins into the relaxed atria.	After the AV valves open, atrial pressure decreases as blood flows out of the atria into the relaxed ventricles.
Ventricular pressure becomes greater than pressure in the aorta as the ventricles continue to contract. The semilunar valves are pushed open as blood flows out of the ventricles. Ventricular pressure peaks as the ventricles contract maximally; then pressure decreases as blood flow out of the ventricles decreases.	Elastic recoil of the aorta pushes blood back toward the heart, causing the semilunar valves to close. After closure of the semilunar valves, the pressure in the relaxing ventricles rapidly decreases.	No significant change occurs in ventricular pressure during this time period.
As ventricular contraction forces blood into the aorta, pressure in the aorta increases to its highest value, called the systolic pressure (approximately 120 mm Hg).	After the semilunar valves close, elastic recoil of the aorta causes a slight increase in aortic pressure, producing the dicrotic notch and dicrotic wave .	Aortic pressure gradually decreases as blood runs out of the aorta into other systemic blood vessels.
After the semilunar valves open, blood volume decreases as blood flows out of the ventricles during the period of ejection . The amount of blood left in a ventricle at the end of the period of ejection is called the end-systolic volume .	During the period of isovolumetric relaxation , ventricular volume does not change because the semilunar and AV valves are closed.	After the AV valves open, blood flows from the atria and veins into the ventricles because of pressure differences. Most ventricular filling occurs during the first one-third of diastole. Little ventricular filling occurs during the middle one-third of diastole.
	Blood flowing from the ventricles toward the aorta and pulmonary trunk closes the semilunar valves. Vibrations of the valves and the turbulent flow of blood produce the second heart sound , which marks the beginning of ventricular diastole.	Sometimes the turbulent flow of blood into the ventricles produces a third heart sound .

Atrial diastole began during ventricular systole, and as the atria relaxed, blood flowed into them from the veins. As the ventricles continue to relax, ventricular pressures drop below atrial pressures, and the AV valves open. Passive ventricular filling begins again (figure 20.18, *step 5*). Note that once the ventricles have fully relaxed, the state of the heart is the same as when the cardiac cycle began, all chambers are relaxed, the AV valves are open, and the semilunar valves are closed. With the next stimulus from the SA node, another cardiac cycle will begin (figure 20.18, *step 1*).

Events Occurring During the Cardiac Cycle

Figure 20.19 graphs the main events of the cardiac cycle and should be examined from top to bottom:

- An ECG indicates the electrical events that cause contraction and relaxation of the atria and ventricles.
- The pressure graph shows the pressure changes within the left atrium, left ventricle, and aorta resulting from atrial and ventricular contraction and relaxation. Although pressure changes

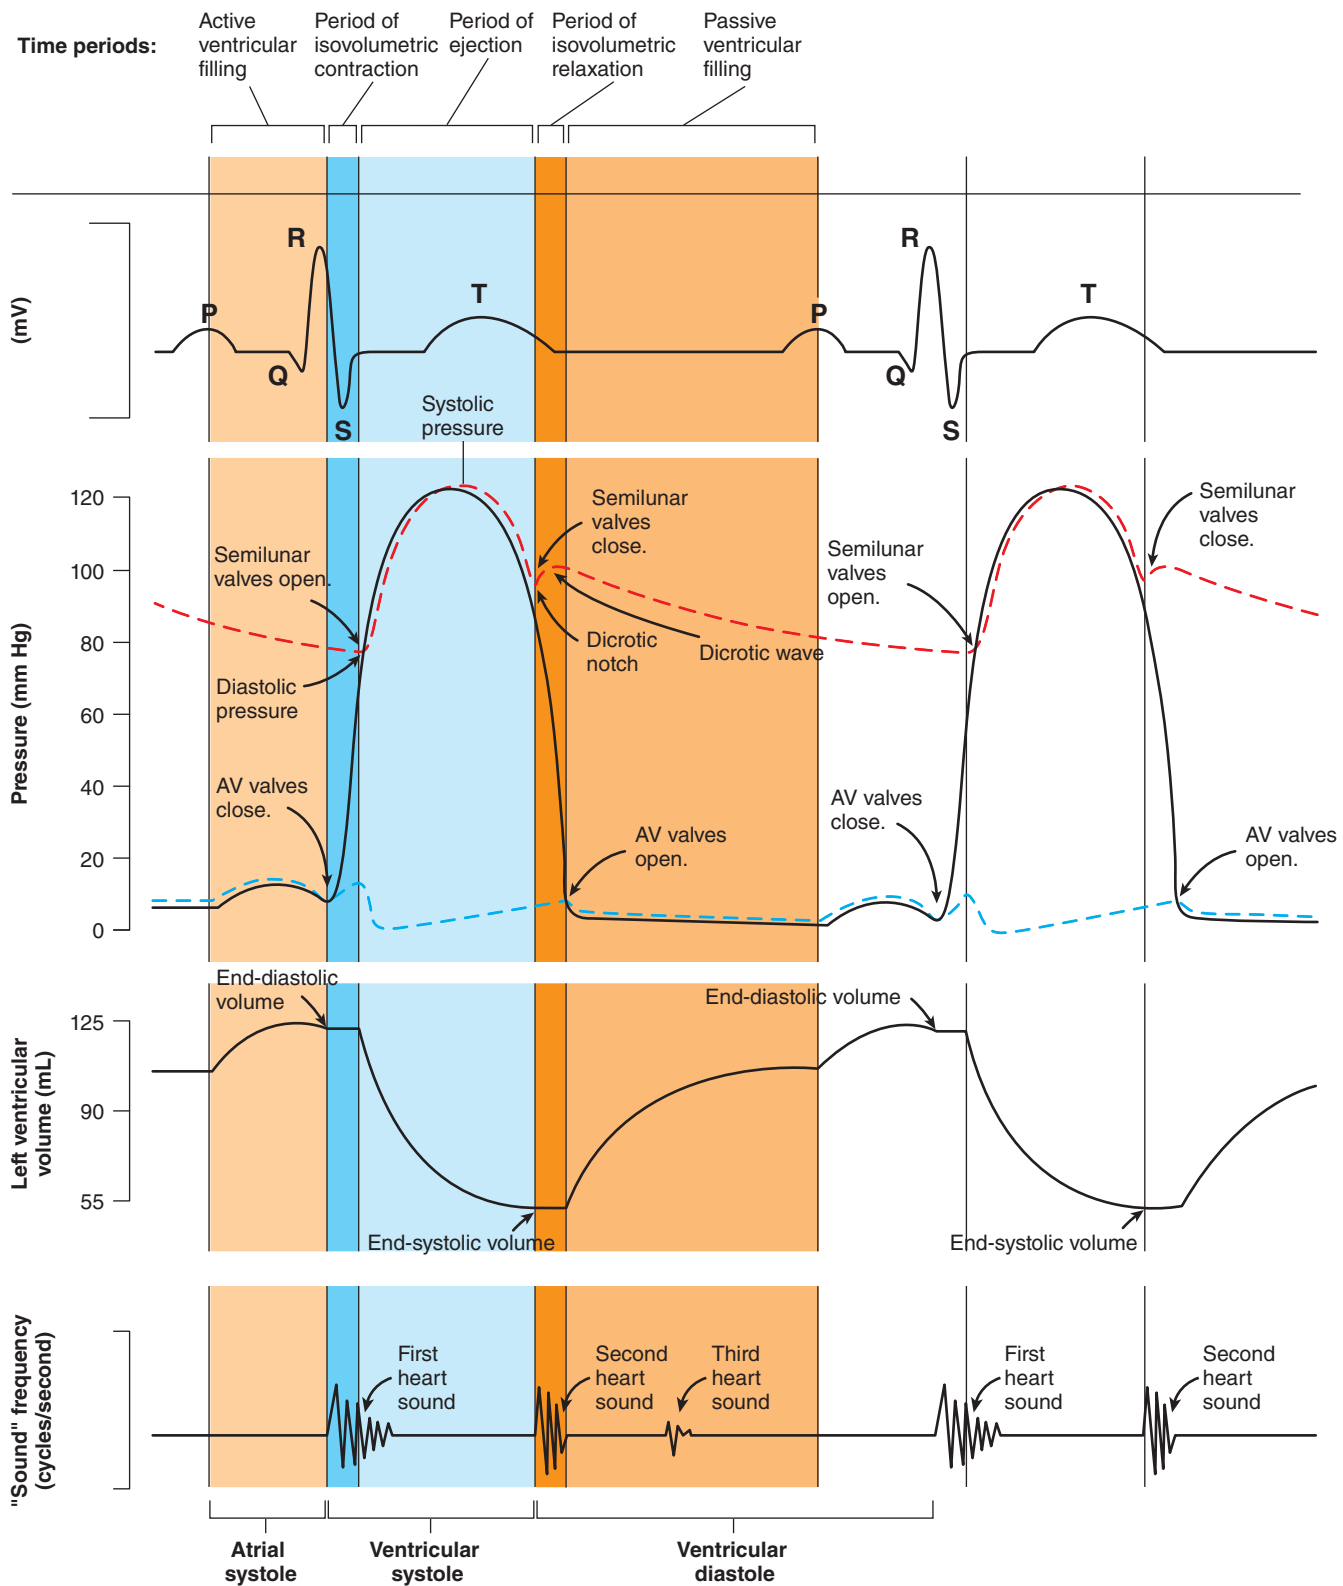

FIGURE 20.19 Events Occurring During the Cardiac Cycle

The cardiac cycle is divided into five time periods (top). From top to bottom: the electrocardiogram; pressure changes for the left atrium (blue line), left ventricle (black line), and aorta (red line); left ventricular volume curve; and heart sounds. **APR**

in the right side of the heart are not shown, they are similar to those in the left side, only lower.

- The volume graph presents the changes in left ventricular volume as blood flows into and out of the left ventricle as a result of the pressure changes.
- The sound graph records the closing of valves caused by blood flow.

See also figure 20.18 for illustrations of the valves and blood flow and table 20.2 for a summary of the events of each period.

Atrial Systole and Active Ventricular Filling

Before the cardiac cycle begins, all chambers are relaxed and blood is flowing from the veins into the atria and passively into the ventricles. Depolarization of the SA node generates action potentials, which spread over the atria, producing the P wave and stimulating both atria to contract (atrial systole). The atria contract during the last one-third of ventricular diastole and complete ventricular filling.

Under most conditions, the atria function primarily as reservoirs, and the ventricles can pump sufficient blood to maintain homeostasis even if the atria do not contract at all. During exercise, however, the heart pumps 300–400% more blood than during rest. As heart rate increases during exercise, atrial contraction is important for ventricular filling because less time is available for passive ventricular filling. Therefore, it is during exercise that the pumping action of the atria becomes important for maintaining the pumping efficiency of the heart.

Ventricular Systole: Period of Isovolumetric Contraction

During the previous ventricular diastole, the ventricles were filled with 120–130 mL of blood. The volume of blood in the ventricles at this point is the **end-diastolic volume**. Completion of the QRS complex initiates contraction of the ventricles. As the ventricles begin to contract, ventricular pressure rapidly increases, resulting in closure of the AV valves. Ventricular volume does not change during the period of isovolumetric contraction because all the heart valves are closed.

Ventricular Systole: Period of Ejection

As soon as ventricular pressures exceed the pressures in the aorta and pulmonary trunk, the semilunar valves open. The aortic semilunar valve opens at approximately 80 mm Hg ventricular pressure, whereas the pulmonary semilunar valve opens at approximately 8 mm Hg. Although the pressures are different, both valves open at nearly the same time.

As blood flows from the ventricles during the period of ejection, the left ventricular pressure continues to climb to approximately 120 mm Hg, and the right ventricular pressure increases to approximately 25 mm Hg. The larger left ventricular pressure causes blood to flow throughout the body (systemic circulation), whereas the lower right ventricular pressure causes blood to flow through the lungs (pulmonary circulation). It is important to note that even though the pressure generated by the left ventricle is much higher than that of the right ventricle, the amount of blood pumped by each is almost the same.

Predict 6

Which ventricle has the thickest wall? Why is it important for each ventricle to pump approximately the same volume of blood?

During the first part of ejection, blood flows rapidly out of the ventricles. Toward the end of ejection, ventricular pressure decreases due to reduced blood flow, despite continued ventricular contraction. By the end of ejection, the volume of blood in the ventricles has decreased to 50–60 mL, which is called the **end-systolic volume**.

Ventricular Diastole: Period of Isovolumetric Relaxation

Completion of the T wave results in ventricular repolarization and relaxation. The already decreasing ventricular pressure falls very rapidly as the ventricles suddenly relax. When the ventricular pressures fall below the pressures in the aorta and pulmonary trunk, the recoil of the elastic arterial walls, which were stretched during the period of ejection, forces the blood to flow back toward the ventricles, thereby closing the semilunar valves. Ventricular volume does not change during the period of isovolumetric relaxation because all the heart valves are closed at this time.

Ventricular Diastole: Passive Ventricular Filling

During ventricular systole and the period of isovolumetric relaxation, the relaxed atria fill with blood. During ventricular diastole, as ventricular pressure drops below atrial pressure, the atrioventricular valves open and allow blood to flow from the atria into the ventricles. At this point the atria and ventricles are relaxed. Blood flows from the area of higher pressure in the veins and atria toward the area of lower pressure in the relaxed ventricles. Most ventricular filling occurs during the first one-third of ventricular diastole. At the end of passive ventricular filling, the ventricles are approximately 70% filled.

Predict 7

Fibrillation is abnormal, rapid contractions of different parts of the heart that prevent the heart muscle from contracting as a single unit. Explain why atrial fibrillation does not immediately cause death but ventricular fibrillation does.

Heart Sounds

The pumping heart produces distinct sounds, as revealed by using a stethoscope (figure 20.19, *bottom*). These sounds are best heard by applying the stethoscope at particular sites in relation to the heart valves (figure 20.20). The **first heart sound** is a low-pitched sound, often described as “lubb.” It occurs at the beginning of ventricular systole and is caused by vibration of the atrioventricular valves and surrounding fluid as the valves close. The **second heart sound** is a higher-pitched sound often described as “dupp.” It occurs at the beginning of ventricular diastole and results from closure of the aortic and pulmonary semilunar valves. Systole is therefore approximately the time between the first and second heart sounds. Diastole, which lasts somewhat longer, is approximately the time between the second heart sound and the next first heart sound.

FIGURE 20.20 Location of the Heart Valves in the Thorax

Surface markings of the heart in the male. The positions of the four heart valves are indicated by blue ellipses, and the sites where the sounds of the valves are best heard with the stethoscope are indicated by pink circles.

A faint **third heart sound** can be heard in some normal people, particularly those who are thin and young. It is caused by blood flowing in a turbulent fashion into the ventricles, and it can be detected near the end of the first one-third of diastole, during passive ventricular filling.

Aortic Pressure Curve

The elastic walls of the aorta are stretched as blood is ejected into the aorta from the left ventricle. Aortic pressure remains slightly

below ventricular pressure during this period of ejection. As ventricular pressure drops below that in the aorta, blood flows back toward the ventricle because of the elastic recoil of the aorta. As the blood flows back, the aortic pressure decreases slightly, producing a **dicrotic (dī-krot'ik) notch**, or *incisura* (in'sī-soo'rá; a cutting into) in the aortic pressure curve. Consequently, the aortic semilunar valve closes, and pressure within the aorta increases slightly, producing a **dicrotic wave** in the aortic pressure curve (see figure 20.19). The term *dicrotic* means “double-beating”; when increased pressure caused by recoil is large, a double pulse can be felt. Aortic pressure then gradually falls throughout the rest of ventricular diastole as blood flows through the peripheral vessels. When aortic pressure has fallen to approximately 80 mm Hg, the ventricles again contract, forcing blood once more into the aorta.

Many of us have had our blood pressure measured during a medical exam. Blood pressure measurements performed for clinical purposes reflect the pressure changes that occur in the aorta rather than in the left ventricle (see chapter 21). The blood pressure in the aorta fluctuates between systolic pressure, which is about 120 mm Hg, and diastolic pressure, which is about 80 mm Hg, for the average young adult at rest.

Predict 8

Predict the pressure changes that occur in the aorta, the left ventricle, and the left atrium after the second heart sound and before the first heart sound of the next cardiac cycle.

ASSESS YOUR PROGRESS

28. Define systole and diastole.
29. List the five periods of the cardiac cycle (see figure 20.18, figure 20.19, and table 20.2). State whether the AV and semilunar valves are open or closed during each period and the phase of the electrocardiogram for each period.
30. Define isovolumetric. When does most ventricular filling occur?

Clinical IMPACT

Abnormal Heart Sounds

Heart sounds provide important information about the normal function of the heart and help clinicians diagnose cardiac abnormalities. Abnormal heart sounds are called **murmurs** (mer'merz), and certain murmurs are important indicators of specific cardiac abnormalities. For example, an **incompetent valve** (also called a valvular insufficiency) leaks significantly. After an incompetent valve closes, blood flows through it but in a reverse direction, called **regurgitation**. Regurgitation results in turbulence, which causes a gurgling or swishing sound immediately after the valve closes. An incompetent tricuspid valve or bicuspid valve makes a

swish sound immediately after the first heart sound, and the first heart sound may be muffled. An incompetent aortic or pulmonary semilunar valve results in a swish sound immediately after the second heart sound.

Stenosed (sten'ōzd) valves have an abnormally narrow opening and produce abnormal heart sounds. Blood flows through stenosed valves very turbulently and produces a rushing sound before the valve closes. For example, a stenosed atrioventricular valve produces a rushing sound immediately before the first heart sound, and a stenosed semilunar valve produces a rushing sound immediately before the second heart sound.

Inflammation of the heart valves, resulting from a condition such as rheumatic fever, can cause valves to become either incompetent or stenosed. In addition, myocardial infarctions that make papillary muscles non-functional can cause bicuspid or tricuspid valves to be incompetent. Heart murmurs also result from congenital abnormalities in the hearts of infants. Two examples are septal defects in the heart and patent ductus arteriosus (see chapter 29).

Either incompetent or stenosed valves increase the amount of work the cardiac muscle must perform. Consequently, these conditions can lead to heart failure.

31. Differentiate between end-diastolic volume and end-systolic volume.
32. What produces the first and the second heart sounds?
33. Explain the production of the following in the aorta: systolic pressure, diastolic pressure, and the aortic notch (*incisura*).

20.8 Mean Arterial Blood Pressure

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Define mean arterial pressure, cardiac output, and peripheral resistance.
- B. Explain the role of MAP in causing blood flow.

Blood pressure is necessary to move the blood and therefore is critical to the maintenance of homeostasis. Recall that blood flows from areas of higher pressure to areas of lower pressure. For example, during one cardiac cycle, blood flows from the higher pressure in the aorta, resulting from contraction of the left

ventricle, through the systemic circulation, toward the lower pressure in the relaxed right atrium.

Mean arterial pressure (MAP) is slightly less than the average of the systolic and diastolic pressures in the aorta. It is proportional to cardiac output times peripheral resistance. **Cardiac output (CO)**, or *minute volume*, is the amount of blood pumped by the heart per minute, and **peripheral resistance (PR)** is the total resistance against which blood must be pumped:

$$\text{MAP} = \text{CO} \times \text{PR}$$

Because mean arterial pressure is determined by both cardiac output and peripheral resistance, changes to either can alter mean arterial pressure (figure 20.21). Cardiac output is discussed in this chapter, and peripheral resistance is explained in chapter 21.

Cardiac output is equal to heart rate times stroke volume. **Heart rate (HR)** is the number of times the heart beats (contracts) per minute. **Stroke volume (SV)** is the volume of blood pumped during each heartbeat (cardiac cycle). If we consider the volumes of blood described in the cardiac cycle discussion, stroke volume is equal to end-diastolic volume minus end-systolic volume. During diastole, blood flows from the atria into the ventricles, and end-diastolic volume normally increases to approximately 125 mL.

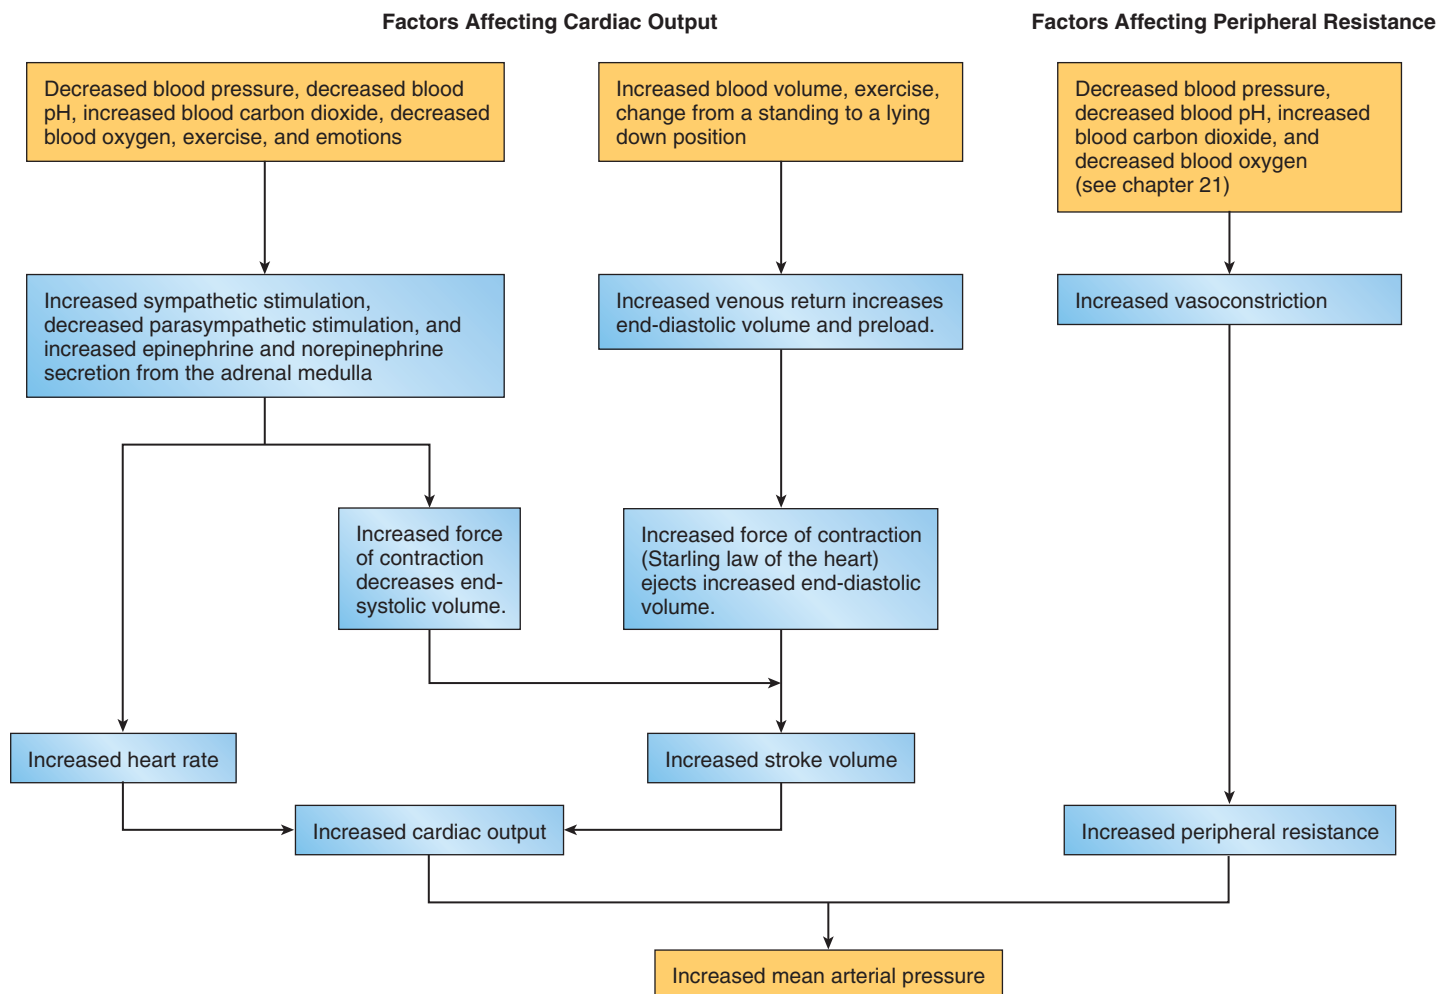

FIGURE 20.21 Factors Affecting Mean Arterial Pressure

Mean arterial pressure is regulated by controlling cardiac output and peripheral resistance.

After the ventricles partially empty during systole, end-systolic volume decreases to approximately 55 mL. Because stroke volume is equal to end-diastolic volume minus end-systolic volume, we can predict that stroke volume is equal to 70 mL (125 – 55).

To better understand stroke volume, imagine that you are squeezing a sponge under a running water faucet. As you relax your fingers, the sponge fills with water; as you contract your fingers, the sponge releases water. Even after you have squeezed the sponge, some water remains in it. In this analogy, the amount of water you squeeze out of the sponge (stroke volume) is the difference between the amount of water in the sponge when your hand is relaxed (end-diastolic volume) and the amount left in the sponge after you squeeze it (end-systolic volume).

Stroke volume can be increased by increasing end-diastolic volume or by decreasing end-systolic volume (figure 20.21). During exercise, end-diastolic volume increases because of an increase in **venous return**, which is the amount of blood returning to the heart from the systemic circulation. End-systolic volume decreases because the heart contracts more forcefully. For example, stroke volume can increase from a resting value of 70 mL to an exercising value of 115 mL by increasing end-diastolic volume to 145 mL and decreasing end-systolic volume to 30 mL.

Cardiac output is also influenced by heart rate ($CO = HR \times SV$). Under resting conditions, the heart rate is approximately 72 bpm, and the stroke volume is approximately 70 mL/beat, although these values can vary considerably from person to person. Therefore, the cardiac output is

$$\begin{aligned} CO &= HR \times SV \\ &= 72 \text{ bpm} \times 70 \text{ mL/beat} \\ &= 5040 \text{ mL/min (approximately 5 L/min)} \end{aligned}$$

Changes in heart rate and stroke volume will result in changes in cardiac output. For example, during exercise, the heart rate can increase to 190 bpm, and the stroke volume can increase to 115 mL. Consequently, cardiac output is

$$\begin{aligned} CO &= 190 \text{ bpm} \times 115 \text{ mL/beat} \\ &= 21,850 \text{ mL/min (approximately 22 L/min)} \end{aligned}$$

Cardiac reserve is the difference between cardiac output when a person is at rest and maximum cardiac output. The greater a person's cardiac reserve, the greater his or her capacity for doing exercise. Cardiovascular disease and lack of exercise can reduce cardiac reserve and affect a person's quality of life. Exercise can greatly increase cardiac reserve by increasing cardiac output. In well-trained athletes, stroke volume during exercise can increase to over 200 mL/beat, resulting in cardiac outputs of 40 L/min or more.

ASSESS YOUR PROGRESS

34. Explain the relationship among mean arterial pressure, cardiac output, and peripheral resistance. Define each.
35. Explain the role of MAP in causing blood flow.
36. What is stroke volume, and what are two ways to increase it?
37. What is cardiac reserve? How can exercise influence cardiac reserve?

20.9 Regulation of the Heart

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe intrinsic regulation of the heart.
- B. Relate the three types of extrinsic regulation of the heart and their effects.

To maintain homeostasis, the amount of blood pumped by the heart must vary dramatically, depending on the level of activity and the oxygen and nutrient needs of the body tissues. For example, during exercise, cardiac output can increase several times over resting values to meet the needs of the active tissues. Intrinsic and extrinsic regulatory mechanisms control cardiac output. **Intrinsic regulation** results from the heart's normal functional characteristics and does not depend on either neural or hormonal regulation. It functions whether the heart is in place in the body or is removed and maintained outside the body under proper conditions. On the other hand, **extrinsic regulation** involves neural and hormonal control. Neural regulation of the heart results from sympathetic and parasympathetic reflexes, and the major hormonal regulation comes from epinephrine and norepinephrine secreted by the adrenal medulla.

Intrinsic Regulation

The force of contraction produced by cardiac muscle is related to the degree of stretch of the cardiac muscle fibers. As venous return increases, end-diastolic volume increases (figure 20.21). A greater end-diastolic volume increases the stretch of the ventricular walls. It is easy to visualize this by thinking of a balloon filling with water. As the volume of water increases in the balloon, the balloon is stretched more and more. The extent to which the ventricular walls are stretched is sometimes called the **preload**. An increased preload increases cardiac output, and a decreased preload decreases cardiac output.

The length-versus-tension relationship in cardiac muscle is similar to that in skeletal muscle. Skeletal muscle, however, is normally stretched to nearly its optimal length before contraction, whereas cardiac muscle cells are not stretched to the point at which they contract with a maximal force (see chapter 9). Thus, an increased preload causes the cardiac muscle cells to contract with a greater force and produce a greater stroke volume. This relationship between preload and stroke volume is commonly referred to as the **Starling law of the heart**, and it describes the relationship between changes in the pumping effectiveness of the heart and changes in preload (figure 20.21). Preload, or ventricular stretching, is directly related to venous return (remember our water balloon analogy). Venous return can decrease to a value as low as 2 L/min or increase to as much as 24 L/min. Such drastic changes in venous return have major effects on the preload.

Afterload is the pressure the contracting left ventricle must produce to overcome the pressure in the aorta and move blood into the aorta. Afterload can be related to the amount of force necessary to open a door. As the ventricles contract, pressure increases, eventually forcing open the semilunar valves. Although the heart's pumping effectiveness is greatly influenced by relatively small changes

in the preload, it is very insensitive to large changes in afterload. Aortic blood pressure must increase to more than 170 mm Hg before it hampers the ventricles' ability to pump blood.

During exercise, blood vessels in exercising skeletal muscles dilate and allow more blood to flow through the vessels. The increased blood flow increases oxygen and nutrient delivery to the exercising muscles. In addition, skeletal muscle contractions repeatedly compress veins and cause blood to flow more rapidly from the skeletal muscles toward the heart. As blood flows rapidly through skeletal muscles and back to the heart, venous return to the heart increases, increasing the preload. The increased preload causes an increased force of cardiac muscle contraction, which increases stroke volume. The increase in stroke volume results in increased cardiac output, and the volume of blood flowing to the exercising muscles increases. When a person rests, venous return to the heart decreases because arteries in the skeletal muscles constrict and because muscular contractions no longer repeatedly compress the veins. As a result, blood flow through skeletal muscles decreases, and preload and cardiac output decrease.

Extrinsic Regulation

The heart is innervated by both **parasympathetic** and **sympathetic** nerve fibers (see figure 16.5). They influence the pumping action of the heart by affecting both heart rate and stroke volume. However, the influence of parasympathetic stimulation on the heart is much less than that of sympathetic stimulation. Sympathetic stimulation can increase cardiac output by 50–100% over resting values, whereas parasympathetic stimulation can cause only a 10–20% decrease.

Extrinsic regulation of the heart keeps blood pressure, blood oxygen levels, blood carbon dioxide levels, and blood pH within their normal ranges of values. For example, if blood pressure suddenly decreases, extrinsic mechanisms detect the decrease and initiate responses that increase cardiac output to bring blood pressure back into its normal range.

Parasympathetic Control

Parasympathetic nerve fibers are in the **vagus nerves**. Preganglionic fibers of the vagus nerve extend from the brainstem to terminal ganglia within the wall of the heart, and postganglionic fibers extend from the ganglia to the SA node, AV node, coronary blood vessels, and atrial myocardium.

Parasympathetic stimulation has an inhibitory influence on the heart, primarily by decreasing the heart rate. When a person is at rest, continuous parasympathetic stimulation inhibits the heart to some degree. An increase in heart rate during exercise results, in part, from decreased parasympathetic stimulation. Strong parasympathetic stimulation can decrease the heart rate below resting levels by at least 20–30 bpm, but it has little effect on stroke volume. In fact, if venous return remains constant while the heart is inhibited by parasympathetic stimulation, stroke volume can actually increase. The longer time between heartbeats allows the heart to fill to a greater capacity, resulting in an increased preload, which in turn increases stroke volume.

Acetylcholine, the neurotransmitter produced by postganglionic parasympathetic neurons, binds to ligand-gated channels that

cause cardiac plasma membranes to become more permeable to K^+ . As a consequence, the membrane hyperpolarizes. Heart rate decreases because the hyperpolarized membrane takes longer to depolarize and cause an action potential.

Sympathetic Control

Sympathetic nerve fibers originate in the thoracic region of the spinal cord as preganglionic neurons. These neurons synapse with postganglionic neurons of the inferior **cervical** and upper **thoracic sympathetic chain ganglia**, which project to the heart as **cardiac nerves** (figure 20.22; see chapter 16). The postganglionic sympathetic nerve fibers innervate the SA and AV nodes, the coronary blood vessels, and the atrial and ventricular myocardia.

Sympathetic stimulation increases both the heart rate and the force of muscular contraction. In response to strong sympathetic stimulation, the heart rate can increase to 250 or, occasionally, 300 bpm. Stronger contractions can also increase stroke volume. The increased force of contraction resulting from sympathetic stimulation causes a lower end-systolic volume in the heart; therefore, the heart empties to a greater extent (see figure 20.21).

Predict 9

What effect does sympathetic stimulation have on stroke volume if the venous return remains constant? Dilation of the coronary blood vessels occurs in response to an increased heart rate and stroke volume. Explain the functional advantage of that effect.

The relationship between increased heart rate and cardiac output is limited. If the heart rate becomes too fast, ventricular diastole does not last long enough to allow complete ventricular filling, end-diastolic volume decreases, and stroke volume actually decreases. In addition, if the heart rate increases beyond a critical level, the strength of contraction decreases, probably because metabolites accumulate in cardiac muscle cells. The heart's ability to increase the cardiac output is limited to heart rates of 170–250 bpm in response to intense sympathetic stimulation.

Sympathetic stimulation of the ventricular myocardium plays a significant role in regulating its contraction force when a person is at rest. Sympathetic stimulation maintains the strength of ventricular contraction at a level approximately 20% greater than it would be without sympathetic stimulation.

Norepinephrine, the postganglionic sympathetic neurotransmitter, increases the rate and degree of cardiac muscle depolarization, so that both the frequency and the amplitude of the action potentials increase. The effect of norepinephrine on the heart involves its association with cell surface β -adrenergic receptors. This combination causes a G protein-mediated synthesis and accumulation of cAMP in the cytoplasm of cardiac muscle cells. Cyclic-AMP increases the permeability of the plasma membrane to Ca^{2+} , primarily by opening calcium channels in the plasma membrane.

Increased sympathetic stimulation causes coronary arteries to constrict to some degree. However, increased metabolism of cardiac muscle, in response to sympathetic stimulation, allows metabolic by-products to accumulate in cardiac muscle, which causes coronary blood vessels to dilate. The dilation effect of these metabolites predominates (see chapter 21).

1 Sensory neurons (*green*) carry action potentials from baroreceptors and carotid body chemoreceptors to the cardiorespiratory center. Chemoreceptors in the medulla oblongata also influence the cardiorespiratory center.

2 The cardiorespiratory center controls the frequency of action potentials in the parasympathetic neurons (*red*) extending to the heart through the vagus nerves. The parasympathetic neurons decrease the heart rate.

3 The cardiorespiratory center controls the frequency of action potentials in the sympathetic neurons (*blue*). The sympathetic neurons extend through the cardiac nerves and increase the heart rate and the stroke volume.

4 The cardiorespiratory center influences the frequency of action potentials in the sympathetic neurons (*blue*) extending to the adrenal medulla. The sympathetic neurons increase the secretion of epinephrine and some norepinephrine into the systemic circulation. Epinephrine and norepinephrine (*dotted green line*) increase the heart rate and stroke volume.

PROCESS FIGURE 20.22 Baroreceptor and Chemoreceptor Reflexes

Sensory neurons (*green*) carry action potentials from sensory receptors to the medulla oblongata. Sympathetic (*blue*) and parasympathetic (*red*) neurons exit the spinal cord or medulla oblongata and extend to the heart to regulate its function. Epinephrine and norepinephrine (*dotted green line*) from the adrenal gland also help regulate the heart's action (SA = sinoatrial). **AP R**

Hormonal Control

Epinephrine and norepinephrine released from the adrenal medulla can markedly influence the heart's pumping effectiveness. Epinephrine has essentially the same effect on cardiac muscle as norepinephrine, increasing the rate and force of heart contractions (see figure 20.21).

The secretion of epinephrine and norepinephrine is controlled by sympathetic stimulation of the adrenal medulla; it occurs in response to increased physical activity, emotional excitement, or other stressful conditions. Many stimuli that increase sympathetic stimulation of the heart also increase the release of epinephrine and norepinephrine from the adrenal medulla (see chapter 18). Epinephrine and norepinephrine travel in the blood through the vessels of the heart to the cardiac muscle cells, where they bind to β -adrenergic receptors and stimulate cAMP synthesis. Epinephrine takes a longer time to act on the heart than sympathetic stimulation does, but the effect lasts longer.

ASSESS YOUR PROGRESS

38. What is venous return? Explain how it affects preload. How does preload affect cardiac output? State the Starling law of the heart.
39. Define afterload, and describe its effect on the pumping effectiveness of the heart.
40. What part of the brain regulates the heart? Describe the autonomic nerve supply to the heart.

41. What effects do parasympathetic stimulation and sympathetic stimulation have on heart rate, force of contraction, and stroke volume?
42. What neurotransmitters are released by the parasympathetic and sympathetic postganglionic neurons of the heart? What effects do they have on membrane permeability and excitability?
43. Name the two main hormones that affect the heart. Where are they produced, what causes their release, and what effects do they have on the heart?

20.10 The Heart and Homeostasis

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe how changes in blood pressure, pH, carbon dioxide, and oxygen affect the function of the heart.
- B. Explain how extracellular ion concentration and body temperature affect the function of the heart.

The pumping efficiency of the heart plays an important role in maintaining homeostasis. Blood pressure in the systemic vessels must be high enough to allow nutrient and waste product exchange across the walls of the capillaries and to meet metabolic demands. In addition, the heart's activity must be regulated because the metabolic activities of the tissues change under such conditions as

exercise and rest. Reflexes help regulate the activity of the heart to maintain homeostasis. Baroreceptor reflexes regulate blood pressure, and chemoreceptor reflexes help regulate the heart's activity.

Effect of Blood Pressure

Baroreceptor (bar'ō-rē-sep'ter, bar'ō-rē-sep'tōr) **reflexes** detect changes in blood pressure and lead to changes in heart rate and force of contraction. Stretch receptors, the sensory receptors of the baroreceptor reflexes, are in the walls of certain large arteries, such as the internal carotid arteries and the aorta. These stretch receptors measure blood pressure (figure 20.22). The anatomy of these sensory structures and their afferent pathways are described in chapter 21.

Changes in blood pressure stimulate baroreceptors, which then communicate with control centers in the medulla oblongata. Afferent neurons, which are primarily found in the glossopharyngeal (cranial nerve IX) and vagus (cranial nerve X) nerves, carry action potentials from the baroreceptors to an area in the medulla oblongata called the **cardioregulatory center**, where sensory action potentials are integrated (figure 20.22). There are two parts to the cardioresgulatory center: the **cardioacceleratory center** increases heart rate, and the **cardioinhibitory center** decreases heart rate. Efferent action potentials then travel from the cardioresgulatory center to the heart through both the sympathetic and the parasympathetic divisions of the autonomic nervous system.

At normal blood pressures (80–120 mm Hg), afferent action potentials are sent from the baroreceptors in the internal carotid arteries and aorta to the medulla oblongata at a relatively constant frequency. When blood pressure rises, the arterial walls are stretched farther, and the afferent action potential frequency increases (figure 20.23). When blood pressure decreases, the arterial walls are stretched to a lesser extent, and the afferent action potential frequency decreases. In response to elevated blood pressure, the baroreceptor reflexes reduce sympathetic stimulation and increase parasympathetic stimulation of the heart, causing the heart rate to slow. Decreased blood pressure causes decreased parasympathetic and increased sympathetic stimulation of the heart, resulting in an increased heart rate and force of contraction. Withdrawal of parasympathetic stimulation is primarily responsible for increases in heart rate up to approximately 100 bpm. Larger increases in heart rate, especially during exercise, result from sympathetic stimulation. The baroreceptor reflexes are homeostatic because they keep the blood pressure within a narrow range of values that is adequate to maintain blood flow to the tissues.

Effect of pH, Carbon Dioxide, and Oxygen

Chemoreceptor (kē'mō-rē-sep'tor) **reflexes** help regulate the heart's activity. Chemoreceptors sensitive to changes in blood pH and carbon dioxide levels are found in the medulla oblongata. A drop in blood pH and a rise in carbon dioxide decrease parasympathetic and increase sympathetic stimulation of the heart, resulting in increased heart rate and force of contraction (figure 20.24).

The increased cardiac output causes greater blood flow through the lungs, where carbon dioxide is eliminated from the body. This helps lower the blood carbon dioxide level to within its normal range and helps increase blood pH.

Chemoreceptors primarily sensitive to blood oxygen levels are found in the carotid and aortic bodies. These small structures are located near large arteries close to the brain and heart, and they monitor blood flowing to the brain and the rest of the body. A dramatic decrease in blood oxygen levels, as occurs during asphyxiation, activates the carotid and aortic body chemoreceptor reflexes. In carefully controlled experiments, it is possible to isolate the effects of the carotid and aortic body chemoreceptor reflexes from other reflexes, such as the medullary chemoreceptor reflexes. These experiments indicate that a reduction in blood oxygen results in decreased heart rate and increased vasoconstriction. The vasoconstriction causes blood pressure to rise, which promotes blood delivery despite the decrease in heart rate. The carotid and aortic body chemoreceptor reflexes may protect the heart for a short time by slowing the heart rate, thereby reducing its need for oxygen. The carotid and aortic body chemoreceptor reflexes normally do not function independently of other regulatory mechanisms. When all the regulatory mechanisms function together, large, prolonged decreases in blood oxygen levels increase the heart rate. Low blood oxygen levels also increase stimulation of respiratory movements (see chapter 23). Increased inflation of the lungs stimulates stretch receptors in the lungs. Afferent action potentials from these stretch receptors influence the cardioresgulatory center, which causes the heart rate to increase. The reduced oxygen levels that exist at high altitudes can cause an increase in heart rate even when blood carbon dioxide levels remain low. However, the carotid and aortic body chemoreceptor reflexes are more important in regulating respiration (see chapter 23) and blood vessel constriction (see chapter 21) than heart rate.

Effect of Extracellular Ion Concentration

The ions that affect cardiac muscle function are the same ions (K^+ , Ca^{2+} , and Na^+) that influence membrane potentials in other electrically excitable tissues. However, cardiac muscle responds to these ions differently than nerve or skeletal muscle tissue does. For example, the extracellular levels of Na^+ rarely deviate enough from normal to significantly affect cardiac muscle function.

Excess extracellular K^+ in cardiac tissue causes the heart rate and stroke volume to decrease. A twofold increase in extracellular K^+ results in **heart block**, which is the loss of action potential conduction through the heart. The excess K^+ in the extracellular fluid causes partial depolarization of the resting membrane potential, resulting in a reduced amplitude of action potentials and, because of the reduced amplitude, a decreased rate at which action potentials are conducted along cardiac muscle cells. As the conduction rates decrease, ectopic action potentials can occur. In many cases, partially depolarized cardiac muscle cells spontaneously produce action potentials because the membrane potential reaches threshold. Elevated blood levels of K^+ can produce enough ectopic action potentials to cause fibrillation. The reduced action potential amplitude also results in less Ca^{2+} entering the sarcoplasm of the cell; thus, the strength of cardiac muscle contraction lessens.

Although the extracellular concentration of K^+ is normally small, a reduction in extracellular K^+ causes the resting membrane potential to become hyperpolarized; as a consequence, it takes longer for the membrane to depolarize to threshold. Ultimately, the reduction in extracellular K^+ results in a decrease in heart rate. The force of contraction is not affected, however.

HOMEOSTASIS FIGURE 20.23 Summary of the Baroreceptor Reflex

The baroreceptor reflex maintains homeostasis in response to changes in blood pressure. (1) Blood pressure is within its normal range. (2) Blood pressure increases outside the normal range, which causes homeostasis to be disturbed. (3) Baroreceptors in the carotid arteries and aorta detect the increase in blood pressure, and the cardioregulatory center in the brain alters autonomic stimulation of the heart. (4) Heart rate and stroke volume decrease. (5) These changes cause blood pressure to decrease. (6) Blood pressure returns to its normal range; homeostasis is restored. Observe the responses to a decrease in blood pressure outside its normal range by following the red arrows.

HOMEOSTASIS FIGURE 20.24 Summary of the Chemoreceptor Reflex

The chemoreceptor reflex maintains homeostasis in response to changes in blood CO₂ and H⁺ concentrations (pH). (1) Blood pH is within its normal range. (2) Blood pH increases outside the normal range. (3) Chemoreceptors in the medulla oblongata detect increased blood pH. Control centers in the brain decrease sympathetic stimulation of the heart and adrenal medulla. (4) Heart rate and stroke volume decrease, reducing blood flow to the lungs. (5) These changes cause blood pH to decrease (as a result of increase in blood CO₂). (6) Blood pH returns to its normal range; homeostasis is restored. Observe the responses to a decrease in blood pH outside its normal range by following the *red arrows*.

Clinical IMPACT

Treatment and Prevention of Heart Disease

Hear disease is a life-threatening condition that affects people of all walks of life. Fortunately, medications and surgical procedures are available to treat many forms of heart disease. Preventive measures have also been identified to help people reduce their chance of developing heart disease.

Heart Medications

Digitalis (dij-i-tal'is, dij-i-ta'lis) slows and strengthens contractions of the heart muscle by increasing the amount of Ca^{2+} that enters cardiac muscle cells and by prolonging the action potentials' refractory period. This drug is frequently given to people who have heart failure, although it also can be used to treat atrial tachycardia.

Nitroglycerin (nī-trō-glis'er-in) causes dilation of all the veins and arteries, including coronary arteries, without an increase in heart rate or stroke volume. When all blood vessels dilate, a greater volume of blood pools in the dilated blood vessels, causing a decrease in the venous return to the heart. The flow of blood through coronary arteries also increases. The reduced preload causes cardiac output to decline, decreasing the amount of work

performed by the heart. Nitroglycerin is frequently given to patients who have coronary artery disease that restricts coronary blood flow. The decreased work performed by the heart reduces the amount of oxygen required by the cardiac muscle. Consequently, the heart does not suffer from lack of oxygen, and angina pectoris does not develop.

Beta-adrenergic blocking agents reduce the rate and strength of cardiac muscle contractions, reducing the heart's demand for oxygen. These blocking agents bind to receptors for norepinephrine and epinephrine and prevent these substances from having their normal effects. These blocking agents are often used to treat rapid heart rate, certain types of arrhythmia, and hypertension.

Calcium channel blockers reduce the rate at which Ca^{2+} diffuses into cardiac and smooth muscle cells. Because the action potentials that produce cardiac muscle contractions depend in part on the flow of Ca^{2+} into cardiac muscle cells, calcium channel blockers can be used to control the force of heart contractions and to reduce arrhythmia, tachycardia, and hypertension. Because the entry of Ca^{2+} into smooth muscle cells causes contraction,

calcium channel blockers dilate coronary blood vessels and can be used to treat angina pectoris.

Antihypertensive agents (an'tē-hī-per-ten'siv) comprise several drugs used to treat hypertension. These drugs lower blood pressure and therefore reduce the work required by the heart to pump blood. In addition, reduced blood pressure decreases the risk for heart attack and stroke. Drugs used to treat hypertension include those that reduce the activity of the sympathetic nervous system, dilate arteries and veins, increase urine production (diuretics), and block the conversion of angiotensinogen to angiotensin I.

Anticoagulants (an'tē-kō-ag'ū-lantz) prevent clot formation in people who have damaged heart valves or blood vessels or in those who have had a myocardial infarction. Aspirin functions as a weak anticoagulant.

Instruments and Selected Procedures

An **artificial pacemaker** is an instrument, placed beneath the skin, equipped with an electrode that extends to the heart and provides an electrical stimulus at a set frequency.

Case STUDY

Aortic Valve Stenosis

Norma is a 62-year-old woman who had rheumatic fever when she was 12 years old. She has had a heart murmur ever since. Norma went to her doctor, complaining of fatigue; dizziness, especially on rising from a sitting or lying position; and pain in her chest when she exercises. Her doctor listened to Norma's heart and determined she has a systolic murmur (see Clinical Impact, "Abnormal Heart Sounds"). Norma's blood pressure (90/65 mm Hg) and heart rate (55 beats/min) were lower than normal. Norma's doctor referred her to a cardiologist, who did additional tests. An electrocardiogram indicated she has left ventricular hypertrophy. Imaging techniques confirmed the left ventricular hypertrophy and indicated a stenosed aortic semilunar valve. The

cardiologist explained to Norma that the rheumatic fever she had as a child damaged her aortic semilunar valve and that the valve's condition had gradually become worse. The cardiologist recommended surgical replacement of Norma's aortic semilunar valve. Otherwise, she is likely to develop heart failure.

➤ Predict 10

- What effect does Norma's stenosed valve have on stroke volume?
- Norma has left ventricular hypertrophy, which means the left ventricle is enlarged and has thicker walls than normal. Explain how that condition developed.
- Explain Norma's low blood pressure.
- Explain why Norma becomes dizzy on rising from a sitting or lying position (*hint*: venous return).
- Predict how Norma's heart rate changes on standing (see figure 20.23).
- Norma experiences chest pain when she exercises, a condition called angina pectoris (see Clinical Impact, "Angina, Infarctions, and the Treatment of Blocked Coronary Arteries"). Why doesn't she feel this pain at rest?

Artificial pacemakers are used in patients whose natural heart pacemakers do not produce a heart rate high enough to sustain normal physical activity. Artificial pacemakers can increase the heart rate as physical activity increases. Pacemakers can also detect cardiac arrest, extreme arrhythmias, or fibrillation. In response, strong stimulation of the heart by the pacemaker may restore heart function.

A **heart-lung machine** temporarily substitutes for a patient's heart and lungs. It oxygenates the blood, removes carbon dioxide, and pumps blood throughout the body. Heart-lung machines have made possible many surgeries on the heart and lungs.

Heart valve replacement or repair is a surgical procedure performed on valves that are so deformed and scarred from conditions such as endocarditis that they have become severely incompetent or stenosed. Substitute valves made of synthetic materials, such as plastic or Dacron, are effective; valves transplanted from pigs are also used.

A **heart transplant** is a surgical procedure in which the heart of a recently deceased donor is transplanted to the recipient, and the recipient's diseased heart is removed. A heart transplant is possible only if the characteristics of the donor closely match those of the recipient

(see chapter 22). People who have received heart transplants must continue to take drugs that suppress their immune responses for the rest of their lives. If they do not, the immune system will reject the transplanted heart.

An **artificial heart** is a mechanical pump that replaces the heart. Although still experimental and not able to substitute permanently for the heart, artificial hearts have been used to keep patients alive until a donor heart can be found.

Cardiac assistance involves temporarily implanting a mechanical device that assists the heart in pumping blood. In some cases, the decreased workload on the heart provided by the device appears to promote recovery of failing hearts, whereupon the device has been successfully removed. In **cardiomyoplasty**, a piece of a back muscle (latissimus dorsi) is wrapped around the heart and stimulated to contract in synchrony with the heart.

Prevention of Heart Disease

Heart disease is a major cause of death. Several precautions can help prevent heart disease. Proper nutrition is important in reducing the risk for heart disease (see chapter 25).

The recommended diet is low in fats, especially saturated fats and cholesterol, and low in refined sugar. The diet should be high in fiber,

whole grains, fruits, and vegetables. Total food intake should be limited to avoid obesity, and sodium chloride intake should be reduced.

Smoking and excessive alcohol consumption should be avoided. Smoking increases the risk for heart disease at least ten-fold, and excessive alcohol consumption substantially increases the risk for heart disease.

Chronic stress, frequent emotional upsets, and lack of physical exercise can increase the risk for cardiovascular disease. Remedies include relaxation techniques and aerobic exercise programs involving gradual increases in the duration and difficulty of activities such as walking, swimming, jogging, and aerobic dancing.

Hypertension (hī'per-ten'shūn), abnormally high systemic blood pressure, affects about one-fifth of the U.S. population. People are advised to have their blood pressure measured regularly because hypertension does not produce obvious symptoms. If hypertension cannot be controlled by diet and exercise, blood pressure-lowering drugs are prescribed. The cause of hypertension is unknown in most cases.

Some data suggest that taking an aspirin daily reduces the chance of having a heart attack. Aspirin inhibits the synthesis of prostaglandins in platelets, thereby helping prevent clot formation (see chapter 19).

A rise in the extracellular concentration of Ca^{2+} produces a greater force of cardiac contraction because of a higher influx of Ca^{2+} into the sarcoplasm during action potential generation. Elevated plasma Ca^{2+} levels have an indirect effect on heart rate because they reduce the frequency of action potentials in nerve fibers, thus reducing sympathetic and parasympathetic stimulation of the heart (see chapter 11). Generally, elevated blood Ca^{2+} levels lower the heart rate.

A low blood Ca^{2+} level increases the heart rate, although the effect is imperceptible until blood Ca^{2+} levels are reduced to approximately one-tenth of their normal value. The reduced extracellular Ca^{2+} levels cause Na^+ channels to open, which allows Na^+ to diffuse more readily into the cell, resulting in depolarization and action potential generation. However, reduced Ca^{2+} levels usually cause death due to tetany of skeletal muscles before they decrease enough to markedly influence the heart's function.

Effect of Body Temperature

Under resting conditions, the temperature of cardiac muscle normally does not change dramatically, although alterations in temperature influence the heart rate. Small increases in cardiac muscle

temperature cause the heart rate to speed up, and decreases in temperature cause the heart rate to slow. For example, during exercise or fever, increased heart rate and force of contraction accompany temperature elevations, but the heart rate drops under conditions of hypothermia. During heart surgery, body temperature is sometimes reduced dramatically on purpose to slow the heart rate and other metabolic functions.

ASSESS YOUR PROGRESS

44. Explain how the nervous system detects and responds to each of the following:
 - a. a decrease in blood pressure
 - b. an increase in blood carbon dioxide level
 - c. a decrease in blood pH
 - d. a decrease in blood oxygen level
45. Describe the baroreceptor reflex and the heart's response to an increase in venous return.
46. What effect does an increase or a decrease in extracellular potassium, calcium, and sodium ions have on the heart's rate and force of contraction?
47. What effect does temperature have on heart rate?

Systems PATHOLOGY

Myocardial Infarction

Occluded coronary artery

Background Information

At the hospital, Paul was given tissue plasminogen activator (t-PA) to improve blood flow to the damaged area of the heart by activating plasminogen, which dissolves blood clots. Over the next few days, enzymes, such as creatine phosphokinase, increased in Paul's blood, which confirmed that cardiac muscle had been damaged by an infarction.

In the hospital, Paul began to experience shortness of breath because of pulmonary edema, and after a few days he developed pneumonia. He was treated for the pneumonia and gradually improved over the next few weeks. An angiogram (an'jē-ō-gram) performed several days after Paul's infarction indicated that he had suffered damage to a significant part of the lateral wall of his left ventricle. Although blood flow in some of Paul's coronary arteries was seriously restricted, his physicians did not believe that angioplasty or bypass surgery was necessary.

Paul experienced a myocardial infarction, in which a thrombosis in one of the branches of the left coronary artery reduced the blood supply to the lateral wall of the left ventricle, resulting in ischemia of the left ventricle wall. The fact that t-PA was an effective treatment supports the conclusion that the infarction was caused by a thrombosis. An ischemic area of the heart wall is not able to contract normally; therefore, Paul's heart's pumping effectiveness was dramatically reduced. The reduced pumping capacity was responsible for the low blood pressure, which decreased the blood flow to Paul's brain, resulting in confusion, disorientation, and unconsciousness.

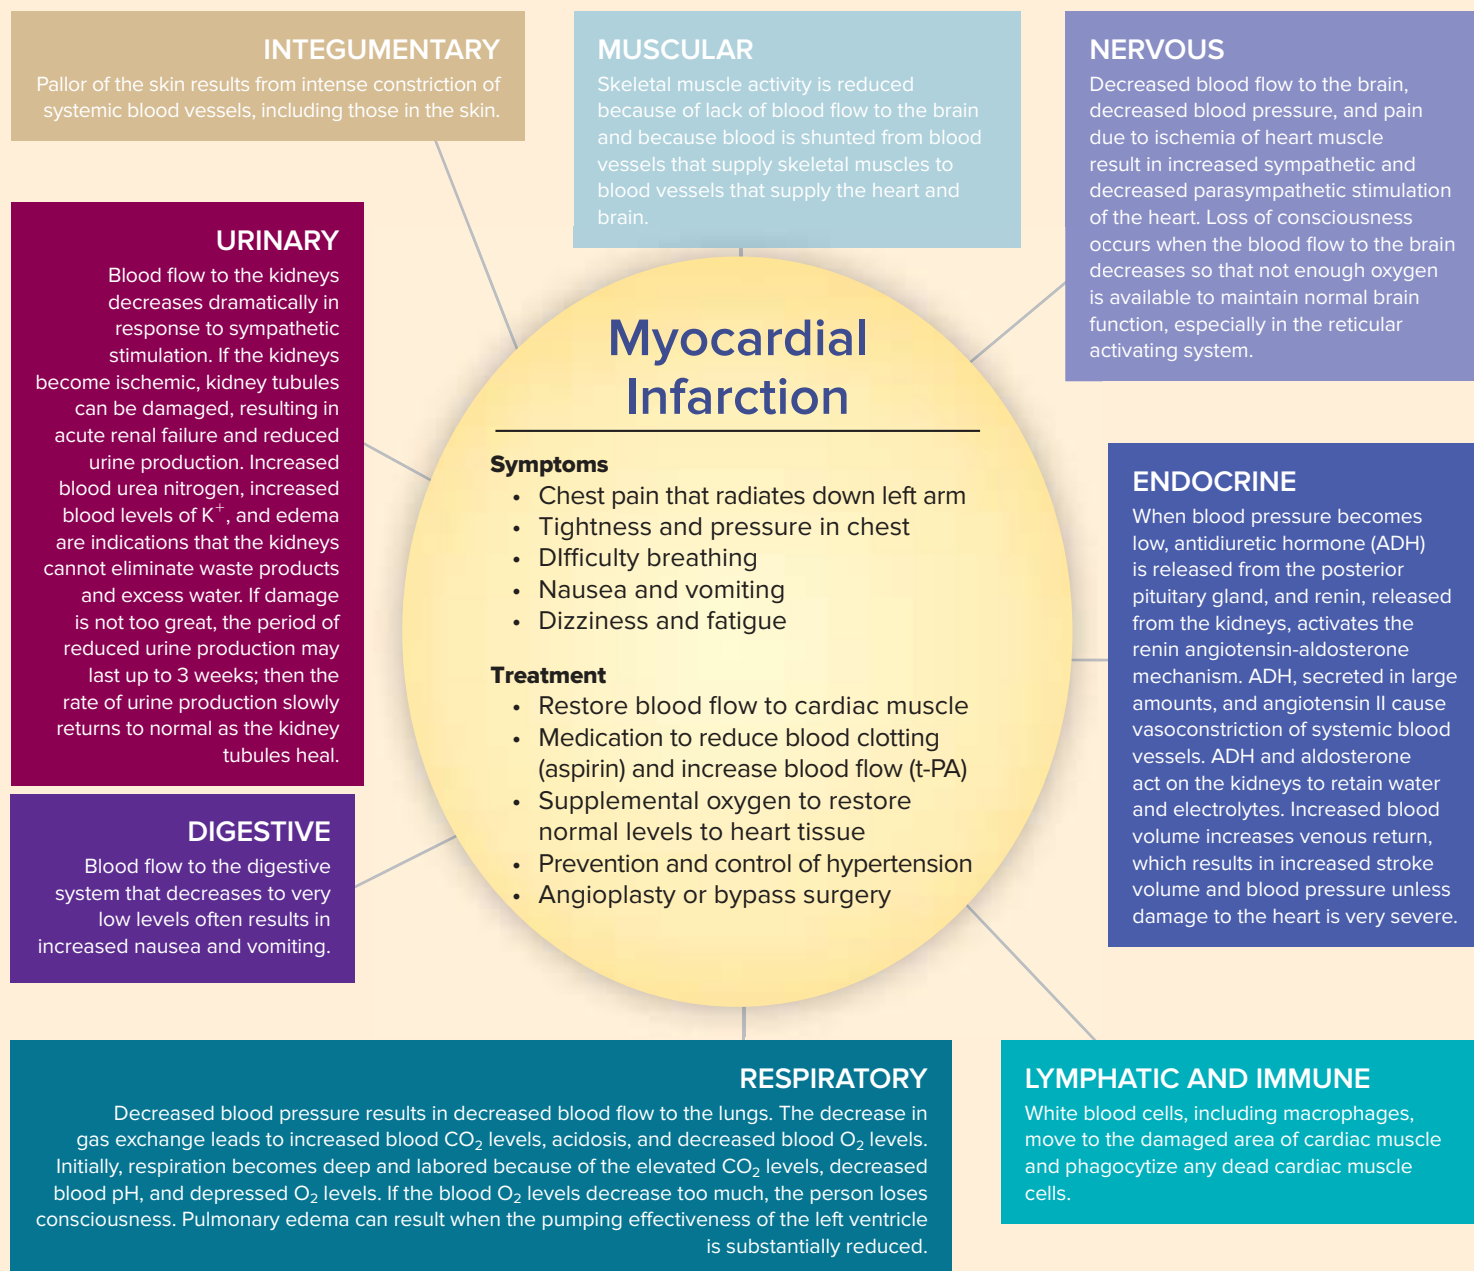

Low blood pressure, increasing blood carbon dioxide levels, pain, and anxiousness increased sympathetic stimulation of the heart and adrenal glands. Increased sympathetic stimulation of the adrenal medulla caused the release of epinephrine. Increased parasympathetic stimulation of the heart resulted from pain sensations. In such cases, the heart is periodically arrhythmic due to the combined effects of parasympathetic stimulation, sympathetic stimulation, and the release of epinephrine and norepinephrine from the adrenal glands. In addition, the ischemic areas of the left ventricle produce ectopic beats.

Pulmonary edema resulted from the increased pressure in Paul's pulmonary veins because of the left ventricle's inability to pump blood. The edema allowed bacteria to infect the lungs and cause pneumonia.

Paul's heart began to beat rhythmically in response to medication because the infarction had not damaged the conducting system of the heart, which is an indication that no permanent arrhythmias had developed. (Permanent arrhythmias indicate damage to cardiac muscle specialized to conduct action potentials in the heart.)

Figure 20A Angiograms

An angiogram is usually obtained by placing a catheter into a blood vessel and injecting a dye that can be detected with x-rays. Note the occluded (blocked) coronary blood vessel in this angiogram, which has been computer-enhanced to show colors. The angiogram on the right is of a normal heart.

Analysis of the electrocardiogram, blood pressure measurements, and an angiogram (figure 20A) indicated that the infarction was located on the left side of Paul's heart. Paul's lifestyle correlated with an increased probability of myocardial infarction in several ways: lack of physical exercise, overweight, smoking, and stress.

Paul's physician made it very clear that he was lucky to have survived a myocardial infarction and recommended a weight-loss program and a low-sodium and low-fat diet. The physician also suggested that Paul stop smoking. She explained that Paul would have to take medication for high blood pressure if his blood pressure did not decrease in response to the recommended changes. The physician recommended an aerobic exercise program for Paul after a period of recovery. She also advised Paul to seek ways to reduce the stress associated with his job and recommended that he take a small amount of aspirin regularly to reduce the probability of thrombosis. Because aspirin inhibits prostaglandin synthesis, it reduces the

tendency for blood to clot. Paul followed the doctor's recommendations; after several months, his blood pressure was normal and he began to feel better than he had in years.

➤ Predict 11

Severe ischemia in the wall of a ventricle can cause the death of cardiac muscle cells. Inflammation develops around the necrotic (dead) tissue, and macrophages invade the necrotic tissue and phagocytize dead cells. At the same time, blood vessels and connective tissue grow into the area and begin to deposit connective tissue to replace the necrotic tissue. Suppose that Paul had been recovering from his myocardial infarction for about a week when suddenly his blood pressure decreased to very low levels and he died within a very short time. At autopsy, a large amount of blood was found in the pericardial sac, and the wall of the left ventricle was ruptured. Explain.

20.11 Effects of Aging on the Heart

LEARNING OUTCOME

After reading this section, you should be able to

A. List the major age-related changes that affect the heart.

Gradual changes in heart function normally occur with aging. These age-related changes are minor under resting conditions but become more significant in response to exercise or other age-related diseases. Under resting conditions, the mechanisms that regulate the heart compensate effectively for most of the age-related changes.

Hypertrophy of the left ventricle is a common age-related change. This appears to result from a gradual increase in the pressure in the aorta, against which the left ventricle must pump blood, and a gradual increase in the stiffness of cardiac muscle tissue. The elevated aortic pressure results from a gradual

reduction in arterial elasticity, leading to increased stiffness of the aorta and other large arteries. Myocardial cells accumulate lipids, and the number of collagen fibers increases in cardiac tissue. These changes make the cardiac muscle tissue stiffer and less compliant. The increased volume of the left ventricle can sometimes result in higher left atrial pressure and increased pulmonary capillary pressure. This can cause pulmonary edema and a tendency for older people to feel out of breath when they exercise strenuously.

The maximum heart rate gradually declines, as can be roughly predicted by the following formula:

$$\text{Maximum heart rate} = 220 - \text{Age of individual}$$

The rate at which cardiac muscle breaks down ATP increases, and the rate of Ca^{2+} transport decreases. The maximum rate at which cardiac muscle can carry out aerobic respiration also decreases. In addition, the degree to which epinephrine and norepinephrine can increase the heart rate declines. These changes lead to longer

Diseases and Disorders

TABLE 20.3

Heart

Condition	Description
Inflammation of Heart Tissue	
Endocarditis	Inflammation of the endocardium; affects the valves more severely than other areas of the endocardium; may lead to scarring, causing stenosed or incompetent valves
Pericarditis	Inflammation of the pericardium; see Clinical Impact, “Pericarditis and Cardiac Tamponade”
Cardiomyopathy	Disease of the myocardium of unknown cause or occurring secondarily to other disease; results in weakened cardiac muscle, causing all chambers of the heart to enlarge; may eventually lead to congestive heart failure
Rheumatic heart disease	Results from a streptococcal infection in young people; toxin produced by the bacteria can cause rheumatic fever several weeks after the infection that can result in rheumatic endocarditis
Reduced Blood Flow to Cardiac Muscle	
Coronary heart disease	Reduces the amount of blood the coronary arteries can deliver to the myocardium
Coronary thrombosis	Formation of blood clot in a coronary artery
Myocardial infarction	Damaged cardiac muscle tissue resulting from lack of blood flow to the myocardium; often referred to as a heart attack; see Clinical Impact, “Angina, Infarctions, and the Treatment of Blocked Coronary Arteries”
Congenital Heart Diseases (occur at birth)	
Septal defect	Hole in the septum between the left and right sides of the heart, allowing blood to flow from one side of the heart to the other and greatly reducing the heart’s pumping effectiveness
Patent ductus arteriosus	Ductus arteriosus fails to close after birth, allowing blood to flow from the aorta to the pulmonary trunk under a higher pressure, which damages the lungs; also, the left ventricle must work harder to maintain adequate systemic pressure
Stenosis of the heart valve	Narrowed opening through one or more of the heart valves; aortic or pulmonary semilunar stenosis increases the heart’s workload; bicuspid valve stenosis causes blood to back up in the left atria and lungs, resulting in edema of the lungs; tricuspid valve stenosis results in similar blood flow problems and edema in the peripheral tissues
Incompetent heart valve	Heart valves do not close correctly, and blood flows through in the reverse direction; see Clinical Impact, “Abnormal Heart Sounds”
Cyanosis (sī-ā-nō’sis; cyan, blue + osis, condition of)	Symptom of inadequate heart function in babies with congenital heart disease; the infant’s skin appears blue because of low oxygen levels in the blood in peripheral blood vessels
Heart Failure	Progressive weakening of the heart muscle, reducing the heart’s pumping action; hypertension leading to heart failure due to increased afterload; advanced age, malnutrition, chronic infections, toxins, severe anemias, hyperthyroidism, and hereditary factors can lead to heart failure

contraction and relaxation times for cardiac muscle and a decrease in the maximum heart rate. Both the resting and maximum cardiac outputs slowly decline as people age; by 85 years of age, the cardiac output may have decreased by 30–60%.

Age-related changes also occur in the connective tissue of the heart valves. The connective tissue becomes less flexible, and Ca^{2+} deposits increase. The result is an increased tendency for the heart valves to function abnormally. The aortic semilunar valve is especially likely to become stenosed, but other heart valves, such as the bicuspid valve, may become either stenosed or incompetent.

The atrophy and replacement of cells of the left bundle branch and a decrease in the number of SA node cells alter the electrical conducting system of the heart and lead to a higher rate of cardiac arrhythmias in elderly people.

The enlarged and thickened cardiac muscle, especially in the left ventricle, requires more oxygen to pump the same amount of blood pumped by a younger heart. This change is not significant unless the coronary circulation is diminished by coronary artery disease. However, the development of coronary artery disease is

age-related, as is congestive heart disease. Approximately 10% of elderly people over 80 have congestive heart failure, and a major contributing factor is coronary artery disease. Because of age-related changes in the heart, many elderly people are limited in their ability to respond to emergencies, infections, blood loss, and stress.

Exercise has many beneficial effects on the heart. Regular aerobic exercise improves the heart's functional capacity at all ages, provided the person has no other conditions that cause the extra workload on the heart to be harmful.

ASSESS YOUR PROGRESS

48. Explain how age-related changes affect the function of the left ventricle.
49. Describe age-related changes in the heart rate.
50. Describe how increasing age affects the function of the conducting system and the heart valves.
51. Discuss the effect of two age-related heart diseases on the function of the aging heart.

Answer

Learn to Predict From page 673

We learned in this chapter that the heart valves maintain a one-way flow of blood through the heart—from the atria to the ventricles. We also learned that an incompetent valve is one that leaks, or allows some blood to flow in the opposite direction—from the ventricles to the atria. An irregular swooshing noise following the first heart sound, as noted by Stan's regular physician, is a typical sign of an incompetent valve. The first heart sound is produced when the bicuspid and tricuspid valves close. The swooshing sound is the regurgitation of blood into the atria. The cardiologist determined that the bicuspid valve was incompetent, resulting in abnormal blood flow on the left side of the heart.

Stan's difficulty breathing resulted from the abnormal blood flow caused by his incompetent valve. After reviewing the blood

flow through the heart in this chapter, we are aware that blood entering the left atrium is returning from the lungs through the pulmonary veins. As a result of the incompetent valve, the pressure in the left atrium, which is normally low, increases substantially during ventricular systole. The increased left atrial pressure causes the pressure in the pulmonary veins and pulmonary capillaries to increase. As a result, fluid leaks from the pulmonary capillaries into the lungs, causing pulmonary edema, or fluid accumulation in the lungs, making it difficult for Stan to breathe.

Answers to the rest of this chapter's Predict questions are in appendix G.

Summary

20.1 Functions of the Heart (p. 674)

The heart produces the force that causes blood to circulate.

20.2 Size, Shape, and Location of the Heart (p. 675)

1. The heart is approximately the size of a closed fist and is shaped like a blunt cone.
2. The heart lies obliquely in the mediastinum, with its base directed posteriorly and slightly superiorly and its apex directed anteriorly, inferiorly, and to the left.

3. The base is deep to the second intercostal space, and the apex extends to the fifth intercostal space.

20.3 Anatomy of the Heart (p. 675)

The heart consists of two atria and two ventricles.

Pericardium

1. The pericardium is a sac that surrounds the heart and consists of the fibrous pericardium and the serous pericardium.
2. The fibrous pericardium helps hold the heart in place.

- The serous pericardium reduces friction as the heart beats. It consists of the following parts:
 - The parietal pericardium lines the fibrous pericardium.
 - The visceral pericardium lines the exterior surface of the heart.
 - The pericardial cavity lies between the parietal and visceral pericardium and is filled with pericardial fluid, which reduces friction as the heart beats.

Heart Wall

- The heart wall has three layers:
 - The outer epicardium (visceral pericardium) provides protection against the friction of rubbing organs.
 - The middle myocardium is responsible for contraction.
 - The inner endocardium reduces the friction resulting from blood passing through the heart.
- The inner surfaces of the atria are mainly smooth. The auricles have muscular ridges called pectinate muscles.
- The ventricles have ridges called trabeculae carneae.

External Anatomy and Coronary Circulation

- Each atrium has a flap called an auricle.
- The coronary sulcus separates the atria from the ventricles. The interventricular grooves separate the right and left ventricles.
- The inferior and superior venae cavae and the coronary sinus enter the right atrium. The four pulmonary veins enter the left atrium.
- The pulmonary trunk exits the right ventricle, and the aorta exits the left ventricle.
- Coronary arteries branch off the aorta to supply the heart. Blood returns from the heart tissues to the right atrium through the coronary sinus and cardiac veins.

Heart Chambers and Valves

- The interatrial septum separates the atria from each other, and the interventricular septum separates the ventricles.
- The tricuspid valve separates the right atrium and ventricle. The bicuspid valve separates the left atrium and ventricle. The chordae tendineae attach the papillary muscles to the atrioventricular valves.
- The semilunar valves separate the aorta and pulmonary trunk from the ventricles.

20.4 Route of Blood Flow Through the Heart (p. 682)

- Blood from the body flows through the right atrium into the right ventricle and then to the lungs.
- Blood returns from the lungs to the left atrium, enters the left ventricle, and is pumped back to the body.

20.5 Histology (p. 683)

Heart Skeleton

The fibrous heart skeleton supports the openings of the heart, electrically insulates the atria from the ventricles, and provides a point of attachment for heart muscle.

Cardiac Muscle

- Cardiac muscle cells are branched and have a centrally located nucleus. Actin and myosin are organized to form sarcomeres. The sarcoplasmic reticulum and T tubules are not as organized as in skeletal muscle.
- Cardiac muscle cells are joined by intercalated disks, which allow action potentials to move from one cell to the next. Thus, cardiac muscle cells function as a unit.

- Cardiac muscle cells have a slow onset of contraction and a prolonged contraction time caused by the length of time required for Ca^{2+} to move to and from the myofibrils.
- Cardiac muscle is well supplied with blood vessels that support aerobic respiration.
- Cardiac muscle aerobically uses glucose, fatty acids, and lactate to produce ATP for energy. Cardiac muscle does not develop a significant oxygen deficit.

Conducting System

- The SA node and the AV node are in the right atrium.
- The AV node is connected to the bundle branches in the interventricular septum by the AV bundle.
- The bundle branches give rise to Purkinje fibers, which supply the ventricles.
- The SA node is made up of small-diameter cardiac muscle cells that initiate action potentials, which spread across the atria and cause them to contract.
- Action potentials are slowed in the AV node, allowing the atria to contract and blood to move into the ventricles. Then the action potentials travel through the AV bundles and bundle branches to the Purkinje fibers, causing the ventricles to contract, starting at the apex. The AV node is also made up of small-diameter cardiac muscle fibers.

20.6 Electrical Properties (p. 687)

Action Potentials

- After depolarization and partial repolarization, a plateau is reached, during which the membrane potential only slowly repolarizes.
- The movement of Na^+ through the voltage-gated Na^+ channels causes depolarization.
- During depolarization, voltage-gated K^+ channels close, and voltage-gated Ca^{2+} channels begin to open.
- Early repolarization results from closure of the voltage-gated Na^+ channels and the opening of some voltage-gated K^+ channels.
- The plateau exists because voltage-gated Ca^{2+} channels remain open.
- The rapid phase of repolarization results from closure of the voltage-gated Ca^{2+} channels and the opening of many voltage-gated K^+ channels.
- The entry of Ca^{2+} into cardiac muscle cells causes Ca^{2+} to be released from the sarcoplasmic reticulum to trigger contractions.

Autorhythmicity of Cardiac Muscle

- Cardiac pacemaker muscle cells are autorhythmic because of the spontaneous development of a pacemaker potential.
- The pacemaker potential results from the movement of Na^+ and Ca^{2+} into the pacemaker cells.
- Ectopic foci are areas of the heart that regulate heart rate under abnormal conditions.

Refractory Periods of Cardiac Muscle

Cardiac muscle has a prolonged depolarization and thus a prolonged refractory period, which allows time for the cardiac muscle to relax before the next action potential causes a contraction.

Electrocardiogram

- An ECG records only the electrical activities of the heart.
 - Depolarization of the atria produces the P wave.
 - Depolarization of the ventricles produces the QRS complex. Repolarization of the atria occurs during the QRS complex.
 - Repolarization of the ventricles produces the T wave.

- Based on the magnitude of the ECG waves and the time between waves, ECGs can be used to diagnose heart abnormalities.

20.7 Cardiac Cycle (p. 694)

- The cardiac cycle involves repetitive contraction and relaxation of the heart chambers.
- Blood moves through the circulatory system from areas of higher pressure to areas of lower pressure. Contraction of the heart produces the pressure.
- The cardiac cycle is divided into five periods:
 - Active ventricular filling results when the atria contract and pump blood into the ventricles.
 - Although the ventricles are contracting, during the period of isovolumetric contraction, ventricular volume does not change because all the heart valves are closed.
 - During the period of ejection, the semilunar valves open, and blood is ejected from the heart.
 - Although the heart is relaxing, during the period of isovolumetric relaxation, ventricular volume does not change because all the heart valves are closed.
 - Passive ventricular filling results when blood flows from the higher pressure in the veins and atria to the lower pressure in the relaxed ventricles.

Events Occurring During the Cardiac Cycle

- Most ventricular filling occurs when blood flows from the higher pressure in the veins and atria to the lower pressure in the relaxed ventricles.
- Contraction of the atria completes ventricular filling.
- Contraction of the ventricles closes the AV valves, opens the semilunar valves, and ejects blood from the heart.
- The volume of blood in a ventricle just before it contracts is the end-diastolic volume. The volume of blood after contraction is the end-systolic volume.
- Relaxation of the ventricles results in the closing of the semilunar valves, the opening of the AV valves, and the movement of blood into the ventricles.

Heart Sounds

- Closure of the atrioventricular valves produces the first heart sound.
- Closure of the semilunar valves produces the second heart sound.
- Turbulent flow of blood into the ventricles can be heard in some people, producing a third heart sound.

Aortic Pressure Curve

- Contraction of the ventricles forces blood into the aorta, producing the peak systolic pressure.
- Blood pressure in the aorta falls to the diastolic level as blood flows out of the aorta.
- Elastic recoil of the aorta maintains pressure in the aorta and produces the dicrotic notch and dicrotic wave.

20.8 Mean Arterial Blood Pressure (p. 701)

- Mean arterial pressure is the average blood pressure in the aorta. Adequate blood pressure is necessary to ensure delivery of blood to the tissues.
- Mean arterial pressure is proportional to cardiac output (amount of blood pumped by the heart per minute) times peripheral resistance (total resistance to blood flow through blood vessels).

- Cardiac output is equal to stroke volume times heart rate.
- Stroke volume, the amount of blood pumped by the heart per beat, is equal to end-diastolic volume minus end-systolic volume.
 - Venous return is the amount of blood returning to the heart. Increased venous return increases stroke volume by increasing end-diastolic volume.
 - Increased force of contraction increases stroke volume by decreasing end-systolic volume.
- Cardiac reserve is the difference between resting and exercising cardiac output.

20.9 Regulation of the Heart (p. 702)

Intrinsic Regulation

- Venous return is the amount of blood that returns to the heart during each cardiac cycle.
- The Starling law of the heart describes the relationship between preload and the stroke volume of the heart. An increased preload causes the cardiac muscle cells to contract with a greater force and produce a greater stroke volume.

Extrinsic Regulation

- The cardioregulatory center in the medulla oblongata regulates parasympathetic and sympathetic nervous control of the heart.
- Parasympathetic stimulation is supplied by the vagus nerve.
 - Parasympathetic stimulation decreases heart rate.
 - Postganglionic neurons secrete acetylcholine, which increases membrane permeability to K^+ , producing hyperpolarization of the membrane.
- Sympathetic stimulation is supplied by the cardiac nerves.
 - Sympathetic stimulation increases heart rate and force of contraction (stroke volume).
 - Postganglionic neurons secrete norepinephrine, which increases membrane permeability to Na^+ and Ca^{2+} and produces depolarization of the membrane.
- Epinephrine and norepinephrine are released into the blood from the adrenal medulla as a result of sympathetic stimulation.
 - The effects of epinephrine and norepinephrine on the heart are long-lasting, compared with those of neural stimulation.
 - Epinephrine and norepinephrine increase the rate and force of heart contraction.

20.10 The Heart and Homeostasis (p. 704)

Effect of Blood Pressure

- Baroreceptors monitor blood pressure.
- In response to a decrease in blood pressure, the baroreceptor reflexes increase sympathetic stimulation and decrease parasympathetic stimulation of the heart, resulting in increased heart rate and force of contraction.

Effect of pH, Carbon Dioxide, and Oxygen

- Chemoreceptors monitor blood carbon dioxide, pH, and oxygen levels.
- In response to increased carbon dioxide and decreased pH, medullary chemoreceptor reflexes increase sympathetic stimulation and decrease parasympathetic stimulation of the heart.
- Carotid body chemoreceptor receptors stimulated by low oxygen levels result in decreased heart rate and vasoconstriction.
- All regulatory mechanisms functioning together in response to low blood pH, high blood carbon dioxide, and low blood oxygen levels usually produce increased heart rate and vasoconstriction. Decreased

oxygen levels stimulate an increase in heart rate indirectly by stimulating respiration, and the stretch of the lungs activates a reflex that increases sympathetic stimulation of the heart.

Effect of Extracellular Ion Concentration

1. An increase or a decrease in extracellular K^+ decreases heart rate.
2. Increased extracellular Ca^{2+} increases force of contraction of the heart and decreases heart rate. Decreased Ca^{2+} levels produce the opposite effect.

Effect of Body Temperature

Heart rate increases when body temperature increases, and it decreases when body temperature decreases.

20.11 Effects of Aging on the Heart (p. 712)

1. Aging results in gradual changes in heart function, which are minor under resting conditions but more significant during exercise.
2. Hypertrophy of the left ventricle is a common age-related condition.
3. The maximum heart rate declines so that, by age 85, the cardiac output may be decreased by 30–60%.
4. There is an increased tendency for valves to function abnormally and for arrhythmias to occur.
5. Because increased oxygen consumption is required to pump the same amount of blood, age-related coronary artery disease is more severe.
6. Exercise improves the functional capacity of the heart at all ages.

REVIEW AND COMPREHENSION

1. Which of these structures returns blood to the right atrium?
 - a. coronary sinus
 - b. inferior vena cava
 - c. superior vena cava
 - d. Both b and c are correct.
 - e. All of these are correct.
2. The valve located between the right atrium and the right ventricle is the
 - a. aortic semilunar valve.
 - b. pulmonary semilunar valve.
 - c. tricuspid valve.
 - d. bicuspid (mitral) valve.
3. The papillary muscles
 - a. are attached to chordae tendineae.
 - b. are found in the atria.
 - c. contract to close the foramen ovale.
 - d. are attached to the semilunar valves.
 - e. surround the openings of the coronary arteries.
4. Given these blood vessels:

(1) aorta	(3) pulmonary trunk
(2) inferior vena cava	(4) pulmonary vein

Choose the arrangement that lists the vessels in the order a red blood cell would encounter them going from the systemic veins to the systemic arteries.

- | | | |
|------------|------------|------------|
| a. 1,3,4,2 | c. 2,4,3,1 | e. 3,4,2,1 |
| b. 2,3,4,1 | d. 3,2,1,4 | |
5. The bulk of the heart wall is
 - a. epicardium.
 - b. pericardium.
 - c. myocardium.
 - d. endocardium.
 - e. exocardium.
 6. Cardiac muscle has
 - a. sarcomeres.
 - b. a sarcoplasmic reticulum.
 - c. transverse tubules.
 - d. many mitochondria.
 - e. All of these are correct.
 7. Action potentials pass from one cardiac muscle cell to another
 - a. through gap junctions.
 - b. by a special cardiac nervous system.
 - c. because of the large voltage of the action potentials.
 - d. because of the plateau phase of the action potentials.
 - e. by neurotransmitters.
 8. During the transmission of action potentials through the conducting system of the heart, there is a temporary delay at the
 - a. bundle branches.
 - b. Purkinje fibers.
 - c. AV node.
 - d. SA node.
 - e. AV bundle.

9. Given these structures of the conducting system of the heart:

(1) atrioventricular bundle	(4) Purkinje fibers
(2) AV node	(5) SA node
(3) bundle branches	

Choose the arrangement that lists the structures in the order an action potential passes through them.

- | | |
|--------------|--------------|
| a. 2,5,1,3,4 | d. 5,2,1,3,4 |
| b. 2,5,3,1,4 | e. 5,2,4,3,1 |
| c. 2,5,4,1,3 | |
10. Purkinje fibers
 - a. are specialized cardiac muscle cells.
 - b. conduct impulses much more slowly than ordinary cardiac muscle.
 - c. conduct action potentials through the atria.
 - d. connect the SA node and the AV node.
 - e. ensure that ventricular contraction starts at the base of the heart.
 11. T waves on an ECG represent
 - a. depolarization of the ventricles.
 - b. repolarization of the ventricles.
 - c. depolarization of the atria.
 - d. repolarization of the atria.
 12. The greatest amount of ventricular filling occurs during
 - a. the first one-third of diastole.
 - b. the middle one-third of diastole.
 - c. the last one-third of diastole.
 - d. ventricular systole.
 13. While the semilunar valves are open during a normal cardiac cycle, the pressure in the left ventricle is
 - a. higher than the pressure in the aorta.
 - b. lower than the pressure in the aorta.
 - c. the same as the pressure in the left atrium.
 - d. lower than the pressure in the left atrium.
 14. Blood flows neither into nor out of the ventricles during
 - a. the period of isovolumetric contraction.
 - b. the period of isovolumetric relaxation.
 - c. diastole.
 - d. systole.
 - e. Both a and b are correct.
 15. Stroke volume is the
 - a. amount of blood pumped by the heart per minute.
 - b. difference between end-diastolic and end-systolic volume.

- c. difference between the amount of blood pumped at rest and that pumped at maximum output.
d. amount of blood pumped from the atria into the ventricles.
16. Cardiac output is defined as
a. blood pressure times peripheral resistance.
b. peripheral resistance times heart rate.
c. heart rate times stroke volume.
d. stroke volume times blood pressure.
e. blood pressure minus peripheral resistance.
17. Pressure in the aorta is at its lowest
a. at the time of the first heart sound.
b. at the time of the second heart sound.
c. just before the AV valves open.
d. just before the semilunar valves open.
18. Just after the aortic valve closure on the aortic pressure curve,
a. the pressure in the aorta is greater than the pressure in the left ventricle.
b. the pressure in the left ventricle is greater than the pressure in the aorta.
c. the pressure in the left atrium is greater than the pressure in the left ventricle.
d. the pressure in the left atrium is greater than the pressure in the aorta.
e. blood pressure in the aorta is 0 mm Hg.
19. The “lubb” sound (first heart sound) is caused by the
a. closing of the AV valves.
b. closing of the semilunar valves.
c. blood rushing out of the ventricles.
d. filling of the ventricles.
e. ventricular contraction.
20. Increased venous return results in
a. increased stroke volume. c. decreased heart rate.
b. increased cardiac output. d. Both a and b are correct.
21. Parasympathetic nerve fibers are found in the _____ nerves and release _____ at the heart.
a. cardiac, acetylcholine
b. cardiac, norepinephrine
c. vagus, acetylcholine
d. vagus, norepinephrine
22. Increased parasympathetic stimulation of the heart
a. increases the force of ventricular contraction.
b. increases the rate of depolarization in the SA node.
c. decreases heart rate.
d. increases cardiac output.
23. Because of the baroreceptor reflex, when normal arterial blood pressure decreases, the
a. heart rate decreases.
b. stroke volume decreases.
c. frequency of afferent action potentials from baroreceptors decreases.
d. cardioregulatory center stimulates parasympathetic neurons.
24. A decrease in blood pH and an increase in blood carbon dioxide levels result in
a. increased heart rate.
b. increased stroke volume.
c. increased sympathetic stimulation of the heart.
d. increased cardiac output.
e. All of these are correct.
25. An increase in extracellular potassium levels can cause
a. an increase in stroke volume.
b. an increase in force of contraction.
c. a decrease in heart rate.
d. Both a and b are correct.

Answers in appendix E

CRITICAL THINKING

- Explain why the walls of the ventricles are thicker than the walls of the atria.
- In most tissues, peak blood flow occurs during systole and decreases during diastole. In heart tissue, however, the opposite is true, and peak blood flow occurs during diastole. Explain this difference.
- Explain why it is more efficient for contraction of the ventricles to begin at the apex of the heart than at the base.
- Predict the consequences for the heart’s pumping effectiveness if numerous ectopic foci in the ventricles produce action potentials.
- A patient has tachycardia. Would you recommend a drug that prolongs or shortens the plateau of cardiac muscle cell action potentials?
- Many endurance-trained athletes have a decreased resting heart rate, compared with that of nonathletes. Explain why an endurance-trained athlete’s resting heart rate decreases rather than increases.
- A doctor lets you listen to a patient’s heart with a stethoscope at the same time that you feel the patient’s pulse. Once in a while, you hear two heartbeats very close together, but you feel only one pulse beat. Later, the doctor tells you that the patient has an ectopic focus in the right atrium. Explain why you hear two heartbeats very close together. The doctor also tells you that the patient exhibits a pulse deficit (the number of pulse beats felt is fewer than the number of heartbeats heard). Explain why a pulse deficit occurs.
- Explain why it is sufficient to replace the ventricles, but not the atria, in artificial heart transplantation.
- A friend tells you an ECG revealed that her son has a slight heart murmur. Should you be convinced that he has a heart murmur? Explain.
- An experiment on a dog was performed in which the mean arterial blood pressure was monitored before and after the common carotid arteries were partially clamped (at time A). The results are graphed here:

Explain the change in mean arterial blood pressure. (*Hint: Baroreceptors are located in the internal carotid arteries, which are superior to the site of clamping of the common carotid arteries.*)

- During hemorrhagic shock (caused by loss of blood), blood pressure may fall dramatically, although the heart rate is elevated. Explain why blood pressure falls despite the increase in heart rate.

Learn to Predict

T.J. and Tyler were building a treehouse. While searching for a board in a pile of used lumber, T.J. stepped on a rusty nail, which penetrated deeply into his foot, causing it to bleed. Neither T.J. nor Tyler wanted to tell their parents about the accident, but after 3 days, T.J. developed septic shock. His foot had become infected, and the infection had spread into his bloodstream. **After reading this chapter and recalling information about the structure and function of the heart, described in chapter 20, explain how T.J.'s blood volume, blood pressure, heart rate, and stroke volume changed due to septic shock. Also, explain how blood flow in the periphery changed and how it affected T.J.'s appearance. Finally, explain the consequences if T.J.'s blood pressure remained abnormally low for a prolonged period of time.**

Cardiovascular System

BLOOD VESSELS AND CIRCULATION

Complex urban water systems seem rather simple when compared with the intricacy and coordinated functions of blood vessels. The heart is the pump that provides the major force causing blood to circulate, and the blood vessels are the pipes that carry blood to the body tissues and back to the heart. In addition, the blood vessels participate in regulating blood pressure and directing blood flow to the body's most active tissues. Blood pressure must be high enough to cause blood flow sufficient to meet the tissues' metabolic needs. Regulation of both the blood vessels and the heart ensure that homeostatic blood pressure is maintained.

Photo: Photograph of medical professional measuring a patient's blood pressure. Blood pressure is the result of the heart forcing blood through the blood vessels.

21.1 Functions of the Circulatory System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Distinguish between pulmonary and systemic vessels.
- B. Recite the functions of the circulatory system.

The circulatory system comprises many blood vessels. These blood vessels are organized into two sets: pulmonary vessels and systemic vessels. **Pulmonary vessels** transport blood from the right ventricle, through the lungs, and back to the left atrium. **Systemic vessels** transport blood from the left ventricle, through all parts of the body, and back to the right atrium (see figure 20.1). As described in chapter 20, the heart provides the major force that causes blood to move through these vessels. The circulatory system has five unique functions:

1. *Carries blood.* Blood vessels carry blood from the heart to almost all the body tissues and back to the heart.
2. *Exchanges nutrients, waste products, and gases with tissues.* Nutrients and oxygen diffuse from blood vessels to cells in all areas of the body. Waste products and carbon dioxide diffuse from the cells, where they are produced, to blood vessels.
3. *Transports substances.* Hormones, components of the immune system, molecules required for coagulation, enzymes, nutrients, gases, waste products, and other substances are transported in the blood to all areas of the body.
4. *Helps regulate blood pressure.* The circulatory system and the heart work together to maintain blood pressure within a normal range of values.
5. *Directs blood flow to tissues.* The circulatory system directs blood to tissues when increased blood flow is required to maintain homeostasis.

ASSESS YOUR PROGRESS

1. What is the difference between pulmonary and systemic vessels?
2. Describe the five functions of the circulatory system.

21.2 Structural Features of Blood Vessels

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the types of capillaries, arteries, and veins.
- B. Describe the structure and function of capillaries, arteries, and veins.
- C. Describe the innervation of the blood vessel walls.
- D. Discuss age-related changes to blood vessels.

Blood vessels are hollow tubes that conduct blood through the tissues of the body. The three main types of blood vessels are arteries, capillaries, and veins. These vessels form a continuous passageway for blood flow from the heart, through the body tissues, and back to the heart. Blood leaving the heart first passes through arteries. Next, the blood flows through the smallest blood vessels, the capillaries. Finally, blood moves through veins as it once again flows into the heart.

Arteries carry blood away from the heart. Although the arteries form a continuum from the largest to the smallest branches, they are normally classified as (1) elastic arteries, (2) muscular arteries, or (3) arterioles. The ventricles pump blood from the heart into large, elastic arteries that branch repeatedly to form many progressively smaller arteries. As they become smaller, the artery walls undergo a gradual transition from having a large amount of elastic tissue and a smaller amount of smooth muscle to having a smaller amount of elastic tissue and a relatively large amount of smooth muscle. From these muscular arteries, blood flows into the arterioles, the smallest of the arteries.

Blood flows from arterioles into **capillaries**, the most common blood vessel type. Capillary walls are the thinnest of all the blood vessels. Most of the exchange that occurs between the blood and interstitial spaces occurs across the thin walls of capillaries. Blood flows through capillaries slowly.

From the capillaries, blood flows into **veins**, vessels that carry blood toward the heart. When compared with arteries, the walls of the veins are thinner and contain less elastic tissue and fewer smooth muscle cells (see figure 21.5). As the blood returns to the heart, it flows through veins with thicker walls and greater diameters. Veins are classified by size as (1) venules, (2) small veins, or (3) medium or large veins.

Capillaries

All blood vessels have an internal lining of simple squamous epithelial cells called the **endothelium** (en-dō-thē'lē-ŭm). In the vessels associated with the heart, this endothelial lining is continuous with the endocardium of the heart.

The thin capillary wall consists primarily of a single layer of endothelial cells (figure 21.1) that rests on a basement membrane. Outside the basement membrane is a delicate layer of loose

FIGURE 21.1 Capillary

Section of a capillary, showing that it is composed primarily of flattened endothelial cells.

connective tissue that merges with the connective tissue surrounding the capillary.

Scattered along the length of the capillary are **pericapillary cells** closely associated with the endothelial cells. These scattered cells lie between the basement membrane and the endothelial cells and are fibroblasts, macrophages, or undifferentiated smooth muscle cells.

Most capillaries range from 7 μm to 9 μm in diameter, and they branch without changing in diameter. Capillaries are variable in length, but in general they are approximately 1 mm long. Red blood cells flow through most capillaries single file and are frequently folded as they pass through the smaller-diameter capillaries.

Types of Capillaries

When comparing the many capillaries of the body, it becomes apparent that these vessels show variation in size and permeability, or the degree to which materials enter or leave the blood. Based on these characteristics, capillaries are classified as continuous, fenestrated, or sinusoidal. **Continuous capillaries** are approximately 7–9 μm in diameter, and their walls exhibit no gaps between the endothelial cells (figure 21.2a). Continuous capillaries are less permeable to large molecules than are other capillary types; they are in muscle, nervous tissue, and many other locations.

In **fenestrated** (fen'es-trā'ted) **capillaries**, endothelial cells have numerous fenestrae (figure 21.2b). The **fenestrae** (fe-nes'trē; windows) are areas approximately 70–100 nm in diameter in which the cytoplasm is absent and the plasma membrane consists of a porous diaphragm that is thinner than the normal plasma membrane. In some capillaries, the diaphragm is not present. Fenestrated capillaries are in tissues where capillaries are highly permeable, such as the intestinal villi, ciliary processes of the eyes, choroid plexuses of the central nervous system, and glomeruli of the kidneys.

Sinusoidal (sī-nū-soy'dāl) **capillaries** are larger in diameter than either continuous or fenestrated capillaries, and their basement membrane is less prominent (figure 21.2c) or completely absent. Their fenestrae are larger than those in fenestrated capillaries, and gaps can exist between endothelial cells. The sinusoidal capillaries occur in places where large molecules move into the blood, such as endocrine glands.

Sinusoids are large-diameter, sinusoidal capillaries. Their basement membrane is sparse and often missing, and their structure suggests that large molecules and sometimes cells can move readily across their walls between the endothelial cells (figure 21.2c). Sinusoids are common in the liver and bone marrow. Macrophages are closely associated with the endothelial cells of the liver sinusoids. **Venous sinuses** are similar in structure to the sinusoidal capillaries but even larger in diameter. They are found primarily in the spleen, and there are large gaps between the endothelial cells that make up their walls.

Substances cross capillary walls by diffusing either (1) through or between the endothelial cells or (2) through fenestrae. Lipid-soluble substances, such as oxygen and carbon dioxide, and small, water-soluble molecules readily diffuse through the endothelial cells. Larger water-soluble substances must pass

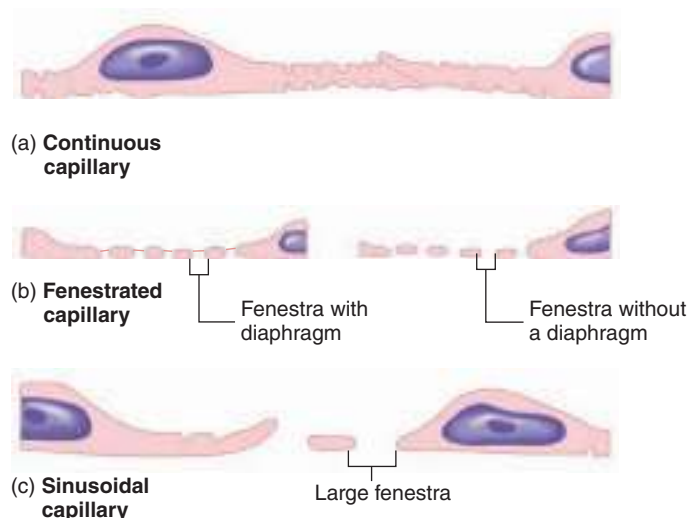

FIGURE 21.2 Structure of Capillary Walls

(a) Continuous capillaries have no gaps between endothelial cells and no fenestrae. They are common in muscle, nervous, and connective tissue. (b) Fenestrated capillaries have fenestrae 7–100 nm in diameter, covered by thin, porous diaphragms, which are not present in some capillaries. They are found in intestinal villi, ciliary processes of the eyes, choroid plexuses of the central nervous system, and glomeruli of the kidneys. (c) Sinusoidal capillaries have larger fenestrae without diaphragms and can have gaps between endothelial cells. They are found in endocrine glands, bone marrow, the liver, the spleen, and the lymphatic organs.

through the fenestrae or gaps between the endothelial cells. In addition, transport by pinocytosis occurs, but little is known about its role in the capillaries. The walls of the capillaries are effective permeability barriers because red blood cells and large, water-soluble molecules, such as proteins, cannot readily pass through them.

Capillary Network

Arterioles supply blood to each capillary network (figure 21.3). Blood flows from arterioles to capillary networks through **metarterioles** (met'ar-tēr'ē-ōlz), vessels with isolated smooth muscle cells along their walls. Blood then flows from a metarteriole into a **thoroughfare channel**, a vessel within the capillary network that extends in a relatively direct fashion from a metarteriole to a venule. Blood flow through thoroughfare channels is relatively continuous. Several capillaries branch from the thoroughfare channels, forming the capillary network. Blood flow is regulated in the capillary branches by **precapillary sphincters**, smooth muscle cells located at the origin of the branches (figure 21.3). Blood flows through the capillary network into the venules. The ends of capillaries closest to the arterioles are **arterial capillaries**, and the ends closest to venules are **venous capillaries**.

Capillary networks are more numerous and more extensive in highly metabolic tissues, such as in the lungs, liver, kidneys, skeletal muscle, and cardiac muscle. Capillaries in the skin function in thermoregulation, and heat loss results from the flow of a large volume of blood through them. Capillary networks in the dermis of skin have many more thoroughfare channels than capillary networks in cardiac or skeletal muscle. The major function of the capillaries in these muscle tissues is nutrient and waste product exchange.

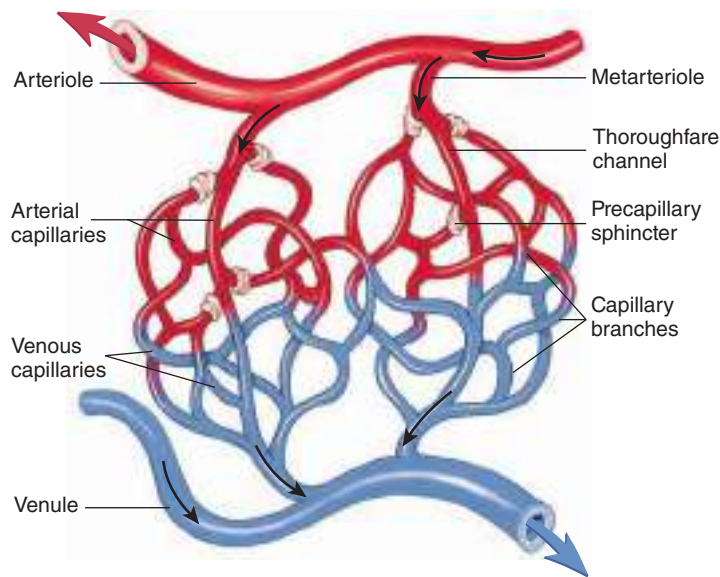

FIGURE 21.3 Capillary Network

A capillary network stems from an arteriole. Blood flows from the arteriole, through metarterioles, through the capillary network, to venules. Smooth muscle cells, called precapillary sphincters, regulate blood flow through the capillaries. Blood flow decreases when the precapillary sphincters constrict and increases when they dilate.

Arteriovenous Anastomoses

Arteriovenous anastomoses (ă-nas'tō-mō'sēz) are specialized vascular connections that allow blood to flow directly from arterioles to small veins without passing through capillaries. A **glomus** (glō'mūs; pl. glomera, glom'er-ă) is an arteriovenous anastomosis that consists of arterioles with abundant smooth muscle in their walls. The vessels are branched and coiled and are surrounded by connective tissue sheaths. Glomera are present in large numbers in the sole of the foot, the palm of the hand, the terminal phalanges, and the nail beds. The glomera help regulate body temperature by regulating blood flow thorough the hands and feet. As body temperature decreases, glomera constrict and less blood flows through them, reducing the rate of heat loss from the body. As body temperature increases, glomera dilate and more blood flows through them, increasing the rate of heat loss from the body. **Pathologic arteriovenous anastomoses** can form in areas of the body as a result of injury or tumors. These abnormal vascular connections allow for the direct flow of blood from arteries to veins. If they are sufficiently large, pathological arteriovenous anastomoses can lead to heart failure because of the tremendous increase in venous return to the heart.

ASSESS YOUR PROGRESS

3. In what direction, relative to the heart, is blood carried by arteries and by veins?
4. Name, in order, all the types of blood vessels, starting at the heart, going into the tissues, and returning to the heart.
5. Describe the general structure of a capillary.

6. Compare the structure of the three types of capillaries. Explain the various ways that materials pass through capillary walls.
7. Describe a capillary network. Where is the smooth muscle that regulates blood flow into and through the capillary network located? What is the function of a thoroughfare channel?
8. Contrast the function of capillaries in the skin with the function of capillaries in muscle tissue.
9. Define arteriovenous anastomosis and glomus, and explain their functions.

Structure of Arteries and Veins

General Features

Except for the capillaries and the venules, the blood vessel walls consist of three relatively distinct layers, which are most evident in the muscular arteries and least evident in the veins. From the lumen to the outer wall of the blood vessels, the layers, or **tunics** (too'niks), are (1) the tunica intima, (2) the tunica media, and (3) the tunica adventitia, or tunica externa (figures 21.4 and 21.5).

The **tunica intima** consists of four layers: (1) endothelium, (2) a basement membrane, (3) a thin layer of connective tissue called the lamina propria, and (4) a fenestrated layer of elastic fibers called the **internal elastic membrane**. The internal elastic membrane separates the tunica intima from the next layer, the tunica media.

The **tunica media**, or middle layer, consists of smooth muscle cells arranged circularly around the blood vessel. The amount of blood flowing through a blood vessel can be regulated by contraction or relaxation of the smooth muscle in the tunica media. **Vasoconstriction** (vā'sō-kon-strik'shūn, vas'ō-kon-strik'shūn) results from smooth muscle contraction and causes a decrease in blood vessel diameter, thereby decreasing blood flow through the vessel. **Vasodilation** (vā'sō-dī-lā'shūn, vas-ō-dī-lā'shūn) results from smooth muscle relaxation and causes an increase in blood vessel diameter, thereby increasing blood flow through the vessel.

The tunica media also contains variable amounts of elastic and collagen fibers, depending on the size of the vessel. An **external elastic membrane** separates the tunica media from the tunica adventitia. It can be identified at the outer border of the tunica media in some arteries. In addition, a few longitudinally oriented smooth muscle cells occur in some arteries near the tunica intima.

The **tunica adventitia** (too'ni-kă ad-ven-tish'ă) is composed of connective tissue, which varies from dense connective tissue near the tunica media to loose connective tissue that merges with the connective tissue surrounding the blood vessels.

The relative thickness and composition of each layer vary with the diameter of the blood vessel and its type. The transition from one vessel type to another is gradual, as are the structural changes.

Types of Arteries

Elastic Arteries

Elastic arteries have the largest diameters (figure 21.6a) and are often called *conducting arteries*. Because these vessels are the first to receive blood from the heart, blood pressure is relatively

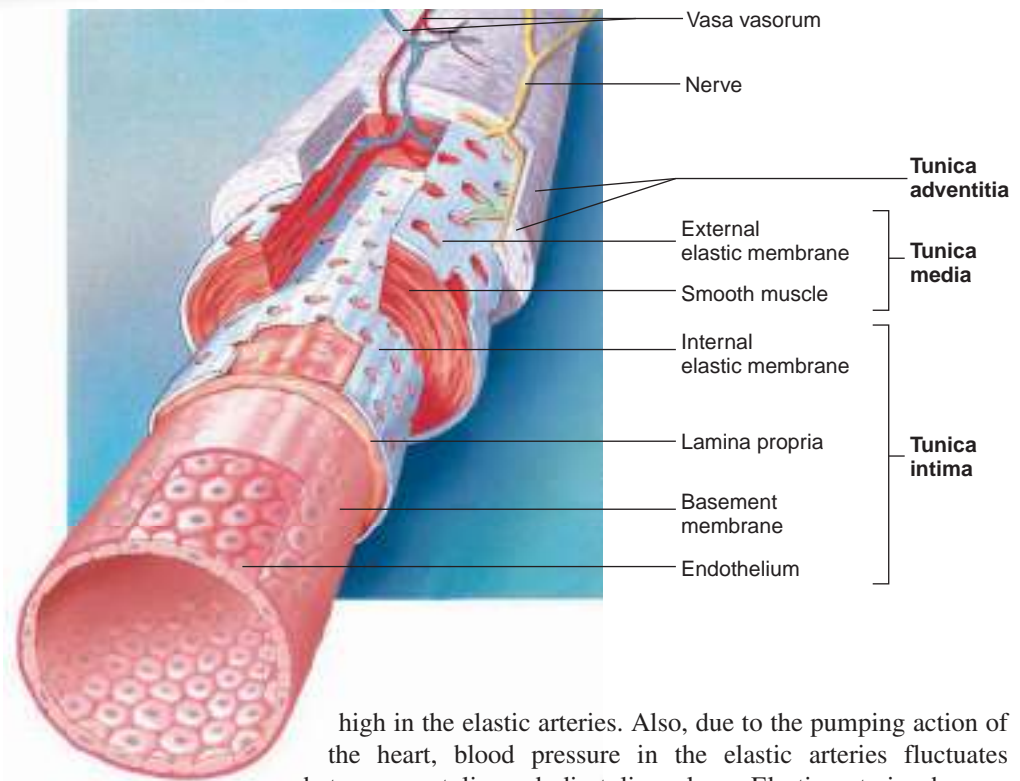

FIGURE 21.4 Histology of a Blood Vessel

The layers, or tunics, of the blood vessel wall are the tunica intima, media, and adventitia. Vasa vasorum are blood vessels that supply blood to the wall of the blood vessel. **APR**

high in the elastic arteries. Also, due to the pumping action of the heart, blood pressure in the elastic arteries fluctuates between systolic and diastolic values. Elastic arteries have a greater amount of elastic tissue and a smaller amount of smooth muscle in their walls, compared with other arteries. The elastic fibers are responsible for the elastic characteristics of the blood vessel wall, but collagenous connective tissue determines the degree to which the arterial wall can stretch.

The tunica intima of elastic arteries is relatively thick. The elastic fibers of the internal and external elastic membranes merge and are not recognizable as distinct layers. The tunica media consists of a meshwork of elastic fibers with interspersed, circular smooth muscle cells and some collagen fibers. The tunica adventitia is relatively thin.

Muscular Arteries

Muscular arteries include medium-sized and small arteries. The use of *muscular* in the name of these vessels refers to their thick tunica media. The walls of some muscular arteries are relatively thick, compared with their diameter, mainly because the tunica media contains 25–40 layers of smooth muscle (figure 21.6b). The tunica intima of the muscular arteries has a well-developed internal elastic membrane. The tunica adventitia is composed of a relatively thick layer of collagenous connective tissue that blends with the surrounding connective tissue. Muscular arteries are frequently called *distributing arteries* because the smooth muscle cells allow them to partially regulate blood supply to different body regions by either constricting or dilating.

Smaller muscular arteries range from 40 μm to 300 μm in diameter. Those that are 40 μm in diameter have approximately three or four layers of smooth muscle in their tunica media, whereas arteries that are 300 μm across have essentially the same structure as the larger muscular arteries. The small muscular arteries are adapted for vasodilation and vasoconstriction.

FIGURE 21.5 Comparison of an Artery and a Vein

The typical structure of a medium-sized artery (A) and a vein (V). Note that the artery has a thicker wall than the vein. The predominant layer in the wall of the artery is the tunica media, with its circular layers of smooth muscle. The predominant layer in the wall of the vein is the tunica adventitia, and the tunica media is thinner than in the artery.

(a) **Elastic arteries.** The tunica media is mostly elastic connective tissue. Elastic arteries recoil when stretched, which prevents blood pressure from falling rapidly.

(b) **Muscular arteries.** The tunica media is a thick layer of smooth muscle. Muscular arteries regulate blood flow to different regions of the body.

(c) **Medium and large veins.** All three layers are present. The tunica media is thin but can regulate vessel diameter because blood pressure in the venous system is low. The predominant layer is the tunica adventitia.

FIGURE 21.6 Structural Comparison of Blood Vessel Types

Arterioles

Arterioles (ar-tēr'ē-ōlz) are the smallest arteries in which the three layers can be identified. They transport blood from small arteries to capillaries (see figure 21.3). They range in diameter from approximately 40 μm to as small as 9 μm . The tunica intima has no observable internal elastic membrane, and the tunica media consists of one or two layers of circular smooth muscle cells. Arterioles, like the small arteries, are capable of vasodilation and vasoconstriction.

Types of Veins

Venules and Small Veins

Venules (ven'oolz, vē'noolz) are the smallest veins. Their structure is very similar to that of capillaries in that they are tubes composed of endothelium resting on a delicate basement membrane. Venules

have diameters up to 50 μm (see figure 21.1). A few isolated smooth muscle cells exist outside the endothelial cells, especially in the larger venules. As the vessels increase to 0.2–0.3 mm in diameter, the smooth muscle cells form a continuous layer; the vessels are then called **small veins**. The small veins also have a tunica adventitia composed of collagenous connective tissue.

The venules collect blood from the capillaries (see figure 21.3) and transport it to small veins, which in turn transport it to medium veins. Nutrient exchange occurs across the venule walls but, as the walls of the small veins increase in thickness, the degree of nutrient exchange decreases.

Medium and Large Veins

Most of the veins observed in gross anatomical dissections are **medium veins** and **large veins**. Medium veins collect blood

from small veins and deliver it to large veins. The **large veins** transport blood from the medium veins to the heart. In medium and large veins, the tunica intima is thin and consists of endothelial cells, a relatively thin layer of collagenous connective tissue, and a few scattered elastic fibers. The tunica media is also thin and is composed of a thin layer of circularly arranged smooth muscle cells containing some collagen fibers and a few sparsely distributed elastic fibers. The tunica adventitia, which is composed of collagenous connective tissue, is the predominant layer (figure 21.6c).

Portal Veins

In some areas of the body, a capillary network is directly connected to another capillary network by **portal** (pōr'tāl; door) **veins**. Specifically, portal veins begin in a primary capillary network, extend some distance, and end in a secondary capillary network. This connection is unique in that there is no pumping mechanism like the heart between the two capillary networks. Two portal vein systems are found in humans: (1) The hepatic portal veins carry blood from the capillaries in the gastrointestinal tract and spleen to dilated capillaries, called sinusoids, in the liver (see figure 21.27). (2) The hypothalamohypophysial portal veins carry blood from the hypothalamus of the brain to the anterior pituitary gland (see figure 18.3).

Valves

Veins that have diameters greater than 2 mm contain **valves**, which allow blood to flow toward the heart, but not in the opposite direction (figure 21.7). The valves consist of folds in the tunica intima that form two flaps shaped like the semilunar valves of the heart. The two folds overlap in the middle of the vein, so that, when blood attempts to flow in a reverse direction, the valves occlude, or block, the vessel. Medium veins contain many valves, and the number of valves is greater in veins of the lower limbs than in veins of the upper limbs.

FIGURE 21.7 Valves

Folds in the tunica intima form the valves of veins, which allow blood to flow toward the heart but not in the opposite direction.

Clinical IMPACT

Varicose Veins, Phlebitis, and Gangrene

The veins of the lower limbs are subject to certain disorders. **Varicose veins** result when the veins of the lower limbs are stretched to the point that the valves become incompetent. Because of the stretching of the vein walls, the flaps of the valves no longer overlap to prevent the backflow of blood. As a consequence, the venous pressure is greater than normal in the veins of the lower limbs, resulting in edema. Blood flow in the veins can become sufficiently stagnant that the blood clots. This condition can result in **phlebitis** (fle-bī'tis), which is inflammation of the veins. If the inflammation is severe and blood flow becomes stagnant in a large area, it can lead to **gangrene** (gang'grēn), tissue death caused by a reduction in or loss of blood supply. Some people have a genetic propensity to develop varicose veins. The condition is further encouraged by activities that increase the pressure in the veins. One such condition is pregnancy, in which the venous pressure in the lower limbs increases because of compression by the expanded uterus. Also, standing in place for prolonged periods can lead to varicose veins.

Vasa Vasorum

For arteries and veins greater than 1 mm in diameter, nutrients cannot diffuse from the lumen of the vessel to all the layers of the wall. Therefore, nutrients are supplied to their walls by way of small blood vessels called **vasa vasorum** (vā'sā vā'sor-ŭm), which penetrate from the exterior of the vessel to form a capillary network in the tunica adventitia and the tunica media (see figure 21.4).

ASSESS YOUR PROGRESS

10. Name the three layers of a blood vessel. What kinds of tissue are in each layer?
11. List the types of arteries and veins. Compare the amount of elastic fibers and smooth muscle in each type of artery and vein.
12. Describe portal veins. Name two examples.
13. In which type of blood vessels are valves found? What is their function?
14. What is the vasa vasorum? What is its function?

Neural Innervation of Blood Vessels

The walls of most blood vessels are richly innervated by unmyelinated sympathetic nerve fibers (see figure 21.4). Some blood vessels, such as those in the penis and clitoris, are innervated by parasympathetic fibers. Small arteries and arterioles are innervated to a greater extent than other blood vessel types. The nerve fibers branch to form plexuses in the tunica adventitia, and nerve

terminals containing neurotransmitter vesicles project among the smooth muscle cells of the tunica media. Synapses consist of several enlargements of each of the nerve fibers among the smooth muscle cells. Sympathetic stimulation causes blood vessels to constrict; parasympathetic stimulation causes blood vessels in the penis and clitoris to dilate.

The smooth muscle cells of blood vessels act to some extent in unison. Gap junctions exist between adjacent smooth muscle cells; as a consequence, stimulation of a few smooth muscle cells in the vessel wall results in constriction of a relatively large segment of the blood vessel.

A few myelinated sensory neurons innervate some blood vessels and function as baroreceptors. They monitor stretch in the blood vessel wall and detect changes in blood pressure.

Aging of the Arteries

The walls of all arteries undergo changes as people age, although some arteries change more rapidly than others and some people are more susceptible to change. The most significant change occurs in the large elastic arteries, such as the aorta, in the large arteries that carry blood to the brain, and in the coronary arteries; the age-related changes described here refer to these blood vessel types. Muscular arteries exhibit age-related changes, but these are less dramatic and seldom disrupt normal vessel function.

Arteriosclerosis (ar-tēr'ē-ō-skler-o'sis; hardening of the arteries) consists of degenerative changes in arteries that make them less elastic. These changes occur in many individuals, and they become more severe with advancing age. Arteriosclerosis greatly increases resistance to blood flow. Therefore, advanced arteriosclerosis reduces the normal circulation of blood and greatly increases the work performed by the heart.

Arteriosclerosis involves general hypertrophy of the tunica intima, including the internal elastic membrane, and hypertrophy of the tunica media. For example, when arteriosclerosis is associated with hypertension, the amount of smooth muscle and elastic tissue in the arterial walls increases. The elastic tissue can form concentric layers in the tunica intima, which becomes less elastic. Also some of the smooth muscle cells of the tunica media can ultimately be replaced by collagen fibers. Arteriosclerosis in some older people can involve the formation of calcium deposits in the tunica media of the arteries, primarily those of the lower limbs, with little or no encroachment on their lumens. The calcium deposits reduce the vessels' elasticity.

Atherosclerosis (ath'er-ō-skler-ō'sis) is the deposition of material in the walls of arteries to form distinct plaques. It is a common type of arteriosclerosis. Like the other types, atherosclerosis is related to age and certain risk factors. Atherosclerosis affects primarily medium and larger arteries, including the coronary arteries. The plaques form when macrophages containing cholesterol accumulate in the tunica intima, and smooth muscle cells of the tunica media proliferate (figure 21.8). After the plaques enlarge, they consist of smooth muscle cells, white blood cells, lipids (including cholesterol), and, in the largest plaques, fibrous connective tissue and calcium deposits. The

FIGURE 21.8 Atherosclerotic Plaque in an Artery

Atherosclerotic plaques develop within the tissue of the artery wall.

plaques narrow the lumens of blood vessels and make their walls less elastic. Atherosclerotic plaques can become so large that they severely restrict or block blood flow through arteries. In addition, the plaques are sites of thrombosis and embolism formation.

Some investigators propose that arteriosclerosis is not a pathological process but an aging or wearing-out process. Evidence also suggests that arteriosclerosis may be caused by inflammation, possibly a result of autoimmune disease. Atherosclerosis has been studied extensively, and many risk factors have been associated with the development of atherosclerotic plaques. These risk factors include being elderly, being a male, being a postmenopausal woman, having a family history of atherosclerosis, smoking cigarettes, having hypertension, having diabetes mellitus, having increased blood LDL and cholesterol levels, being overweight, leading a sedentary lifestyle, and having high blood triglyceride levels. Avoiding the environmental factors that influence atherosclerosis slows the development of atherosclerotic plaques. In some cases, the severity of the plaques can be reduced by behavioral modifications and/or drug therapy. For example, regulating blood glucose levels in people with diabetes mellitus and taking drugs that lower high blood cholesterol can provide some protection.

ASSESS YOUR PROGRESS

- Describe the innervation of blood vessel walls. Which types of vessels have the most innervation?
- Describe the changes that occur in arteries due to aging. In which vessels do the most significant changes occur?

21.3 Pulmonary Circulation

LEARNING OUTCOME

After reading this section, you should be able to

- Trace the path of blood flow in pulmonary circulation.

The **pulmonary** (pŭl'mō-nār-ē; relating to the lungs) **circulation** is the system of blood vessels that carries blood from the right ventricle of the heart to the lungs and back to the left atrium of the heart. The heart pumps deoxygenated blood from the right ventricle into a short artery (about 5 cm long) called the **pulmonary trunk** (figure 21.9). The pulmonary trunk then branches into the right and left **pulmonary arteries**, transporting blood to the right lung and left lung, respectively. Within the lungs, gas exchange occurs between the air in the lungs and the blood. Two **pulmonary veins** exit each lung. All four of the pulmonary veins carry oxygenated blood to the left atrium (see figure 20.10).

ASSESS YOUR PROGRESS

17. Name, in order, the vessels of pulmonary circulation, beginning with the right ventricle.

21.4 Systemic Circulation: Arteries

LEARNING OUTCOME

After reading this section, you should be able to

- A. List the major arteries that supply each of the body areas.**

The **systemic circulation** is the system of vessels that carries blood from the left ventricle of the heart to the tissues of the body and back to the right atrium. Oxygenated blood entering the heart from the pulmonary veins passes through the left atrium into the left ventricle. The left ventricle pumps blood into the aorta. Blood flows from the aorta to all parts of the body (figure 21.9).

Aorta

All arteries of the systemic circulation are derived either directly or indirectly from the **aorta** (ā-ōr'tă), which is usually divided into three general parts: (1) the ascending aorta, (2) the aortic arch, and (3) the descending aorta. The descending aorta is divided further into a thoracic aorta and an abdominal aorta (see figure 21.15).

At its origin from the left ventricle, the aorta is approximately 2.8 cm in diameter. Because it passes superiorly from the heart, this part is called the **ascending aorta**. It is approximately 5 cm long and has only two arteries branching from it: the right and left **coronary arteries**, which supply blood to the cardiac muscle (see figure 20.6a).

The aorta then arches posteriorly and to the left as the **aortic arch**. Three major arteries branch from the aortic arch and carry blood to the head and upper limbs. These arteries are (1) the brachiocephalic artery, (2) the left common carotid artery, and (3) the left subclavian artery.

The next part of the aorta is the **descending aorta**. The descending aorta is the longest part of the aorta and it extends through the thorax in the left side of the mediastinum and through the abdomen to the superior margin of the pelvis. The descending aorta is described in two parts: the thoracic aorta and the abdominal aorta. The **thoracic aorta** is the portion of the descending aorta located in the thorax. It has several branches that supply various structures between the aortic arch and the diaphragm. The

abdominal aorta is the part of the descending aorta that extends from the diaphragm to the point at which the aorta divides into the two **common iliac** (il'ē-ak; relating to the flank area) **arteries**. The abdominal aorta has several branches that supply the abdominal wall and organs. Its terminal branches, the common iliac arteries, supply blood to the pelvis and lower limbs.

Coronary Arteries

The **coronary** (kōr'o-nār-ē; encircling the heart like a crown) **arteries**, which are the only branches of the ascending aorta, are described in chapter 20.

Arteries of the Head and Neck

The first vessel to branch from the aortic arch is the **brachiocephalic** (brā'kē-ō-se-fal'ik; arm and head) **artery** (figure 21.10). This short artery branches at the level of the clavicle to form the **right common carotid** (ka-rot'id) **artery** and the **right subclavian** (süb-klā'vē-an; below the clavicle) **artery**. The right common carotid artery transports blood to the right side of the head and neck, and the right subclavian artery transports blood to the right upper limb (see figures 21.9, 21.10, and 21.12).

The second branch of the aortic arch is the **left common carotid artery**, which transports blood to the left side of the head and neck. The third branch of the aortic arch is the **left subclavian artery**, which transports blood to the left upper limb.

The common carotid arteries extend superiorly, without branching, along each side of the neck, from their base to the inferior angle of the mandible. At this point, each common carotid artery branches into **internal** and **external carotid arteries** (figure 21.10; see figure 21.12). At the point of bifurcation on each side of the neck, the common carotid artery and the base of the internal carotid artery are dilated slightly to form the **carotid sinus**, which is important in monitoring blood pressure (baroreceptor reflex). The external carotid arteries have several branches that supply the structures of the neck and face (table 21.1; figure 21.10;

Clinical IMPACT

Trauma and the Aorta

Trauma that ruptures the aorta is almost immediately fatal. Trauma can also lead to an **aneurysm** (an'ū-rizm), a bulge caused by a weakened spot in the aortic wall. Once the aneurysm forms, it is likely to enlarge and may rupture. The weakened aortic wall may leak blood slowly into the thorax and must be corrected surgically. The majority of traumatic aortic arch ruptures occur during automobile accidents when the body is thrown with great force into the steering wheel, the dashboard, or some other object. This type of injury is effectively prevented by shoulder-type safety belts and air bags.

FIGURE 21.9 Major Arteries

These major arteries carry blood from the heart to the body tissues. **APR**

FIGURE 21.10 Arteries of the Head and Neck

The brachiocephalic artery, the right common carotid artery, and the right vertebral artery supply the head and neck. The right common carotid artery branches from the brachiocephalic artery, and the vertebral artery branches from the subclavian artery. **AP R**

FIGURE 21.11 Cerebral Arterial Circle (Circle of Willis)

The internal carotid and vertebral arteries carry blood to the brain. The vertebral arteries join to form the basilar artery. Branches of the internal carotid arteries and the basilar artery supply blood to the brain and complete a circle of arteries around the pituitary gland and the base of the brain called the cerebral arterial circle (circle of Willis). **AP R**

TABLE 21.1 Arteries of the Head and Neck (figures 21.10, 21.11, and 21.12)

Arteries	Tissues Supplied
Common Carotid Arteries	Head and neck by branches listed below
<i>External Carotid</i>	
Superior thyroid	Neck, larynx, and thyroid gland
Lingual	Tongue, mouth, and submandibular and sublingual glands
Facial	Mouth, pharynx, and face
Occipital	Posterior head and neck and meninges around posterior brain
Posterior auricular	Middle and inner ear, head, and neck
Ascending pharyngeal	Deep neck muscles, middle ear, pharynx, soft palate, and meninges around posterior brain
Superficial temporal	Temple, face, and anterior ear
Maxillary	Middle and inner ears, meninges, lower jaw and teeth, upper jaw and teeth, temple, external eye structures, face, palate, and nose
<i>Internal Carotid</i>	
Posterior communicating	Joins the posterior cerebral artery
Anterior cerebral	Anterior portions of the cerebrum; forms the anterior communicating arteries
Middle cerebral	Most of the lateral surface of the cerebrum
Vertebral Arteries (branches of the subclavian arteries)	
Anterior spinal	Anterior spinal cord
Posterior inferior cerebellar	Cerebellum and fourth ventricle
Basilar Artery (formed by junction of vertebral arteries)	
Anterior inferior cerebellar	Cerebellum
Superior cerebellar	Cerebellum and midbrain
Posterior cerebral	Posterior portions of the cerebrum

see figure 21.12). The internal carotid arteries, together with the vertebral arteries, which are branches of the subclavian arteries, supply the brain (see figures 21.10, 21.11, and 21.12; table 21.1).

➤ Predict 2

The term *carotid* means “to put to sleep,” implying that, if the carotid arteries are occluded for even a short time, the patient can lose consciousness (go to sleep). The blood supply to the brain is extremely important to brain function. Elimination of this supply for even a relatively short time can result in permanent brain damage because the brain is dependent on oxidative metabolism and quickly malfunctions in the absence of oxygen. What is the physiological significance of arteriosclerosis, which slowly reduces blood flow through the carotid arteries?

The **left and right vertebral arteries** originate from the left and right subclavian arteries, respectively, and pass through the transverse foramina of the cervical vertebrae. They enter the cranial cavity through the foramen magnum. Within the cranial cavity, the left and right vertebral arteries both give off arteries to

the cerebellum. The left and right vertebral arteries unite to form a single, midline **basilar** (bas’i-lār) **artery** (figures 21.11 and 21.12; table 21.1). The basilar artery gives off branches to the pons and the cerebellum. The left and right vertebral arteries branch to form the **posterior cerebral arteries**, which supply the posterior part of the cerebrum (see figure 21.11).

The internal carotid arteries enter the cranial cavity through the carotid canals and give off branches, including the **middle cerebral arteries** and the **anterior cerebral arteries**. The middle cerebral arteries supply large parts of the lateral cerebral cortex and the anterior cerebral arteries supply blood to the frontal lobes of the cerebrum (see figure 21.11). The two anterior cerebral arteries are connected to each other by an anterior communicating artery. The middle cerebral arteries connect to the posterior cerebral arteries by way of the **posterior communicating arteries**. These connections complete a circle around the pituitary gland and the base of the brain called the **cerebral arterial circle** (circle of Willis; see figures 21.11 and 21.12).

A **stroke** is a sudden neurological disorder, often caused by decreased blood supply to a part of the brain. It can occur as a

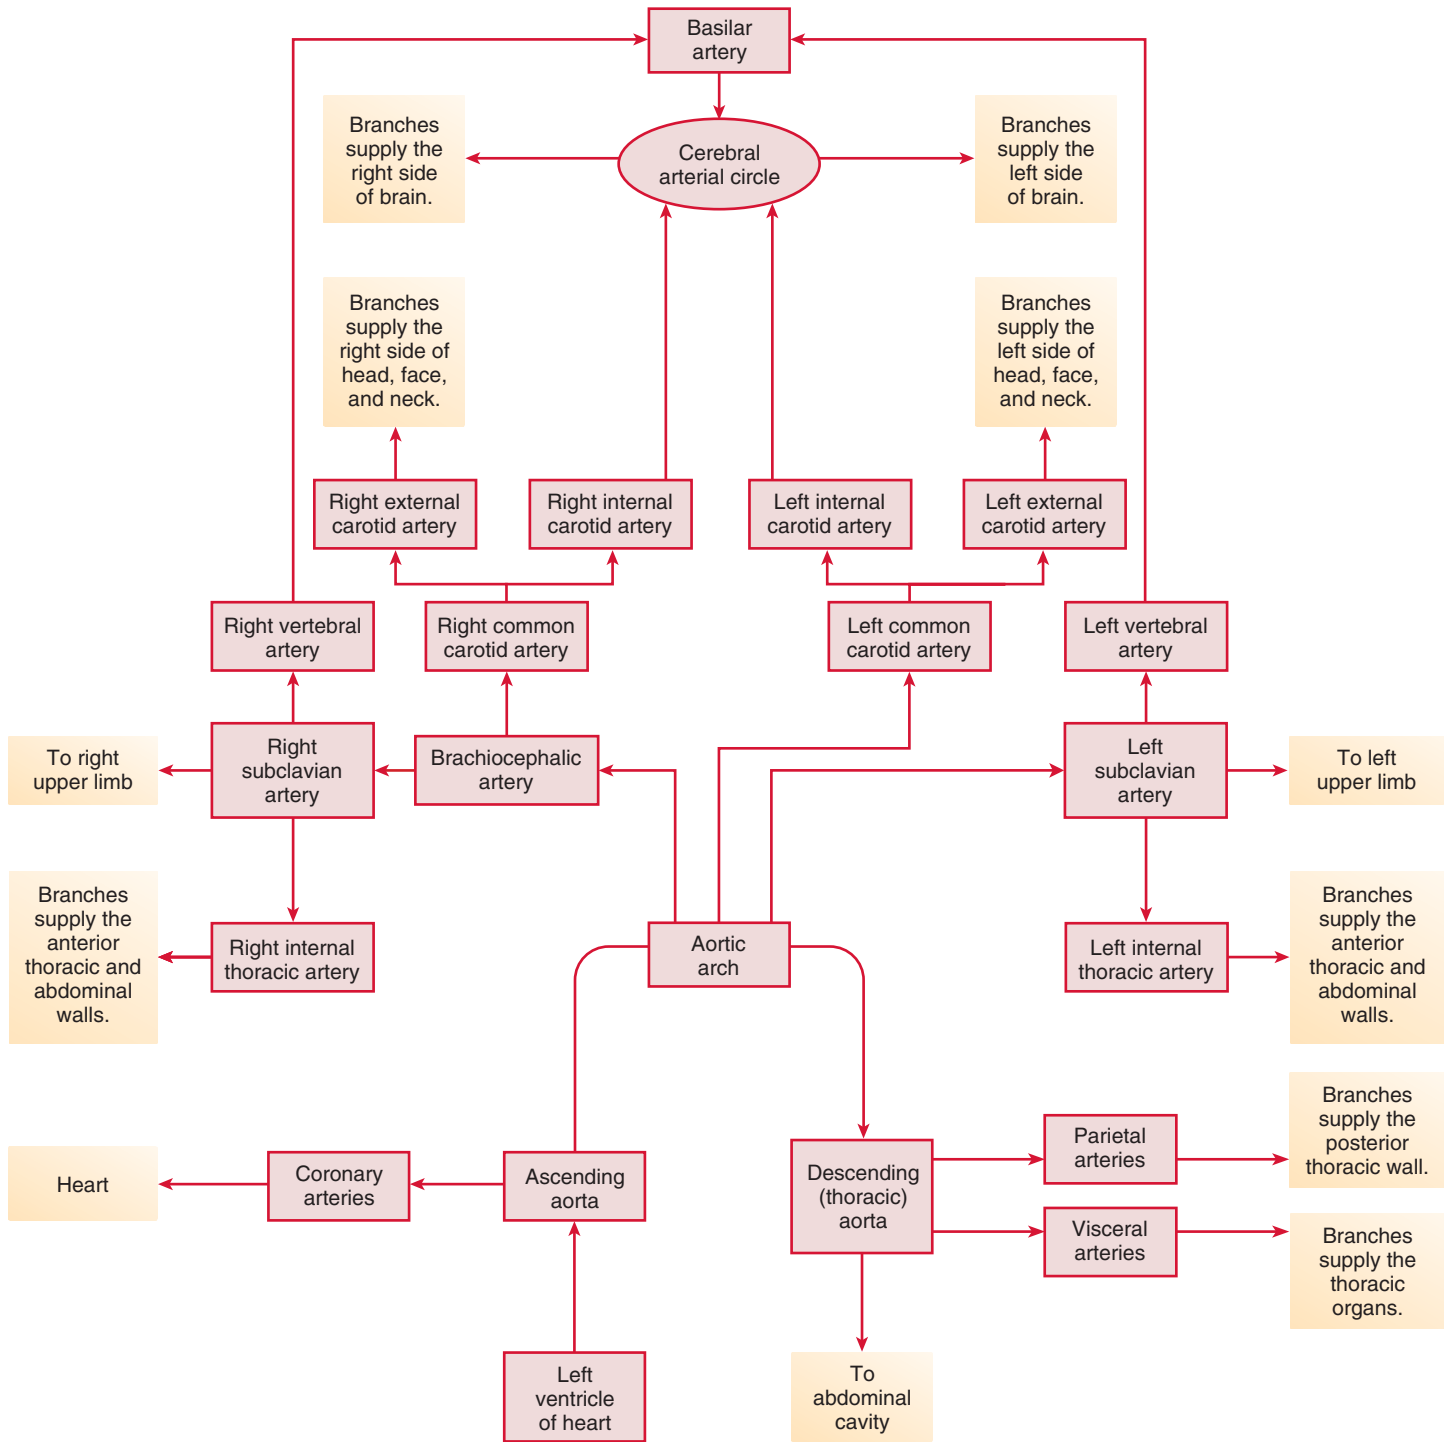

FIGURE 21.12 Major Arteries of the Head and Thorax

result of a thrombosis, an embolism, or a hemorrhage. Any one of these conditions can reduce the brain's blood supply or cause trauma to a part of the brain. As a result, the tissue normally supplied by the arteries becomes **necrotic** (ně-krot'ik; dead), forming an infarct in the affected area(s). The neurological results of a stroke are described in chapter 14.

Arteries of the Upper Limb

The three major arteries of the upper limb are the **subclavian**, **axillary**, and **brachial arteries**. These arteries form a continuum rather than a branching system. The subclavian artery is located deep to the clavicle. The axillary artery is the continuation of the

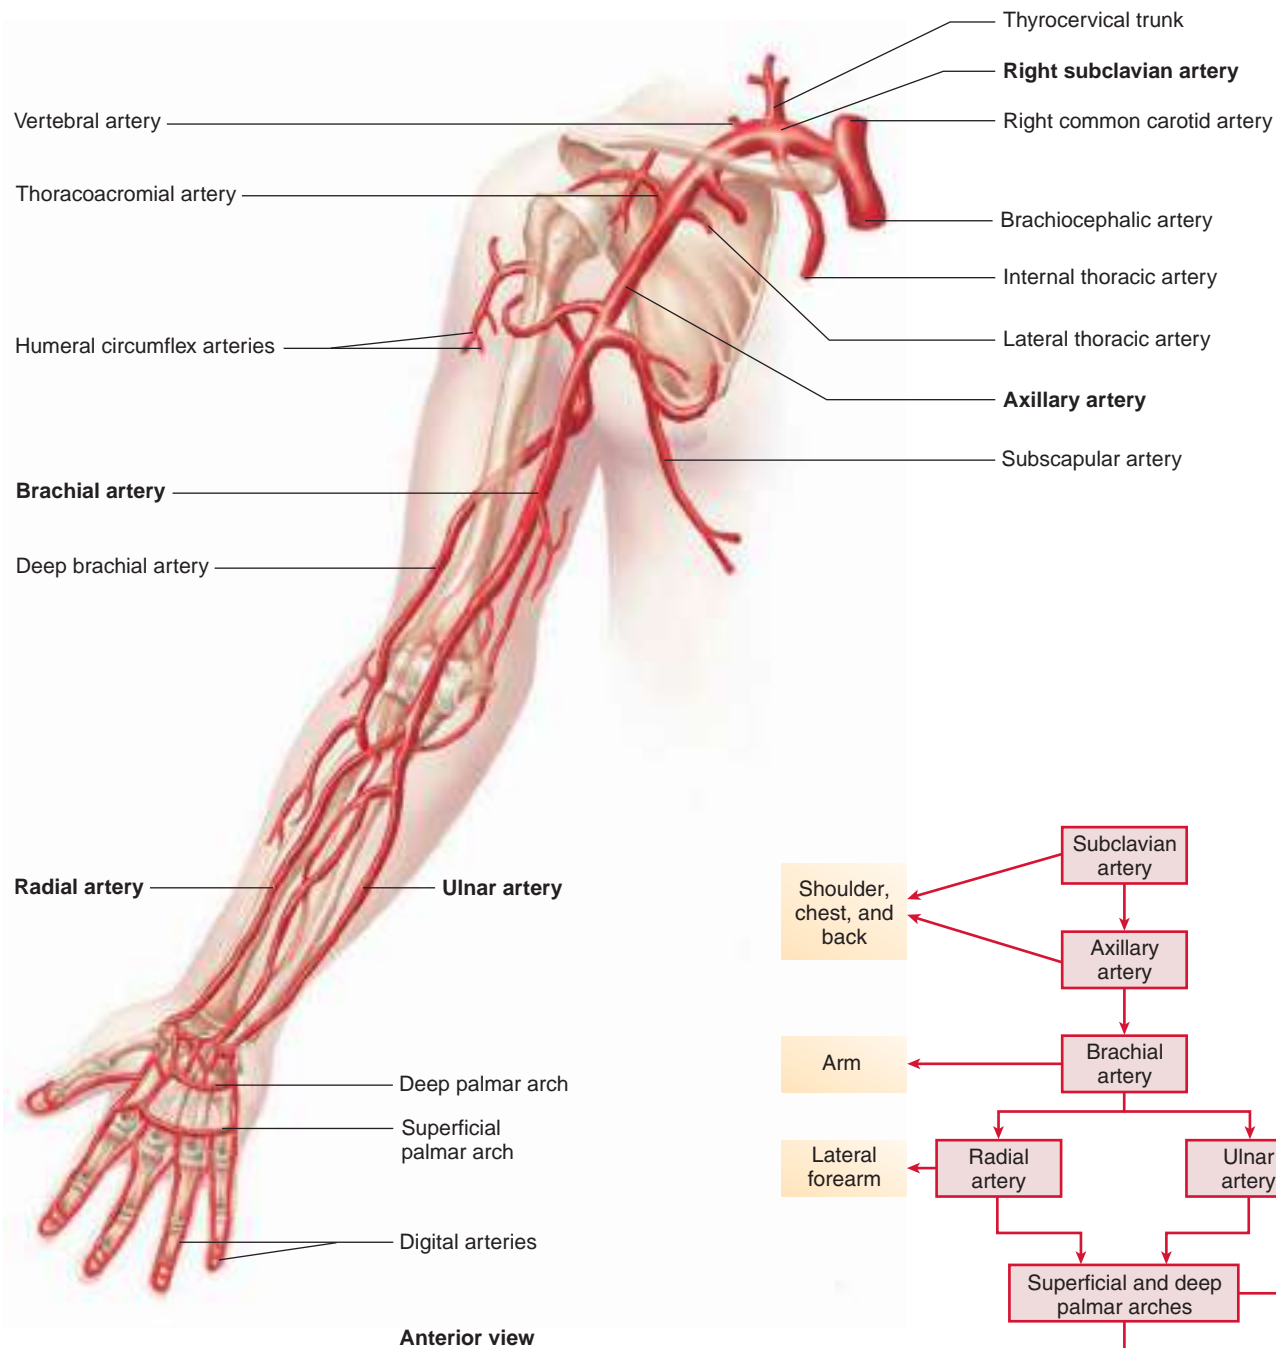

FIGURE 21.13 Arteries of the Upper Limb

The arteries of the right upper limb and their branches: the right brachiocephalic, subclavian, axillary, radial, and ulnar arteries and their branches. **APR**

subclavian artery in the axilla. The brachial artery is the continuation of the axillary artery as it passes into the arm (figures 21.13 and 21.14; table 21.2).

The brachial artery divides at the elbow into **ulnar** and **radial arteries**, which form two arches within the palm of the hand. The **superficial palmar arch** is formed by the ulnar artery and is completed by anastomosing with the radial artery. The **deep palmar**

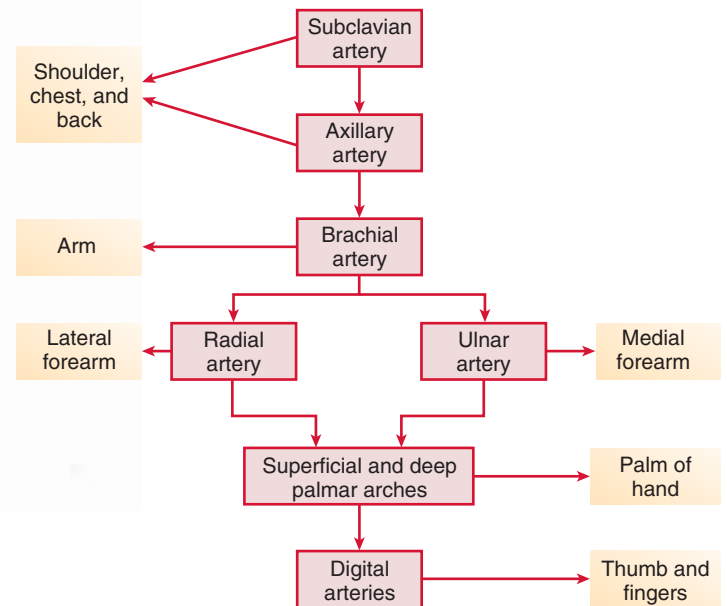

FIGURE 21.14 Major Arteries of the Shoulder and Upper Limb

arch is formed by the radial artery and is completed by anastomosing with the ulnar artery. This arch is not only deep to the superficial arch but proximal as well.

Digital (dij/i-täl; relating to the digits—the fingers and the thumb) **arteries** branch from each of the two palmar arches and unite to form single arteries on the medial and lateral sides of each digit.

TABLE 21.2 Arteries of the Upper Limb (figures 21.13 and 21.14)

Arteries	Tissues Supplied
Subclavian Arteries (right subclavian originates from the brachiocephalic artery, and left subclavian originates directly from the aorta)	
Vertebral	Spinal cord and cerebellum form the basilar artery (see table 21.1)
Internal thoracic	Diaphragm, mediastinum, pericardium, anterior thoracic wall, and anterior abdominal wall
Thyrocervical trunk	Inferior neck and shoulder
Axillary Arteries (continuation of subclavian)	
Thoracoacromial	Pectoral region and shoulder
Lateral thoracic	Pectoral muscles, mammary gland, and axilla
Subscapular	Scapular muscles
Brachial Arteries (continuation of axillary arteries)	
Deep brachial	Arm and humerus
Radial	Forearm
Deep palmar arch	Hand and fingers
Digital arteries	Fingers
Ulnar	Forearm
Superficial palmar arch	Hand and fingers
Digital arteries	Fingers

ASSESS YOUR PROGRESS

18. Name the parts of the aorta.
19. Name the arteries that branch from the ascending aorta to supply the heart.
20. Name the arteries that branch from the aorta to supply the head and neck.
21. List the arteries that are part of, and branch from, the cerebral arterial circle.
22. Name the arteries that branch from the aorta to supply the upper limbs.
23. List, in order, the arteries that travel through the upper limb to the digits.

Thoracic Aorta and Its Branches

Recall that the descending aorta is divided into the thoracic aorta of the thoracic cavity and the abdominal aorta of the abdominal cavity. The branches of the thoracic aorta are divided into two groups: the **visceral branches** supplying portions of the thoracic organs and the **parietal branches** supplying portions of the thoracic wall (figure 21.15*a,b*; table 21.3). The visceral branches supply a portion of the lungs, including the bronchi and bronchioles (see chapter 23), as well as the esophagus, and the pericardium. Even though a large quantity of blood flows to the lungs through the pulmonary arteries, the bronchi and bronchioles

require a separate oxygenated blood supply through small bronchial branches from the thoracic aorta.

The thoracic walls are supplied with blood by the **intercostal** (in-ter-kos'täl; between the ribs) **arteries**, which consist of two sets: the anterior intercostals and the posterior intercostals. The **anterior intercostals** are derived from the **internal thoracic arteries**, which are branches of the subclavian arteries. They lie on the inner surface of the anterior thoracic wall (figure 21.15*a,b*; table 21.3). The **posterior intercostals** are parietal arteries that are derived as bilateral branches directly from the descending aorta. The anterior and posterior intercostal arteries lie along the inferior margin of each rib and anastomose with each other approximately midway between the ends of the ribs. **Superior phrenic** (fren'ik; to the diaphragm) **arteries** supply blood to the diaphragm.

Abdominal Aorta and Its Branches

The branches of the abdominal aorta, like those of the thoracic aorta, are divided into visceral and parietal parts (figures 21.15*a,c* and 21.16; table 21.3). The visceral arteries are in turn divided into paired and unpaired branches. There are three major unpaired branches of the abdominal aorta: (1) the **celiac** (sē'lē-ak; belly) **trunk**, (2) the **superior mesenteric** (mez-en-ter'ik; relating to the mesenteries) **artery**, and (3) the **inferior mesenteric artery** (see figure 21.15*a,c*). Each has several major branches supplying the abdominal organs.

TABLE 21.3 Thoracic and Abdominal Aorta (figures 21.15 and 21.16)

Arteries	Tissues Supplied
Thoracic Aorta	
<i>Visceral Branches</i>	
Bronchial	Lung tissue
Esophageal	Esophagus
<i>Parietal Branches</i>	
Intercostal	Thoracic wall
Superior phrenic	Superior surface of diaphragm
Abdominal Aorta	
<i>Visceral Branches</i>	
Unpaired	
Celiac trunk	
Left gastric	Stomach and esophagus
Common hepatic	
Gastroduodenal	Stomach and duodenum
Right gastric	Stomach
Hepatic	Liver
Splenic	Spleen and pancreas
Left gastroepiploic	Stomach
Superior mesenteric	Pancreas, small intestine, and colon
Inferior mesenteric	Descending colon and rectum
Paired	
Suprarenal	Adrenal gland
Renal	Kidney
Gonadal	
Testicular (male)	Testis and ureter
Ovarian (female)	Ovary, ureter, and uterine tube
<i>Parietal Branches</i>	
Inferior phrenic	Adrenal gland and inferior surface of diaphragm
Lumbar	Lumbar vertebrae and back muscles
Median sacral	Inferior vertebrae
Common iliac	
External iliac	Lower limb (see table 21.5)
Internal iliac	Lower back, hip, pelvis, urinary bladder, vagina, uterus, rectum, and external genitalia (see table 21.4)

TABLE 21.4 Arteries of the Pelvis (figures 21.16 and 21.17)

Arteries	Tissues Supplied
Internal iliac	Pelvis through the branches listed below
<i>Visceral Branches</i>	
Middle rectal	Rectum
Vaginal	Vagina and uterus
Uterine	Uterus, vagina, uterine tube, and ovary
<i>Parietal Branches</i>	
Lateral sacral	Sacrum
Superior gluteal	Muscles of the gluteal region
Obturator	Pubic region, deep groin muscles, and hip joint
Internal pudendal	Rectum, external genitalia, and floor of pelvis
Inferior gluteal	Inferior gluteal region, coccyx, and proximal thigh

The paired visceral branches of the abdominal aorta supply the kidneys, adrenal glands, and gonads (testes and ovaries). The parietal arteries of the abdominal aorta supply the diaphragm and the abdominal wall (figure 21.16).

Arteries of the Pelvis

At the level of the fifth lumbar vertebra, the abdominal aorta divides into two **common iliac arteries**. The common iliac arteries then divide to form the **external iliac arteries**, which enter the lower limbs, and the **internal iliac arteries**, which supply the pelvic area. Visceral branches of the abdominal aorta supply the pelvic organs, such as the urinary bladder, rectum, uterus, and vagina. Parietal branches of the abdominal aorta supply blood to the walls and floor of the pelvis; the lumbar, gluteal, and proximal thigh muscles; and the external genitalia (figures 21.16 and 21.17; table 21.4).

Arteries of the Lower Limb

The arteries of the lower limb form a continuum similar to that of the arteries of the upper limb. The **external iliac artery** becomes the **femoral** (fem'ō-rāl; relating to the thigh) **artery** in the thigh, which becomes the **popliteal** (pop-lit'ē-āl, pop-li-tē'āl; ham, the hamstring area posterior to the knee) **artery** in the popliteal space. The popliteal artery gives off the **anterior tibial artery** just inferior to the knee and then continues as the **posterior tibial artery**. The anterior tibial artery becomes the **dorsalis pedis artery** at the foot. The posterior tibial artery gives off the **fibular artery**, or *peroneal artery*, and then gives rise to **medial** and **lateral plantar** (plan'tār; the sole of the foot) **arteries**, which in turn give off **digital branches** to the toes. The

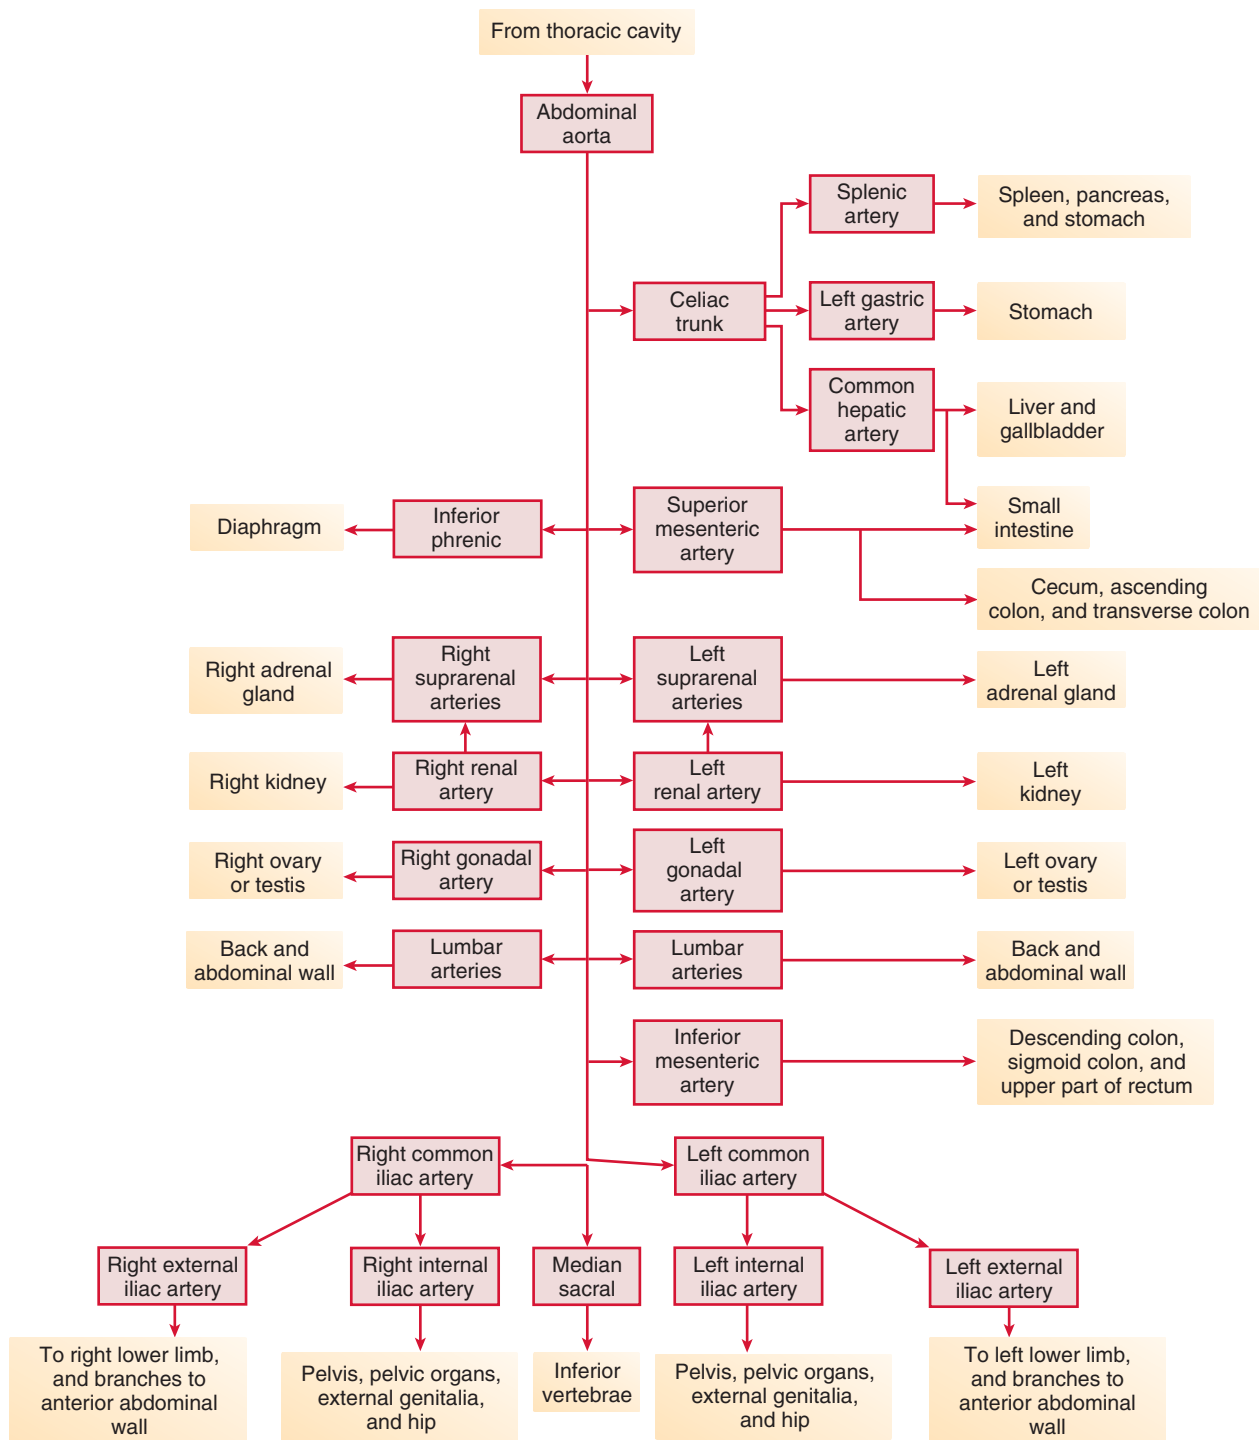

FIGURE 21.16 Major Arteries of the Abdomen and Pelvis

Visceral branches include those that are unpaired (celiac trunk, superior mesenteric, and inferior mesenteric) and those that are paired (renal, suprarenal, testicular, and ovarian). Parietal branches include inferior phrenic, lumbar, and median sacral.

arteries of the lower limb are illustrated in figures 21.17 and 21.18 and are listed in table 21.5.

ASSESS YOUR PROGRESS

24. Name the two types of branches arising from the thoracic aorta. What structures are supplied from each group?

- 25.** What areas of the body are supplied by the paired arteries that branch from the abdominal aorta? The unpaired arteries? Name the three major unpaired arteries.
- 26.** Name the arteries that branch from the aorta to supply the pelvic area. List the organs of the pelvis that are supplied by branches of these arteries.
- 27.** List, in order, the arteries that travel from the aorta to the digits of the lower limbs.

FIGURE 21.17 Arteries of the Pelvis and Lower Limb

The internal and external iliac arteries and their branches. The internal iliac artery supplies the pelvis and hip, and the external iliac artery supplies the lower limb through the femoral artery.

21.5 Systemic Circulation: Veins

LEARNING OUTCOME

After reading this section, you should be able to

- A. List the major veins that carry blood away from each of the body areas.**

Deoxygenated blood from the body is returned to the right atrium through three major veins: (1) the **coronary sinus**, returning blood from the walls of the heart (see figures 20.6b and 20.7); (2) the **superior vena cava** (vē'nă kă'vă, kă'vă; venous cave), returning blood from the head, neck, thorax, and upper limbs; and (3) the **inferior vena cava**, returning blood from the abdomen, pelvis, and lower limbs (figure 21.19).

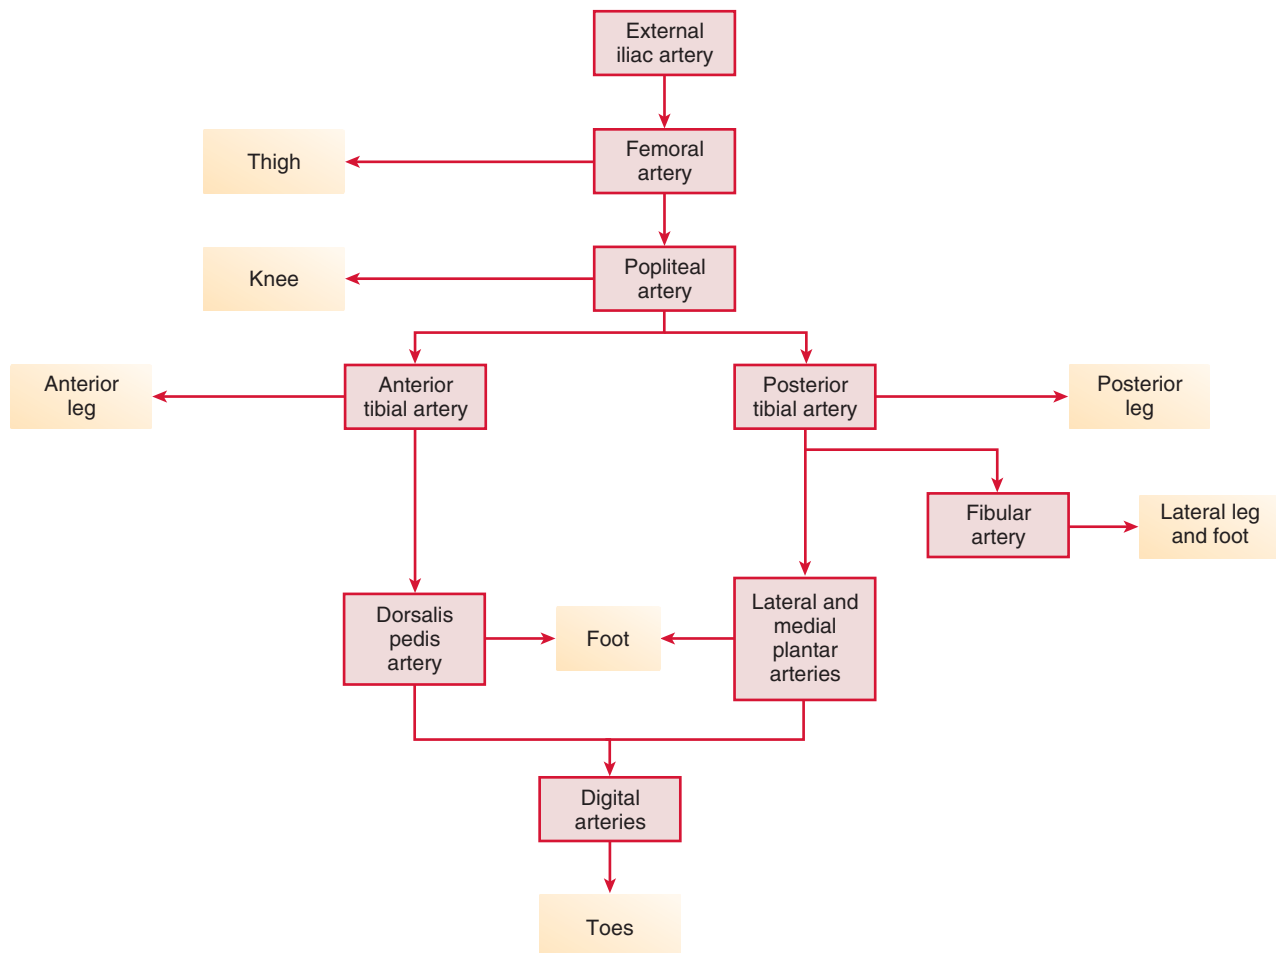

FIGURE 21.18 Major Arteries of the Lower Limb

TABLE 21.5 Arteries of the Lower Limb (figures 21.17 and 21.18)

Arteries	Tissues Supplied
Femoral	Thigh, external genitalia, and anterior abdominal wall
Deep femoral	Thigh, knee, and femur
Popliteal (continuation of the femoral artery)	
Posterior tibial	Knee and leg
Fibular (peroneal)	Calf and peroneal muscles and ankle
Medial plantar	Plantar region of foot
Digital	Digits of foot
Lateral plantar	Plantar region of foot
Digital	Digits of foot
Anterior tibial	Knee and leg
Dorsalis pedis	Dorsum of foot
Digital	Digits of foot

In a very general way, the smaller veins follow the same course as the arteries, and many are given the same names. The veins, however, are more numerous and more variable. The larger veins often follow a very different course and have names different from the arteries.

Earlier in the chapter, we categorized veins based on size as venules, small veins, medium veins, and large veins. When describing the specific veins of the body, we often categorize veins based on location. In that situation, there are three major types of veins: (1) superficial veins, (2) deep veins, and (3) sinuses. In general, the superficial veins of the limbs are larger than the deep veins, whereas in the head and trunk the opposite is the case. Venous sinuses occur primarily in the cranial cavity and the heart.

Veins Draining the Heart

The **cardiac veins** transport blood from the walls of the heart and return it through the coronary sinus to the right atrium. A detailed description of the cardiac veins is found in chapter 20.

Veins of the Head and Neck

The two pairs of major veins that drain blood from the head and neck are the **external** and **internal jugular** (jŭg'ŭ-lar; neck)

FIGURE 21.19 Major Veins

These veins carry blood from the body tissues to the heart. **APR**

Anterior view

veins. The external jugular veins are the more superficial of the two sets, and they drain blood primarily from the posterior head and neck. The external jugular vein drains into the subclavian vein. The internal jugular veins are much larger and deeper than the external jugular veins. The internal jugular veins drain blood from the cranial cavity and the anterior head, face, and neck.

The internal jugular vein is formed primarily as the continuation of the **venous sinuses** of the cranial cavity. The venous sinuses are actually spaces within the dura mater surrounding the brain (see chapter 13). They are depicted in figure 21.20 and listed in table 21.6.

Once the internal jugular veins exit the cranial cavity, they receive several venous tributaries that drain the external head and face (figures 21.21 and 21.22; table 21.7). On each side of the body the internal jugular veins merge with the **subclavian veins** to form the **brachiocephalic veins**.

Veins of the Upper Limb

The **cephalic** (se-fal'ik; toward the head), **basilic** (ba-sil'ik), and **brachial veins** are responsible for draining most of the blood from the upper limbs (figures 21.23 and 21.24; table 21.8). Many of the tributaries of the cephalic and basilic veins in the forearm and hand can be seen through the skin. Because of the considerable variation in the tributary veins of the forearm and hand, they often are left unnamed. The basilic vein of the arm becomes the **axillary vein** as

TABLE 21.6

Venous Sinuses of the Cranial Cavity (figure 21.20)

Veins	Tissues Drained
Internal Jugular Vein	
Sigmoid sinus	
Superior and inferior petrosal sinuses	Anterior portion of cranial cavity

Ophthalmic veins	Orbit
Transverse sinus	
Occipital sinus	Central floor of posterior fossa of skull
Superior sagittal sinus	Superior portion of cranial cavity and brain
Straight sinus	
Inferior sagittal sinus	Deep portion of longitudinal fissure

it passes through the axillary region. The cephalic vein empties into the axillary vein then becomes the **subclavian vein** at the margin of the first rib.

FIGURE 21.20 Venous Sinuses Associated with the Brain

Anterior view

FIGURE 21.21 Veins of the Head and Neck

The right brachiocephalic vein and its tributaries. The major veins draining the head and neck are the internal and external jugular veins. **APR**

TABLE 21.7**Veins Draining the Head and Neck (figures 21.21 and 21.22)**

Veins	Tissues Drained
Brachiocephalic	
Internal jugular	Brain
Lingual	Tongue and mouth
Superior thyroid	Thyroid and deep posterior facial structures (also empties into external jugular)
Facial	Superficial and anterior facial structures
External jugular	Superficial surface of posterior head and neck

The **median cubital** (kū'bi-tāl; pertaining to the elbow) **vein** is a variable vein that usually connects the cephalic vein or its tributaries with the basilic vein. In many people, this vein is quite prominent on the anterior surface of the upper limb at the level of the elbow (cubital fossa); therefore, it is often used as a site for drawing blood from a patient.

The deep veins draining the upper limb follow the same course as the arteries. Thus, the **radial** and **ulnar veins** are named for the arteries they attend. They are usually paired, with one small vein lying on each side of the artery, and they have numerous connections with one another and with the superficial veins. The radial and ulnar veins empty into the **brachial veins**, which accompany the brachial artery and empty into the axillary vein (see figures 21.23 and 21.24).

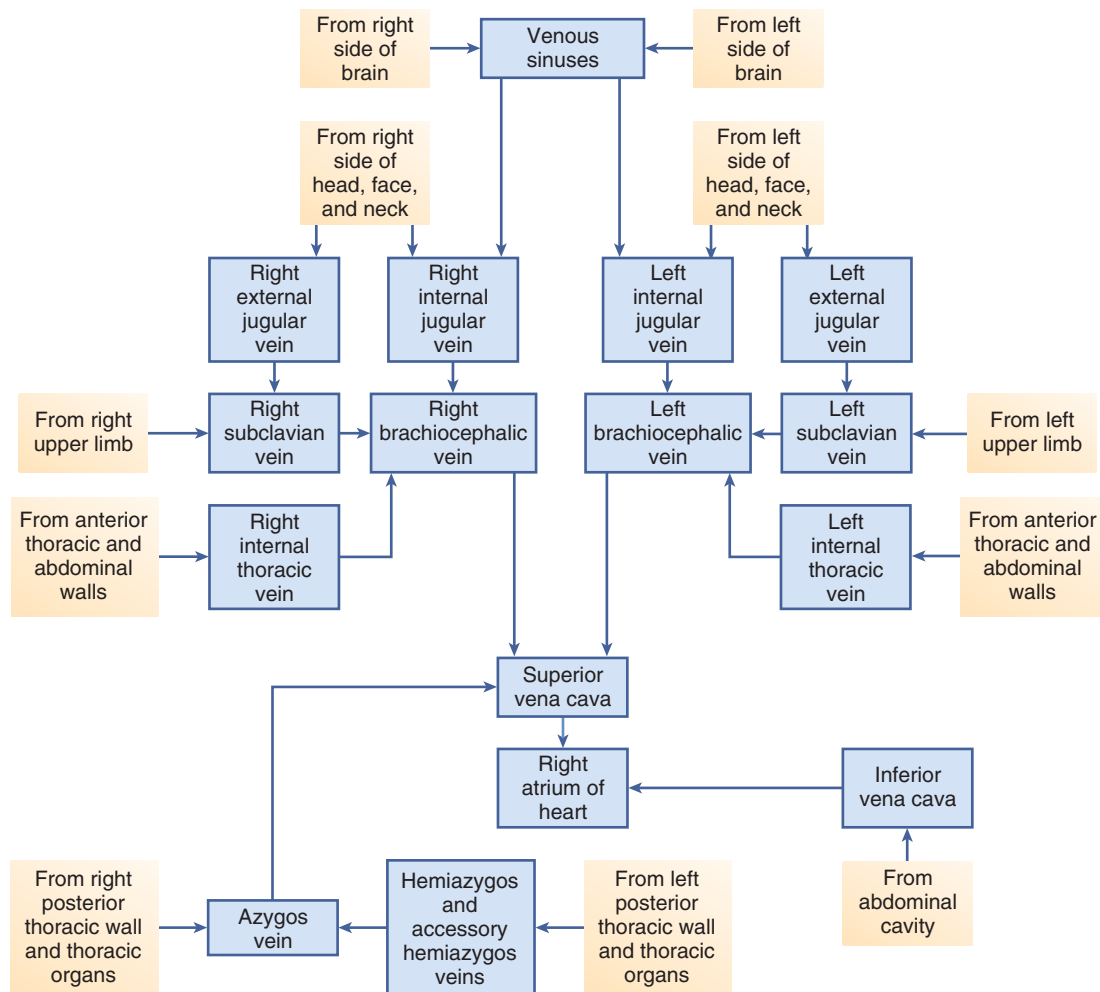

FIGURE 21.22 Major Veins of the Head and Thorax

TABLE 21.8

Veins of the Upper Limb
(figures 21.23 and 21.24)

Veins	Tissues Drained

Cephalic	Lateral arm, forearm, and hand (superficial veins of the forearm and hand are variable)
Brachial (paired, deep veins)	Deep structures of the arm
Radial	Deep forearm
Ulnar	Deep forearm
Basilic	Medial arm, forearm, and hand (superficial veins of the forearm and hand are variable)
Median cubital	Connects basilic and cephalic veins
Deep and superficial palmar venous arches	Drain into superficial and deep veins of the forearm
Digital	Fingers

Veins of the Thorax

Three major veins return blood from the thorax to the superior vena cava: the right and left brachiocephalic veins and the **azygos** (az'ī-gos; unpaired) **vein**. The thoracic drainage to the brachiocephalic veins is through the anterior thoracic wall by way of the **internal thoracic veins**. They receive blood from the **anterior intercostal veins**. Blood from the posterior thoracic wall is collected by **posterior intercostal veins** that drain into the azygos vein on the right side of the thorax and the **hemiazygos vein** (hem'ē-az'ī-gos) or the **accessory hemiazygos vein** on the left side of the thorax. The hemiazygos and accessory hemiazygos veins empty into the azygos vein, which drains into the superior vena cava. The thoracic veins are listed in table 21.9 and illustrated in figure 21.25 (also see figure 21.22).

ASSESS YOUR PROGRESS

28. What are the three major veins that return blood to the right atrium?
29. What veins collect blood from the heart muscle?

Anterior view

FIGURE 21.23 Veins of the Upper Limb

kidneys, and adrenal glands are the only abdominal organs outside the pelvis that drain directly into the inferior vena cava. The **internal iliac veins** drain the pelvis and join the **external iliac veins** from the lower limbs to form the **common iliac veins**, which unite to form the inferior vena cava. The major abdominal and pelvic veins are listed in table 21.10 and illustrated in figure 21.26; also see figure 21.28.

Hepatic Portal System

The **hepatic** (he-pat'ik; relating to the liver) **portal system** (figures 21.27 and 21.28; table 21.11) carries blood drained from capillaries within most of the abdominal viscera, such as the stomach, intestines, and spleen, to a series of dilated capillaries, called sinusoids, in the liver. This system delivers nutrients and other substances absorbed from the stomach or small intestine to the liver (see chapter 24).

The **hepatic portal vein**, the largest vein of the system, is formed by the union of the **superior mesenteric vein**, which drains the small intestine, and the **splenic vein**, which drains the spleen. The splenic vein receives blood from the **inferior mesenteric vein**,

TABLE 21.10

Veins Draining the Abdomen and Pelvis (figures 21.26 and 21.28)

Veins	Tissues Drained
Inferior Vena Cava	
Hepatic	Liver (see the section "Hepatic Portal System")
Common iliac	
External iliac	Lower limb (see table 21.12)
Internal iliac	Pelvis and its viscera
Ascending lumbar	Posterior abdominal wall (empties into common iliac, azygos, and hemiazygos veins)
Renal	Kidney
Suprarenal	Adrenal gland
Gonadal	
Testicular (male)	Testis
Ovarian (female)	Ovary
Phrenic	Diaphragm

FIGURE 21.27 Veins of the Hepatic Portal System

The hepatic portal system begins as capillary beds in the stomach, pancreas, spleen, small intestine, and large intestine. The veins of the hepatic portal system converge on the hepatic portal vein, which carries blood to a series of capillaries (sinusoids) in the liver. Hepatic veins carry blood from capillaries in the liver to the inferior vena cava (also see figure 21.26).

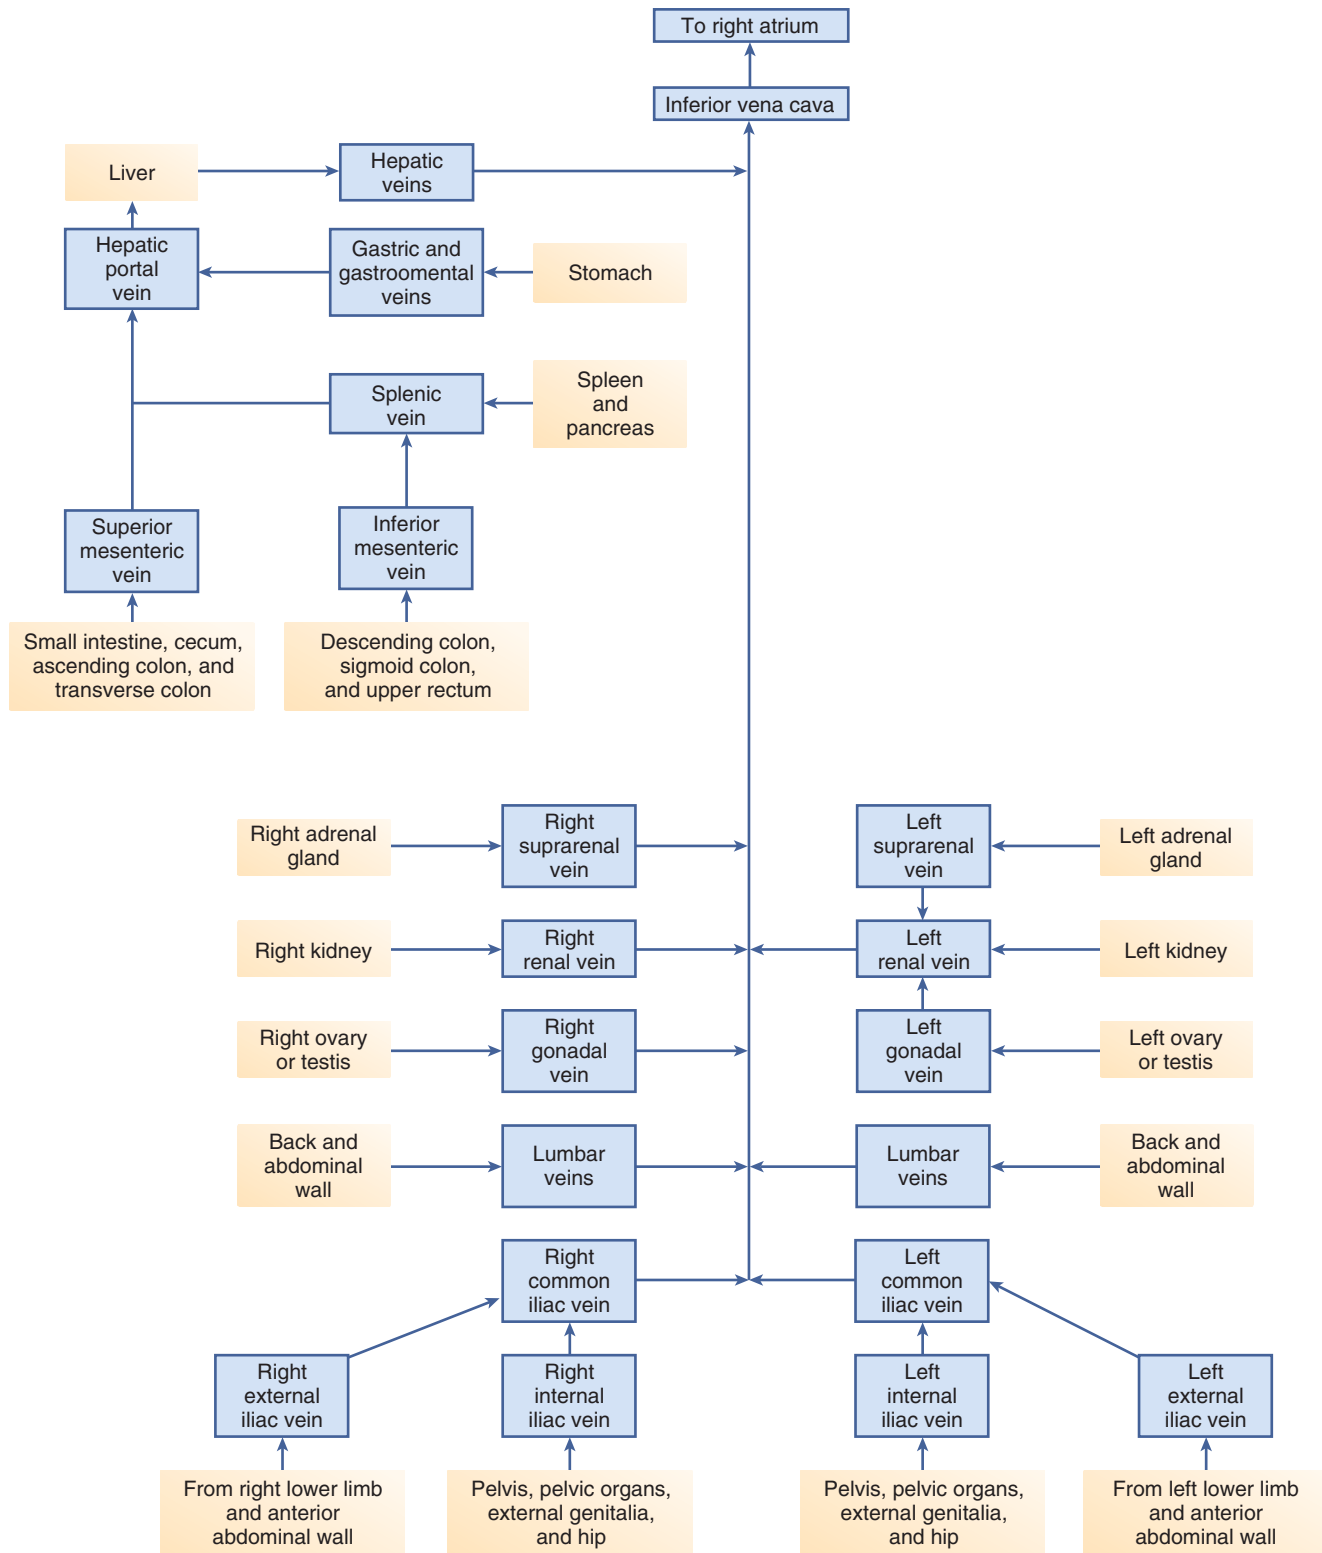

FIGURE 21.28 Major Veins of the Abdomen and Pelvis

which drains part of the large intestine, and the **pancreatic veins**, which drain the pancreas. The hepatic portal vein also receives blood from gastric veins before entering the liver.

Blood from the liver sinusoids is collected into **central veins**, which empty into **hepatic veins**. Blood from the **cystic veins**, which drain the gallbladder, also enters the hepatic veins.

TABLE 21.11 Hepatic Portal System (figures 21.27 and 21.28)

Veins	Tissues Drained
Hepatic Portal	
Superior mesenteric	Small intestine and most of the colon
Splenic	Spleen
Inferior mesenteric	Descending colon and rectum
Pancreatic	Pancreas
Gastrointestinal	Stomach
Gastric	Stomach
Cystic	Gallbladder

The hepatic veins empty into the inferior vena cava. Blood entering the liver through the hepatic portal vein is rich with nutrients collected from the small intestine, but it can also contain a number of toxic substances harmful to the body tissues. Within the liver, the nutrients are either taken up and stored or modified chemically so they can be used by other cells of the body (see chapter 24). The liver cells also help remove toxic substances by altering their structure or making them water-soluble, a process called **biotransformation**. The water-soluble substances can then be transported in the blood to the kidneys, which excrete them in the urine (see chapter 26).

Veins of the Lower Limb

The veins of the lower limb, like those of the upper limb, consist of superficial and deep groups. The distal deep veins of each limb are paired and follow the same path as the arteries, whereas the proximal deep veins are unpaired. The **anterior** and **posterior tibial veins** are paired and accompany the anterior and posterior tibial arteries. They unite just inferior to the knee to form the single **popliteal vein**, which ascends through the thigh and becomes the **femoral vein**. The femoral vein becomes the external iliac vein. **Fibular veins**, or *peroneal* (per-ō-nē'āl) *veins*, are also paired in each leg and accompany the fibular arteries. They empty into the posterior tibial veins just before those veins contribute to the popliteal vein.

The superficial veins consist of the great and small saphenous veins. The **great saphenous** (să-fē'nūs; visible) **vein** is the longest vein of the body. It originates over the dorsal and medial side of the foot and ascends along the medial side of the leg and thigh to empty into the femoral vein. The **small saphenous vein** begins over the lateral side of the foot and ascends along the posterior leg to the popliteal space, where it empties into the popliteal vein. The saphenous veins can be removed and used as a source of blood vessels for coronary bypass surgery (see chapter 20). The veins of the lower limb are illustrated in figures 21.29 and 21.30 and listed in table 21.12.

TABLE 21.12 Veins of the Lower Limb (figures 21.29 and 21.30)

Veins	Tissues Drained
External Iliac Vein (continuation of the femoral vein)	
Femoral (continuation of the popliteal vein)	Thigh
Popliteal	
Anterior tibial	Deep anterior leg
Dorsal vein of foot	Dorsum of foot
Posterior tibial	Deep posterior leg
Plantar veins	Plantar region of foot
Fibular (peroneal)	Deep lateral leg and foot
Small saphenous	Superficial posterior leg and lateral side of foot
Great saphenous	Superficial anterior and medial leg, thigh, and dorsum of foot
Dorsal vein of foot	Dorsum of foot
Dorsal venous arch	Foot
Digital veins	Toes

ASSESS YOUR PROGRESS

33. Explain the three ways that blood from the abdomen returns to the heart.
34. List the vessels that carry blood from the abdominal organs to the hepatic portal vein. What happens to the blood of the hepatic portal system as it filters through the liver?
35. List the major deep and superficial veins of the lower limbs.

21.6 Dynamics of Blood Circulation

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Compare laminar and turbulent blood flow.**
- B. Define blood pressure. Describe how it is measured.**
- C. Summarize Poiseuille's law.**
- D. Describe the relationship of viscosity to blood flow.**
- E. Relate Laplace's law to critical closing pressure.**
- F. Explain how vessel diameter and vascular compliance affect blood pressure.**

The dynamics of blood circulating through blood vessels are the same as those of water flowing through pipes. Blood movement through the vessels is determined by pressure, flow, and resistance. As we will find in the next section, these factors are closely

FIGURE 21.29 Veins of the Pelvis and Lower Limb

The right common iliac vein and its tributaries. **APR**

interrelated, and many of these interrelationships are clinically significant. Control mechanisms that regulate blood pressure and blood flow through the tissues are critical to the functions of the circulatory system and the homeostasis of the whole body.

Laminar and Turbulent Flow in Vessels

Fluid, including blood, tends to flow through long, smooth-walled tubes in a streamlined fashion called **laminar flow** (figure 21.31a). Fluid behaves as if it were composed of a large number of concentric

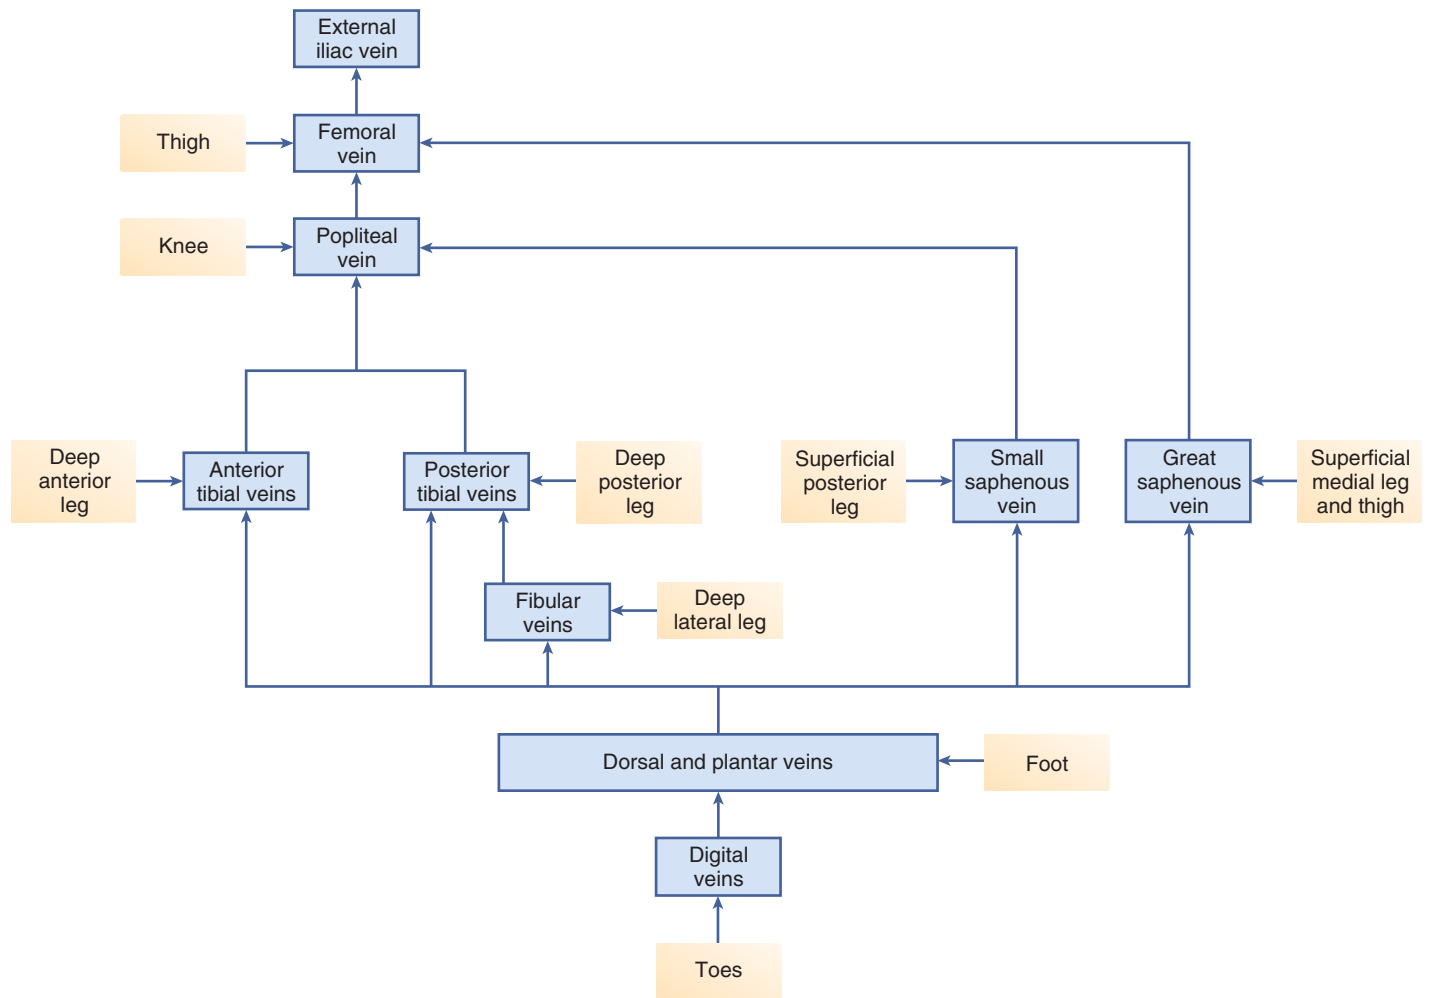

FIGURE 21.30 Major Veins of the Lower Limb

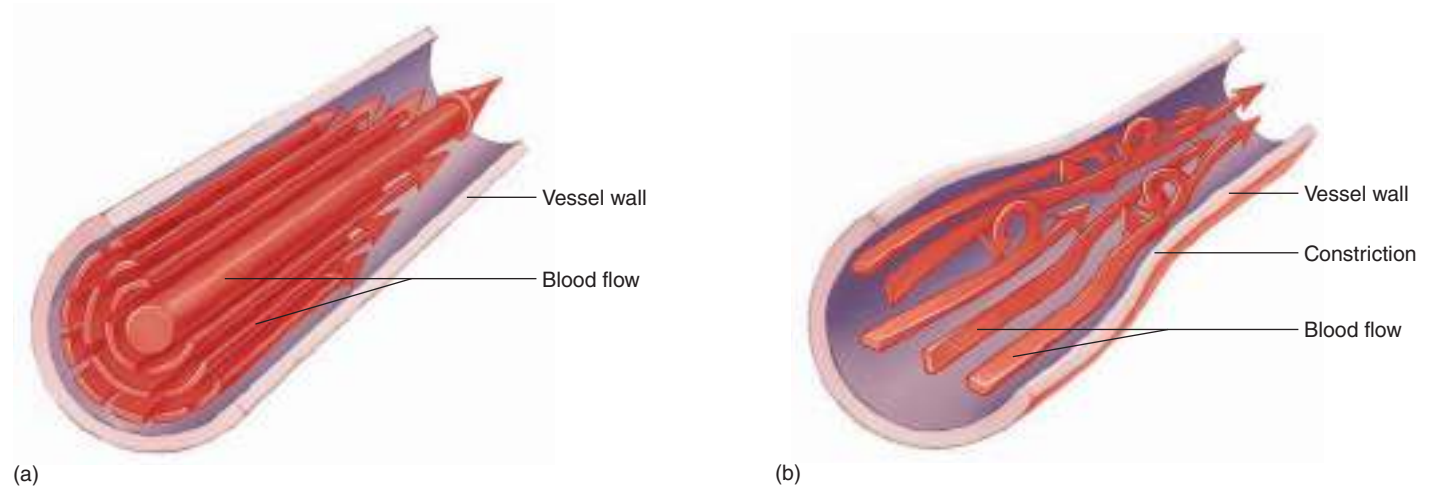

FIGURE 21.31 Laminar and Turbulent Flow

(a) In laminar flow, fluid flows in long, smooth-walled tubes as if it were composed of a large number of concentric layers. (b) Turbulent flow is caused by numerous small currents flowing crosswise or obliquely to the long axis of the vessel, resulting in flowing whorls and eddy currents.

layers. The layer nearest the wall of the tube experiences the greatest resistance to flow because it moves against the stationary wall. The innermost layers slip over the surface of the outermost layers and experience less resistance to movement. Thus, flow in a vessel consists of movement of concentric layers, with the outer layer moving most slowly and the layer at the center moving most rapidly.

Laminar flow is interrupted and becomes **turbulent flow** when the rate of flow exceeds a critical velocity or when the fluid passes a constriction, a sharp turn, or a rough surface. Turbulent flow is caused by numerous small currents flowing crosswise or obliquely to the long axis of the vessels. These small currents result in flowing whorls or eddy currents in the blood vessel (figure 21.31b). Vibrations of the liquid and blood vessel walls during turbulent flow cause the sounds heard when blood pressure is measured using a blood pressure cuff. Turbulent flow is also common as blood flows past the valves in the heart and is partially responsible for the heart sounds (see chapter 20).

Turbulent flow of blood through vessels occurs primarily in the heart and to a lesser extent where arteries branch. Sounds caused by turbulent blood flow in arteries are not normal and usually indicate that the artery is abnormally constricted. Turbulent flow in abnormally constricted arteries may indicate an increased probability that thromboses will develop.

Blood Pressure

Blood pressure is a measure of the force blood exerts against blood vessel walls. An instrument called a **mercury (Hg) manometer** measures blood pressure in millimeters of mercury (mm Hg). A blood pressure of 100 mm Hg is great enough to lift a column of mercury 100 mm.

Blood pressure can be measured directly by inserting a **cannula** (tube) into a blood vessel and connecting a manometer or an electronic pressure transducer to it. Electronic transducers are very sensitive and can precisely detect rapid fluctuations in pressure.

Placing a catheter into a blood vessel or into a chamber of the heart to monitor pressure changes is possible but not appropriate for routine clinical examinations. Health professionals most often use the **auscultatory** (aws-kŭl'tă-tŏ'rĕ) **method** to measure blood pressure. They wrap a blood pressure cuff connected to a **sphygmomanometer** (sfig'mŏ-mă-nom'ĕ-ter) around a patient's arm just above the elbow and place a stethoscope over the brachial artery (figure 21.32). Some sphygmomanometers have mercury manometers, and others have digital manometers, but they all measure pressure in terms of millimeters of mercury. The blood pressure cuff is inflated until the brachial artery is completely collapsed. Because no blood flows through the constricted area at this point, no sounds can be heard through the stethoscope. Then the pressure in the cuff is gradually lowered. As soon as it declines below the systolic pressure, blood flows through the constricted area during systole. The blood flow is turbulent and produces vibrations in the blood and surrounding tissues that can be heard through the stethoscope. These sounds are called **Korotkoff** (kŏ-rot'kof) **sounds**, and the pressure at which a Korotkoff sound is first heard represents the **systolic pressure**.

As the pressure in the blood pressure cuff is lowered still more, the Korotkoff sounds change tone and loudness. When the pressure has dropped until continuous laminar blood flow is reestablished, the

sound disappears completely. The pressure at which continuous laminar flow is reestablished is the **diastolic pressure**. This method for determining systolic and diastolic pressures is not entirely accurate, but its results are within 10% of methods that are more direct.

ASSESS YOUR PROGRESS

36. Describe laminar flow and turbulent flow through a tube. What conditions cause turbulent flow of blood?
37. What creates blood pressure? Describe the auscultatory method of measuring blood pressure.
38. What are Korotkoff sounds?

Blood Flow and Poiseuille's Law

The **rate** at which a liquid, such as blood, flows through a tube can be expressed as the volume that passes a specific point per unit of time. Blood flow is usually reported in either milliliters (mL) or liters (L) per minute. For example, when a person is resting, the **cardiac output** of the heart is approximately 5 L/min; thus, the rate of blood flow through the aorta is approximately 5 L/min. The rate of blood flow is influenced by pressure differences within the vessel and resistance to flow. Mathematically, the rate of blood flow in a vessel can be described by the following equation:

$$\text{Flow} = \frac{P_1 - P_2}{R}$$

where P_1 and P_2 are the pressures in the vessel at points one and two, respectively, and R is the resistance to flow. Blood always flows from an area of higher pressure to an area of lower pressure; the greater the pressure difference, the greater the rate of flow. For example, the average blood pressure in the aorta (P_1) is greater than the blood pressure in the vessels of the relaxed right atrium (P_2). Therefore, blood flows from the aorta to tissues and from tissues to the right atrium. If the heart should stop contracting, the pressure in the aorta would become equal to that in the right atrium, and blood would no longer flow.

The flow of blood, resulting from a pressure difference between the two ends of a blood vessel, is opposed by a resistance to flow. As the resistance increases, blood flow decreases; as the resistance decreases, blood flow increases. Resistance is affected by blood viscosity, vessel length, and vessel diameter and can be represented mathematically as follows:

$$\text{Resistance} = \frac{128vl}{\pi D^4}$$

where v is the viscosity of blood, l is the length of the vessel, and D is the diameter of the vessel. Both 128 and π are constants and for practical purposes the length of the blood vessel is constant. Thus, the diameter of the blood vessel and the viscosity of the blood determine resistance. The viscosity of blood changes slowly.

When the equation for resistance is combined with the equation for flow, the following relationship, called **Poiseuille's** (pwah-zuh'yeh) **law**, results:

$$\text{Flow} = \frac{P_1 - P_2}{R} = \frac{\pi(P_1 - P_2)D^4}{128vl}$$

In Poiseuille's law, the value for diameter (D) is raised to the fourth power, so we know that it has a great impact on the overall

FUNDAMENTAL Figure

- 1 When the cuff pressure is high enough to keep the brachial artery closed, no blood flows through it, and no sound is heard.
- 2 When cuff pressure decreases and is no longer able to keep the brachial artery closed, blood is pushed through the partially opened brachial artery, producing turbulent blood flow and a sound. **Systolic pressure** is the pressure at which a sound is first heard.
- 3 As cuff pressure continues to decrease, the brachial artery opens even more during systole. At first, the artery is closed during diastole, but as cuff pressure continues to decrease, the brachial artery partially opens during diastole. Turbulent blood flow during systole produces Korotkoff sounds, although the pitch of the sounds changes as the artery becomes more open.
- 4 Eventually, cuff pressure decreases below the pressure in the brachial artery, and it remains open during systole and diastole. Nonturbulent flow is reestablished, and no sounds are heard. **Diastolic pressure** is the pressure at which the sound disappears.

PROCESS FIGURE 21.32 Blood Pressure Measurement

calculation of flow. Specifically, a small change in the diameter of a vessel dramatically changes the resistance to flow, and therefore the amount of blood that flows through it. For example, decreasing the diameter of a vessel by half increases the resistance to flow 16-fold and decreases flow 16-fold. Vasoconstriction decreases the diameter of a vessel, increases resistance to flow, and decreases blood flow through the vessel. Vasodilation increases the diameter of a vessel, decreases resistance to flow, and increases blood flow through the vessel.

Changes in blood pressure and blood vessel diameter produce the major changes in blood flow through blood vessels. During exercise, heart rate and stroke volume increase, causing blood pressure in the aorta to increase. In addition, blood vessels in skeletal muscles vasodilate, and resistance to flow decreases. As a consequence, a dramatic increase in blood flow through blood vessels in exercising skeletal muscles occurs.

Viscosity (vis-kos'i-tē) is a measure of a liquid's resistance to flow. As the viscosity of a liquid increases, the pressure required to force it to flow also increases. The viscosity of liquids is

commonly determined by considering the viscosity of distilled water as 1 and then comparing the viscosity of other liquids with that. Using this procedure, whole blood has a viscosity of 3.0–4.5, which means that about three times as much pressure is required to force whole blood through a given tube at the same rate as forcing water through the same tube.

The viscosity of blood is influenced largely by **hematocrit** (hē'mă-tō-krit, hem'ă-tō-krit), which is the percentage of the total blood volume composed of red blood cells (see chapter 19). As the hematocrit increases, the viscosity of blood increases logarithmically. Blood with a hematocrit of 45% has a viscosity about three times that of water, whereas blood with a very high hematocrit of 65% has a viscosity about seven to eight times that of water. The plasma proteins have only a minor effect on the viscosity of blood, but dehydration or uncontrolled production of red blood cells can increase the hematocrit and the viscosity of blood substantially. Viscosity above the normal range increases the workload on the heart. If this workload is great enough, heart failure can result.

Predict 3

Predict the effect of each of the following conditions on blood flow: (a) vasoconstriction of blood vessels in the skin in response to cold exposure, (b) vasodilation of blood vessels in the skin in response to elevated body temperature, and (c) erythrocytosis, which results in a greatly increased hematocrit.

Critical Closing Pressure and Laplace's Law

The **critical closing pressure** of a blood vessel is the pressure below which the vessel collapses and blood flow through the vessel stops. When a person is in shock, blood pressure can decrease below the critical closing pressure in vessels (see Clinical Impact, “Circulatory Shock,” later in this chapter). As a consequence, the blood vessels collapse, and flow ceases. The tissues supplied by those vessels can become necrotic because of the lack of blood supply. **Laplace's** (la-plas'ez) **law**, which helps explain the critical closing pressure, states that the force that stretches the vascular wall is proportional to the diameter of the vessel times the blood pressure.

Laplace's law is expressed by the following formula:

$$F = D \times P$$

where F is force, D is vessel diameter, and P is pressure. As the pressure in a vessel decreases, the force that stretches the vessel wall also decreases. Some minimum force is required to keep the vessel open. If the pressure decreases, so that the force is below that minimum requirement, the vessel closes. As the pressure in a vessel increases, the force that stretches the vessel wall also increases.

According to Laplace's law, as the diameter of a vessel increases, the force applied to the vessel wall increases, even if the pressure remains constant. Sometimes a part of an arterial wall becomes weakened and a bulge, called an **aneurysm**, forms in it. Because the diameter of the vessel at the sight of the aneurysm is greater than other areas of the vessel, the force applied to the weakened part is also greater than at other points along the blood vessel. The greater force causes the weakened vessel wall to bulge even more, further increasing the pressure on it. This series of events can proceed until the vessel finally ruptures. Ruptured aneurysms in the blood vessels of the brain or in the aorta are often fatal.

Predict 4

Richard does not know it, but he has an aneurysm at the base of his left middle cerebral artery. One of Richard's favorite activities is to take a hot sauna bath and then jump into cold water. Richard does not realize that this causes rapid vasoconstriction of his cutaneous blood vessels. How will this activity affect Richard's aneurysm?

Vascular Compliance

Compliance (kom-pli'ans) is the tendency for blood vessel volume to increase as blood pressure increases. The more easily the vessel

wall stretches, the greater is its compliance. The less easily the vessel wall stretches, the smaller is its compliance.

Compliance is expressed by the following formula:

$$\text{Compliance} = \frac{\text{Increase in volume (mL)}}{\text{Increase in pressure (mm Hg)}}$$

Vessels with a large compliance exhibit a large increase in volume when the pressure increases a small amount. Vessels with a small compliance do not show a large increase in volume when the pressure increases.

Recall that veins have thinner walls than arteries. This difference also affects the compliance of the vessel. Venous compliance is approximately 24 times greater than arterial compliance. As venous pressure increases, the volume of the veins increases greatly. Consequently, veins act as storage areas, or reservoirs, for blood because their large compliance allows them to hold much more blood than other areas of the circulatory system (table 21.13).

ASSESS YOUR PROGRESS

39. Describe the relationship among blood flow, blood pressure, and resistance.
40. According to Poiseuille's law, what effects do viscosity, blood vessel diameter, and blood vessel length have on resistance? On blood flow?
41. Define viscosity, and state the effect of hematocrit on viscosity.
42. State Laplace's law. How does it relate to critical closing pressure and aneurysm?
43. What is vascular compliance? Do veins or arteries have greater compliance? Explain why.

TABLE 21.13

Distribution of Blood Volume in Blood Vessels

Vessels	Total Blood Volume (%)
Systemic	
Veins	64
Large veins (39%)	
Small veins (25%)	
Arteries	15
Large arteries (8%)	
Small arteries (5%)	
Arterioles (2%)	
Capillaries	5
TOTAL IN SYSTEMIC VESSELS	84
Pulmonary vessels	9
Heart	7
TOTAL BLOOD VOLUME	100

21.7 Physiology of the Systemic Circulation

LEARNING OUTCOMES

After reading this section, you should be able to

- List the percent distribution of blood in each of the systemic vessel types.
- Explain the relationship between cross-sectional area of blood vessels and the rate of blood flow.
- Explain how blood pressure and resistance to flow change as blood flows through the blood vessels.
- Define *pulse pressure* and list locations on the body surface where the pulse can be detected.
- Describe the exchange of materials across a capillary wall.
- Explain how preload, venous tone, and gravity affect cardiac output.

The anatomy of the circulatory system, the dynamics of blood flow, and the regulatory mechanisms that control the heart and blood vessels determine the physiological characteristics of the circulatory system. The entire circulatory system maintains adequate blood flow to all tissues.

Approximately 84% of the total blood volume is contained in the systemic blood vessels. Recall that because of their larger compliance compared to other vessels, veins can hold a larger volume of blood. So it is not surprising that most of that blood is in the veins (64%). Smaller volumes of blood are in the arteries (15%) and the capillaries (5%; table 21.13).

Cross-Sectional Area of Blood Vessels

If the cross-sectional area of each blood vessel type is determined and multiplied by the number of each type of blood vessel, the result is the total cross-sectional area for each blood vessel type. For example, only one aorta exists, and it has a cross-sectional area of 5 square centimeters (cm^2). An individual capillary has a very small cross-sectional area. However, the total cross-sectional area considers the combined area of all capillaries, which number approximately 10 billion in the body. So the total cross-sectional area of all capillaries is 2500 cm^2 , which is much greater than the cross-sectional area of the aorta (figure 21.33).

As blood flows through the circulation, the velocity of flow changes relative to the total cross-sectional area. The velocity of blood flow is greatest in the aorta, but the total cross-sectional area is small. In contrast, the total cross-sectional area of the capillaries is large, but the velocity of blood flow is low. As the veins become larger in diameter, their total cross-sectional area decreases, and the velocity of blood flow increases. The relationship between total cross-sectional area and velocity of blood flow is much like a stream that flows rapidly through a narrow gorge but more slowly through a broad plane (figure 21.33).

FIGURE 21.33 Blood Vessel Area and Velocity of Blood Flow

(a) A schematic representing the total cross-sectional area for each of the major blood vessel types. The total cross-sectional area of all the capillaries is much greater (2500 cm^2) than that of the aorta (5 cm^2), although the cross-sectional area of each capillary is much smaller than that of the aorta. (b) Blood velocity decreases dramatically in arterioles, capillaries, and venules and is greater in the aorta and the large veins. As the total cross-sectional area increases, the velocity of blood flow decreases.

Pressure and Resistance

The left ventricle forcefully ejects blood from the heart into the aorta. Because the heart's pumping action is pulsatile, the aortic pressure fluctuates between a systolic pressure of 120 mm Hg and a diastolic pressure of 80 mm Hg (table 21.14; figure 21.34). As blood flows through the circulation, from arteries through the capillaries and the veins, the pressure falls progressively to a minimum of approximately 0 mm Hg or even slightly lower by the time it returns to the right atrium.

The decrease in blood pressure in each part of the systemic circulation is directly proportional to the resistance to blood flow. In other words, the greater the resistance in a blood vessel, the more rapidly the pressure decreases as blood flows through it. This resistance to flow is also associated with the diameter of the vessel. As vessel diameter decreases, resistance to flow increases. Resistance is small in the aorta, so the average pressure at the end of the aorta is nearly the same as at the beginning of the aorta, about 100 mm Hg. The resistance in medium arteries, which are as small as 3 mm in diameter, is also small, so their average pressure is only decreased to 95 mm Hg. In the smaller arteries, however, the resistance to blood flow is greater; by the time blood reaches the arterioles, the average pressure is approximately 85 mm Hg. The resistance to flow is greater in the arterioles than in any other part of the systemic circulation; at their ends, the average pressure is only approximately 30 mm Hg. The resistance is also fairly high in the capillaries. The

TABLE 21.14 Blood Pressure Classification in Adults

	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)
Normal blood pressure	<120	<80
Prehypertension	120–139	80–89
Stage 1 hypertension	140–159	90–99
Stage 2 hypertension	≥160	≥100

Source: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, U.S. Dept. of Health and Human Services, NIH Publication No. 03–5233, May 2003.

blood pressure at the arterial end of the capillaries is approximately 30 mm Hg, and it decreases to approximately 10 mm Hg at the venous end. Resistance to blood flow in the veins is small because of their relatively large diameter; by the time the blood reaches the right atrium in the venous system, the average pressure has decreased from 10 mm Hg to approximately 0 mm Hg.

The muscular arteries and arterioles are capable of constricting or dilating in response to autonomic and hormonal stimulation, altering resistance and blood flow. If vessels constrict, resistance to blood flow increases, less blood flows through the constricted blood vessels, and blood is shunted to other, nonconstricted areas of the body. Muscular arteries help control the amount of blood flowing to each body region, and arterioles regulate blood flow

through specific tissues. Constriction of an arteriole decreases blood flow through the local area it supplies, and vasodilation increases blood flow.

ASSESS YOUR PROGRESS

44. List the percent distribution of blood in the large arteries, small arteries, arterioles, capillaries, small veins, and large veins.
45. Describe the total cross-sectional areas of the aorta, arteries, arterioles, capillaries, venules, veins, and venae cavae.
46. Describe how the rate changes as blood flows through the aorta to the venae cavae.
47. Describe the changes in resistance and blood pressure as blood flows through the aorta to the venae cavae.
48. Explain how constriction and dilation of muscular arteries shunt blood from one area of the body to another and how constriction and dilation of arterioles change blood flow through local areas.

FIGURE 21.34 Blood Pressure in the Major Blood Vessel Types

In small arteries and arterioles, blood pressure fluctuations between systole and diastole are reduced. No fluctuations in blood pressure occur in capillaries and veins.

Pulse Pressure

Pulse pressure is the difference between systolic and diastolic pressures (figure 21.34). For example, in a healthy, young adult at rest, systolic pressure is approximately 120 mm Hg, and diastolic pressure is approximately 80 mm Hg; thus, the pulse pressure is approximately 40 mm Hg ($= 120 \text{ mm Hg} - 80 \text{ mm Hg}$). Two major factors influence pulse pressure: (1) stroke volume of the heart and (2) vascular compliance. Pulse pressure is directly related to stroke volume. When stroke volume decreases, pulse pressure also decreases; when stroke volume increases, pulse pressure increases. For example, during exercise, such as running, the stroke volume increases; as a consequence, the pulse pressure also increases. After running, the pulse pressure gradually returns to its resting value as the stroke volume of the heart decreases.

Pulse pressure is inversely related to vascular compliance. As vascular compliance increases, pulse pressure decreases. Conversely, as vascular compliance decreases, pulse pressure increases. The vascular compliance decreases as a person ages. Arteries in older people become less elastic, or arteriosclerotic, causing the pressure in the aorta to rise more rapidly and to a greater degree during systole and to fall more rapidly to its diastolic value. Thus, for a given stroke volume, systolic pressure and pulse pressure are higher as vascular compliance decreases.

The pulse pressure caused by the ejection of blood from the left ventricle into the aorta produces a pressure wave, or **pulse**, that travels rapidly along the arteries. Its rate of transmission is approximately 15 times greater in the aorta (7–10 m/s) and 100 times greater in the distal arteries (15–35 m/s) than the velocity of blood flow.

You are most likely familiar with the practice of “taking a person’s pulse” in a clinical situation. The pulse is important clinically because health professionals can determine heart rate, rhythm, and other characteristics by feeling it. The pulse can be felt at 10 major locations on each side of the body where large arteries are close to the surface (figure 21.35).

On the head and neck, a pulse can be felt in three arteries: (1) the common carotid artery in the neck, (2) the superficial temporal artery immediately anterior to the ear, and (3) the facial artery at the point where it crosses the inferior border of the mandible approximately midway between the angle and the genu.

On the upper limb, a pulse can also be felt in three arteries: (1) the axillary artery in the axilla, (2) the brachial artery on the medial side of the arm slightly proximal to the elbow, and (3) the radial artery on the lateral side of the anterior forearm just proximal to the wrist. The **radial pulse**, taken at the radial artery, is traditionally used because it is the most easily accessible artery in the body.

In the lower part of the body, a pulse can be felt in four locations: (1) the femoral artery in the groin, (2) the popliteal artery just proximal to the knee, (3) the dorsalis pedis artery at the ankle, and (4) the posterior tibial artery at the ankle.

As the pulse passes through the smallest arteries and arterioles, it is gradually damped, so that the fluctuation between the systolic

and diastolic pressures becomes smaller until the difference is almost absent at the end of the arterioles (see figure 21.34). At the beginning of the capillary, there is a steady pressure of close to 30 mm Hg, which is adequate to force blood through the capillaries if the precapillary sphincters dilate.

Capillary Exchange and Regulation of Interstitial Fluid Volume

Approximately 10 billion capillaries exist in the body. The heart and blood vessels maintain blood flow through those capillaries and support **capillary exchange**, which is the movement of substances into and out of capillaries. Capillary exchange is the process by which cells receive everything they need to survive and to eliminate metabolic waste products. If blood flow through capillaries is not maintained, cells cannot survive.

By far, the most important means by which capillary exchange occurs is **diffusion**. Oxygen, hormones, and nutrients, such as glucose and amino acids, diffuse from a higher concentration in capillaries to a lower concentration in the interstitial fluid. Waste products, including carbon dioxide, diffuse from a higher concentration in the interstitial fluid to a lower concentration in the capillaries. Similar to the diffusion into and out of cells (see figure 3.11), how a substance moves into and out of the capillaries depends on its solubility characteristics. Lipid-soluble molecules, such as oxygen, carbon dioxide, steroid-hormones, and fatty acids, diffuse through the plasma membranes of the endothelial cells of the capillaries. Water-soluble substances, such as glucose and amino acids, diffuse through intercellular spaces or through fenestrations of capillaries. In a few areas of the body, such as the spleen and liver, the spaces between the endothelial cells are large enough to allow proteins to pass through them. In other areas, the connections between endothelial cells are extensive, and few molecules pass between the endothelial cells; such is the case in the capillaries of the brain that form the blood-brain barrier. In these capillaries, mediated transport moves water-soluble substances across the capillary walls (see chapter 13 for a description of the blood-brain barrier).

The endothelial cells of capillaries appear to take up small pinocytotic vesicles and transport them across the capillary wall. However, the pinocytotic vesicles do not appear to be a major means by which molecules move across the capillary wall.

Blood enters capillaries at their arterial ends and exits the capillaries at their venous ends. A small amount of fluid moves out of capillaries at their arterial ends, and most of that fluid reenters the capillaries at their venous ends (figure 21.36). The remaining fluid enters lymphatic vessels, which eventually return it to the venous circulation (see chapter 22). Alterations in the forces affecting fluid movement across capillary walls are responsible for edema (see Clinical Impact, “Edema and Capillary Exchange”).

Net filtration pressure (NFP) is the force responsible for moving fluid across capillary walls. It is the difference between net hydrostatic pressure and net osmotic pressure:

$$\text{NFP} = \text{Net hydrostatic pressure} - \text{Net osmotic pressure}$$

Net hydrostatic pressure is the difference in pressure between the blood and the interstitial fluid. Blood pressure (BP) at

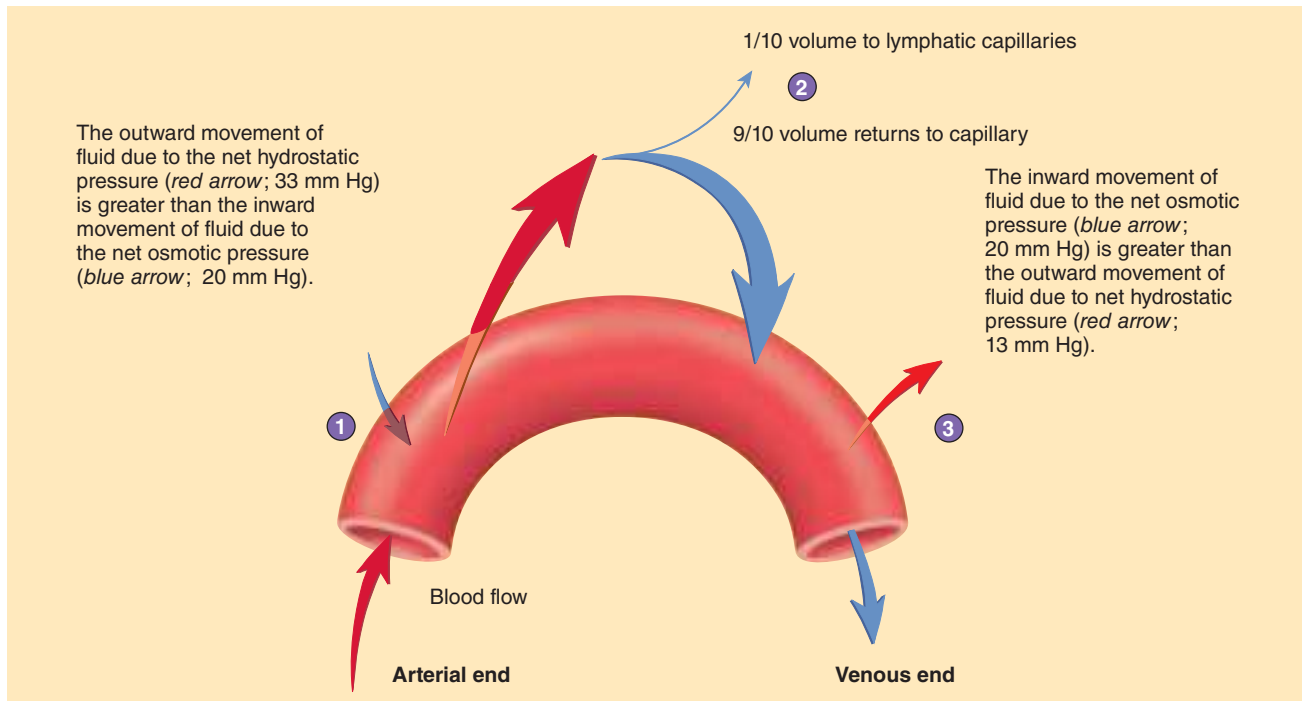

FIGURE 21.35 Major Points at Which the Pulse Can Be Monitored

Each pulse point is named after the artery on which it occurs.

1 At the arterial end of the capillary, the **net hydrostatic pressure** is greater than the **net osmotic pressure**. When the net osmotic pressure is subtracted from the net hydrostatic pressure, the result is a positive **net filtration pressure** that causes fluid to move out of the capillary.

$$\begin{array}{r} 33 \text{ mm Hg (Net hydrostatic pressure)} \\ -20 \text{ mm Hg (Net osmotic pressure)} \\ \hline 13 \text{ mm Hg (Net filtration pressure)} \end{array}$$

2 Approximately nine-tenths of the fluid that leaves the capillary at its arterial end reenters the capillary at its venous end. About one-tenth of the fluid passes into the lymphatic capillaries.

3 At the venous end of the capillary, the **net hydrostatic pressure** is less than the **net osmotic pressure**. When the net osmotic pressure is subtracted from the net hydrostatic pressure, the result is a negative **net filtration pressure** that causes fluid to move into the capillary.

$$\begin{array}{r} 13 \text{ mm Hg (Net hydrostatic pressure)} \\ -20 \text{ mm Hg (Net osmotic pressure)} \\ \hline -7 \text{ mm Hg (Net filtration pressure)} \end{array}$$

PROCESS FIGURE 21.36 Fluid Exchange Across the Walls of Capillaries

Pressure differences exist between the inside and the outside of capillaries at their arterial and venous ends.

the arterial end of a capillary is about 30 mm Hg. This pressure results mainly from the force of contraction of the heart, but it can be modified by the effect of gravity on fluids within the body (see “Blood Pressure and the Effect of Gravity,” later in this section).

At the arterial end of capillaries, the net hydrostatic pressure that moves fluid across the capillary walls into the tissue spaces is the difference between blood pressure (BP) and interstitial fluid pressure (IFP):

$$\begin{aligned} \text{Net hydrostatic pressure} &= \text{BP} - \text{IFP} \\ &= 30 - (-3) \\ &= 33 \text{ mm Hg} \end{aligned}$$

Interstitial fluid pressure (IFP), the pressure of interstitial fluid within the tissue spaces, is -3 mm Hg. IFP is a negative number because of the suction effect produced by the lymphatic vessels as they pump excess fluid from the tissue spaces. The lymphatic system is described in chapter 22. Here, it is only necessary

to understand that excess interstitial fluid enters lymphatic capillaries and is eventually returned to the blood.

Net osmotic pressure is the difference in osmotic pressure between the blood and the interstitial fluid. Osmotic pressure is the result of solute differences across a selectively permeable barrier, such as a capillary wall (see chapter 3). Solutes, such as proteins in the blood and interstitial fluids, will greatly affect the osmotic pressure. The osmotic pressure caused by the plasma proteins in the blood is called the **blood colloid osmotic pressure (BCOP)**, and the osmotic pressure caused by proteins in the interstitial fluid is called the **interstitial colloid osmotic pressure (ICOP)**. Large proteins do not pass freely through the capillary walls, and the difference in protein concentrations between the blood and the interstitial fluid is responsible for osmosis across the capillary wall. Ions and small molecules do not make a significant contribution to osmosis across the capillary wall because they pass freely through it and their concentrations are approximately the same in the blood as in the interstitial fluid.

Clinical IMPACT

Edema

Increases in the permeability of capillaries allow plasma proteins to move from capillaries into the interstitial fluid. This causes an increase in the interstitial colloid osmotic pressure, which causes a net increase in the amount of fluid moving from capillaries into interstitial spaces. The result is edema, swelling due to excessive fluid accumulation in tissues.

Edema can result from many different conditions. Chemical mediators of inflammation increase the permeability of the capillary walls and can cause edema. Decreases in plasma protein concentration reduce the blood colloid osmotic pressure, so more fluid moves out of the capillary at its arterial end and less fluid moves into the capillary at its venous end. The result once again is edema. Severe liver infections that reduce plasma protein synthesis, loss of protein molecules in urine through the kidneys, and protein starvation all lead to edema. Blockage of veins, as in venous thrombosis, increases blood pressure in capillaries and can cause edema. Either blockage or removal of lymphatic vessels, as occurs when lymph nodes are suspected of being cancerous, allows fluid to accumulate in the interstitial spaces and results in edema.

The BCOP (28 mm Hg) is several times larger than the ICOP (8 mm Hg) because of the presence of albumin and other proteins in the plasma (see chapter 19). Therefore, the net osmotic pressure is equal to BCOP – ICOP:

$$\begin{aligned}\text{Net osmotic pressure} &= \text{BCOP} - \text{ICOP} \\ &= 28 - 8 \\ &= 20 \text{ mm Hg}\end{aligned}$$

The greater the osmotic pressure of a fluid, the greater the tendency for water to move into that fluid (see chapter 3). The net osmotic pressure results in the osmosis of water into the capillary because water has a greater tendency to move into the blood than into the interstitial fluid.

The net filtration pressure at the arterial end of the capillary is equal to the net hydrostatic pressure, which moves fluid out of the capillary, minus the net osmotic pressure, which moves fluid into the capillary. Since the net hydrostatic pressure is greater than the net osmotic pressure at the arterial end of the capillary, there is a net movement of fluid out of the capillary:

$$\begin{aligned}\text{NFP} &= \text{Net hydrostatic pressure} - \text{Net osmotic pressure} \\ &= 33 - 20 \\ &= 13 \text{ mm Hg}\end{aligned}$$

The blood pressure decreases as blood moves through the capillary. The decrease is from about 30 mm Hg at the arterial end of the capillary to 10 mm Hg at the venous end of the capillary. This

causes a reduction in the net hydrostatic pressure moving fluid out of the venous end of the capillary:

$$\begin{aligned}\text{Net hydrostatic pressure} &= \text{BP} - \text{IFP} \\ &= 10 - (-3) \\ &= 13 \text{ mm Hg}\end{aligned}$$

The concentration of proteins within capillaries and the concentration of proteins within interstitial fluid do not change significantly because only a small amount of fluid passes from the capillaries into the tissue spaces. Therefore, the net osmotic pressure moving fluid into capillaries by osmosis is still approximately 20 mm Hg. At the venous end of capillaries, the NFP now causes fluid to reenter the capillary:

$$\begin{aligned}\text{NFP} &= \text{Net hydrostatic pressure} - \text{Net osmotic pressure} \\ &= 13 - 20 \\ &= -7 \text{ mm Hg}\end{aligned}$$

Exchange of fluid across the capillary wall and movement of fluid into lymphatic capillaries keep the volume of the interstitial fluid within a narrow range of values. Disruptions in the movement of fluid across the wall of the capillary can result in edema, or swelling, as a result of increased interstitial fluid volume.

Predict 5

Edema often results from a disruption in the normal inwardly and outwardly directed pressures across the capillary wall. On the basis of what you know about fluid movement across the wall of the capillary and the regulation of capillary blood pressure, explain why large fluctuations in arterial blood pressure do not cause significant edema, whereas small increases in venous pressure can lead to edema.

ASSESS YOUR PROGRESS

49. What is pulse pressure? How do stroke volume and vascular compliance affect pulse pressure?
50. List the locations on the body where the pulse can easily be detected.
51. What is the most important means by which capillary exchange occurs?
52. Describe the factors that influence the movement of fluid from capillaries into the tissues.
53. What is the main force for the return of fluids at the venous end of capillaries?
54. What happens to the fluid in the tissues? What is edema?

Functional Characteristics of Veins

In chapter 20, factors that affect cardiac output were described. One important factor that is influenced by veins is the preload, which is determined by the volume of blood that enters the heart from the veins (see chapter 20). Therefore, the factors that affect flow in the veins are of great importance to the overall function of the cardiovascular system. If the volume of blood is increased because of a rapid transfusion, the amount of blood flow to the heart through the veins increases. This increases the preload, which causes the cardiac output to increase because of the Starling

Case STUDY

Venous Thrombosis

Harry is a 55-year-old college professor who teaches a night class in a small town about 50 miles from his home. One night, as he walked to his car after class, Harry noticed that his right leg was uncomfortable. When he arrived home, about 90 minutes later, Harry realized that the calf of his right leg had become very swollen. When he extended his knee and plantar flexed his foot, the pain in his right leg increased. Harry thought this might be a serious condition, so he drove to the hospital.

In the emergency room, technicians performed a Doppler test, which monitors the flow of blood through blood vessels. The test confirmed that a thrombus had formed in one of the deep veins of Harry's right leg. His pain and edema were consistent with the presence of a venous thrombosis.

Harry was admitted to the hospital, and his physician prescribed intravenous (IV) heparin. About 4 a.m., Harry experienced an increase in his respiratory rate, his breathing became labored, he felt pain in his chest and

back, and his arterial oxygen levels decreased. In response to these changes, Harry's physician increased the amount of heparin. The chest pain subsided, and Harry's respiratory movements improved over the next 24 hours. The next day, a CT scan revealed pulmonary emboli, but no infarctions of the lung. The edema in Harry's leg also slowly improved.

Harry remained in the hospital for several days, during which heparin was continued and then oral coumadin was prescribed. Frequent blood samples were taken to determine Harry's prothrombin time (see chapter 19). After about a week, Harry was released from the hospital. His physician, however, prescribed oral coumadin for at least several months. In addition, Harry was required to have his prothrombin time checked periodically.

➤ Predict 6

- Explain why edema and pain developed in response to a thrombus in a deep vein of Harry's right leg.

- If a thrombus in the posterior tibial vein gave rise to an embolus, name in order the parts of the circulatory system the embolus would pass through before lodging in a blood vessel in the lungs. Explain why the lungs are the most likely places the embolus will lodge.
- Predict the effect of pulmonary emboli on the right ventricle's ability to pump blood.
- Predict the effect of pulmonary emboli on blood oxygen levels, on the left ventricle's ability to pump blood, and on systemic blood pressure. What responses would be activated by this change in blood pressure? (*Hint:* See figure 21.40.)
- Explain why Harry's physician prescribed heparin and coumadin and why coumadin was continued long after the venous thrombosis and lung emboli had dissolved.

law of the heart. On the other hand, rapid loss of a large volume of blood decreases venous return to the heart, which decreases the preload and cardiac output.

Venous tone is a continual state of partial contraction of the veins as a result of sympathetic stimulation (see chapter 16). Increased sympathetic stimulation increases venous tone by causing the veins to constrict more, which forces the large venous volume to flow toward the heart. Consequently, venous return and preload increase, causing an increase in cardiac output. Conversely, decreased sympathetic stimulation decreases venous tone, allowing veins to relax and dilate. As the veins fill with blood, venous return to the heart, preload, and cardiac output decrease.

The periodic muscular compression of veins forces blood to flow more rapidly through them toward the heart. The valves in the veins prevent flow away from the heart, so that, when veins are compressed, blood is forced toward the heart. The combination of arterial dilation and compression of the veins by muscles during exercise causes blood to return to the heart more rapidly than under conditions of rest.

Blood Pressure and the Effect of Gravity

Blood pressure is approximately 0 mm Hg in the right atrium and approximately 100 mm Hg in the aorta. However, the pressure in the vessels above and below the heart is affected by gravity. While

a person is standing, the pressure in the venules of the feet can be as much as 90 mm Hg, instead of the usual 10 mm Hg. Arterial pressure is influenced by gravity to the same degree; thus, the arterial ends of the capillaries can have a pressure of 110 mm Hg rather than 30 mm Hg. The normal pressure difference between the arterial and the venous ends of capillaries remains the same, so that blood continues to flow through the capillaries. The major effect of the high pressure in the feet and legs when a person stands for a prolonged time without moving is edema. Without muscular movement, the pressure at the venous end of the capillaries increases. Up to 15–20% of the total blood volume can pass through the walls of the capillaries into the interstitial spaces of the lower limbs during 15 minutes of standing still.

When a person changes position from lying down to standing, the blood pressure in the veins of the lower limbs increases. Because of the structure of their walls, the compliance of veins is approximately 24 times greater than the compliance of arteries. The increased blood pressure causes the distensible (compliant) veins to expand but has little effect on the arteries. As the veins expand and fill with blood, venous return decreases because less blood is returning to the heart. As venous return decreases, cardiac output and blood pressure decrease (see chapter 20). If negative-feedback mechanisms do not compensate and cause blood pressure to increase, the delivery of blood to the brain is not adequate to maintain homeostasis, and the person may feel dizzy or even faint.

ASSESS YOUR PROGRESS

55. How do blood volume and venous tone affect cardiac output?
56. What effect does standing still for a prolonged time have on the blood pressure in the feet and in the head? Explain why this effect occurs.
57. Why does a person feel dizzy if he or she stands up too quickly from sitting or lying down?

21.8 Control of Blood Flow in Tissues

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Explain how local mechanisms regulate blood flow.
- B. Explain how nervous and hormonal mechanisms control blood flow.

Blood flow provided to the tissues by the circulatory system is highly controlled and matched closely to the metabolic needs of tissues. Mechanisms that control blood flow through tissues are classified as (1) local control and (2) nervous and hormonal control (table 21.15).

Local Control of Blood Flow in Tissues

Blood flow is not equal in all tissues of the body. Some organs require a greater blood flow than others. For example, blood flow through the brain, kidneys, and liver is relatively high. By contrast, blood flow through resting skeletal muscles is not high, but it is greater than that through other tissue types because skeletal muscle constitutes 35–40% of the total body mass. However, blood flow through exercising skeletal muscles can increase up to 20-fold, and the flow through the viscera, including the kidneys and liver, either remains the same or decreases. Local control of blood flow is achieved by the periodic relaxation and contraction of precapillary sphincters regulating blood flow through the tissues. In most tissues, blood flow is proportional to the metabolic

TABLE 21.15 Homeostasis: Control of Blood Flow

Stimulus	Response
Local Control	
<i>Regulation by Metabolic Need of Tissues</i>	
Increased vasodilator substances (e.g., CO ₂ , lactate, adenosine, adenosine monophosphate, adenosine diphosphate, endothelium-derived relaxation factor, K ⁺ , decreased pH) or decreased O ₂ and nutrients (e.g., glucose, amino acids, fatty acids, and other nutrients) as a result of increased metabolism	Relaxation of precapillary sphincters and subsequent increase in blood flow through capillaries
Decreased vasodilator substances and a reduced need for O ₂ and nutrients	Contraction of precapillary sphincters and subsequent decrease in blood flow through capillaries
<i>Autoregulation</i>	
Increased blood pressure	Contraction of precapillary sphincters to maintain constant capillary blood flow
Decreased blood pressure	Relaxation of precapillary sphincters to maintain constant capillary blood flow
<i>Long-Term Local Blood Flow</i>	
Increased metabolic activity of tissues over a long period	Increased diameter and number of capillaries
Decreased metabolic activity of tissues over a long period	Decreased diameter and number of capillaries
Nervous Control	
Increased physical activity or increased sympathetic activity	Constriction of blood vessels in skin and viscera
Increased body temperature detected by neurons of the hypothalamus	Dilation of blood vessels in skin (see chapter 5)
Decreased body temperature detected by neurons of the hypothalamus	Constriction of blood vessels in skin (see chapter 5)
Decreased skin temperature below a critical value	Dilation of blood vessels in skin (protects skin from extreme cold)
Anger or embarrassment	Dilation of blood vessels in skin of face and upper thorax
Hormonal Control (reinforces increased activity of the sympathetic nervous system)	
Increased physical activity and increased sympathetic activity, causing release of epinephrine and small amounts of norepinephrine from adrenal medulla	Constriction of blood vessels in skin and viscera; dilation of blood vessels in skeletal and cardiac muscle

needs of the tissue; therefore, as metabolic needs increase, as is the case when the activity of skeletal muscle increases, blood flow increases to supply the greater need for oxygen and other nutrients. Blood flow also increases in response to a buildup of metabolic end products.

In some tissues, blood flow serves purposes other than delivering nutrients and removing waste products. In the skin, blood flow dissipates heat from the body. In the kidneys, it eliminates metabolic waste products, regulates water balance, and controls the pH of body fluids. Among other functions, blood flow delivers nutrients that enter the blood from the small intestine to the liver for processing.

Functional Characteristics of the Capillary Bed

The innervation of the metarterioles and the precapillary sphincters in capillary beds is sparse. Local factors primarily regulate these structures. As the rate of metabolism increases in a tissue, blood flow through its capillaries increases. The precapillary sphincters relax, allowing blood to flow into the local capillary bed. Blood flow can increase sevenfold to eightfold as a result of vasodilation of the metarterioles and the relaxation of precapillary sphincters in response to an increased rate of metabolism.

As the rate of metabolism increases in a tissue, **vasodilator substances** are produced in the extracellular fluid. These substances include carbon dioxide, lactate, adenosine, adenosine monophosphate, adenosine diphosphate, endothelium-derived relaxation factor (EDRF), K^+ , and H^+ . Once produced, the vasodilator substances diffuse from the tissues supplied by the capillary to the area of the precapillary sphincter, the metarterioles, and the arterioles to cause vasodilation and relaxation of the precapillary sphincters (figure 21.37).

Lack of oxygen and nutrients can also be important in regulating blood flow in tissues. For example, oxygen and nutrients are

required to maintain vascular smooth muscle contraction. An increased rate of metabolism decreases the amount of oxygen and nutrients in the tissues. Smooth muscle cells of the precapillary sphincter relax in response to lower levels of oxygen and nutrients, resulting in vasodilation (figure 21.37).

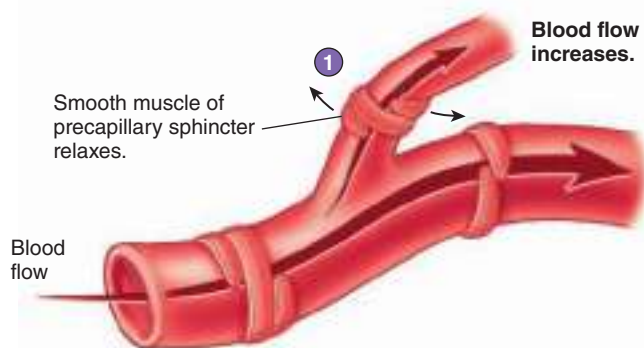

The rate of blood flow through capillaries is not constant, but fluctuates. The cyclic fluctuation is the result of periodic contraction and relaxation of the precapillary sphincters, called **vasomotion** (vā-sō-mō'shūn, vas-ō-mō'shūn). Blood flows through the capillaries until the by-products of metabolism are reduced in concentration and until nutrient supplies to precapillary smooth muscles are replenished. Then the precapillary sphincters constrict and remain constricted until the by-products of metabolism increase and nutrients decrease (figure 21.37).

Autoregulation of Blood Flow

Arterial pressure can change over a wide range, whereas blood flow through tissues remains relatively constant. The maintenance of blood flow by tissues is called **autoregulation** (aw'tō-reg-ū-lā'shūn). Between arterial pressures of approximately 75 mm Hg and 175 mm Hg, blood flow through tissues remains within 10–15% of its normal value. The mechanisms responsible for autoregulation are the same as those for vasomotion. The need for oxygen and nutrients and the buildup of metabolic by-products cause precapillary sphincters to dilate, and blood flow through tissues increases if a minimum blood pressure exists. On the other hand, once the supply of oxygen and nutrients to tissues is adequate, the precapillary sphincters constrict, and blood flow through the tissues decreases, even if blood pressure is very high.

Long-Term Local Blood Flow

The long-term regulation of blood flow through tissues is matched closely to the tissues' metabolic requirements. Because of this

- 1 Vasodilation of precapillary sphincters**
Precapillary sphincters relax as the tissue concentration of O_2 and nutrients, such as glucose, amino acids, and fatty acids, decreases. The sphincters also relax as the concentration of vasodilator substances, such as CO_2 , lactate, adenosine, adenosine monophosphate, adenosine diphosphate, nitric oxide, and K^+ , increase, and as the pH decreases.

- 2 Constriction of precapillary sphincters**
Precapillary sphincters contract as the tissue concentration of O_2 and nutrients, such as glucose, amino acids, and fatty acids, increases. The sphincters also contract as the tissue concentration of metabolic by-products, such as CO_2 , lactate, adenosine, adenosine monophosphate, adenosine diphosphate, nitric oxide, and K^+ , decrease, and as the pH increases.

Clinical IMPACT

Hypertension

Hypertension, or high blood pressure, affects nearly 30% of the population at sometime in their lives. Generally, a person is considered hypertensive if the systolic blood pressure is greater than 140 mm Hg and the diastolic pressure is greater than 90 mm Hg. However, current methods of evaluation take into consideration diastolic and systolic pressures in determining whether a person is suffering from hypertension (see table 21.14). In addition, normal blood pressure is age-dependent, so classification of an individual as hypertensive also depends on the person's age.

Chronic hypertension has an adverse effect on the function of both the heart and the blood vessels. Hypertension requires the heart to work harder than normal. This extra work leads to hypertrophy of the cardiac muscle, especially in the left ventricle, and can result in heart failure. Hypertension also increases the

rate at which arteriosclerosis develops. Arteriosclerosis, in turn, increases the probability that blood clots, or thromboemboli (throm'bō-em'bō-lī), will form and that blood vessels will rupture. Common medical problems associated with hypertension are cerebral hemorrhage, coronary infarction, hemorrhage of renal blood vessels, and poor vision caused by burst blood vessels in the retina.

Some conditions leading to hypertension include a decrease in functional kidney mass, excess aldosterone or angiotensin production, and increased resistance to blood flow in the renal arteries. All of these conditions lead to an increase in total blood volume, which causes cardiac output to increase. Increased cardiac output forces blood to flow through tissue capillaries, causing the precapillary sphincters to constrict. Thus, increased blood volume increases cardiac output and peripheral resistance, both of which result in greater blood pressure.

Although many known conditions result in hypertension, roughly 90% of the diagnosed cases are called **idiopathic hypertension**, or *essential hypertension*, which means that the cause of the condition is unknown. Drugs that dilate blood vessels (called vasodilators), drugs that increase the rate of urine production (called diuretics), and drugs that decrease cardiac output are normally used to treat idiopathic hypertension. The vasodilator drugs increase the rate of blood flow through the kidneys and thus increase urine production; the diuretics increase urine production as well. Increased urine production reduces blood volume, which reduces blood pressure. Substances that decrease cardiac output, such as β -adrenergic blocking agents, decrease the heart rate and force of contraction. In addition to these treatments, low-salt diets are normally recommended to reduce the amount of sodium chloride (NaCl) and water absorbed from the intestine into the bloodstream.

close association between regulation and metabolic requirements, a tissue's capillary density can change over time. If the metabolic activity of a tissue increases and remains elevated for an extended period, the diameter and the number of capillaries in the tissue increase, and local blood flow increases. An example is the increased density of capillaries in the well-trained skeletal muscles of athletes, compared with that in poorly trained skeletal muscles.

The availability of oxygen to a tissue can be a major factor in determining the adjustment of the tissue's vascularity to its long-term metabolic needs. If oxygen is scarce, capillaries increase in diameter and in number but, if oxygen levels remain elevated in a tissue, the vascularity decreases.

Nervous and Hormonal Control of Blood Flow in Tissues

Nervous control of arterial blood pressure is important in the minute-to-minute regulation of blood flow in tissues. The blood pressure must be adequate to cause blood to flow through capillaries while at rest, during exercise, or in response to circulatory shock, during which blood pressure becomes very low. For example, during exercise, increased arterial blood pressure is needed to sustain increased blood flow through the capillaries of skeletal muscles, in which precapillary sphincters have dilated. The increased blood flow is needed to supply oxygen and nutrients to the exercising skeletal muscles.

Nervous regulation also provides a means to regulate blood flow by altering the volume of blood flowing to different regions of the body. For example, in response to blood loss, blood flow to the viscera and the skin is reduced dramatically. This helps maintain the arterial blood pressure within a range sufficient to allow adequate blood flow through the capillaries of the brain and cardiac muscle.

Nervous regulation by the autonomic nervous system, particularly the sympathetic division, can function rapidly (within 1–30 seconds). Sympathetic vasomotor fibers are neurons that regulate the level of smooth muscle contraction in vessel walls. Because of their control of vasoconstriction, these fibers are referred to as

Clinical IMPACT

Occlusion of Blood Vessels and Collateral Circulation

Occclusion, or blockage, of a blood vessel leads to an increase in the diameter of smaller blood vessels that bypass the occluded vessel. In many cases, the development of these collateral vessels is marked. For example, if the femoral artery is occluded, the small vessels that bypass the occluded vessel become greatly enlarged, and an adequate blood supply to the lower limb is often reestablished over a period of weeks. If the occlusion is sudden and so complete that tissues supplied by a blood vessel suffer from ischemia (lack of blood flow), cell necrosis (death) can occur. In this instance, collateral circulation does not have a chance to develop before necrosis sets in.

FIGURE 21.38 Nervous Regulation of Blood Vessels

Most blood vessels are innervated by sympathetic nerve fibers. The vasomotor center within the medulla oblongata plays a major role in regulating the frequency of action potentials in nerve fibers that innervate blood vessels.

vasoconstrictor fibers. These fibers innervate all the blood vessels of the body except the capillaries, the precapillary sphincters, and most metarterioles (figure 21.38). The innervation of the small arteries and arterioles allows the sympathetic nervous system to increase or decrease resistance to blood flow. Though sympathetic fibers extend to most parts of the circulatory system, sympathetic innervation of blood vessels is not the same in all tissues of the body. Sympathetic vasoconstrictor fibers are less prominent in skeletal muscle, cardiac muscle, and the brain and more prominent in the kidneys, the digestive tract, the spleen, and the skin.

The degree to which blood vessels are constricted is regulated by centers in the brain. An area of the lower pons and upper medulla oblongata, called the **vasomotor** (*vā-sō-mō'ter*, *vas-ō-mō'ter*) **center** (figure 21.38), is tonically active. A low frequency of action potentials is transmitted continually through the sympathetic vasoconstrictor fibers. As a consequence, the peripheral blood vessels are partially constricted, a condition called **vasomotor tone**.

Predict 7

A strong athlete just finished a 1-mile run and sat down to have a drink with her friends. During the run, her blood pressure was not dramatically elevated, but her cardiac output increased greatly. After the run, her cardiac output decreased dramatically, but her blood pressure decreased only to its resting level. Predict how the sympathetic stimulation of her large veins, the arteries in her digestive system, and the arteries in her skeletal muscles changes while she is relaxing. Explain why this is consistent with the decrease in her cardiac output.

Part of the vasomotor center inhibits vasomotor tone. Thus, the vasomotor center consists of an excitatory part, which is tonically active, and an inhibitory part, which can induce vasodilation. Vasoconstriction results from an increase in vasomotor tone, whereas vasodilation results from a decrease in vasomotor tone.

Areas throughout the brain can either stimulate or inhibit the vasomotor center. For example, the hypothalamus can exert either strong excitatory or strong inhibitory effects on the vasomotor center. Increased body temperature detected by temperature receptors in the hypothalamus causes vasodilation of blood vessels in the skin (see chapter 5). The cerebral cortex can also either excite or inhibit the vasomotor center. For example, action potentials that originate in the cerebral cortex during periods of emotional excitement activate hypothalamic centers, which in turn increase vasomotor tone (table 21.15).

The neurotransmitter for the vasoconstrictor fibers is norepinephrine, which binds to α -adrenergic receptors on vascular smooth muscle cells to cause vasoconstriction. Sympathetic action potentials also cause the release of epinephrine and norepinephrine into the blood from the adrenal medulla. These hormones are transported in the blood to all parts of the body. In most vessels, they cause vasoconstriction, but in some vessels, especially those in skeletal muscle, epinephrine binds to β -adrenergic receptors, which are present in larger numbers, and can cause the blood vessels in skeletal muscle to dilate.

ASSESS YOUR PROGRESS

58. How is local control of blood flow in tissues achieved?
59. Explain how vasodilator substances, oxygen, and nutrients are involved with local control of blood flow.
60. What is vasomotion? What is autoregulation of local blood flow?
61. How is long-term regulation of blood flow through tissues accomplished?
62. Describe nervous and hormonal control of blood flow. Under what conditions is nervous control of blood flow important? What is vasomotor tone?

21.9 Regulation of Mean Arterial Pressure

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Recall the definitions of mean arterial pressure, cardiac output, and peripheral resistance.
- B. Relate the factors that determine mean arterial pressure.
- C. Describe the short-term and the long-term mechanisms that regulate arterial blood pressure.

Blood flow to all areas of the body depends on the maintenance of adequate pressure in the arteries. As long as arterial blood pressure is adequate, local control of blood flow is appropriately matched to tissues' metabolic needs. Blood flow through tissues

cannot be adequate if arterial blood pressure is too low. Inadequate blood flow throughout the body due to the failure of mechanisms to maintain normal blood pressure is **circulatory shock**. If normal blood pressure is not maintained, damage to the body tissues can lead to death (see Clinical Impact, “Circulatory Shock,” later in this chapter). On the other hand, if arterial blood pressure is too high, the heart and blood vessels may be damaged.

Mean arterial pressure (MAP) is slightly less than the average of systolic and diastolic pressures because diastole lasts longer than systole. MAP changes over a person’s lifetime. It is approximately 70 mm Hg at birth, slightly less than 100 mm Hg from adolescence to middle age, and 110–130 mm Hg in healthy older persons (see table 21.14).

MAP is proportional to cardiac output times peripheral resistance. **Cardiac output (CO)** is the volume of blood pumped by the heart each minute. It is equal to the **heart rate (HR)** times the **stroke volume (SV)**. **Peripheral resistance (PR)** is the resistance to blood flow in all the blood vessels. MAP is mathematically represented as

$$\text{MAP} = \text{CO} \times \text{PR} \text{ or } \text{MAP} = \text{HR} \times \text{SV} \times \text{PR}$$

As indicated by the equations, blood pressure is influenced by three factors: (1) heart rate, (2) stroke volume, and (3) peripheral resistance. An increase in any one of these elevates blood pressure. Conversely, a decrease in any one of them reduces blood pressure.

Because stroke volume depends on the amount of blood entering the heart, regulatory mechanisms that control blood volume also affect blood pressure. For example, an increase in blood volume increases venous return, which increases preload, and the increased preload increases stroke volume.

When blood pressure suddenly drops because of hemorrhage or some other cause, the control systems respond by increasing blood pressure to a value consistent with life and by increasing blood volume to its normal value. Two major types of control systems operate to achieve these responses: (1) those that respond in the short term and (2) those that respond in the long term. The short-term regulatory mechanisms respond quickly but begin to lose their capacity to regulate blood pressure a few hours to a few days after blood pressure is maintained at homeostatic values. This occurs because sensory receptors adapt to the altered pressures. Long-term regulation of blood pressure is controlled primarily by mechanisms that influence kidney function. Those mechanisms do not adapt rapidly to altered blood pressures.

Short-Term Regulation of Blood Pressure

The short-term, rapidly acting mechanisms controlling blood pressure involve neural and hormonal control mechanisms. These mechanisms include the baroreceptor reflexes, the adrenal medullary mechanism, chemoreceptor reflexes, and the central nervous system’s ischemic response. Some of these reflex mechanisms operate on a minute-to-minute basis and help regulate blood pressure within a narrow range of values. Other mechanisms respond primarily to emergency situations (see figures 21.41 and 21.43).

Baroreceptor Reflexes

Baroreceptor reflexes are very important in regulating blood pressure on a minute-to-minute basis. They detect even small changes in blood pressure and respond quickly. However, they are not as important as other mechanisms in regulating blood pressure over long periods of time.

Baroreceptors, or *pressoreceptors*, are sensory receptors sensitive to stretch. They are scattered along the walls of most of the large arteries of the neck and thorax and are most numerous in the area of the carotid sinus at the base of the internal carotid artery and in the walls of the aortic arch. Action potentials travel from the carotid sinus baroreceptors through the glossopharyngeal (IX) nerves to the cardioregulatory and vasomotor centers in the medulla oblongata and from the aortic arch through the vagus (X) nerves to the medulla oblongata (figure 21.39). Stimulation of baroreceptors in the carotid sinus activates the **carotid sinus reflex**, and stimulation of baroreceptors in the aortic arch activates the **aortic arch reflex**. Both of these reflexes are baroreceptor reflexes, and they help keep blood pressure within homeostatic values.

In the carotid sinus and the aortic arch, the arterial walls are partially stretched by normal blood pressure, so that the baroreceptors produce a constant but low frequency of action potentials. Increased pressure in the blood vessels stretches the vessel walls more, increasing the frequency of action potentials produced by the baroreceptors. Conversely, a decrease in blood pressure reduces the stretch of the arterial wall, causing a decrease in the frequency of action potentials produced by the baroreceptors.

A sudden increase in blood pressure causes the action potential frequency produced in the baroreceptors to also increase. In response to these changes, the vasomotor center decreases sympathetic stimulation of blood vessels, and the cardioregulatory center increases parasympathetic stimulation of the heart. As a result, peripheral blood vessels dilate, heart rate decreases, and blood pressure decreases (figure 21.40).

Similarly, a sudden decrease in blood pressure causes the action potential frequency produced by the baroreceptors to also decrease. In response, the vasomotor center increases sympathetic stimulation of the blood vessels, and the cardioregulatory center increases sympathetic stimulation and decreases parasympathetic stimulation of the heart. As a result, peripheral blood vessels constrict, heart rate and stroke volume increase, and blood pressure increases (see figures 21.39 and 21.40).

The carotid sinus and aortic arch baroreceptor reflexes are important in regulating blood pressure moment to moment. When a person rises rapidly from sitting or lying to a standing position, blood pressure in the neck and thoracic regions drops dramatically because of the pull of gravity on the blood. This reduction can cause blood flow to the brain to become so sluggish that dizziness or loss of consciousness results. The falling blood pressure activates the baroreceptor reflexes, which reestablish normal blood pressure within a few seconds. A healthy person may experience only a temporary sensation of dizziness.

Predict 8

Explain how the baroreceptor reflexes respond when a person does a headstand.

- 1 Baroreceptors in the carotid sinus and aortic arch monitor blood pressure.
- 2 The glossopharyngeal and vagus nerves conduct action potentials to the cardioregulatory and vasomotor centers in the medulla oblongata.
- 3 Increased parasympathetic stimulation of the heart decreases the heart rate.
- 4 Increased sympathetic stimulation of the heart increases the heart rate and stroke volume.
- 5 Increased sympathetic stimulation of blood vessels increases vasoconstriction.

PROCESS FIGURE 21.39 Baroreceptor Reflex Control of Blood Pressure

An increase in blood pressure increases parasympathetic stimulation of the heart and decreases sympathetic stimulation of the heart and blood vessels, resulting in a decrease in blood pressure. A decrease in blood pressure decreases parasympathetic stimulation of the heart and increases sympathetic stimulation of the heart and blood vessels, resulting in an increase in blood pressure.

Clinical IMPACT

Blood Flow Through Tissues During Exercise

Exercise greatly increases blood flow through muscles and keeps blood flow through other organs at a value just adequate to supply their metabolic needs. During exercise, blood flow through skeletal muscles can be 15–20 times greater than through resting muscles. The increase in blood flow ensures that the skeletal muscles receive adequate oxygen and nutrients to sustain activity and remove metabolic waste. Local, nervous, and hormonal regulatory mechanisms are responsible for the increased blood flow. When skeletal muscle is resting, only 20–25% of the capillaries in the skeletal muscle are open, whereas during exercise 100% of the capillaries are open.

Low blood oxygen levels resulting from greatly increased muscular activity and the release of vasodilator substances, such as lactate, CO_2 , and K^+ , cause the dilation of precapillary sphincters. Increased sympathetic

stimulation and epinephrine released from the adrenal medulla cause vasoconstriction in the blood vessels of the skin and viscera, but only some vasoconstriction in the blood vessels of skeletal muscles. Even though some vasoconstriction in skeletal muscle blood vessels occurs, the total resistance to blood flow in skeletal muscle decreases because all the capillaries are open. Blood flow through the skeletal muscles is also enhanced because the increased resistance to blood flow in the skin and viscera causes blood to be shunted from these areas to the skeletal muscles.

The movement of skeletal muscles compresses veins in a cyclic fashion and greatly increases venous return to the heart. In addition, veins undergo some constriction, which reduces the total volume of blood in the veins without dramatically increasing resistance to blood flow. The resulting increase in the

preload and increased sympathetic stimulation of the heart lead to elevated heart rate and stroke volume, which increases cardiac output. As a consequence, blood pressure usually increases by 20–60 mm Hg, which also helps sustain the increased blood flow through skeletal muscle blood vessels.

As previously mentioned, blood flow through the skin decreases at the beginning of exercise in response to sympathetic stimulation. However, as body temperature increases in response to increased muscular activity, temperature receptors in the hypothalamus are stimulated. As a result, action potentials in sympathetic nerve fibers causing vasoconstriction decrease, allowing vasodilation of blood vessels in the skin. As a consequence, the skin turns a red or pinkish color, and a great deal of excess heat is lost as blood flows through the dilated blood vessels.

HOMEOSTASIS FIGURE 21.40 Summary of the Baroreceptor Effects on Blood Pressure

(1) Blood pressure is within its normal range. (2) Blood pressure increases outside the normal range, which causes homeostasis to be disturbed. (3) Baroreceptors detect the increase in blood pressure. The cardioregulatory and vasomotor centers in the brain respond to changes in blood pressure. (4) Nervous and hormonal changes alter the activity of cardiac muscle of the heart and smooth muscle of the blood vessels (effectors), causing heart rate and stroke volume to decrease and blood vessels to dilate. (5) These changes cause blood pressure to decrease. (6) Blood pressure returns to its normal range, and homeostasis is restored. Observe the responses to a decrease in blood pressure outside its normal range by following the *red arrows*. For more information on the baroreceptor reflex, see figure 21.39; for the adrenal medullary mechanism, see figure 21.41.

The baroreceptor reflexes are short-term and rapid-acting; however they are adaptable, meaning they do not change the average blood pressure in the long run. The baroreceptors adapt within 1–3 days to any new, sustained blood pressure to which they are exposed. If blood pressure is elevated for more than a few days, as is the case in a person with hypertension, the baroreceptors adapt to the elevated pressure, and the baroreceptor reflexes do not reduce blood pressure to its original value.

Adrenal Medullary Mechanism

The adrenal medullary mechanism is activated by a substantial increase in sympathetic stimulation of the heart and blood vessels (figure 21.41; see figure 21.40). Examples of times when this mechanism is activated include large decreases in blood pressure, sudden and substantial increases in physical activity, and other stressful conditions. The adrenal medullary mechanism results from stimulation of the adrenal medulla by the sympathetic nerve fibers. The adrenal medulla releases epinephrine and smaller amounts of norepinephrine into the bloodstream (figure 21.41; see figure 21.40). These hormones affect the cardiovascular system in a fashion similar to direct sympathetic stimulation, causing increased heart rate, increased stroke volume, and vasoconstriction in blood vessels to the skin and viscera. Epinephrine also causes vasodilation of blood vessels of the heart. The adrenal medullary mechanism is short-term and rapid-acting. It responds within seconds to minutes and is usually active for minutes to hours. Other hormonal mechanisms are long-term and slow-acting. They respond within minutes to hours and continue to function for many hours to days.

Chemoreceptor Reflexes

The **chemoreceptor** (kē'mō-rē-sep'tor) **reflexes** help maintain homeostasis by responding to changes in blood composition.

FIGURE 21.41 Adrenal Medullary Mechanism

Stimuli that increase sympathetic stimulation of the heart and blood vessels also result in increased sympathetic stimulation of the adrenal medulla and result in epinephrine and some norepinephrine secretion.

Specifically, these reflexes are stimulated by decreases in blood oxygen levels or increases in blood carbon dioxide levels. Changes in blood carbon dioxide levels cause changes in blood pH. As blood carbon dioxide levels increase, blood pH decreases. Conversely, as blood carbon dioxide levels decrease, blood pH increases. So chemoreceptor reflexes are also stimulated by decreases in blood pH (figures 21.42 and 21.43). Chemoreceptors are located in **carotid bodies**, small organs approximately 1–2 mm in diameter, which lie near the carotid sinuses, and in several **aortic bodies** lying adjacent to the aorta. Afferent nerve fibers pass to the medulla oblongata through the glossopharyngeal nerve (IX) from the carotid bodies and through the vagus nerve (X) from the aortic bodies.

The chemoreceptors receive an abundant blood supply. However, when oxygen availability decreases in the chemoreceptor cells, the frequency of action potentials increases and stimulates the vasomotor center, resulting in increased vasomotor tone. The chemoreceptors act under emergency conditions and do not regulate the cardiovascular system under resting conditions. They normally do not respond strongly unless blood oxygen decreases markedly. The chemoreceptor cells are also stimulated by increased carbon dioxide and decreased blood pH to increase vasomotor tone, which causes the mean arterial pressure to rise. The elevated mean arterial pressure increases blood flow through tissues in which blood vessels do not constrict, such as the brain and cardiac muscle. Thus, the reflex helps provide adequate oxygen to the brain and the heart when blood oxygen levels in the blood decrease.

Central Nervous System's Ischemic Response

Elevated blood pressure in response to lack of blood flow to the medulla oblongata of the brain is called the **central nervous system (CNS) ischemic response**. The CNS ischemic response does not play an important role in regulating blood pressure under normal conditions. It functions primarily in response to emergency situations, as when blood flow to the brain is severely restricted or when blood pressure falls below approximately 50 mm Hg.

Reduced blood flow results in decreased oxygen, increased carbon dioxide, and decreased pH within the medulla oblongata. Neurons of the vasomotor center are strongly stimulated. As a result, the vasomotor center stimulates vasoconstriction, and blood pressure rises dramatically.

The increase in blood pressure that occurs in response to CNS ischemia increases blood flow to the CNS, provided the blood vessels are intact. However, if severe ischemia lasts longer than a few minutes, metabolism in the brain fails because of the lack of oxygen. The vasomotor center becomes inactive, and extensive vasodilation occurs in the periphery as vasomotor tone decreases. Prolonged ischemia of the medulla oblongata leads to a massive decline in blood pressure and ultimately death.

Summary of Short-Term Regulation of Blood Pressure

Each of the four short-term regulatory mechanisms of blood pressure are important for specific circumstances. In most circumstances throughout the day, the baroreceptor reflex is the most important short-term regulatory mechanism for maintaining blood pressure. The adrenal medullary mechanism plays a role during

PROCESS FIGURE 21.42 Chemoreceptor Reflex

An increase in blood CO_2 and a decrease in pH and O_2 result in an increased heart rate and vasoconstriction. A decrease in blood CO_2 and an increase in blood pH result in a decreased heart rate and vasodilation.

exercise and emergencies. The chemoreceptor mechanism is more important when blood oxygen levels are reduced, such as at high altitudes or when carbon dioxide is elevated or pH is reduced. Thus, it is more important in emergency situations. The CNS ischemic response is activated only in rare, emergency conditions when the brain receives too little oxygen.

ASSESS YOUR PROGRESS

63. Explain the relationship among mean arterial pressure, cardiac output, and peripheral resistance.
64. What are the two major control systems that provide homeostasis of blood pressure? Give a definition of each.
65. Where are baroreceptors located? Describe the response of the baroreceptor reflexes when blood pressure increases and decreases.
66. Elaborate on the adrenal medullary control mechanism.
67. Where are the chemoreceptors for oxygen, CO_2 , and pH levels located? Discuss what happens when oxygen levels in the blood decrease markedly.
68. Describe the CNS ischemic response. Under what conditions does this mechanism operate?
69. What mechanism is most important for short-term regulation of blood pressure under resting conditions?

Long-Term Regulation of Blood Pressure

Long-term (slow-acting) regulation of blood pressure involves the regulation of blood concentration and volume by the kidneys, the movement of fluid across the wall of blood vessels, and alterations in the volume of the blood vessels. Some of the long-term

regulatory mechanisms begin to respond in minutes, but they continue to function for hours, days, or longer. They adjust blood pressure precisely and keep it within a narrow range of values for years. Major regulatory mechanisms include the renin-angiotensin-aldosterone mechanism, the antidiuretic hormone (vasopressin) mechanism, the atrial natriuretic mechanism, the fluid shift mechanism, and the stress-relaxation response.

Renin-Angiotensin-Aldosterone Mechanism

The kidneys increase urine output as the blood volume and arterial pressure increase, and they decrease urine output as the blood volume and arterial pressure decrease. Increased urine output reduces blood volume and blood pressure, and decreased urine output resists a further decrease in blood volume and blood pressure. Controlling urine output is an important means by which blood pressure is regulated, and it continues to operate until blood pressure is precisely within its normal range of values. The **renin-angiotensin-aldosterone mechanism** helps regulate blood pressure by altering blood volume.

The kidneys release an enzyme, called **renin** (rē'nin), into the blood (figure 21.44; see chapter 26) from specialized structures called the **juxtaglomerular** (jŭks'tă-glŏ-mer'ŭ-lăr) **apparatuses**. Renin acts on a plasma protein, synthesized by the liver, called **angiotensinogen** (an'jē-ō-ten-sin'ō-jen) to split a fragment off one end. The fragment, called **angiotensin** (an-jē-ō-ten'sin) **I**, contains 10 amino acids. Another enzyme, called **angiotensin-converting enzyme**, found primarily in small blood vessels of the lungs, cleaves 2 additional amino acids from angiotensin I to produce a fragment consisting of 8 amino acids, called **angiotensin II**, or **active angiotensin**.

HOMEOSTASIS FIGURE 21.43 Summary of the Effects of pH and Gases on Blood Pressure

(1) Blood pH is within its normal range. (2) Blood pH increases outside the normal range, which causes homeostasis to be disturbed. (3) Chemoreceptors detect the increase in blood pH. The cardioregulatory and vasomotor centers in the brain are inhibited. (4) Nervous and hormonal changes alter the activity of cardiac muscle of the heart and smooth muscle of the blood vessels (effectors), causing heart rate and stroke volume to decrease and blood vessels to dilate, reducing blood flow to the lungs, which increases blood CO_2 . (5) These changes cause blood pH to decrease. (6) Blood pH returns to its normal range, and homeostasis is restored. Observe the responses to a decrease in blood pH outside its normal range by following the *red arrows*. For more information on the chemoreceptor reflex, see figure 21.42; for the central nervous system ischemic response, see the text.

PROCESS FIGURE 21.44 Renin-Angiotensin-Aldosterone Mechanism

The kidneys detect decreased blood pressure and increase renin secretion. The result is vasoconstriction, increased water reabsorption, and decreased urine volume, changes that maintain blood pressure.

Angiotensin II causes vasoconstriction in arterioles and, to some degree, in veins. As a result, it increases peripheral resistance and venous return to the heart, both of which raise blood pressure. Angiotensin II also stimulates aldosterone secretion from the adrenal

cortex. **Aldosterone** (al-dos'ter-ōn) acts on the kidneys to increase the reabsorption of Na^+ and Cl^- from the filtrate into the extracellular fluid. If antidiuretic hormone (ADH; see chapter 18) is present, water moves by osmosis with the Na^+ and Cl^- . Consequently,

aldosterone causes the kidneys to retain solutes, such as Na^+ and Cl^- , and water. The result is increased blood volume by decreasing the production of urine and conserving water (see chapter 26). Angiotensin II also increases salt appetite, thirst, and ADH secretion.

Secretion of renin is dependent on changes in blood pressure. Decreased blood pressure stimulates renin secretion, and increased blood pressure decreases renin secretion. The renin-angiotensin-aldosterone mechanism is important in maintaining blood pressure on a daily basis. It also reacts strongly under conditions of circulatory shock, but it requires many hours to become maximally effective. Its onset is not as fast as that of nervous reflexes or the adrenal medullary response, but its duration is longer. Once renin is secreted, it remains active for approximately 1 hour, and the effect of aldosterone lasts much longer (many hours).

Angiotensin-converting enzyme (ACE) inhibitors are a class of drugs that inhibit angiotensin-converting enzyme, which converts angiotensin I to angiotensin II. These drugs were first identified as components of the venom of pit vipers. Subsequently, several ACE inhibitors were synthesized. ACE inhibitors are commonly administered to combat hypertension.

Angiotensin II is not the only stimulus for aldosterone secretion. Other stimuli can directly stimulate aldosterone secretion. For example, an increased plasma ion concentration of K^+ and a reduced plasma concentration of Na^+ directly stimulate aldosterone secretion from the adrenal cortex (see chapters 18 and 27). Aldosterone regulates the concentration of these ions in the plasma. A decreased blood pressure and an elevated K^+ concentration occur during plasma loss, during dehydration, and in response to tissue damage, such as burns and crushing injuries.

Antidiuretic Hormone (Vasopressin) Mechanism

The **antidiuretic hormone (vasopressin) mechanism** works in harmony with the renin-angiotensin-aldosterone mechanism in response to changes in blood pressure (figure 21.45). Baroreceptors are sensitive to changes in blood pressure. Decreases in blood pressure detected by the baroreceptors result in the release of antidiuretic hormone (ADH) from the posterior pituitary, although the blood pressure must decrease substantially before the mechanism is activated.

ADH acts directly on blood vessels to cause vasoconstriction, although it is not as potent as other vasoconstrictors. Within minutes after a rapid and substantial decline in blood pressure, ADH is released in sufficient quantities to help reestablish normal blood pressure. ADH also decreases the rate of urine production by the kidneys, thereby helping maintain blood volume and blood pressure.

Neurons of the hypothalamus are sensitive to changes in the solute concentration of the plasma. Even small increases directly stimulate hypothalamic neurons that increase ADH secretion (figure 21.45; see chapter 26). Increases in the concentration of the plasma, as occur during dehydration, and decreases in blood pressure, as happens after plasma loss, such as in extensive burns or crushing injuries, stimulate ADH secretion.

Atrial Natriuretic Mechanism

A polypeptide called **atrial natriuretic hormone (ANH)** is released from cells in the atria of the heart. A major stimulus for its release is increased venous return, which

FIGURE 21.45 Antidiuretic Hormone (Vasopressin) Mechanism

Increases in the osmolality of blood or decreases in blood pressure result in antidiuretic hormone (ADH) secretion. ADH increases water reabsorption by the kidneys, and large amounts of ADH result in vasoconstriction. These changes maintain blood pressure.

stretches atrial cardiac muscle cells. Atrial natriuretic hormone acts on the kidneys to increase the rate of urine production and Na^+ loss in the urine. It also dilates arteries and veins. Loss of water and Na^+ in the urine causes the blood volume to decrease, which decreases venous return, and vasodilation results in a decrease in peripheral resistance. These effects cause a decrease in blood pressure.

The renin-angiotensin-aldosterone, ADH, and atrial natriuretic mechanisms work simultaneously to help regulate blood pressure by controlling urine production by the kidneys. If blood pressure drops below 50 mm Hg, the volume of urine produced by the kidneys is reduced to nearly zero. If blood pressure is increased to 200 mm Hg, the urine volume produced is approximately six to eight times greater than normal. The mechanisms that regulate blood pressure in the long term are summarized in figure 21.46.

HOMEOSTASIS FIGURE 21.46 Summary of Long-Term (Slow-Acting) Blood Pressure Control Mechanisms

(1) Blood pressure is within its normal range. (2) Blood pressure increases outside the normal range, which causes homeostasis to be disturbed. (3) Increased blood pressure is detected by cardiac muscle cells and the kidneys (receptors). The heart and kidneys (control center) respond to increased blood pressure by secretion of hormones. (4) Blood vessels of the body and the kidneys (effectors) respond to the hormones by dilating or adjusting blood volume through urine formation. (5) These changes cause blood pressure to decrease. (6) Blood pressure returns to its normal range, and homeostasis is restored. Observe the responses to a decrease in blood pressure outside its normal range by following the *red arrows*. For more information on the renin-angiotensin-aldosterone mechanism, see figure 21.44; for the antidiuretic hormone mechanism, see figure 21.45; for the atrial natriuretic mechanism, see figure 27.6.

Clinical IMPACT

Circulatory Shock

Circulatory shock is inadequate blood flow throughout the body due to the failure of the mechanisms that maintain normal blood pressure. As a consequence, tissues suffer damage due to lack of oxygen. Severe shock can damage vital body tissues to the extent that the patient dies.

Depending on its severity, circulatory shock can be divided into three stages: (1) compensated shock, (2) progressive shock, and (3) irreversible shock. All types of circulatory shock exhibit one or more of these stages, regardless of their cause. Several causes of circulatory shock exist. Hemorrhagic, or hypovolemic, shock, caused by excessive blood loss, is used here to illustrate the characteristics of each stage.

In **compensated shock**, blood pressure decreases only a moderate amount, and the mechanisms that regulate blood pressure successfully reestablish normal blood pressure and blood flow. The baroreceptor reflexes, chemoreceptor reflexes, and ischemia within the medulla oblongata initiate strong sympathetic responses that result in intense vasoconstriction and increased heart rate. As blood volume decreases, the stress-relaxation response of blood vessels causes them to contract and helps sustain blood pressure. In response to reduced blood flow through the kidneys, increased amounts of renin are released. The elevated renin release causes a greater rate of angiotensin II formation, resulting in vasoconstriction and increased aldosterone release from the adrenal cortex. Aldosterone, in turn, promotes water and salt retention by the kidneys, thereby conserving water. In addition, ADH is released from the posterior pituitary gland and enhances the kidneys' retention of water. Because of the fluid shift mechanism, water also moves from the interstitial spaces and the intestinal lumen to restore normal blood volume. An intense sensation of thirst increases water intake, also helping elevate normal blood volume. In mild cases of compensated shock, baroreceptor reflexes can compensate for blood loss until blood volume is restored but, in more severe cases, all the mechanisms described are required to compensate for the blood loss.

In **progressive shock**, the regulatory mechanisms are inadequate to compensate for

the reduction in blood volume. As a consequence, a positive-feedback cycle develops. As circulatory shock worsens, regulatory mechanisms become even less able to compensate for the increasing severity. The cycle proceeds until the next stage of shock is reached or until medical treatment assists the regulatory mechanisms in reestablishing adequate blood flow to the tissues.

During progressive shock, blood pressure declines to a level that is inadequate for maintaining blood flow to cardiac muscle; thus, the heart begins to deteriorate. Tissues subject to severe ischemia release substances that are toxic to the heart. When blood pressure declines to a very low level, blood begins to clot in the small vessels. Eventually, blood vessels begin to dilate due to decreased sympathetic activity and a lack of oxygen in capillary beds. Capillary permeability increases under ischemic conditions, allowing fluid to leave the blood vessels and enter the interstitial spaces. Finally, intense tissue deterioration begins in response to inadequate blood flow.

Without medical intervention, progressive shock leads to **irreversible shock**, which results in death, regardless of the medical treatment applied. In this stage, the damage to tissues, including cardiac muscle, is so extensive that the patient is destined to die, even if adequate blood volume is reestablished and blood pressure is elevated to its normal value. Irreversible shock is characterized by decreasing heart function and progressive dilation of and increased permeability of peripheral blood vessels.

Patients suffering from circulatory shock are normally placed in a horizontal position, usually with the head slightly lower than the feet. Oxygen is often supplied. **Replacement therapy**, which includes transfusions of whole blood, plasma, artificial solutions called plasma substitutes, and physiological saline solutions, is administered to increase blood volume. In some circumstances, drugs that enhance vasoconstriction are also administered. Patients in anaphylactic (an'ă-fĭ-lak'tik; allergic) shock are given anti-inflammatory substances, such as glucocorticoids and antihistamines. The basic

objective in treating shock is to reverse the condition and prevent it from progressing to the irreversible stage, as well as to reestablish normal blood flow through tissues.

Several types of shock can be classified by cause:

- **Hemorrhagic shock** is caused by external or internal bleeding that reduces blood volume.
- **Plasma loss shock** is reduced blood volume due to loss of plasma into the interstitial spaces and greatly increased blood viscosity. Causes of plasma loss shock include intestinal obstruction, in which a large amount of plasma moves from the blood into the intestines, and severe burns, which cause large amounts of plasma to be lost from the burned surface.
- **Dehydration** results from a severe and prolonged shortage of fluid intake.
- **Severe diarrhea or vomiting** causes a loss of plasma through the intestinal wall.
- **Neurogenic shock** is a rapid loss of vasomotor tone, leading to vasodilation so extensive that blood pressure declines severely.
- **Anesthesia** includes deep general anesthesia and spinal anesthesia that decrease the activity of the medullary vasomotor center or the sympathetic nerve fibers.
- **Brain damage** leads to an ineffective medullary vasomotor function.
- **Emotional shock** (*vasovagal syncope*) stems from emotions that cause strong parasympathetic stimulation of the heart and results in vasodilation in skeletal muscles and in the viscera.
- **Anaphylactic shock** results from an allergic response in which the release of inflammatory substances increases vasodilation and capillary permeability.
- **Septic shock** results from peritoneal, systemic, and gangrenous infections that cause the release of toxic substances into the blood (*blood poisoning*), depressing the activity of the heart and leading to vasodilation and increased capillary permeability.
- **Cardiogenic shock** occurs when the heart stops pumping in response to various conditions, such as heart attack or electrocution.

Fluid Shift Mechanism

The **fluid shift mechanism** occurs in response to small changes in pressures across capillary walls. As blood pressure increases, some fluid is forced from the capillaries into the interstitial spaces. This movement of fluid helps prevent the development of high blood pressure. As blood pressure falls, interstitial fluid moves into capillaries, and this fluid movement resists a further decline in blood pressure. Fluid shift is a powerful mechanism by which blood pressure is maintained, because the interstitial volume acts as a reservoir and is in equilibrium with the large volume of intercellular fluid.

The fluid shift mechanism begins to act within a few minutes of a stimulus, but it requires hours to achieve its full functional capacity. It plays a very important role when dehydration develops over several hours, or when a large volume of saline is administered over several hours.

Stress-Relaxation Response

A **stress-relaxation response** is characteristic of smooth muscle cells (see chapter 9). When blood volume suddenly declines, blood pressure also decreases, reducing the force applied to smooth muscle cells in blood vessel walls. As a result, during the next few minutes to an hour, the smooth muscle cells contract,

reducing the volume of the blood vessels and thus resisting a further decline in blood pressure. Conversely, when blood volume increases rapidly, as occurs during a transfusion, blood pressure increases, and smooth muscle cells of the blood vessel walls relax, resulting in a more gradual increase in blood pressure. The stress-relaxation mechanism is most effective when changes in blood pressure occur over a period of many minutes.

Predict 9

Explain the various mechanisms that regulate blood pressure in response to the rapid loss of a large volume of blood, compared with the loss of the same volume of blood over a period of several hours.

ASSESS YOUR PROGRESS

70. What stimulates renin secretion in the kidneys?
71. For each of these chemicals—angiotensin II, aldosterone, antidiuretic hormone, and atrial natriuretic hormone—state where each is produced and how each affects the circulatory system.
72. What is fluid shift, and what does it accomplish?
73. Describe the stress-relaxation response of a blood vessel.

Answer

Learn to Predict From page 718

After reading the Clinical Impact, “Circulatory Shock,” in this chapter, we learned that circulatory shock is inadequate blood flow throughout the body. More specifically, septic shock results from infections that cause the release of toxic substances into the circulatory system that depress heart activity, cause vasodilation, and increase capillary permeability. After T.J. developed septic shock, we would expect his blood volume to decrease as fluid moved from the more permeable capillaries to the interstitial spaces. The reduction in blood volume would lead to a drop in his blood pressure, stimulating the baroreceptor reflex

mechanism and subsequently an increase in heart rate. We would also expect T.J.’s stroke volume to decrease with a drop in blood volume. Increased sympathetic stimulation would cause vasoconstriction of blood vessels as T.J.’s body tried to maintain normal blood pressure. With the reduction in blood flow through the skin, T.J. would appear very pale. If T.J.’s blood pressure is not maintained, he could progress to irreversible shock, which is lethal.

Answers to the rest of this chapter’s Predict questions are in appendix G.

21.1 Functions of the Circulatory System (p. 719)

1. The circulatory system carries blood from the heart to the tissues of the body and returns the blood to the heart.
2. The circulatory system allows for nutrient, waste, and gas exchange with the tissues.
3. The circulatory system transports other substances (hormones, enzymes, etc.) through the body.
4. The circulatory system regulates blood pressure and blood flow to the tissues.

Summary

21.2 Structural Features of Blood Vessels (p. 719)

1. Blood flows from the heart through elastic arteries, muscular arteries, and arterioles to the capillaries.
2. Blood returns to the heart from the capillaries through venules, small veins, and large veins.

Capillaries

1. The entire circulatory system is lined with simple squamous epithelium called endothelium. Capillaries consist only of endothelium.
2. Capillaries are surrounded by loose connective tissue, the adventitia, that contains pericapillary cells.
3. Three types of capillaries exist.
 - The walls of continuous capillaries have no gaps between the endothelial cells.
 - Fenestrated capillaries have pores, called fenestrae, that extend completely through the cell.
 - Sinusoidal capillaries are large-diameter capillaries with large fenestrae.
4. Materials pass through the capillaries in several ways: between the endothelial cells, through the fenestrae, and through the plasma membrane.
5. Blood flows from arterioles through metarterioles and then through the capillary network. Venules drain the capillary network.
 - Smooth muscle in the arterioles, metarterioles, and precapillary sphincters regulates blood flow into the capillaries.
 - Blood can pass rapidly through the thoroughfare channel.
6. Arteriovenous anastomoses allow blood to flow from arteries to veins without passing through the capillaries. They function in temperature regulation.

Structure of Arteries and Veins

Except for capillaries and venules, blood vessels have three layers.

1. The inner tunica intima consists of endothelium, a basement membrane, and an internal elastic lamina.
2. The tunica media, the middle layer, contains circular smooth muscle and elastic fibers.
3. The outer tunica adventitia is connective tissue.

Types of Arteries

1. Large elastic arteries are thin-walled with large diameters. The tunica media has many elastic fibers and little smooth muscle.
2. Muscular arteries are thick-walled with small diameters. The tunica media has abundant smooth muscle and some elastic fibers.
3. Arterioles are the smallest arteries. The tunica media consists of smooth muscle cells and a few elastic fibers.

Types of Veins

1. Venules are composed of endothelium surrounded by a few smooth muscle cells.
2. Small veins are venules covered with a layer of smooth muscle.
3. Medium-sized veins and large veins contain less smooth muscle and fewer elastic fibers than arteries of the same size.
4. Valves prevent the backflow of blood in the veins.
5. Vasa vasorum are blood vessels that supply the tunica adventitia and tunica media.

Neural Innervation of Blood Vessels

Sympathetic nerve fibers supply the smooth muscle of the tunica media.

Aging of the Arteries

Arteriosclerosis results from a loss of elasticity in the aorta, large arteries, and coronary arteries.

21.3 Pulmonary Circulation (p. 725)

The pulmonary circulation moves blood to and from the lungs. The pulmonary trunk arises from the right ventricle and divides to form the pulmonary arteries, which project to the lungs. From the lungs, the pulmonary veins return to the left atrium.

21.4 Systemic Circulation: Arteries (p. 726)

Arteries carry blood from the left ventricle of the heart to all parts of the body.

Aorta

The aorta leaves the left ventricle to form the ascending aorta, aortic arch, and descending aorta (consisting of the thoracic and abdominal aortae).

Coronary Arteries

Coronary arteries supply the heart.

Arteries of the Head and Neck

1. The brachiocephalic, left common carotid, and left subclavian arteries branch from the aortic arch to supply the head and the upper limbs. The brachiocephalic artery divides to form the right common carotid and the right subclavian arteries. The vertebral arteries branch from the subclavian arteries.
2. The common carotid arteries and the vertebral arteries supply the head.
 - The common carotid arteries divide to form the external carotids, which supply the face and mouth, and the internal carotids, which supply the brain.
 - The vertebral arteries join within the cranial cavity to form the basilar artery, which supplies the brain.

Arteries of the Upper Limb

1. The subclavian artery continues (without branching) as the axillary artery and then as the brachial artery. The brachial artery divides into the radial and ulnar arteries.
2. The radial artery supplies the deep palmar arch, and the ulnar artery supplies the superficial palmar arch. Both arches give rise to the digital arteries.

Thoracic Aorta and Its Branches

The thoracic aorta has visceral branches that supply the thoracic organs and parietal branches that supply the thoracic wall.

Abdominal Aorta and Its Branches

1. The abdominal aorta has visceral branches that supply the abdominal organs and parietal branches that supply the abdominal wall.
2. The visceral branches are paired and unpaired. The paired arteries supply the kidneys, adrenal glands, and gonads. The unpaired arteries supply the stomach, spleen, and liver (celiac trunk); the small intestine and upper part of the large intestine (superior mesenteric); and the lower part of the large intestine (inferior mesenteric).

Arteries of the Pelvis

1. The common iliac arteries arise from the abdominal aorta, and the internal iliac arteries branch from the common iliac arteries.
2. The visceral branches of the internal iliac arteries supply the pelvic organs, and the parietal branches supply the pelvic wall and floor and the external genitalia.

Arteries of the Lower Limb

1. The external iliac arteries branch from the common iliac arteries.
2. The external iliac artery continues (without branching) as the femoral artery and then as the popliteal artery. The popliteal artery divides to form the anterior and posterior tibial arteries.
3. The posterior tibial artery gives rise to the fibular (peroneal) and plantar arteries. The plantar arteries form the plantar arch from which the digital arteries arise.

21.5 Systemic Circulation: Veins (p. 736)

1. The three major veins returning blood to the heart are the superior vena cava (head, neck, thorax, and upper limbs), the inferior vena cava (abdomen, pelvis, and lower limbs), and the coronary sinus (heart).
2. Veins are of three types: superficial, deep, and sinuses.

Veins Draining the Heart

Coronary veins enter the coronary sinus or the right atrium.

Veins of the Head and Neck

1. The internal jugular veins drain the venous sinuses of the anterior head and neck.
2. The external jugular veins and the vertebral veins drain the posterior head and neck.

Veins of the Upper Limb

1. The deep veins are the small ulnar and radial veins of the forearm, which join the brachial veins of the arm. The brachial veins drain into the axillary vein.
2. The superficial veins are the basilic, cephalic, and median cubital. The basilic vein becomes the axillary vein, which then becomes the subclavian vein. The cephalic vein drains into the axillary vein.

Veins of the Thorax

The left and right brachiocephalic veins and the azygos veins return blood to the superior vena cava.

Veins of the Abdomen and Pelvis

1. Ascending lumbar veins from the abdomen join the azygos and hemiazygos veins.
2. Vessels from the kidneys, adrenal gland, and gonads directly enter the inferior vena cava.
3. Vessels from the stomach, intestines, spleen, and pancreas connect with the hepatic portal vein. The hepatic portal vein transports blood to the liver for processing. Hepatic veins from the liver join the inferior vena cava.

Veins of the Lower Limb

1. The deep veins are the fibular (peroneal), anterior and posterior tibial, popliteal, femoral, and external iliac.
2. The superficial veins are the great and small saphenous veins.

21.6 Dynamics of Blood Circulation (p. 747)

The interrelationships among pressure, flow, resistance, and the control mechanisms that regulate blood pressure and blood flow play a critical role in the function of the circulatory system.

Laminar and Turbulent Flow in Vessels

Blood flow through vessels is normally streamlined, or laminar. Turbulent flow is disruption of laminar flow.

Blood Pressure

1. Blood pressure is a measure of the force exerted by blood against the blood vessel wall. Blood moves through vessels because of blood pressure.

2. Blood pressure can be measured by listening for Korotkoff sounds produced by turbulent flow in arteries as pressure is released from a blood pressure cuff.

Blood Flow and Poiseuille's Law

1. Blood flow is the amount of blood that moves through a vessel in a given period. Blood flow is directly proportional to pressure differences and inversely proportional to resistance.
2. Resistance is the sum of all the factors that inhibit blood flow. Resistance increases when viscosity increases and when blood vessels become smaller in diameter or increase in length.
3. Viscosity is the resistance of a liquid to flow. Most of the viscosity of blood results from red blood cells. The viscosity of blood increases when the hematocrit increases.

Critical Closing Pressure and Laplace's Law

1. As pressure in a vessel decreases, the force holding it open decreases, and the vessel tends to collapse. The critical closing pressure is the pressure at which a blood vessel closes.
2. Laplace's law states that the force acting on the wall of a blood vessel is proportional to the diameter of the vessel times blood pressure.

Vascular Compliance

Vascular compliance is a measure of the change in volume of blood vessels produced by a change in pressure. The venous system has a large compliance and acts as a blood reservoir.

21.7 Physiology of the Systemic Circulation (p. 753)

The greatest volume of blood is contained in the veins. The smallest volume is in the arterioles.

Cross-Sectional Area of Blood Vessels

As the diameter of vessels decreases, their total cross-sectional area increases, and the velocity of blood flow through them decreases.

Pressure and Resistance

Blood pressure averages 100 mm Hg in the aorta and drops to 0 mm Hg in the right atrium. The greatest drop occurs in the arterioles, which regulate blood flow through tissues.

Pulse Pressure

1. Pulse pressure is the difference between systolic and diastolic pressures. Pulse pressure increases when stroke volume increases or vascular compliance decreases.
2. Pulse pressure waves travel through the vascular system faster than the blood flows.
3. Pulse pressure can be used to take the pulse, which can serve as an indicator of heart rate and rhythm.

Capillary Exchange and Regulation of Interstitial Fluid Volume

1. Blood pressure, capillary permeability, and osmosis affect the movement of fluid from the capillaries.
2. A net movement of fluid occurs from the blood into the tissues. The fluid gained by the tissues is removed by the lymphatic system.

Functional Characteristics of Veins

Venous return to the heart increases because of an increase in blood volume, venous tone, and arteriole dilation.

Blood Pressure and the Effect of Gravity

In a standing person, hydrostatic pressure caused by gravity increases blood pressure below the heart and decreases pressure above the heart.

21.8 Control of Blood Flow in Tissues (p. 759)

Blood flow through tissues is highly controlled and matched closely to the metabolic needs of tissues.

Local Control of Blood Flow in Tissues

1. Blood flow through a tissue is usually proportional to the tissue's metabolic needs. Exceptions are tissues that perform functions that require additional blood.
2. Control of blood flow by the metarterioles and precapillary sphincters can be regulated by vasodilator substances or by lack of O₂ and nutrients.
3. Only large changes in blood pressure have an effect on blood flow through tissues.
4. If the metabolic activity of a tissue increases, the number and the diameter of capillaries in the tissue increase over time.

Autoregulation of Blood Flow

1. Autoregulation refers to changes in blood flow in response to changes in O₂, nutrients, and metabolic by-products, which alter vasoconstriction and contraction of precapillary sphincters to adjust blood flow through tissues.
2. Long-term regulation of blood flow results in alteration in capillary diameter and number of capillaries in a tissue.

Nervous and Hormonal Control of Blood Flow in Tissues

1. The sympathetic nervous system (vasomotor center in the medulla) controls blood vessel diameter. Other brain areas can excite or inhibit the vasomotor center.
2. Vasomotor tone is a state of partial contraction of blood vessels.
3. The nervous system is responsible for routing the flow of blood and maintaining blood pressure.
4. Sympathetic action potentials stimulate epinephrine and norepinephrine release from the adrenal medulla, and these hormones cause vasoconstriction in most blood vessels.

21.9 Regulation of Mean Arterial Pressure (p. 762)

Mean arterial pressure (MAP) is proportional to cardiac output times peripheral resistance.

Short-Term Regulation of Blood Pressure

1. Baroreceptors are sensory receptors sensitive to stretch.
 - Baroreceptors are located in the carotid sinuses and the aortic arch.
 - The baroreceptor reflex changes peripheral resistance, heart rate, and stroke volume in response to changes in blood pressure.
2. Chemoreceptors are sensory receptors sensitive to O₂, CO₂, and pH levels in the blood.
3. Epinephrine and norepinephrine are released from the adrenal medulla as a result of sympathetic stimulation. They increase heart rate, stroke volume, and vasoconstriction.
4. The CNS ischemic response, which results from high CO₂ or low pH levels in the medulla, increases peripheral resistance.

Long-Term Regulation of Blood Pressure

1. In the renin-angiotensin-aldosterone mechanism, renin is released by the kidneys in response to low blood pressure. Renin promotes the production of angiotensin II, which causes vasoconstriction and an increase in aldosterone secretion.
2. The antidiuretic hormone (vasopressin) mechanism causes ADH release from the posterior pituitary in response to a substantial decrease in blood pressure. ADH acts directly on blood vessels to cause vasoconstriction.
3. The atrial natriuretic mechanism causes atrial natriuretic hormone release from the cardiac muscle cells when atrial blood pressure increases. It stimulates an increase in urine production, causing a decrease in blood volume and blood pressure.
4. The fluid shift mechanism causes fluid shift, which is the movement of fluid between the interstitial spaces and capillaries in response to changes in blood pressure to maintain blood volume.
5. The stress-relaxation response is an adjustment of the smooth muscles of blood vessels in response to a change in blood volume.

REVIEW AND COMPREHENSION

1. Given these blood vessels:

(1) arteriole	(3) elastic artery	(5) vein
(2) capillary	(4) muscular artery	(6) venule

Choose the arrangement that lists the blood vessels in the order a red blood cell passes through them as it leaves the heart, travels to a tissue, and returns to the heart.

a. 3,4,2,1,5,6	c. 4,3,1,2,5,6	e. 4,2,3,5,1,6
b. 3,4,1,2,6,5	d. 4,3,2,1,6,5	
2. Given these structures:

(1) metarteriole	(3) thoroughfare channel
(2) precapillary sphincter	

Choose the arrangement that lists the structures in the order a red blood cell encounters them as it passes through a tissue.

a. 1,3,2	b. 2,1,3	c. 2,3,1	d. 3,1,2	e. 3,2,1
----------	----------	----------	----------	----------
3. In which of these blood vessels are elastic fibers present in the largest amounts?

a. large arteries	c. arterioles	e. large veins
b. medium arteries	d. venules	
4. Comparing and contrasting arteries and veins, veins have
 - a. thicker walls.
 - a greater amount of smooth muscle than arteries.
 - a tunica media, but arteries do not.
 - valves, but arteries do not.
 - All of these are correct.
5. The structures that supply the walls of blood vessels with blood are

a. venous shunts.	d. vasa vasorum.
b. tunic channels.	e. coronary arteries.
c. arteriovenous anastomoses.	

6. Given these arteries:
 (1) basilar (3) internal carotid
 (2) common carotid (4) vertebral
 Which of these arteries have *direct* connections with the cerebral arterial circle (circle of Willis)?
 a. 1,2 b. 2,4 c. 1,3 d. 3,4 e. 2,3
7. Given these blood vessels:
 (1) axillary artery (4) radial artery
 (2) brachial artery (5) subclavian artery
 (3) brachiocephalic artery
 Choose the arrangement that lists the vessels in order, from the aorta to the right hand.
 a. 2,5,4,1 b. 5,2,1,4 c. 5,3,1,4,2 d. 3,5,1,2,4 e. 4,5,1,2,3
8. A branch of the aorta that supplies the liver, stomach, and spleen is the
 a. celiac trunk. d. superior mesenteric.
 b. common iliac. e. renal.
 c. inferior mesenteric.
9. Given these arteries:
 (1) common iliac (3) femoral
 (2) external iliac (4) popliteal
 Choose the arrangement that lists the arteries in order, from the aorta to the knee.
 a. 1,2,3,4 b. 1,2,4,3 c. 2,1,3,4 d. 2,1,4,3 e. 3,1,2,4
10. Given these veins:
 (1) brachiocephalic (3) superior vena cava
 (2) internal jugular (4) venous sinus
 Choose the arrangement that lists the veins in order, from the brain to the heart.
 a. 1,2,4,3 b. 2,4,1,3 c. 2,4,3,1 d. 4,2,1,3 e. 4,2,3,1
11. Blood returning from the arm to the subclavian vein passes through which of these veins?
 a. cephalic d. Both a and b are correct.
 b. basilic e. All of these are correct.
 c. brachial
12. Given these blood vessels:
 (1) inferior mesenteric vein (3) hepatic portal vein
 (2) superior mesenteric vein (4) hepatic vein
 Choose the arrangement that lists the vessels in order, from the small intestine to the inferior vena cava.
 a. 1,3,4 b. 1,4,3 c. 2,3,4 d. 2,4,3 e. 3,1,4
13. Given these veins:
 (1) small saphenous (3) fibular (peroneal)
 (2) great saphenous (4) posterior tibial
 Which are superficial veins?
 a. 1,2 b. 1,3 c. 2,3 d. 2,4 e. 3,4
14. Vascular compliance is
 a. greater in arteries than in veins.
 b. the increase in vessel volume divided by the increase in vessel pressure.
 c. the pressure at which blood vessels collapse.
 d. proportional to the diameter of the blood vessel times pressure.
 e. All of these are correct.
15. The resistance to blood flow is greatest in the
 a. aorta. c. capillaries. e. veins.
 b. arterioles. d. venules.
16. Veins
 a. increase their volume because of their large compliance.
 b. increase venous return to the heart when they vasodilate.
 c. vasodilate because of increased sympathetic stimulation.
 d. All of these are correct.
17. Local direct control of blood flow through a tissue
 a. maintains an adequate rate of flow despite large changes in arterial blood pressure.
 b. results from relaxation and contraction of precapillary sphincters.
 c. occurs in response to a buildup in CO₂ in the tissues.
 d. occurs in response to a decrease in oxygen in the tissues.
 e. All of these are correct.
18. An increase in mean arterial pressure can result from
 a. an increase in peripheral resistance.
 b. an increase in heart rate.
 c. an increase in stroke volume.
 d. All of these are correct.
19. When blood O₂ levels markedly decrease, the chemoreceptor reflex causes
 a. peripheral resistance to decrease.
 b. mean arterial blood pressure to increase.
 c. vasomotor tone to decrease.
 d. vasodilation.
 e. All of these are correct.
20. When blood pressure is suddenly decreased a small amount (10 mm Hg), which of these mechanisms are activated to restore blood pressure to normal levels?
 a. chemoreceptor reflexes c. CNS ischemic responses
 b. baroreceptor reflexes d. All of these are correct.
21. A sudden release of epinephrine from the adrenal medulla
 a. increases heart rate.
 b. increases stroke volume.
 c. causes vasoconstriction in visceral blood vessels.
 d. All of these are correct.
22. In response to a decrease in blood pressure,
 a. ADH secretion increases.
 b. the kidneys decrease urine production.
 c. blood volume increases.
 d. All of these are correct.
23. In response to a decrease in blood pressure,
 a. more fluid than normal enters the tissues (fluid shift mechanism).
 b. smooth muscles in blood vessels relax (stress-relaxation response).
 c. the kidneys retain more salts and water than normal.
 d. All of these are correct.
24. A patient is found to have severe arteriosclerosis of the renal arteries, which has reduced renal blood pressure. Which of these is consistent with that condition?
 a. hypotension
 b. hypertension
 c. decreased vasomotor tone
 d. exaggerated sympathetic stimulation of the heart
 e. Both a and c are correct.
25. During exercise, the blood flow through skeletal muscle may increase up to 20-fold. However, the cardiac output does not increase that much. This occurs because of
 a. vasoconstriction in the viscera.
 b. vasoconstriction in the skin (at least temporarily).
 c. vasodilation of skeletal muscle blood vessels.
 d. Both a and b are correct.
 e. All of these are correct.

CRITICAL THINKING

- For each of the following destinations, name all the arteries that a red blood cell would encounter if it started its journey in the left ventricle.
 - posterior interventricular groove of the heart
 - anterior neck to the brain (give two ways)
 - posterior neck to the brain (give two ways)
 - external skull
 - tip of the fingers of the left hand (what other blood vessel would be encountered if the trip were through the right upper limb?)
 - anterior compartment of the leg
 - liver
 - small intestine
 - urinary bladder
- For each of the following starting places, name all the veins that a red blood cell would encounter on its way back to the right atrium.
 - anterior interventricular groove of the heart (give two ways)
 - venous sinus near the brain
 - external posterior of skull
 - hand (return deep and superficial)
 - foot (return deep and superficial)
 - stomach
 - kidney
 - left inferior wall of the thorax
- In a study of heart valve functions, it is necessary to inject a dye into the right atrium of the heart by inserting a catheter into a blood vessel and moving the catheter into the right atrium. What route would you suggest? If you wanted to do this procedure into the left atrium, what would you do differently?
- All the blood that passes through the aorta, except the blood that flows into the coronary vessels, returns to the heart through the venae cavae. (*Hint:* The diameter of the aorta is 26 mm, and the diameter of a vena cava is 32 mm.) Explain why the resistance to blood flow in the aorta is greater than the resistance to blood flow in the venae cavae. Because the resistances are different, explain why blood flow can be the same.
- As blood vessels increase in diameter, the amount of smooth muscle decreases and the amount of connective tissue increases. Explain why. (*Hint:* Remember Laplace's law.)
- A very short nursing student is asked to measure the blood pressure of a very tall person. She decides to measure the blood pressure at the level of the tall person's foot while he is standing. What artery does she use? After taking the blood pressure, she decides that the tall person is suffering from hypertension because the systolic pressure is 200 mm Hg. Is her diagnosis correct? Why or why not?
- David was suffering from severe cirrhosis of the liver and hepatitis. Over a period of time, he developed severe edema. Explain how decreased liver function can result in edema.
- During hyperventilation, CO_2 is "blown off," and CO_2 levels in the blood decrease. What effect does this decrease have on blood pressure? Explain. What symptoms do you expect to see as a result?
- Epinephrine causes vasodilation of blood vessels in cardiac muscle but vasoconstriction of blood vessels in the skin. Explain why this is a beneficial arrangement.
- While Dick and Jane were backpacking on a trail in Yellowstone Park, they encountered a grizzly bear cub that seemed amazingly tame. However, while Dick tried to feed the cub, its mother appeared and attacked him. Jane escaped by climbing a tree, but Dick received several deep lacerations (cuts) and lost a lot of blood over the next several hours. Jane helped him reach medical aid, and he survived. Which of the following mechanisms was (were) activated to help keep Dick alive? Explain your choice.
 - baroreceptor mechanism
 - CNS ischemic response
 - renin-angiotensin-aldosterone mechanism
 - fluid shift mechanism
 - antidiuretic hormone mechanism
 - adrenal medullary response

a. 1,2,3,4,5,6 b. 1,3,4,5,6 c. 1,6 d. 1,4,6 e. 1
- Mr. Wilson, age 85, lives in a care facility, where he is not very mobile and is often lethargic. One day an aide noticed that he was sitting in his usual chair but appeared to be unconscious. She took his pulse, which was 140 beats/minute and then took his blood pressure, which was 190/130. Which of the following conditions is (are) consistent with these observations?
 - stroke
 - activation of the CNS ischemic response
 - heart attack
 - shock
 - Both a and b are correct.

Answers in appendix F

22

Learn to Predict

The next time autumn leaves drift by Maddie's window, she may just let them lie. During the last week of September, city workers sprayed chemicals on the trees along the street in front of her house. In October, when the leaves from those trees began to fall, Maddie raked them up and stuffed them into several large garbage bags. The next day, her hands were red and itchy, and by the day after that, the itching had become intense. In addition, Maddie's hands were covered with blisterlike lesions and so swollen that she could hardly move her fingers. Maddie suspected she was having an allergic reaction. Was she right? **After reading about the lymphatic system and immunity in this chapter and connecting that information with what you learned about the peripheral circulation in chapter 21, explain the probable cause of Maddie's symptoms.**

Lymphatic System and Immunity

One of the basic themes of life is that many organisms consume other organisms—or use them to survive. For example, a parasite lives on or in another organism, called the host. The host provides the parasite with the conditions and food necessary for survival. Humans are host to many kinds of organisms, including microorganisms (bacteria, viruses, fungi, and protozoans), insects, and worms. Some of these microorganisms are beneficial, like the bacteria of the digestive tract, but that is not the case with all of them. Hookworms, for example, can live in the sheltered environment of the human intestines, where they feed on blood. Often, parasites harm humans, causing disease and sometimes death. However, our bodies have ways to resist or destroy harmful microorganisms. The lymphatic system and immunity are the body's defense systems against threats arising both inside and outside the body.

22.1 Functions of the Lymphatic System

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe the functions of the lymphatic system.**

The lymphatic system has three main functions:

1. **Fluid balance.** Approximately 30 L of fluid pass from the blood capillaries into the interstitial fluid each day, whereas only 27 L pass from the interstitial fluid back into the capillaries. The difference is 3 L of fluid in the interstitial fluid. If the extra 3 L of fluid were to remain in the interstitial fluid, edema would result, causing tissue damage and eventual death. Instead, lymphatic capillaries collect the 3 L of fluid, where it is called **lymph** (limf). Lymph passes through the lymphatic vessels back to the blood. In addition to water, lymph contains solutes derived from (a) substances in plasma, such as ions, nutrients, gases, and some proteins, which pass from blood capillaries into the interstitial fluid, and (b) substances derived from cells, such as hormones, enzymes, and waste products.
2. **Lipid absorption.** **Lacteals** (lak'tē-älz) are lymphatic vessels located in the lining of the digestive tract. The lymphatic system absorbs lipids and other substances from the digestive tract (see chapter 24) through the lacteals. Lipids enter the lacteals and pass through the lymphatic vessels to the venous circulation. The lymph passing through these lymphatic vessels, called **chyle** (kīl), appears white because of its lipid content.
3. **Defense.** Microorganisms and other foreign substances are filtered from lymph by lymph nodes and from blood by the spleen. In addition, lymphocytes and other cells are capable of destroying microorganisms and other foreign substances. Because the lymphatic system fights infections, and filters blood and lymph to remove microorganisms, many infectious diseases produce symptoms associated with the lymphatic system (see the Diseases and Disorders table, later in this chapter).

ASSESS YOUR PROGRESS

1. Describe the three functions of the lymphatic system.

22.2 Anatomy of the Lymphatic System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the parts of the lymphatic system.**
B. Describe the structure of lymphatic vessels.
C. Explain how lymph is formed and transported through lymphatic vessels.

- D. Distinguish between lymphatic tissue and a lymphatic organ.**
E. Describe the structure and function of tonsils, lymph nodes, the spleen, and the thymus.

The **lymphatic** (lim-fat'ik) **system** includes lymph, lymphatic vessels, lymphatic tissue, lymphatic nodules, lymph nodes, the tonsils, the spleen, and the thymus (figure 22.1).

Lymphatic Vessels

The lymphatic vessels are essential for the maintenance of fluid balance. Lymphatic vessels originate as small, dead-end tubes called **lymphatic capillaries** (figure 22.2a). Fluids tend to move out of blood capillaries into tissue spaces (see “Capillary Exchange and Regulation of Interstitial Fluid Volume,” section 21.7). Excess fluid passes through the tissue spaces and enters lymphatic capillaries to become lymph. Lymphatic capillaries are in most tissues of the body. Areas of the body that lack lymphatic vessels are the central nervous system, the bone marrow, and tissues without blood vessels, such as cartilage, epidermis, and the cornea. A superficial group of lymphatic capillaries is in the dermis of the skin and the subcutaneous tissue. A deep group of lymphatic capillaries drains the muscles, joints, viscera, and other deep structures.

Lymphatic capillary structure is different from that of blood capillaries. Lymphatic capillaries lack a basement membrane. Also, the cells of the simple squamous epithelium slightly overlap and are loosely attached to one another (figure 22.2b). This structure facilitates their function in two ways: First, the lymphatic capillaries are far more permeable than blood capillaries, so nothing in the interstitial fluid is excluded from entering the lymphatic capillaries. Second, the overlapping cells of the lymphatic capillary epithelium function as a series of one-way valves that allow fluid to enter the capillary but prevent it from passing back into the interstitial spaces.

The lymphatic capillaries join to form larger **lymphatic vessels**, which resemble small veins. The inner layer of the lymphatic vessel consists of endothelium surrounded by an elastic membrane; the middle layer consists of smooth muscle cells and elastic fibers; and the outer layer is a thin layer of fibrous connective tissue.

Small lymphatic vessels have one-way valves along their lengths that are similar to the valves of veins (see figure 22.2b). The presence of these valves causes small lymphatic vessels to have a beaded appearance. When a lymphatic vessel is compressed, the valves close and prevent backward movement of lymph; as a consequence, the lymph moves forward through the lymphatic vessel.

Lymph moves through lymphatic vessels by three mechanisms:

1. **Contraction of lymphatic vessels.** In many parts of the body, lymphatic vessels pump lymph. The unidirectional valves divide lymphatic vessels into a series of chambers, which function as “primitive hearts.” Lymph moves into a chamber, smooth muscle in the chamber wall contracts, and lymph moves into the next chamber. Some of the smooth muscle cells in the walls of lymphatic vessels are pacemaker cells (see “Electrical Properties of Smooth Muscle,” chapter 9).

FUNDAMENTAL Figure

FIGURE 22.1 Lymphatic System **AP R**

FIGURE 22.2 Lymph Formation and Movement

(a) Fluid from blood capillaries moves into tissues and from tissues into lymphatic capillaries to form lymph. (b) The overlap of epithelial cells of the lymphatic capillary allows fluid to enter but prevents it from moving back into the tissue. Valves, located farther along in lymphatic vessels, also ensure one-way flow of lymph.

The pacemaker cells spontaneously depolarize, resulting in periodic contraction of the lymphatic vessels.

2. *Contraction of skeletal muscles.* When surrounding muscle cells contract, lymphatic vessels are compressed, causing lymph to move.
3. *Thoracic pressure changes.* During inspiration, pressure in the thoracic cavity decreases, lymphatic vessels expand, and lymph flows into them. During expiration, pressure in the thoracic cavity increases, and lymphatic vessels are compressed, causing lymph to move.

Lymph nodes are round, oval, or bean-shaped bodies distributed along the various lymphatic vessels (see “Lymph Nodes,” later in this section). They filter lymph, which enters and exits the lymph nodes through the lymphatic vessels. The lymph nodes are connected in a series, so that lymph leaving one lymph node is carried to another lymph node, and so on.

After passing through the lymph nodes, the lymphatic vessels converge to form larger vessels called **lymphatic trunks**, each of which drains lymph from a major portion of the body (figure 22.3a,b). The **jugular trunks** drain lymph from the head

FIGURE 22.3 Lymph Drainage into Veins

(a) Anterior view of the major lymphatic vessels in the thorax and abdomen. (b) Close-up view of the lymphatic vessels from which lymph enters the blood. (c) Regions of the body drained by the right and left lymphatic vessels. **APR**

and neck; the **subclavian trunks** drain lymph from the upper limbs, superficial thoracic wall, and mammary glands; the **bronchomediastinal** (brong'kō-mē'dē-as-tī'nāl) **trunks** drain lymph from the thoracic organs and the deep thoracic wall; the **intestinal trunks** drain lymph from abdominal organs, such as the intestines, stomach, pancreas, spleen, and liver; and the **lumbar trunks** drain lymph from the lower limbs, pelvic and abdominal walls, pelvic organs, ovaries or testes, kidneys, and adrenal glands.

The lymphatic trunks either connect to large veins in the thorax or join to yet larger vessels called **lymphatic ducts**, which then connect to the large veins. The connections of the lymphatic trunks and ducts to veins are quite variable. Many connect at the junction of the internal jugular and subclavian veins, but connections on the subclavian, the jugular, and even the brachiocephalic veins exist.

On the right side, the jugular, subclavian, and bronchomediastinal trunks typically join a right thoracic vein separately (figure 22.3*b*). However, in about 20% of people, the three trunks converge to form a single, short duct 1 cm in length called the **right lymphatic duct** (see figure 22.1), which joins a right thoracic vein. These trunks drain lymph from the right side of the head, upper-right limb, and right thorax (figure 22.3*c*).

The largest lymphatic vessel is the **thoracic duct** (figure 22.3*a,b*). It is approximately 38–45 cm in length, extending from the twelfth thoracic vertebra to the base of the neck (figure 22.3*a*). The thoracic duct drains lymph from the right side of the body inferior to the thorax and the entire left side of the body (figure 22.3*c*). The jugular and subclavian trunks join the thoracic duct. The bronchomediastinal trunk sometimes connects to the thoracic duct but typically joins a vein. The intestinal and lumbar trunks, which drain lymph inferior to the diaphragm, supply the inferior end of the thoracic duct. They can directly join the thoracic duct or merge to form a network that connects to the thoracic duct. In a small proportion of cases, the lymphatic trunks form a sac called the **cisterna chyli** (sis-ter'nā kī'li).

In summary, excess interstitial fluid enters lymphatic capillaries, forming lymph. Lymphatic capillaries converge to form larger lymphatic vessels. Lymph passes through the lymphatic vessels and through associated lymph nodes, where it is filtered. Lymphatic vessels converge to form larger lymphatic trunks, which drain lymph from major regions of the body. Lymphatic trunks empty directly into thoracic veins or combine to form larger lymphatic ducts, which empty into thoracic veins.

ASSESS YOUR PROGRESS

2. Name the parts of the lymphatic system.
3. How is lymph formed?
4. Describe the structure of a lymphatic capillary. Why is it easy for fluid and other substances to enter a lymphatic capillary?
5. What is the function of valves in lymphatic vessels? Name three mechanisms responsible for moving lymph through the lymphatic vessels.
6. What are lymphatic trunks and ducts? Name the largest lymphatic vessel. What is the cisterna chyli?
7. What areas of the body are drained by the right lymphatic trunks, left lymphatic trunks, and thoracic duct?

Lymphatic Tissue and Organs

Lymphatic organs contain **lymphatic tissue**, which consists primarily of lymphocytes but also includes macrophages, dendritic cells, reticular cells, and other cell types. Recall from chapter 19 that **lymphocytes** are white blood cells. The two types of lymphocytes, **B cells** and **T cells**, originate from red bone marrow and are carried by the blood to lymphatic organs and other tissues. When the body is exposed to microorganisms or other foreign substances, the lymphocytes divide, increase in number, and become part of the immune response that destroys microorganisms and foreign substances. In addition to cells, lymphatic tissue is composed of very fine collagen fibers, called **reticular fibers** produced by a specific type of fibroblast called a **reticular cell**. Lymphocytes and other cells attach to these fibers. When lymph or blood passes through lymphatic organs, the fiber network traps microorganisms and other particles, filtering the fluid.

Lymphatic tissue of the body may or may not be separated from other tissues by a connective tissue capsule. Lymphatic tissue that is not surrounded by a connective tissue capsule is called non-encapsulated, whereas lymphatic tissue surrounded by a capsule is said to be encapsulated. Encapsulated lymphatic tissue forms most of the organs of the lymphatic tissue: lymph nodes, the spleen, and the thymus. Aggregations of nonencapsulated lymphatic tissue are often associated with organs of other systems. **Mucosa-associated lymphoid tissue (MALT)** is aggregates of nonencapsulated lymphatic tissue found in and beneath the mucous membranes lining the digestive, respiratory, urinary, and reproductive tracts. In these locations, the lymphatic tissue is well positioned to intercept microorganisms as they enter the body. Examples of MALT include diffuse lymphatic tissue, lymphatic nodules, and the tonsils.

Diffuse Lymphatic Tissue and Lymphatic Nodules

Diffuse lymphatic tissue contains dispersed lymphocytes, macrophages, and other cells. Diffuse lymphatic tissue has no clear boundary and blends with surrounding tissues (figure 22.4). It is

FIGURE 22.4 Diffuse Lymphatic Tissue and a Lymphatic Nodule

Diffuse lymphatic tissue surrounding a lymphatic nodule in the small intestine. **AP R**

located deep to mucous membranes, around lymphatic nodules, and within the lymph nodes and spleen.

Lymphatic nodules are denser arrangements of lymphatic tissue organized into compact, somewhat spherical structures ranging in size from a few hundred microns to a few millimeters or more in diameter (figure 22.4). Lymphatic nodules are numerous in the loose connective tissue of the digestive, respiratory, urinary, and reproductive systems. **Peyer patches** are aggregations of lymphatic nodules in the distal half of the small intestine and the appendix. In addition to MALT, lymphatic nodules are found within lymph nodes and the spleen, where they are usually referred to as **lymphatic follicles**.

Tonsils

Tonsils are large groups of lymphatic nodules and diffuse lymphatic tissue located deep to the mucous membranes within the pharynx (throat; figure 22.5). The tonsils protect against bacteria and other potentially harmful material entering the pharynx from the nasal or oral cavity. In adults, the tonsils decrease in size and eventually may disappear.

Though we often just think of one pair of tonsils, there are actually three groups of tonsils: (1) the palatine tonsils, (2) the pharyngeal tonsil, and (3) the lingual tonsil. What most of us think of as our “tonsils” are the **palatine tonsils**. They are relatively large, oval, lymphatic masses on each side of the junction between the oral cavity and the pharynx. The **pharyngeal** (fă-rin'jē-ăl) **tonsil** is a collection of somewhat closely aggregated lymphatic nodules near the junction between the nasal cavity and the pharynx. When the pharyngeal tonsil is enlarged, it is commonly called the **adenoid** (ad'ĕ-noyd; glandlike) or **adenoids** (ad'ĕ-noydz). An enlarged pharyngeal tonsil can interfere with normal breathing. The **lingual tonsil** is a loosely associated collection of lymphatic nodules on the posterior surface of the tongue.

Sometimes the palatine or pharyngeal tonsils become chronically infected and must be removed. The lingual tonsil becomes infected less often than the other tonsils and is more difficult to remove.

FIGURE 22.5 Tonsils

ASSESS YOUR PROGRESS

- What are the functions of lymphocytes and reticular fibers in lymphatic tissue?
- What is mucosa-associated lymphoid tissue (MALT)? In what way is the location of MALT beneficial?
- Distinguish among lymphatic tissue, lymphatic nodules, Peyer patches, and lymphatic follicles.
- Describe the structure, function, and location of the tonsils.

Lymph Nodes

Lymph nodes are small, round or bean-shaped structures ranging from 1 mm to 25 mm long. They are distributed along the course of the lymphatic vessels (figure 22.6; see figure 22.1). An important function of lymph nodes is to filter the lymph, removing bacteria and other materials. In addition, lymphocytes congregate, function, and proliferate within lymph nodes.

Lymph nodes are categorized as superficial or deep. **Superficial lymph nodes** are in the subcutaneous tissue beneath the skin, and **deep lymph nodes** are everywhere else. Most superficial and deep lymph nodes are located near or on blood vessels. Approximately 450 lymph nodes are distributed throughout the body. Cervical and head lymph nodes (about 70) filter lymph from the head and neck, axillary lymph nodes (about 30) filter lymph from the upper limbs and superficial thorax, thoracic lymph nodes (about 100) filter lymph from the thoracic wall and organs, abdominopelvic lymph nodes (about 230) filter lymph from the abdomen and pelvis, and inguinal and popliteal lymph nodes (about 20) filter lymph from the lower limbs and the superficial pelvis.

A dense connective tissue **capsule** surrounds each lymph node (figure 22.6). Extensions of the capsule, called **trabeculae** (trä-bek'ū-lē), form a delicate internal skeleton in the lymph node. Reticular fibers extend from the capsule and trabeculae to form a fibrous network throughout the lymph node. In some areas of the lymph node, lymphocytes and macrophages are packed around the reticular fibers to form lymphatic tissue; in other areas, the reticular fibers extend across open spaces to form **lymphatic sinuses**. The lymphatic tissue and sinuses within the lymph node are arranged into two somewhat indistinct layers, an outer cortex and an inner medulla. The **cortex** consists of a subcapsular sinus, beneath the capsule, and cortical sinuses, which are separated by diffuse lymphatic tissue, trabeculae, and lymphatic nodules. The inner **medulla** is organized into branching, irregular strands of diffuse lymphatic tissue, called the **medullary cords**, separated by medullary sinuses.

Lymph nodes are the only structures that filter lymph. **Afferent lymphatic vessels** carry lymph to the lymph nodes, where it is filtered, and **efferent lymphatic vessels** carry lymph away from the lymph nodes. Lymph from afferent lymphatic vessels enters the subcapsular sinus, filters through the cortex and medulla, and exits the lymph node through efferent lymphatic vessels. The efferent vessels of one lymph node may become the afferent vessels of another lymph node or may converge to form lymphatic trunks, which carry lymph to the blood at thoracic veins.

Macrophages lining the lymphatic sinuses remove bacteria and other foreign substances from the lymph as it slowly filters through the sinuses. Microorganisms and other foreign substances

(a)

(b)

FIGURE 22.6 Lymph Node

in the lymph can stimulate lymphocytes throughout the lymph node to undergo cell division, with proliferation especially evident in the lymphatic nodules of the cortex. These areas of rapid lymphocyte division are called **germinal centers**. The newly produced lymphocytes are released into the lymph and eventually reach the bloodstream, where they circulate. Subsequently, the lymphocytes can leave the blood and enter other lymphatic tissues.

Spleen

The **spleen** is roughly the size of a clenched fist and is located on the left, superior part of the abdominal cavity (figure 22.7). The average weight of the adult spleen is 180 g in males and 140 g in females. The size and weight of the spleen tend to decrease in older people, but in certain diseases the spleen can achieve a

weight of 2000 g or more. For example, about 50% of individuals who have infectious mononucleosis develop an enlarged spleen as a result of increased numbers of defense cells. Usually, the spleen will reduce in size following the infection.

The spleen has an outer capsule of dense irregular connective tissue and a small amount of smooth muscle. Bundles of connective tissue fibers from the capsule form trabeculae, which extend into the organ, subdividing it into small, interconnected compartments. Arteries, veins, and lymphatic vessels extend through the trabeculae to supply the compartments, which are filled with white and red pulp. **White pulp** is lymphatic tissue surrounding the arteries within the spleen. **Red pulp** is associated with the veins within the spleen. Red pulp consists of a fibrous network, filled with macrophages and red blood cells, and enlarged capillaries that connect to the veins.

- 1 Branches from the trabecular arteries are surrounded by periarterial lymphatic sheaths.
- 2 An arteriole enters a lymphatic nodule and divides.
- 3 A few capillaries directly connect to a venous sinus.
- 4 The ends of most capillaries are separated from the beginning of the venous sinuses by a small gap. Blood rapidly crosses the gap.
- 5 Some capillaries empty into the splenic cords. Blood percolates through the splenic cords and passes through the walls of the venous sinuses.
- 6 The venous sinuses connect to the trabecular vein.

PROCESS FIGURE 22.7 Spleen

(a) Inferior view of the spleen. (b) Section of the spleen, showing the arrangement of arteries, veins, white pulp, and red pulp. White pulp is associated with arteries, and red pulp is associated with veins. (c) Steps 1–6 trace blood flow through the white and red pulp. (d) Histology of the spleen. **APR**

Approximately one-fourth of the volume of the spleen is white pulp, and three-fourths is red pulp.

Branches of the **splenic** (splen'ik) **artery** enter the spleen at the **hilum**, and their branches follow the various trabeculae into the spleen (figure 22.7a,b). From the trabeculae, arterial branches extend into the white pulp, which consists of the periarterial lymphatic sheath and lymphatic nodules (figure 22.7c). The **periarterial lymphatic sheath** is composed of diffuse lymphatic tissue surrounding arteries and arterioles extending to lymphatic nodules. Arterioles

enter lymphatic nodules and give rise to capillaries. Blood flows from the capillaries into the red pulp, which consists of the splenic cords and the venous sinuses. The **splenic cords** are a network of reticular cells that produce reticular fibers (see chapter 4). The spaces between the reticular cells are occupied by splenic macrophages and blood cells that have come from the capillaries. The **venous sinuses** are enlarged capillaries between the splenic cords. The venous sinuses typically connect to trabecular veins, which unite to form vessels that leave the spleen to form the **splenic vein**.

Case STUDY

Lymphedema

Cindy is a 40-year-old woman who has been diagnosed with breast cancer. Before removing the cancerous tumor from her left breast, her surgeon injected a dye and a radioactive tracer, technetium-99, at the tumor site. The dye and tracer enabled the surgeon to find **sentinel lymph nodes**, those lymph nodes closest to the tumor. The sentinel lymph nodes were sampled for cancer. When cancer cells were found in all of them, the surgeon removed the axillary lymph nodes from under Cindy's left arm.

A few days after the surgery, Cindy noticed that the skin on her left arm felt tight and the arm felt heavy. In addition, her wedding ring was tighter than usual. These symptoms were due to an abnormal accumulation of fluid in Cindy's upper limb, called **lymphedema** (limf'e-dē'mă), caused by the removal of her axillary lymph nodes. In the United States, the most common cause of lymphedema is removal of or damage to lymph nodes and vessels as a result of cancer surgery or radiation treatment. Approximately 10–20% of women whose axillary lymph nodes have been removed develop lymphedema.

➤ Predict 2

- What is the rationale for testing sentinel lymph nodes for cancer?
- What was the rationale for removing Cindy's axillary lymph nodes?
- Why does removing the axillary lymph nodes result in lymphedema?
- Exercise can help reduce lymphedema. Explain.
- A compression bandage or garment can help reduce lymphedema. Explain.
- In intermittent pneumatic pump compression therapy, the pressure of a garment enclosing a limb increases and decreases periodically. In addition, the pressure increases sequentially from the distal part to the proximal part of a limb. How does this therapy help reduce lymphedema?

Although blood flow through the spleen can take from a few seconds to an hour or more, most blood flows through the spleen rapidly. The rapid flow results from the movement of blood from the ends of capillaries into the beginning of the venous sinuses. Although a few capillaries connect directly to venous sinuses, most capillaries are separated by a small gap (figure 22.7c). Slower blood flow occurs when blood leaves the ends of the capillaries, enters the splenic cords, percolates through them, and passes through the walls of the venous sinuses.

The spleen has several functions, including destroying defective red blood cells, detecting and responding to foreign substances in the blood, and acting as a blood reservoir. As red blood cells age, they lose their ability to bend and fold. Consequently, the cells can rupture as they pass slowly through the meshwork of the splenic cords or the intercellular slits of the venous sinus walls. Splenic macrophages then phagocytize the cellular debris.

Foreign substances in the blood passing through the spleen can stimulate an immune response because of the presence of

specialized lymphocytes in the white pulp (see section 22.5). There are high concentrations of T cells in the periarterial lymphatic sheath and B cells in the lymphatic nodules.

The splenic cords of the spleen are a limited reservoir for blood. For example, during exercise splenic volume can be reduced by 40–50%. The resulting small increase in circulating red blood cells can promote better oxygen delivery to muscles during exercise or emergency situations. Physiologists do not presently know if this reduction results from the contraction of smooth muscle within the capsule, from the contraction of smooth muscle (myofibroblast) within the trabeculae, or from the reduced blood flow through the spleen caused by the constriction of blood vessels.

Although the ribs protect the spleen, it is often ruptured in traumatic abdominal injuries. A ruptured spleen can cause severe bleeding, shock, and death. Surgical intervention may stop the bleeding. Cracks in the spleen are repaired using sutures and blood clotting agents. Mesh wrapped around the spleen can hold it together. If these techniques do not stop the bleeding, a **splenectomy** (splē-nek'tō-mē), removal of the spleen, may be necessary. After removal of the spleen, other lymphatic organs and the liver compensate for the loss of its functions.

Thymus

The **thymus** (thī'mūs) is a bilobed gland (figure 22.8) located in the superior mediastinum, the partition dividing the thoracic cavity into the left and right parts. The thymus increases in size until the first year of life, after which it remains approximately the same size until 60 years of age, when it decreases in size (see section 22.9).

Each lobe of the thymus is surrounded by a thin connective tissue capsule. Trabeculae extend from the capsule into the substance of the gland, dividing it into **lobules**. Unlike other lymphatic tissue, which has a fibrous network of reticular fibers, the framework of thymic tissue consists of epithelial cells. The processes of the epithelial cells are joined by desmosomes, and the cells form small, irregularly shaped compartments filled with lymphocytes. Near the capsule and trabeculae, the lymphocytes are numerous and form dark-staining areas of the lobules called the cortex. A lighter-staining, central portion of the lobules, called the medulla, has fewer lymphocytes. The medulla also contains rounded epithelial structures, called **thymic corpuscles** (Hassall corpuscles). For more than 150 years, the function of these structures was unknown, but current research indicates that thymic corpuscles function in the development of **regulatory T cells**. Regulatory T cells suppress the body's immune response and protect against autoimmune diseases (see section 22.5). However, the extent of thymic corpuscle function is still unclear.

The thymus is the site for the maturation of T cells. **Thymosin**, a hormone secreted by the thymus, is important in the T-cell maturation process. Large numbers of lymphocytes are produced in the thymus, but most degenerate. The lymphocytes that survive the maturation process are capable of reacting to foreign substances, but they normally do not react to and destroy healthy body cells (see “Origin and Development of Lymphocytes,” in section 22.5). These surviving thymic lymphocytes migrate to the medulla, enter the blood, and travel to other lymphatic tissues.

FIGURE 22.8 Thymus

ASSESS YOUR PROGRESS

12. Where are lymph nodes found? Describe the parts of a lymph node, and explain how lymph flows through a lymph node.
13. Describe the functions of lymph nodes. What is a germinal center?
14. Where is the spleen located? Describe the structure of the spleen.
15. Explain how the spleen performs its three main functions.
16. Where is the thymus located? Describe its structure and function.

Overview of the Lymphatic System

Figure 22.9 summarizes the processes performed by the lymphatic system. Lymphatic capillaries and vessels remove excess fluid from tissues and absorb lipids from the small intestine. Lymph nodes filter lymph, and the spleen filters blood.

Figure 22.9 also illustrates two types of lymphocytes, B cells and T cells. B cells originate and mature in red bone marrow. Pre-T cells are produced in red bone marrow and migrate to the thymus, where they mature to become T cells. B cells from red bone marrow and T cells from the thymus circulate to and populate other lymphatic tissues.

B cells and T cells are responsible for much of immunity. In response to infections, B cells and T cells increase in number and circulate to lymphatic and infected tissues. How B cells and T cells protect the body is discussed in section 22.5.

22.3 Immunity

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Define the concepts of specificity and memory as they apply to immunity.**

B. Distinguish between the general characteristics of innate immunity and adaptive immunity.

Immunity is the ability to resist damage from foreign substances, such as microorganisms; harmful chemicals, such as toxins released by microorganisms; and internal threats, such as cancer cells. Immunity is categorized as **innate immunity** (also called *nonspecific resistance*) and **adaptive immunity** (also called *specific immunity*), although the two systems are fully integrated in the body. In innate immunity, the body recognizes and destroys certain foreign substances, but the response to them is the same each time the body is exposed. In adaptive immunity, the body recognizes and destroys foreign substances, but the response to them is faster and stronger each time the foreign substance is encountered.

Specificity and memory are characteristics of adaptive immunity, but not of innate immunity. **Specificity** is the ability of adaptive immunity to recognize a particular substance. For example, innate immunity can act against bacteria in general, whereas adaptive immunity can distinguish among various kinds of bacteria. **Memory** is the ability of adaptive immunity to “remember” previous encounters with a particular substance. As a result, the response is faster, stronger, and longer-lasting.

Innate immunity includes body defenses that are present at birth and genetically determined. In innate immunity, each time the body is exposed to a substance, the response is the same because specificity and memory of previous encounters do not apply. For example, each time a bacterial cell is introduced into the body, it is phagocytized with the same speed and efficiency. Innate immunity is present to some degree in all multicellular organisms.

Adaptive immunity includes body defenses that are acquired through a person’s lifetime, depending on exposure to different microorganisms. In adaptive immunity, the response during the second exposure is faster and stronger than the response to the first exposure because the immune system “remembers” the bacteria from the first exposure. For example, following the first exposure to the bacteria, the body can take many days to destroy them.

- 1 Lymphatic capillaries remove fluid from tissues. The fluid becomes lymph (see figure 22.2a).
- 2 Lymph flows through lymphatic vessels, which have valves that prevent the backflow of lymph (see figure 22.2b).
- 3 Lymph nodes filter lymph (see figure 22.6) and are sites where lymphocytes respond to infections.
- 4 Lymph enters the thoracic duct or the right lymphatic duct.
- 5 Lymph enters the blood.
- 6 Lacteals in the small intestine (see figure 24.16c) absorb lipids, which enter the thoracic duct (see figure 22.3a).
- 7 Chyle, which is lymph containing lipids, enters the blood.
- 8 The spleen (see figure 22.7) filters blood and is a site where lymphocytes respond to infections.
- 9 Lymphocytes (pre-B and pre-T cells) originate from stem cells in the red bone marrow (see figure 22.12). The pre-B cells become mature B cells in the red bone marrow and are released into the blood. The pre-T cells enter the blood and migrate to the thymus.
- 10 The thymus (see figure 22.8) is where pre-T cells derived from red bone marrow increase in number and become mature T cells that are released into the blood (see figure 22.12).
- 11 B cells and T cells from the blood enter and populate all lymphatic tissues. These lymphocytes can remain in tissues or pass through them and return to the blood. B cells and T cells can also respond to infections by dividing and increasing in number (see figures 22.18 and 22.22). Some of the newly formed cells enter the blood and circulate to other tissues.

PROCESS FIGURE 22.9 Overview of the Lymphatic System **APR**

During this time, the bacteria damage tissues and produce the symptoms of disease. Following the second exposure to the same bacteria, the response is rapid and effective. Bacteria are destroyed before any symptoms develop, and the person is said to be **immune**. Adaptive immunity is unique to vertebrates.

Innate and adaptive immunity are intimately linked. Most importantly, mediators of innate immunity are required to initiate and regulate adaptive immunity.

ASSESS YOUR PROGRESS

17. What is immunity?
18. Why do specificity and memory relate to adaptive immunity but not to innate immunity?
19. What are the differences between innate immunity and adaptive immunity?

22.4 Innate Immunity

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the three components of innate immunity.
- B. Describe the chemical mediators and cells involved with innate immunity.
- C. List the events of the inflammatory response and explain their significance.

Innate immunity includes body defenses that are present at birth and genetically determined. The main components of innate immunity are (1) physical barriers that prevent microbes from entering the body or that physically remove them from body surfaces; (2) chemical mediators that act directly against microorganisms or activate other mechanisms, leading to the destruction of the microorganisms; and (3) cells involved in phagocytosis and the production of chemicals that participate in the immune response.

Physical Barriers

Physical barriers, such as the skin and mucous membranes, prevent microorganisms and chemicals from entering the body. They also remove microorganisms and other substances from the body surface in several ways. The substances are washed from the eyes by tears, from the mouth by saliva, and from the urinary tract by urine. In the respiratory tract, ciliated mucous membranes sweep microbes trapped in the mucus to the back of the throat, where they are swallowed. Coughing and sneezing also remove microorganisms from the respiratory tract.

Chemical Mediators

Chemical mediators are molecules responsible for many aspects of innate immunity (table 22.1). Some chemical mediators on the surface of cells, such as lysozyme, sebum, and mucus, kill microorganisms or prevent them from entering the cells. Other chemical mediators, such as histamine, complement, and eicosanoids (e.g., prostaglandins and leukotrienes), promote inflammation by causing vasodilation and increasing vascular permeability, attract white blood cells, and stimulate phagocytosis. **Cytokines** (si'tō-kīnz) are proteins or peptides secreted by cells that bind to receptors on cell surfaces, stimulating a response. They usually bind to receptors on neighboring cells, but sometimes they bind to receptors on the secreting cell. Cytokines regulate the intensity and duration of immune responses and stimulate the proliferation and differentiation of cells. Examples of cytokines are interferons, interleukins, and lymphokines.

Complement

Complement is a group of about 20 proteins that protect the body by destroying abnormal cells or enhancing other components of immunity. Complement proteins make up approximately 10% of the globulin part of plasma proteins. They include proteins named C1–C9 and factors B, D, and P (properdin). Normally, complement proteins circulate in the blood in an inactive, nonfunctional form. They become activated in the **complement cascade**, a series of reactions in which each component of the series activates the

TABLE 22.1 Chemical Mediators of Innate Immunity and Their Functions

Chemical	Description	Chemical	Description
Surface chemicals	Lysozymes (in tears, saliva, nasal secretions, and sweat) lyse cells; acid secretions (sebum in the skin and hydrochloric acid in the stomach) prevent microbial growth or kill microorganisms; mucus on the mucous membranes traps microorganisms until they can be destroyed.	Complement	Complement is a group of plasma proteins that increase vascular permeability, stimulate the release of histamine, activate kinins, lyse cells, promote phagocytosis, and attract neutrophils, monocytes, macrophages, and eosinophils.
Histamine	Histamine is an amine released from mast cells, basophils, and platelets; histamine causes vasodilation, increases vascular permeability, stimulates gland secretions (especially mucus and tear production), causes smooth muscle contraction of airway passages (bronchioles) in the lungs, and attracts eosinophils.	Prostaglandins	Prostaglandins are a group of lipids (PGEs, PGFs, thromboxanes, and prostacyclins), some of which cause smooth muscle relaxation and vasodilation, increase vascular permeability, and stimulate pain receptors.
Kinins	Kinins are polypeptides derived from plasma proteins; kinins cause vasodilation, increase vascular permeability, stimulate pain receptors, and attract neutrophils.	Leukotrienes	Leukotrienes are a group of lipids, produced primarily by mast cells and basophils, that cause prolonged smooth muscle contraction (especially in the lung bronchioles), increase vascular permeability, and attract neutrophils and eosinophils.
Interferons	Interferons are proteins, produced by most cells, that interfere with virus production and infection.	Pyrogens	Pyrogens are chemicals, released by neutrophils, monocytes, and other cells, that stimulate fever production.

Abbreviations: PGE = prostaglandin E; PGF = prostaglandin F.

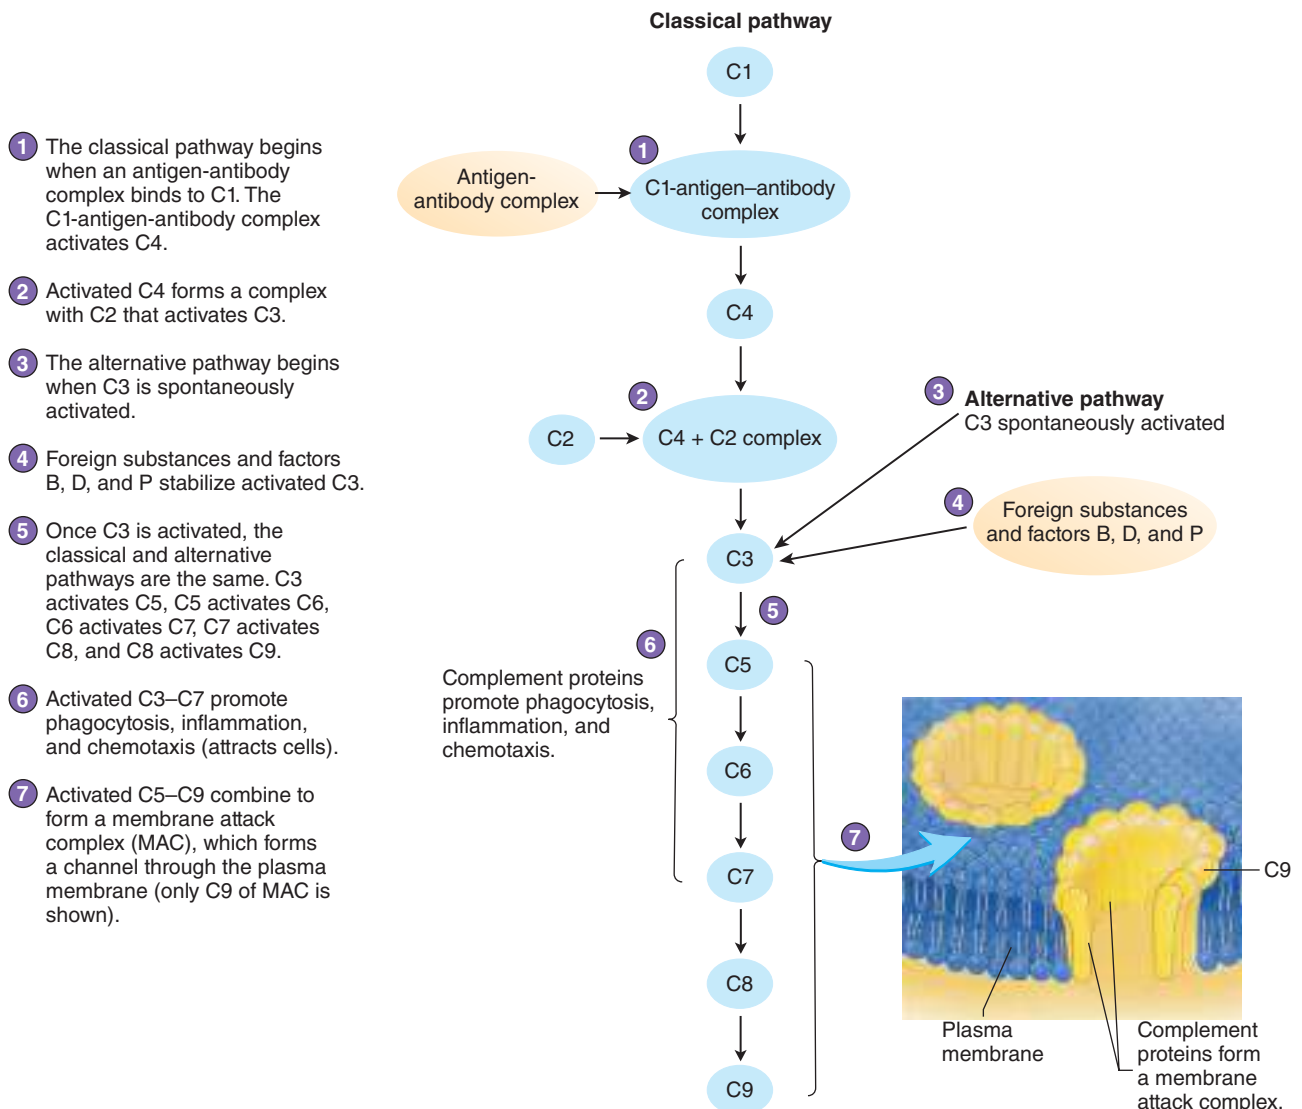

next component (figure 22.10). The complement cascade begins through either the alternative pathway or the classical pathway.

The **alternative pathway**, which is part of innate immunity, is initiated when the complement protein C3 becomes spontaneously active. If activated C3 does not interact with a microorganism, it is quickly inactivated by proteins on the surface of the body's cells. However, in the event of an infection, activated C3 can combine with some foreign substances, such as part of a bacterial cell or virus. Activated C3 becomes stabilized and stimulates the complement cascade. The **classical pathway** is part of adaptive immunity and will be discussed in detail in section 22.5. The activation of complement by the alternative and classical pathways is one of several ways in which innate and adaptive responses are integrated.

Activated complement proteins provide protection in several ways (figure 22.10). They can form a **membrane attack complex (MAC)** that produces a channel through a cell's plasma membrane

that ultimately destroys the cell. MAC formation begins when activated C3 attaches to a plasma membrane, stimulating a series of reactions activating C5–C9. The main component of a MAC is activated C9 molecules, which change shape, attach to each other, and form a channel through the membrane. Cell death as a consequence of MACs is different in nucleated cells versus bacterial cells. When MACs form in the plasma membrane of a nucleated cell, Na^+ and water enter the cell through the channel and cause the cell to lyse. When MACs form in the outer membrane of certain bacteria (Gram negative), an enzyme called lysozyme passes through the channel and digests the bacterial cell wall. When the wall breaks apart, the bacterial cell undergoes lysis.

Complement proteins can also attach to the surface of bacterial cells and stimulate macrophages to phagocytize the bacteria. This process is called **opsonization**. In addition, complement proteins attract immune system cells to sites of infection and promote inflammation.

PROCESS FIGURE 22.10 Complement Cascade

Complement proteins circulate in the blood in an inactive form. Only the activated proteins are shown. The complement cascade begins with either the alternative pathway or the classical pathway.

Interferons

Interferons (in-ter-fēr'onz) are proteins that protect the body against viral infection and perhaps some forms of cancer. After a virus infects a cell, viral replication can occur. Viral nucleic acids and proteins, which are produced using the infected cell's organelles, are assembled into new viruses. The new viruses are released from the infected cell to infect other cells. Because infected cells usually stop their normal functions or die during viral replication, viral infections are clearly harmful to the body. Fortunately, viruses and other substances can stimulate infected cells to produce interferons, which neither protect the cell that produces them nor act directly against viruses. Instead, interferons bind to the surface of neighboring cells and stimulate them to produce antiviral proteins. These antiviral proteins stop viral reproduction in the neighboring cells by preventing the production of viral nucleic acids and proteins. Interferon viral resistance is innate rather than adaptive, and the same interferons act against many different viruses. Infection by one kind of virus can actually protect against infection by other kinds of viruses. Some interferons also play a role in activating immune cells, such as macrophages and natural killer cells.

Because viruses induce some cancers, interferons may play a role in controlling cancers. Interferons activate macrophages and natural killer cells (a type of lymphocyte) that attack tumor cells. Through genetic engineering, interferons are produced in sufficient quantities for clinical use and, along with other therapies, have been effective in treating certain viral infections and cancers. For example, interferons are used to treat hepatitis C, a viral disorder that can cause cirrhosis and cancer of the liver, and to treat genital warts caused by the herpes virus. Interferons are also approved to treat Kaposi sarcoma, a cancer that can develop in AIDS patients.

ASSESS YOUR PROGRESS

20. List the three components of innate immunity.
21. Name two physical barriers that prevent microorganisms from entering the body. In what ways are microorganisms removed from body surfaces?
22. What roles do cytokines play as chemical mediators?
23. What is complement? In what two ways is it activated? How does complement provide protection?
24. What are interferons? How do they protect against viral infection?

White Blood Cells

White blood cells and the cells derived from them (see table 19.2) are the most important cellular components of the immune system (table 22.2). White blood cells are produced in red bone marrow and lymphatic tissue and are released into the blood, where they are transported throughout the body. To be effective, white blood cells must move into the tissues where they are needed. White blood cells are attracted to chemical signals called **chemotactic** (kē-mō-tak'tik) **factors**. Chemotactic factors include parts of microbes as well as chemicals released by cells of the body. Important chemotactic factors include complement, leukotrienes, kinins, and histamine. They diffuse from the area where they are released. White blood cells can detect small differences in chemotactic factor concentration and move from areas of lower chemotactic factor concentration to areas of higher concentration. Thus, they move toward the source of these substances, an ability called **chemotaxis**. White blood cells can move by amoeboid motion over the surface of cells, can squeeze between cells, and can sometimes pass directly through other cells.

Phagocytosis (fag-ō-sī-tō'sis) is the endocytosis and destruction of particles by cells called **phagocytes** (see figure 3.17). The

TABLE 22.2 Immune System Cells and Their Primary Functions

Cell	Primary Function	Cell	Primary Function
Innate Immunity		Adaptive Immunity	
Neutrophil	Phagocytosis and inflammation; usually the first cell to leave the blood and enter infected tissues	B cell	After activation, differentiates to become plasma cell or memory B cell
Monocyte	Leaves the blood and enters tissues to become a macrophage	Plasma cell	Produces antibodies that are directly or indirectly responsible for destroying the antigen
Macrophage	Most effective phagocyte; important in later stages of infection and in tissue repair; located throughout the body to "intercept" foreign substances; processes antigens; involved in the activation of B cells and T cells	Memory B cell	Quick and effective response to an antigen against which the immune system has previously reacted; responsible for adaptive immunity
Basophil	Motile cell that leaves the blood, enters tissues, and releases chemicals that promote inflammation	Cytotoxic T cell	Responsible for destroying cells by lysis or by producing cytokines
Mast cell	Nonmotile cell in connective tissues that promotes inflammation through the release of chemicals	Helper T cell	Activates B cells and cytotoxic T cells
Eosinophil	Enters tissues from the blood and defends against parasitic infections; participates in inflammation associated with asthma and allergies	Regulatory T cell	Inhibits B cells, helper T cells, and cytotoxic T cells
Natural killer cell	Lyses tumor and virus-infected cells	Memory T cell	Quick and effective response to an antigen against which the immune system has previously reacted; responsible for adaptive immunity
		Dendritic cell	Processes antigen and is involved in the activation of B cells and T cells

particles can be microorganisms or their parts, foreign substances, or dead cells from the body. The most important phagocytic cells are neutrophils and macrophages.

Neutrophils

Neutrophils are small, phagocytic cells produced in large numbers in red bone marrow and released into the blood, where they circulate for a few hours. Approximately 126 billion neutrophils per day leave the blood and pass through the wall of the digestive tract, where they provide phagocytic protection. The neutrophils are then eliminated as part of the feces. Neutrophils are usually the first cells to enter infected tissues in large numbers. They release chemical signals, such as cytokines and chemotactic factors, that increase the inflammatory response by recruiting and activating other immune cells. Neutrophils often die after a single phagocytic event.

Neutrophils also release lysosomal enzymes that kill microorganisms and cause tissue damage and inflammation. **Pus** is an accumulation of dead neutrophils, dead microorganisms, debris from dead tissue, and fluid.

Macrophages

Macrophages are large phagocytic cells. Macrophages are derived from monocytes, one of the classes of white blood cells described in chapter 19. When monocytes leave the blood and enter tissues, they mature into macrophages by enlarging about fivefold and increasing their number of lysosomes and mitochondria. Though neutrophils and macrophages are both phagocytic cells, macrophages have longer life spans than neutrophils. In addition, they can ingest more and larger phagocytic particles than neutrophils. Macrophages usually accumulate in tissues after neutrophils do, and they are responsible for most of the phagocytic activity in the late stages of an infection, including cleaning up dead neutrophils and other cellular debris. In addition to their phagocytic role, macrophages produce a variety of chemicals, such as interferons, prostaglandins, and complement, that enhance the immune response (see table 22.1).

Macrophages are beneath the free surfaces of the body, such as in the skin (dermis), subcutaneous tissue, mucous membranes, and serous membranes. They are also found around blood and lymphatic vessels. Macrophages provide protection in these areas by trapping and destroying microorganisms entering the tissues.

If microbes do gain entry to the blood or lymphatic system, macrophages are waiting within enlarged spaces, called **sinuses**, to phagocytize them. Blood vessels in the spleen, bone marrow, and liver have sinuses, as do lymph nodes. Within the sinuses, reticular cells produce a fine network of reticular fibers that slows the flow of blood or lymph and provides a large surface area for the attachment of macrophages. In addition, macrophages are on the endothelial lining of the sinuses.

Based on their location and structure, macrophages may be referred to by various names. Because macrophages on the reticular fibers and endothelial lining of the sinuses were among the first macrophages studied, these cells are referred to as the **reticuloendothelial system**. However, researchers now recognize that macrophages are derived from monocytes and are in locations other than the sinuses. Because monocytes and macrophages have a single, unlobed nucleus, they are also called the **mononuclear phagocytic system**. Sometimes macrophages are given specific

names—for instance, *dust cells* in the lungs, *Kupffer cells* in the liver, and *microglia* in the central nervous system.

Basophils and Mast Cells

Basophils and mast cells play important roles in stimulating inflammation. **Basophils**, which are white blood cells derived from red bone marrow, are motile cells that can leave the blood and enter infected tissues. **Mast cells**, which are also derived from red bone marrow, are nonmotile cells in connective tissue, especially near capillaries. Like macrophages, mast cells are located at points where microorganisms may enter the body, such as the skin, lungs, digestive tract, and urogenital tract.

Basophils and mast cells can be activated through innate immunity (e.g., by complement) or through adaptive immunity (see “Effects of Antibodies” in section 22.5). When activated, they release chemicals—for example, histamine and leukotrienes—that produce an inflammatory response or activate other mechanisms, such as smooth muscle contraction in the lungs.

Eosinophils

Eosinophils are white blood cells. They are produced in red bone marrow, enter the blood, and within a few minutes enter tissues. Eosinophil numbers increase in response to parasitic infections. Eosinophils secrete enzymes that effectively kill some parasites. Also, eosinophil numbers greatly increase in the case of an allergic reaction with much inflammation.

Natural Killer (NK) Cells

Natural killer (NK) cells are a type of lymphocyte produced in red bone marrow and account for up to 15% of lymphocytes. Though these are lymphocytes, they are not part of adaptive immunity. NK cells recognize classes of cells, such as tumor cells or virus-infected cells in general, rather than specific tumor cells or cells infected by a specific virus. For this reason, and because NK cells do not exhibit a memory response, they are classified as part of innate immunity. NK cells use a variety of methods to kill their target cells, including releasing chemicals that damage plasma membranes and cause the cells to lyse.

ASSESS YOUR PROGRESS

25. Define chemotactic factor, chemotaxis, and phagocytosis.
26. What are the functions of neutrophils and macrophages? What is pus?
27. What effects are produced by the chemicals released from basophils, mast cells, and eosinophils?
28. How do NK cells function?

Inflammatory Response

The **inflammatory response** is a complex sequence of events involving many of the chemical mediators and cells of innate immunity. Trauma, burns, chemicals, and infections can damage tissues, resulting in inflammation. Here we use a bacterial infection to illustrate an inflammatory response (figure 22.11). Bacteria enter the tissue, causing damage that stimulates the release or activation of chemical mediators, such as histamine, complement, kinins, and

eicosanoids (e.g., prostaglandins and leukotrienes). The chemical mediators produce several effects: (1) Vasodilation increases blood flow, bringing phagocytes and other white blood cells to the area; (2) phagocytes and other white blood cells leave the blood and enter the tissue; and (3) increased vascular permeability allows fibrinogen and complement to enter the tissue from the blood. Fibrinogen is converted to fibrin, which walls off the infected area, preventing the spread of infection. Complement further enhances the inflammatory response and attracts additional phagocytes. The process of releasing chemical mediators and attracting phagocytes and other white blood cells continues until the bacteria are destroyed. Phagocytes, such as neutrophils and macrophages, remove microorganisms and dead tissue, and the damaged tissues are repaired.

Inflammation can be local or systemic. **Local inflammation** is an inflammatory response confined to a specific area of the body (see chapter 4). Symptoms of local inflammation include redness, heat, and swelling due to increased blood flow and increased vascular permeability, as well as pain caused by swelling and by chemical mediators acting on pain receptors. The tissue destruction, swelling, and pain lead to loss of function.

Systemic inflammation is an inflammatory response that occurs in many parts of the body. In addition to the local symptoms at the sites of inflammation, three additional features can be present:

1. Red bone marrow produces and releases large numbers of neutrophils, which promote phagocytosis.
2. Fever is induced by the release of pyrogens. **Pyrogens** (pī'rō-jenz; fire-producing) are chemicals released by microorganisms, macrophages, neutrophils, and other cells. These chemicals in turn stimulate fever production by affecting the body's temperature-regulating mechanism in the hypothalamus. As a consequence, heat production and heat conservation increase, raising body temperature. Fever promotes the activities of the immune system, such as phagocytosis, and inhibits the growth of some microorganisms.
3. In severe cases of systemic inflammation, increased vascular permeability is so widespread that large amounts of fluid are lost from the blood into the tissues. The decreased blood volume can cause shock and death.

ASSESS YOUR PROGRESS

29. What kinds of tissue damage can result in inflammation?
30. Describe the events that take place during an inflammatory response.
31. What are the symptoms of local inflammation and of systemic inflammation?

22.5 Adaptive Immunity

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Define antigen and describe the two groups of antigens.**
- B. Explain the role of haptens in allergic reactions.**
- C. Describe the origin, development, activation, proliferation, and inhibition of lymphocytes.**

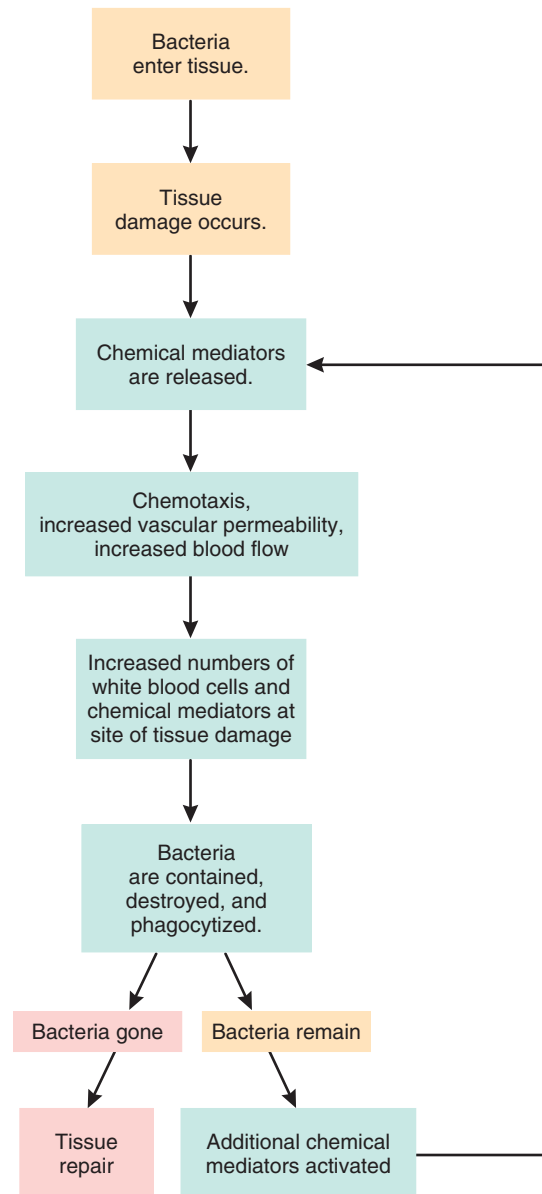

FIGURE 22.11 Inflammatory Response

Bacteria cause tissue damage and the release of chemical mediators, which initiate inflammation and phagocytosis, resulting in the destruction of the bacteria. If any bacteria remain, additional chemical mediators are activated. After all the bacteria have been destroyed, the tissue is repaired. **APR**

D. Describe the function of major histocompatibility complex (MHC) molecules in immunity.

E. Distinguish between MHC class I molecules and MHC class II molecules.

F. Define antibody-mediated immunity and cell-mediated immunity and name the cells responsible for each.

G. Diagram the structure of an antibody and describe the effects produced by antibodies.

H. Discuss the primary and secondary responses to an antigen and explain the basis for long-lasting immunity.

I. Describe the types and functions of T cells.

Adaptive immunity can recognize, respond to, and remember a particular substance. Substances that stimulate adaptive immunity are called **antigens** (an'ti-jenz). They are usually large molecules with a molecular weight of 10,000 or more.

Antigens are divided into two groups: foreign antigens and self-antigens. **Foreign antigens** are not produced by the body but are introduced from outside it. Components of bacteria, viruses, and other microorganisms are examples of foreign antigens. Other foreign antigens include pollen, animal dander (scaly, dried skin), feces of house dust mites, foods, and drugs. Many of these trigger an **allergic reaction**, an overreaction of the immune system in some people. Transplanted tissues and organs that contain foreign antigens cause rejection of the transplant. **Self-antigens** are molecules the body produces to stimulate an adaptive immune system response. The response to self-antigens can be beneficial or harmful. For example, the recognition of tumor antigens can result in tumor destruction, whereas **autoimmune disease** can develop when self-antigens stimulate unwanted tissue destruction. An example is rheumatoid arthritis, which destroys the tissues within joints.

Adaptive immunity can be divided into antibody-mediated immunity and cell-mediated immunity. **Antibody-mediated immunity** involves proteins called **antibodies**, which are found in extracellular fluids, such as the plasma of blood, interstitial fluid, and lymph. B cells give rise to cells that produce antibodies. **Cell-mediated immunity** involves the actions of a second type of lymphocyte, called T cells. Several subpopulations of T cells exist, each responsible for a particular aspect of cell-mediated immunity. For example, **cytotoxic T cells** are responsible for producing the effects of cell-mediated immunity. **Helper T cells** and **regulatory**

T cells can promote or inhibit the activities of both antibody-mediated immunity and cell-mediated immunity.

Table 22.3 summarizes and contrasts the main features of innate immunity and the two categories of adaptive immunity.

ASSESS YOUR PROGRESS

32. Define antigen. Distinguish between a foreign antigen and a self-antigen.
33. What are allergic reactions and autoimmune diseases?
34. What are the two types of adaptive immunity?

Origin and Development of Lymphocytes

All blood cells, including lymphocytes, are derived from stem cells in the red bone marrow (see chapter 19). The process of blood cell formation begins during embryonic development and continues throughout life. Some stem cells give rise to pre-T cells, which migrate through the blood to the thymus, where they divide and are processed into T cells (figure 22.12; see figure 22.9). The thymus produces hormones, such as **thymosin**, which stimulate T-cell maturation. Other stem cells produce pre-B cells, which are processed in the red bone marrow into B cells. A **positive selection** process results in the survival of pre-B and pre-T cells that are capable of an immune response. Cells that are incapable of an immune response die.

The B cells and T cells are members of **clones**, small groups of identical lymphocytes. All lymphocytes of a given clone respond to the same specific antigen. Although each clone can respond only to a

TABLE 22.3

Comparison of Innate and Adaptive Immunity

Characteristics	INNATE IMMUNITY	ADAPTIVE IMMUNITY	
		Antibody-Mediated Immunity	Cell-Mediated Immunity
Primary cells	Neutrophils, eosinophils, basophils, mast cells, monocytes, and macrophages	B cells	T cells
Origin of cells	Red bone marrow	Red bone marrow	Red bone marrow
Site of maturation	Red bone marrow (neutrophils, eosinophils, basophils, and monocytes) and tissues (mast cells and macrophages)	Red bone marrow	Thymus
Location of mature cells	Blood, connective tissue, and lymphatic tissue	Blood and lymphatic tissue	Blood and lymphatic tissue
Primary secretory products	Histamine, kinins, complement, prostaglandins, leukotrienes, and interferons	Antibodies	Cytokines
Primary actions	Inflammatory response and phagocytosis	Protection against extracellular antigens (bacteria, toxins, parasites, and viruses outside cells)	Protection against intracellular antigens (viruses, intracellular bacteria, and intracellular fungi) and tumors; regulates antibody-mediated immunity and cell-mediated immunity responses (helper T and regulatory T cells)
Hypersensitivity reactions	None	Immediate hypersensitivity (atopy, anaphylaxis, cytotoxic reactions, and immune complex disease)	Delayed hypersensitivity (allergic reaction to infection or contact hypersensitivity)

particular antigen, such a large number of clones exist that the immune system can react to most molecules. Some of the clones can also respond to self-antigens, causing the destruction of body cells. A **negative selection** process eliminates or suppresses clones acting against self-antigens, thereby preventing the destruction of a person's own cells. Although the negative selection process occurs mostly during prenatal development, it continues throughout life (see "Inhibition of Lymphocytes," later in this section).

B cells are released from red bone marrow, T cells are released from the thymus, and both types of cells move through the blood to lymphatic tissue. T cells are more numerous than B cells; there are approximately five T cells for every B cell in the blood. Lymphocytes live for a few months to many years and continually circulate between the blood and the lymphatic tissues. Antigens can come into contact with and activate lymphocytes, resulting in cell divisions that increase the number of lymphocytes able to recognize the antigen. These lymphocytes can circulate in blood and lymph to reach antigens in tissues throughout the body.

During the development of a lymphocyte, it will move from the area in which it matures to an area in which it carries out its function. Lymphocytes mature into functional cells in the **primary lymphatic organs**, which are the red bone marrow and thymus. In the **secondary lymphatic organs and tissues**, lymphocytes interact with each other, antigen-presenting cells, and antigens to produce an immune response. The secondary lymphatic organs and tissues include the diffuse lymphatic tissue, lymphatic nodules, tonsils, lymph nodes, and spleen.

Activation of Lymphocytes

Antigens activate lymphocytes in different ways, depending on the type of lymphocyte and the type of antigen involved. Despite these differences, however, two general principles of lymphocyte

FIGURE 22.12 Origin and Processing of B Cells and T Cells

Pre-B cells and pre-T cells originate from stem cells in red bone marrow. The pre-B cells remain in the red bone marrow and become B cells. The pre-T cells circulate to the thymus, where they become T cells. Both B cells and T cells circulate to other lymphatic tissues, such as lymph nodes, where they can divide and increase in number in response to antigens. **APR**

Clinical IMPACT

Haptens and Allergic Reactions

Haptens (hap'tenz), often referred to as incomplete antigens, are small molecules (of low molecular weight) that can combine with large molecules, such as blood proteins, to stimulate an adaptive immune response. In many cases, however, haptens lead to allergic reactions (see the Diseases and Disorders table, later in this chapter). For example, penicillin, a common antibiotic prescribed to combat bacterial infections, is a hapten that can break down and bind to other molecules in the blood. The combined molecule can then stimulate an allergic reaction that ranges from a rash and fever to severe symptoms that can lead to death. It is estimated that 20% of patients have allergic reactions when administered penicillin. Research indicates that the likelihood of a reaction increases with subsequent prescriptions. Skin tests are available to determine a patient's susceptibility to an allergic reaction to penicillin.

activation exist: (1) Lymphocytes must be able to recognize the antigen; (2) after recognition, the lymphocytes must increase in number to destroy the antigen.

Antigenic Determinants and Antigen Receptors

If an adaptive immune system response is to occur, lymphocytes must recognize an antigen. However, lymphocytes do not interact with an entire antigen. Instead, lymphocytes interact with specific regions of the antigen called **antigenic determinants**, or *epitopes* (ep'i-tōps). Each antigen has many different antigenic determinants (figure 22.13). All the lymphocytes of a given clone have, on their surfaces, identical proteins called **antigen receptors**, which combine with a specific antigenic determinant. The immune system response to an antigen with a particular antigenic determinant is similar to the lock-and-key model for enzymes (see chapter 2), and any given antigenic determinant can combine only with a

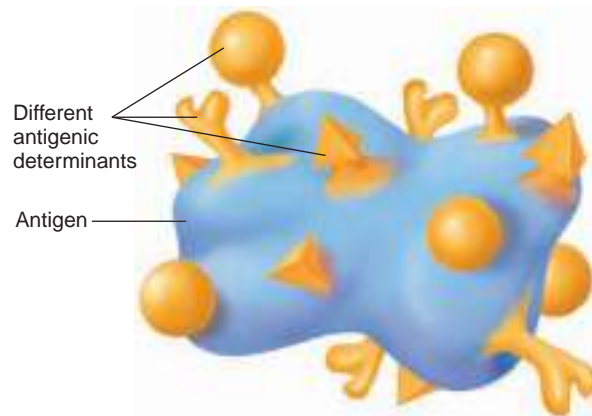

FIGURE 22.13 Antigenic Determinants

An antigen has many antigenic determinants to which lymphocytes can respond.

MICROBES In Your Body

Do Our Gut Bacteria Drive Immune Development and Function?

“All disease begins in the gut.” This quote from Hippocrates (460–377 B.C.), the father of Western medicine, is still relevant today. Over the last four decades, increasing numbers of people have suffered from allergies and autoimmune disorders. Researchers hypothesize that the increase in these conditions stems from inadequate development of immune function. In turn, they hypothesize that underdeveloped immune function is due to deficiencies in our gut microbiota. This has led to the Hygiene Hypothesis, which states that the increased use of antibiotics and antimicrobial chemicals damages the normal gut microbiota and other microbiota that are critical for immune system development and function.

Could the Hygiene Hypothesis explain the observed increases in allergies and autoimmune disorders? Much of the evidence for the importance of gut microbiota for immune function is derived from studies with germ-free mice. These lab-raised mice lack the natural microorganisms in their gut and in their body. As a result, the mice have multiple defects with their lymphatic tissues, such as fewer and smaller Peyer patches in the gut and fewer B and T lymphocytes. However, if scientists place intestinal or fecal microbiota from normal mice into the gut of germ-free mice, the immune tissues of the germ-free mice begin developing and functioning normally.

The importance of the gut in immune development is further supported by the fact that it contains the largest concentration of lymphatic tissue and microbiota in the human body. In humans, the gut microbiota begin to appear just before birth. As the baby passes through the birth canal, more microorganisms are transferred from the mother to the baby. The makeup of a baby’s microbiota is

influenced by many factors, including genetics, the mode of delivery (vaginal or C-section), antibiotic use, stress, and the mother’s diet during late pregnancy. The first year of life is the most critical for the accumulation of gut bacteria, but this process continues through childhood. At about 10 years of age, a person’s gut microbiota are established and remain similar in composition throughout life. Humans and their gut microbiota have a symbiotic relationship, in that the gut provides space and nutrients for the microbiota, which in turn provide their host with specialized nutrition, physiological regulators, and protection against pathogens. Because of these ever-present microbiota (“good” bacteria), human gut epithelial and immune cells must maintain tolerance to them yet still protect against invading gut pathogens (“bad” bacteria).

How do our cells distinguish between “good” and “bad” bacteria? As it turns out, gut microbiota help stimulate the development of immune cells by triggering the production of different receptors. These receptors are found in the plasma membranes of white blood cells, such as macrophages and neutrophils, as well as in the plasma membranes of intestinal epithelial cells. The surface of all bacterial cells has bacteria-specific molecules that can be recognized by the receptors of defense cells, which is what allows for distinction between “good” and “bad” microorganisms. Activation of the receptors triggers a cascade of events, which result in immune responses such as T-lymphocyte activation and the production of immunity chemicals. In addition, the “good” bacteria attack invading “bad” bacteria by secreting antimicrobial substances against them and competing with them for nutrients and space.

Thus, without appropriate amounts and/or types of gut microbiota, the body’s immune system may not have all of the messages that are essential for producing specific immune cells and chemicals that kill pathogenic intestinal microorganisms.

Medical professionals are interested in manipulating gut microbiota to reduce allergies and other diseases and to promote healing. First, and perhaps most importantly, is to get the desired population of gut microbiota started immediately in infancy through breastfeeding. Human breast milk contains carbohydrates that stimulate the growth of specific intestinal microbiota while preventing infection by some pathogens. And the use of prebiotics (nondigestible carbohydrates that promote the growth of healthy microbiota) and probiotics (live normal gut microbiota) is being actively explored for the treatment of problems that arise later in life. However, there is still much work to be done before we fully understand the extent to which gut microbiota are involved in human immune function.

► Predict 3

In some underdeveloped countries, children are nutritionally deprived. Studies of twins in these countries have demonstrated that sometimes one of the twins thrives, whereas the other twin is malnourished. In the malnourished twin, the gut microbiota population is far less diverse and much smaller than that of the thriving twin. Using what you have learned about the role of gut microbiota in immune function, predict a possible developmental repercussion in the malnourished twin. Propose some possible solutions that might result in both twins having a normal gut microbe population.

specific antigen receptor. The **T-cell receptor** consists of two polypeptide chains, which are subdivided into a variable region and a constant region (figure 22.14). The variable region can bind to an antigen. The many different types of T-cell receptors respond to different antigens because they have different variable regions. The **B-cell receptor**, consisting of four polypeptide chains with two identical variable regions, is a type of antibody.

Major Histocompatibility Complex Molecules

Although some antigens can interact with and directly activate B cells and some T cells, most lymphocyte activation involves **major histocompatibility complex (MHC) molecules**. MHC molecules are glycoproteins found on the plasma membranes of

most of the body’s cells. Each MHC molecule has a variable region that can bind antigens found inside the cell. The immune system cannot directly respond to an antigen inside a cell. Instead, MHC molecules display antigens produced or processed inside the cell on the cell’s surface. Two classes of MHC molecules are present in the body: MHC class I and MHC class II.

MHC class I molecules are found on nucleated cells; they display antigens produced inside the cell on the cell’s surface (figure 22.15a). For example, viruses reproduce inside a cell, forming viral proteins that act as foreign antigens. Some of these viral proteins are broken down in the cytoplasm. The protein fragments enter the rough endoplasmic reticulum and combine with MHC class I molecules to form complexes that move

FIGURE 22.14 T-Cell Receptor

A T-cell receptor consists of two polypeptide chains. The variable region of each type of T-cell receptor is specific for a given antigen. The constant region attaches the T-cell receptor to the plasma membrane.

through the Golgi apparatus to be distributed on the cell's surface (see chapter 3).

MHC class I/antigen complexes on the surface of cells can bind to T-cell receptors on the surface of T cells. This combination is a signal that activates T cells. Activated T cells can destroy infected cells, which effectively stops viral replication (see “Cell-Mediated Immunity,” later in this section). Thus, the MHC class I/antigen complex functions as a signal, or “red flag,” that prompts the immune system to destroy the displaying cell. In essence, the cell is displaying a sign that says, “Kill me!” This process is said to be **MHC-restricted** because both the antigen and the individual organism's own MHC molecule are required.

➤ Predict 4

In mouse A, T cells can respond to virus X. If these T cells are transferred to mouse B, which is infected with virus X, will the T cells respond to the virus? Explain.

The same process that moves foreign protein fragments to the cell's surface can also inadvertently transport self-protein fragments (figure 22.15a). As part of normal protein metabolism, cells continually break down old proteins and synthesize new ones. Some self-protein fragments that result from protein breakdown can combine with MHC class I molecules and be displayed on the surface of the cell, thus becoming self-antigens. Normally, the immune system does not respond to self-antigens in combination with MHC molecules because the lymphocytes that could respond have been eliminated or inactivated (see “Inhibition of Lymphocytes,” later in this section).

MHC class II molecules are found on **antigen-presenting cells**, which include B cells, macrophages, monocytes, and

dendritic cells. **Dendritic** (den-drit'ik) **cells** are large, motile cells with long cytoplasmic extensions. These cells are scattered throughout most tissues (except the brain), with their highest concentrations in lymphatic tissues and the skin. Dendritic cells in the skin are often called **Langerhans cells**.

Antigen-presenting cells can take in foreign antigens by endocytosis (figure 22.15b). Within the endocytotic vesicle, the antigen is broken down into fragments to form processed antigens. Vesicles from the Golgi apparatus containing MHC class II molecules combine with the endocytotic vesicles. The MHC class II molecules and processed antigens combine, and the MHC class II/antigen complexes are transported to the cell's surface, where they are displayed to other immune cells.

MHC class II/antigen complexes on the cell's surface can bind to T-cell receptors on the surfaces of T cells. The presentation of antigen using MHC class II molecules is MHC-restricted because both the antigen and the individual's own MHC class II molecule are required. Unlike MHC class I molecules, however, this display does not result in the destruction of the antigen-presenting cell. Instead, the MHC class II/antigen complex is a “rally around the flag” signal that stimulates other immune system cells to respond to the antigen. The displaying cell is like Paul Revere, who spread the alarm for the militia to arm and organize. The militia then went out and killed the enemy. For example, when the lymphocytes of the B-cell clone that can recognize the antigen come into contact with the MHC class II/antigen complex, they are stimulated to divide. The activities of these lymphocytes, such as the production of antibodies, then destroy the antigen.

MHC molecules are genetically determined. Due to the complexity of the genes involved in MHC protein production, the variation in MHC molecules is great in the population. As a result, it is rare for two people to have exactly the same MHC molecules, except in the case of identical twins. MHC molecule differences are of major concern when tissue is transplanted from one individual to another. Genetically similar individuals (siblings or parent and offspring) are more likely to have similar MHC molecules and, therefore, a better “match” for tissue transplants (see Clinical Impact, “Transplant Rejection”).

➤ Predict 5

Antibodies bind to a foreign antigen, resulting in removal of that foreign antigen from the body. Explain what happens to antibody production as the foreign antigens decrease.

ASSESS YOUR PROGRESS

35. Describe the origin and development of B cells and T cells.
36. What are lymphocyte clones? What is the difference between positive and negative lymphocyte selection?
37. What are the primary lymphatic organs? What are the secondary lymphatic organs and tissues?
38. Define antigenic determinant and antigen receptor. How are they related to each other?
39. What types of cells display MHC class I and class II antigen complexes, and what happens as a result?

FUNDAMENTAL Figure

- 1 Foreign proteins or self-proteins within the cytosol are broken down into fragments that are antigens.
- 2 Antigens are transported into the rough endoplasmic reticulum.
- 3 Antigens combine with MHC class I molecules.
- 4 The MHC class I/antigen complex is transported to the Golgi apparatus, packaged into a vesicle, and transported to the plasma membrane.
- 5 Foreign antigens combined with MHC class I molecules stimulate cell destruction.
- 6 Self-antigens combined with MHC class I molecules do not stimulate cell destruction.

(a)

- 1 A foreign antigen is ingested by endocytosis and is within a vesicle.
- 2 The antigen is broken down into fragments to form processed foreign antigens.
- 3 The vesicle containing the processed foreign antigens fuses with vesicles produced by the Golgi apparatus that contain MHC class II molecules. Processed foreign antigens and MHC class II molecules combine.
- 4 The MHC class II/antigen complex is transported to the plasma membrane.
- 5 The displayed MHC class II/antigen complex can stimulate immune cells.

 (b) Foreign antigens are taken into an antigen-presenting cell, processed, and presented at the cell surface by MHC class II molecules. **APR**

40. What types of antigens are displayed by MHC class I molecules? By MHC class II molecules?

41. What does MHC-restricted mean?

Costimulation

The combination of an MHC class II/antigen complex with an antigen receptor is usually only the first signal necessary to produce a response from a B cell or a T cell. In many cases, **costimulation** by additional signals is also required. Costimulation is accomplished

by cytokines released from cells as well as molecules attached to the surfaces of cells (figure 22.16a). Cytokines produced by lymphocytes are often called **lymphokines** (lim'fō-kīnz). Table 22.4 lists important cytokines and their functions.

Certain pairs of surface molecules can also be involved in costimulation (figure 22.16b). When the surface molecule on one cell combines with the surface molecule on another, the combination can act as a signal that stimulates one of the cells to respond, or the combination can hold the cells together. Typically, several kinds of surface molecules are necessary to produce a response. For example,

Clinical IMPACT

Transplant Rejection

Genes that code for the production of MHC molecules are generally called major histocompatibility complex genes. Histocompatibility is the tissues' ability (Gr. *histo*) to get along (compatibility) when tissues are transplanted from one individual to another. In humans, the major histocompatibility complex genes are often referred to as **human leukocyte antigen (HLA) genes** because they were first identified in leukocytes. The HLA genes control the production of MHC antigens, which are found on the plasma membrane of cells. Millions of possible combinations of the HLA genes exist, and it is very rare for two individuals (except identical twins) to have the same set of HLA genes. The closer the relationship between two people, the greater the likelihood they share the same HLA genes.

The immune system can distinguish between self cells and foreign cells because they are both marked with MHCs. Rejection of a transplanted tissue is caused by a normal immune system response to the foreign MHCs. **Acute rejection** occurs several weeks after transplantation and results from a delayed hypersensitivity reaction and cell lysis. Lymphocytes and macrophages infiltrate the area, a strong inflammatory response occurs, and the foreign tissue is destroyed. If acute rejection does not develop, **chronic rejection** may occur at a later time. In chronic rejection, immune complexes form in the arteries supplying the graft, the blood supply fails, and the transplanted tissue is rejected.

Graft rejection can occur in two different directions. In **host-versus-graft rejection**, the recipient's (host's) immune system recognizes the donor's (graft) tissue as foreign and rejects the transplant. In **graft-versus-host rejection**, the donor tissue (graft) recognizes the recipient's (host's) tissue as foreign, and the transplant rejects the recipient, causing destruction of the recipient's tissues and death.

To reduce graft rejection, a tissue match is performed. Only tissues with MHCs similar to the recipient's have a chance of acceptance. Even when the match is close, immunosuppressive drugs must be administered throughout the person's life to prevent rejection. Unfortunately, the person then has a drug-produced immunodeficiency and is more susceptible to infections. An exact match is possible only for a graft from one part to another part of a person's body or between identical twins.

a molecule called B7 on macrophages must bind with a molecule called CD28 on helper T cells before the helper T cells can respond to the antigen presented by the macrophage. In addition, helper T cells have a glycoprotein called CD4, which helps connect helper T cells to the macrophage by binding to MHC class II molecules. For this reason, helper T cells are sometimes referred to as *CD4 cells* or *T4 cells*. In a similar fashion, cytotoxic T cells are sometimes called *CD8 cells* or *T8 cells* because they have a glycoprotein called CD8, which helps connect cytotoxic T cells to cells displaying MHC class I molecules. The CD designation stands for "cluster of differentiation," which is a system used to classify many surface molecules.

Lymphocyte Proliferation

Before exposure to an antigen, the number of lymphocytes in a clone is too small to produce an effective response against the antigen. Exposure to an antigen results in an increase in lymphocyte number. The first lymphocytes to increase in number are the helper T cells. This is important because the increased number of helper T cells responding to the antigen can find and stimulate B cells or cytotoxic T cells. Subsequently, the number of B cells or cytotoxic T cells increases. This is important because these cells are responsible for the immune response that destroys the antigen.

1. *Proliferation of helper T cells* (figure 22.17). Antigen-presenting cells use MHC class II molecules to present processed antigens to helper T cells. Only the helper T cells with the T-cell receptors that can bind to the antigen respond. These helper T cells respond to the MHC class II/antigen complex and costimulation by dividing. As a result, the number of helper T cells that recognize the antigen increases.
2. *Proliferation and activation of B cells or cytotoxic T cells*. Typically, the proliferation and activation of B cells or cytotoxic T cells involve helper T cells. This process is illustrated in figure 22.18 for B cells (see "Cell-Mediated Immunity," later in this section, for activation of cytotoxic T cells). The clone of B cells that can recognize a particular antigen has B-cell receptors that can bind to that antigen. The antigens and receptors enter the B cell by receptor-mediated endocytosis. The antigens break down into fragments to form processed antigens that combine with MHC class II molecules. B cells use MHC class II/antigen complexes to present antigens to the helper T cells that increased in number in response to the same antigen. These helper T cells stimulate the B cells to divide. Many of the resulting daughter cells differentiate to become specialized cells, called **plasma cells**, which produce antibodies. The increased number of plasma cells, each producing antibodies, can produce an immune response that destroys the antigens (see "Effects of Antibodies," later in this section).

Inhibition of Lymphocytes

Tolerance is a state of unresponsiveness of lymphocytes to a specific antigen. The most important function of tolerance is to prevent the immune system from responding to self-antigens, although foreign antigens can also induce tolerance. The need to maintain tolerance and to avoid the development of autoimmune disease is obvious. Tolerance can be induced in three primary ways:

1. *Deletion of self-reactive lymphocytes*. During prenatal development and after birth, stem cells in red bone marrow and the thymus give rise to immature lymphocytes that develop into mature lymphocytes capable of an immune response. When immature lymphocytes are exposed to antigens, instead of responding in ways that cause elimination of the antigen, they respond by dying. Because immature lymphocytes are exposed to self-antigens, this process eliminates self-reactive lymphocytes. In addition, immature lymphocytes that escape deletion during their development and become mature, self-reacting lymphocytes can still be deleted most likely by the activities of regulatory T cells.

(a) Helper T cells are activated by a first signal and by costimulation. The first signal is the binding of the MHC class II/antigen complex to the T-cell receptor. Costimulation is an additional signal, such as molecules released from another cell. For example, macrophages release cytokines that bind to receptors on helper T cells, resulting in costimulation.

(b) Other costimulatory signals are the combining of surface molecules between cells, such as the binding of a B7 molecule of the macrophage with a CD28 molecule of the helper T cell. The CD4 molecule of the helper T cell binds to the macrophage's MHC class II molecule and helps hold the cells together.

FIGURE 22.16 Costimulation

TABLE 22.4 Cytokines and Their Functions

Cytokine*	Description
Interferon alpha (IFN α)	Prevents viral replication and inhibits cell growth; secreted by virus-infected cells
Interferon beta (IFN β)	Prevents viral replication, inhibits cell growth, and decreases the expression of major histocompatibility complex (MHC) class I and II molecules; secreted by virus-infected fibroblasts
Interferon gamma (IFN γ)	About 20 different proteins that activate macrophages and natural killer (NK) cells, stimulate adaptive immunity by increasing the expression of MHC class I and II molecules, and prevent viral replication; secreted by helper T, cytotoxic T, and NK cells
Interleukin-1 (IL-1)	Costimulation of B cells and T cells; promotes inflammation through prostaglandin production and induces fever acting through the hypothalamus (pyrogen); secreted by macrophages, B cells, and fibroblasts
Interleukin-2 (IL-2)	Costimulation of B cells and T cells and activation of macrophages and NK cells; secreted by helper T cells
Interleukin-4 (IL-4)	Plays a role in allergic reactions by activation of B cells, resulting in the production of immunoglobulin E (IgE); secreted by helper T cells
Interleukin-5 (IL-5)	Part of the response against parasites by stimulating eosinophil production; secreted by helper T cells
Interleukin-8 (IL-8)	Chemotactic factor that promotes inflammation by attracting neutrophils and basophils; secreted by macrophages
Interleukin-10 (IL-10)	Inhibits the secretion of interferon gamma and interleukins; secreted by regulatory T cells
Interleukin-15 (IL-15)	Promotes inflammation and activates memory T cells and natural killer cells
Lymphotoxin	Kills target cells; secreted by cytotoxic T cells
Perforin	Makes a hole in the membrane of target cells, resulting in lysis of the cell; secreted by cytotoxic T cells
Tumor necrosis factor α (TNF α)	Activates macrophages and promotes fever (pyrogen); secreted by macrophages

*Some cytokines were named according to the laboratory test first used to identify them; however, these names are rarely an accurate description of the actual function of the cytokine.

- 1 Antigen-presenting cells, such as macrophages, take in, process, and display antigens on the cell's surface.
- 2 The antigen is bound to an MHC class II molecule, which functions to present the processed antigen to a T-cell receptor of a helper T cell for recognition.
- 3 Costimulation occurs by a CD4 glycoprotein of the helper T cell or by cytokines. The macrophage secretes a cytokine called interleukin-1.
- 4 Interleukin-1 attaches to interleukin receptors and stimulates the helper T cell to secrete the cytokine interleukin-2 and to produce interleukin-2 receptors.
- 5 The helper T cell stimulates itself to divide when interleukin-2 binds to interleukin-2 receptors.
- 6 The "daughter" helper T cells resulting from this division can be stimulated to divide again if they are exposed to the same antigen that stimulated the "parent" helper T cell. This greatly increases the number of helper T cells.
- 7 The increased number of helper T cells can facilitate the activation of B cells or effector T cells.

PROCESS FIGURE 22.17 Proliferation of Helper T Cells

An antigen-presenting cell (macrophage) stimulates helper T cells to divide and produce cytokines.

2. *Prevention of the activation of lymphocytes.* For lymphocytes to be activated, two signals are usually required: (1) the MHC/antigen complex binding with an antigen receptor and (2) costimulation. Preventing either of these events stops lymphocyte activation. For example, blocking, altering, or deleting an antigen receptor prevents activation. **Anergy** (an'er-jē; without working) is a condition of inactivity in which a B cell or T cell does not respond to an antigen. Anergy develops when an MHC-antigen complex binds to an antigen receptor and no costimulation occurs. For example, if a helper T cell encounters a self-antigen on a cell that cannot provide costimulation, the T cell is turned off. It is likely that only antigen-presenting cells can provide costimulation.
3. *Activation of regulatory T cells.* **Regulatory T cells**, also called *suppressor T cells*, are a poorly understood group of T cells that are defined by their ability to suppress immune responses. Regulatory T cells develop in the thymus and then

enter the tissues of the body. Regulatory T cells reduce adaptive immune response by releasing cytokines that inhibit helper T cells and cytotoxic T cells, thereby regulating the activities of both antibody-mediated immunity and cell-mediated immunity. Decreasing the production or activity of cytokines can suppress the immune system. For example, cyclosporine, a drug used to prevent the rejection of transplanted organs, inhibits the production of interleukin-2. Conversely, genetically engineered interleukins can be used to stimulate the immune system. Administering interleukin-2 has promoted the destruction of cancer cells in some cases by increasing the activities of cytotoxic T cells.

ASSESS YOUR PROGRESS

42. What is costimulation? State two ways it can happen.
43. Why are helper T cells sometimes called CD4 or T4 cells? Why are cytotoxic T cells sometimes called CD8 or T8 cells?

FUNDAMENTAL Figure

- 1 Before a B cell can be activated by a helper T cell, the B cell must endocytose and process the same antigen that activated the helper T cell. The antigen binds to a B-cell receptor, and both the receptor and the antigen are taken into the cell by endocytosis.
- 2 The B cell uses an MHC class II molecule to present the processed antigen to the helper T cell.
- 3 The T-cell receptor binds to the MHC class II/antigen complex.
- 4 Costimulation of the B cell by CD4 and other surface molecules occurs.
- 5 Costimulation by interleukins (cytokines) released from the helper T cell occurs.
- 6 The B cell divides, and the resulting daughter cells divide, and so on, eventually producing many cells (only two are shown here) that recognize the same antigen.
- 7 Many of the daughter cells differentiate to become plasma cells, which produce antibodies. Antibodies are part of the immune response that eliminates the antigen.

45. Describe how helper T cells stimulate an increase in the number of B cells or T cells. Why is this important?
46. What is tolerance? Explain three ways it is accomplished.

Antibody-Mediated Immunity

Antibody-mediated immunity involves the production of antibodies in response to extracellular antigens. Exposure of the body to an antigen can lead to the activation of B cells and to the production of antibodies, which are responsible for destroying the antigen. Because antibodies occur in body fluids, antibody-mediated immunity is effective against extracellular antigens, such as bacteria, viruses, protozoans, fungi, parasites, and toxins, when they

are outside cells. Antibody-mediated immunity can also cause immediate hypersensitivity reactions (see the Diseases and Disorders table, later in this chapter).

Structure of Antibodies

Antibodies are proteins produced in response to an antigen. Large numbers of antibodies exist in plasma, although plasma also contains other proteins. On the basis of protein type and associated lipids, plasma proteins are separated into albumin and alpha-(α), beta-(β), and gamma-(γ) globulin parts. As a group, antibodies are sometimes called *gamma globulins* because they are found mostly in the γ -globulin part of plasma, or **immunoglobulins (Ig)**, because they are globulin proteins involved in immunity.

The five general classes of antibodies are denoted IgG, IgM, IgA, IgE, and IgD (table 22.5). All classes of antibodies have a

similar structure. This structure is a Y-shaped protein consisting of four polypeptide chains: two identical heavy chains and two identical light chains (figure 22.19). Each light chain is attached to a heavy chain. The ends of the combined heavy and light chains form the **variable region** of the antibody. This is the part of the antibody that combines with the antigenic determinant of the antigen. Different antibodies have different variable regions, and they are specific for different antigens. The rest of the antibody is the **constant region**. The constant region is responsible for the activities of antibodies, such as the ability to activate complement or to attach the antibody to cells such as macrophages, basophils, mast cells, and eosinophils. The constant region is nearly the same for all the antibodies of a particular class.

Effects of Antibodies

Antibodies can directly affect antigens in two ways: (1) The antibody can bind to the antigenic determinant and interfere with the antigen's ability to function (figure 22.20a) or (2) the antibody can combine with an antigenic determinant on two different antigens, rendering the antigens ineffective (figure 22.20b). The ability of antibodies to join antigens together is the basis for many clinical tests, such as blood typing, because, when enough antigens are bound together, they become visible as a clump or a precipitate.

Although antibodies can directly affect antigens, most of their effectiveness results from other mechanisms. When an antibody (IgG or IgM) combines with an antigen through the variable region, the constant region can activate the complement cascade through the classical pathway (figure 22.20c; see figure 22.10). Activated complement stimulates inflammation; attracts neutrophils, monocytes, macrophages, and eosinophils to sites of infection; and kills bacteria by lysis.

Antibodies (IgE) can initiate an inflammatory response (figure 22.20d). The antibodies attach to mast cells or basophils through their constant region. When antigens combine with the variable region of the antibodies, the mast cells or basophils release

chemicals through exocytosis, and inflammation results. For example, people who have hay fever inhale antigens (usually, plant pollen), which are then absorbed through the respiratory mucous membrane. The combination of the antigens with antibodies stimulates mast cells to release inflammatory chemicals, such as histamine. The resulting localized inflammatory response produces swelling and increased mucus production in the respiratory tract.

Opsinins (op'sō-ninz) are substances that make an antigen more susceptible to phagocytosis. An antibody (IgG) acts as an opsonin by connecting to an antigen through the variable region of the antibody and to a macrophage through the constant region of the antibody. The macrophage then phagocytizes the antigen and the antibody (figure 22.20e).

Antibody Production

Antibody production after the first exposure to an antigen is different from that after a second or subsequent exposure. The first exposure of a B cell to an antigen for which it is specific causes the **primary response**. This primary response includes a series of cell divisions, cell differentiation, and antibody production. The B-cell receptors on the surface of B cells are actually antibodies, usually IgM and IgD. The receptors have the same variable region as the antibodies that are eventually produced by the B cell. Before stimulation by an antigen, B cells are small lymphocytes. After activation, the B cells undergo a series of divisions to produce large lymphocytes. Some of these enlarged cells become **plasma cells**, which produce antibodies. Those enlarged lymphocytes that do not become plasma cells revert to small lymphocytes and become **memory B cells** (figure 22.21). Usually, IgM is the first antibody produced in response to an antigen, but later other classes of antibodies are produced as well. The primary response normally takes 3–14 days to produce enough antibodies to be effective against the antigen. In the meantime, disease symptoms usually develop because the antigen has had time to cause tissue damage.

TABLE 22.5 Classes of Antibodies and Their Functions

Antibody	Total Serum Antibody (%)	Description	Structure
IgG	80–85	Activates complement and promotes phagocytosis; can cross the placenta and provide immune protection to the fetus and newborn; responsible for Rh reactions, such as hemolytic disease of the newborn	
IgM	5–10	Activates complement and acts as an antigen-binding receptor on the surface of B cells; responsible for transfusion reactions in the ABO blood system; often the first antibody produced in response to an antigen	
IgA	15	Secreted into saliva, into tears, and onto mucous membranes to provide protection on body surfaces; found in colostrum and milk to provide immune protection to newborns	
IgE	0.002	Binds to mast cells and basophils and stimulates the inflammatory response	
IgD	0.2	Functions as antigen-binding receptors on B cells	

■ Heavy chain

■ Light chain

FIGURE 22.19 Structure of an Antibody

Antibodies consist of two heavy and two light polypeptide chains. The variable region of the antibody binds to the antigen. The constant region of the antibody can activate the classical pathway of the complement cascade. The constant region can also attach the antibody to the plasma membrane of cells such as macrophages, basophils, and mast cells.

The **secondary response**, or *memory response*, occurs when the immune system is exposed to an antigen against which it has already produced a primary response. When exposed to the antigen, memory B cells rapidly divide to produce plasma cells, which produce large amounts of antibody. The secondary response provides better protection than the primary response for two reasons: (1) The time required to start producing antibodies is less (hours to a few days), and (2) the amount of antibody produced is much larger. As a consequence, the antigen is quickly destroyed, no disease symptoms develop, and the person is immune.

The secondary response also includes the formation of new memory B cells, which protect against additional exposures to the antigen. Memory B cells are the basis for adaptive immunity.

After destruction of the antigen, plasma cells die, the antibodies they released are degraded, and antibody levels decline to the point at which they can no longer provide adequate protection. Memory B cells persist for many years—for life, in some cases. However, if memory cell production is not stimulated or if the memory B cells produced are short-lived, repeated infections of the same disease are possible. For example, the same cold virus can cause the common cold more than once in the same person.

➤ Predict 6

One theory for long-lasting immunity assumes that humans are continually exposed to the disease-causing agent. Explain how this exposure can produce lifelong immunity.

Clinical IMPACT

Uses of Monoclonal Antibodies

A **monoclonal antibody** is a pure antibody preparation that is specific for only one antigen. A monoclonal antibody preparation can be produced by injecting a laboratory animal with a specific antigen. The antigen activates a B-cell clone against the antigen. The B cells are removed from the animal and fused with tumor cells, which divide to form large numbers of cells. The tumor cells of a given clone produce only one kind of antibody.

Monoclonal antibodies are used for determining pregnancy and for diagnosing diseases, such as gonorrhea, syphilis, hepatitis, rabies, and cancer. These tests are specific and rapid because the monoclonal antibodies bind only to the antigen being tested. Monoclonal antibodies have been used to treat some autoimmune diseases and reduce the chances of tissue rejection after transplant. They may also be used as treatments for certain cancers, such as breast cancer (see section 22.8).

ASSESS YOUR PROGRESS

47. What type of lymphocyte is responsible for antibody-mediated immunity? What are the functions of antibody-mediated immunity?
48. What are the functions of the variable and constant regions of an antibody?
49. List the five classes of antibodies, and state their functions.
50. Describe the different ways that antibodies participate in destroying antigens.
51. What are plasma cells and memory B cells, and how do they function?
52. What are the primary and secondary antibody responses? Why doesn't the primary response prevent illness, whereas the secondary response does?

Cell-Mediated Immunity

Cell-mediated immunity is most effective against intracellular microorganisms through the action of cytotoxic T cells. Through interactions with MHC molecules, cytotoxic T cells can identify abnormal or infected cells of the body. Cell-mediated immunity

(a) **Inactivate the antigen.** An antibody binds to an antigen and inactivates it.

(b) **Bind antigens together.** Antibodies bind several antigens together.

(c) **Activate the complement cascade.** An antigen binds to an antibody. As a result, the antibody can activate complement proteins, which can produce inflammation, chemotaxis, and lysis.

(d) **Initiate the release of inflammatory chemicals.** An antibody binds to a mast cell or a basophil. When an antigen binds to the antibody, it triggers the release of chemicals that cause inflammation.

(e) **Facilitate phagocytosis.** An antibody binds to an antigen and then to a macrophage, which phagocytizes the antibody and antigen.

FIGURE 22.20 Effects of Antibodies

Antibodies directly affect antigens by inactivating the antigens or binding the antigens together. Antibodies indirectly affect antigens by activating other mechanisms through the constant region of the antibody. Indirect mechanisms include activation of complement, increased inflammation resulting from the release of inflammatory chemicals from mast cells or basophils, and increased phagocytosis resulting from antibody attachment to macrophages.

PROCESS FIGURE 22.21 Antibody Production

involves delayed hypersensitivity reactions and the control of tumors (see the Diseases and Disorders table in this chapter).

Because antibodies cannot cross the plasma membrane of a cell, antibody-mediated immunity is not effective against intracellular microorganisms, such as viruses, fungi, intracellular bacteria, and parasites. However, cell-mediated immunity is effective against these intracellular microorganisms because it destroys the cells in which the microorganisms are located. For example, viruses enter cells and direct the cells to make new viruses, which are then released to infect other cells. Thus, cells are turned into virus-manufacturing cells. Cell-mediated immunity fights viral infections by destroying virally infected cells, reducing the chance that the virus can spread to other cells of the body. When viruses infect cells, some viral proteins are broken down and become processed foreign antigens that are combined with MHC class I molecules and displayed on the surface of the infected cells (figure 22.22). T cells can distinguish between virally infected cells and noninfected cells because MHC class I/antigen complexes are on the surface of infected cells, but not on

the surface of uninfected cells. Binding of the T-cell receptor to the MHC class I/antigen complex is a signal for activating cytotoxic T cells. Costimulation by other surface molecules, such as CD8, also occurs. Helper T cells provide costimulation by releasing cytokines, such as interleukin-2, which stimulates activation and cell division of T cells. However, unlike their interactions with macrophages and B cells, helper T cells do not connect to T cells through MHC class II/antigen complexes or other surface molecules.

An increased number of helper T cells results in greater stimulation of cytotoxic T cells. In cell-mediated responses, helper T cells are activated and stimulated to divide in the same fashion as in antibody-mediated responses (see figure 22.17).

After T cells are activated by an antigen on the surface of a target cell, they undergo a series of divisions to produce cytotoxic T cells and memory T cells (figure 22.23). The cytotoxic T cells are responsible for the cell-mediated immune response. Memory T cells can provide a secondary response and long-lasting immunity in the same fashion as memory B cells.

Cytotoxic T Cells

Cytotoxic T cells have two main effects: (1) they lyse cells and (2) they produce cytokines (figure 22.23). Cytotoxic T cells can come into contact with other cells and cause them to lyse. Virus-infected cells have viral antigens, tumor cells have tumor antigens, and tissue transplants have foreign antigens on their surfaces that can stimulate cytotoxic T-cell activity. A cytotoxic T cell binds to a target cell and releases chemicals that cause the target cell to lyse. The major method of lysis involves a protein called **perforin**, which is similar to the complement protein C9 (see figure 22.10). Perforin released by cytotoxic T cells forms a channel in the plasma membrane of the target cell. Water enters the cell through the channel, causing the cell to swell and lyse. The cytotoxic T cell then moves on to destroy additional target cells.

In addition to lysing cells, cytotoxic T cells release cytokines that activate additional components of the immune system. For example, one important function of cytokines is the recruitment of cells, such as macrophages. These cells are then responsible for phagocytosis and inflammation.

Predict 7

In patients with acquired immunodeficiency syndrome (AIDS), the HIV virus infects and destroys helper T cells. Patients often die of pneumonia caused by an intracellular fungus (*Pneumocystis carinii*) or of Kaposi sarcoma, which is characterized by tumorous growths in the skin and lymph nodes. Explain what is happening.

ASSESS YOUR PROGRESS

- What type of lymphocyte is responsible for cell-mediated immunity? What are the functions of cell-mediated immunity?
- How do intracellular microorganisms stimulate cytotoxic T cells? What role do helper T cells play in this process?
- State the two main responses of cytotoxic T cells.
- How is long-lasting immunity achieved in cell-mediated immunity?

22.6 Acquired Adaptive Immunity

LEARNING OUTCOME

After reading this section, you should be able to

- A. Explain the four ways that adaptive immunity can be acquired.**

Unlike innate immunity, adaptive immunity is not necessarily present at birth. Instead, adaptive immunity must be acquired. Adaptive immunity can be broken down into four types, based on the way it is acquired: active natural, active artificial, passive natural, and passive artificial (figure 22.24). **Active immunity** results when an individual is exposed to an antigen (either naturally or artificially) and the response of the individual's immune system is the cause of the immunity. **Passive immunity** occurs when another person or an animal develops immunity and the immunity is transferred to a

- An MHC class I molecule displays an antigen, such as a viral protein, on the surface of a target cell.
- The activation of a cytotoxic T cell begins when the T-cell receptor binds to the MHC class I/antigen complex.
- There is costimulation of the cytotoxic T cell by CD8 and other surface molecules.
- There is costimulation by cytokines, such as interleukin-2, released from helper T cells.
- The activated cytotoxic T cell divides, the resulting daughter cells divide, and so on, eventually producing many cytotoxic T cells (only two are shown here).

FIGURE 22.23 Stimulation and Effects of T Cells

When activated, cytotoxic T cells form many additional cytotoxic T cells, as well as memory T cells. The cytotoxic T cells release cytokines that promote the destruction of the antigen or cause the lysis of target cells, such as virus-infected cells, tumor cells, or transplanted cells. The memory T cells are responsible for the secondary response.

Clinical GENETICS

Gluten-Sensitive Enteropathy

Gluten-sensitive enteropathy, also called *celiac* (sē'lē-āk) *disease*, is a malabsorption disorder, meaning that nutrients are poorly absorbed. Gluten-sensitive enteropathy results from damage to the lining of the small intestine, specifically the fingerlike projections, called villi, that increase the surface area for nutrient absorption (see figure 24.16). In a healthy intestine, the lining resembles a shag carpet. In gluten-sensitive enteropathy, the epithelium has become damaged, and the intestinal villi are flattened and inflamed.

Gluten-sensitive enteropathy is usually characterized by gastrointestinal symptoms, such as diarrhea, painful abdominal cramping, bloating, and intestinal gas. Prolonged gluten-sensitive enteropathy leads to additional complications, including anemia, osteoporosis, and neurological problems, in part due to nutritional deficiencies.

Gluten-sensitive enteropathy occurs in about 1 in 133 people, but the frequency may actually be even higher because the widely varying symptoms and severity of the disease make diagnosis difficult.

Gluten-sensitive enteropathy is an autoimmune disease and is often associated with

other autoimmune diseases, such as systemic lupus erythematosus (see Systems Pathology, later in this chapter). The damage to the intestinal lining is caused by an inappropriate immune response, which is triggered by the gluten proteins in wheat, barley, and rye. Although neither rice nor corn contains gluten proteins, gluten is often hidden as an additive in prepared foods and sauces.

Gluten-sensitive enteropathy has a genetic component. Most patients have mutated variants of some of the MHC class II genes. As a result, abnormal MHC class II molecules are produced and can bind to digested fragments of gluten. However, the genetics of gluten-sensitive enteropathy are complex and not fully understood. For example, the variant MHC alleles alone are not sufficient to cause the disease, since many people who have the variant alleles do not develop gluten-sensitive enteropathy. Furthermore, the genetic expression of the disease is influenced by variable environmental factors because the onset and severity of the disease can be triggered by unknown factors at any time in life.

Gluten-sensitive enteropathy results from both adaptive and innate immune responses. On the surface of antigen-presenting cells, the

MHC class II/gluten complex is presented to helper T cells to initiate an adaptive immune response (see figure 22.15*b*). The adaptive immune response includes antibody production and the activation of cytotoxic T cells. The innate immune response promotes inflammation through the activation of the alternative complement pathway and the release of cytokines, such as interleukin-15 (IL-15), from macrophages, dendritic cells, and other cells. In addition, exposure to gluten can activate natural killer cells and dendritic cells. The result of these immune responses is a deleterious attack on the epithelial lining of the small intestine, leading to the damaged villi common to gluten-sensitive enteropathy.

The only treatment for gluten-sensitive enteropathy is a strict, gluten-free diet. Before embarking on a life-long gluten-free diet, however, it is important to have a definitive diagnosis. Tests for higher than normal levels of antibodies produced in gluten-sensitive enteropathy, such as anti-tissue transglutaminase, and a biopsy of the small intestine to examine the villi are recommended. In the future, early genetic diagnosis and manipulation of the immune response may be able to reduce the sensitivity to gluten.

nonimmune individual. *Natural* and *artificial* refer to the method of exposure. *Natural exposure* implies that contact with an antigen or antibody occurs as part of everyday living and is not deliberate. Artificial exposure, also called **immunization**, is the deliberate introduction of an antigen or antibody into the body.

How long the immunity lasts differs for active and passive immunity. Active immunity can persist for a few weeks (e.g., the common cold) to a lifetime (e.g., whooping cough, polio). Immunity can be long-lasting if enough memory B cells or memory T cells are produced and persist to respond to later antigen exposure. Because an individual does not produce his or her own memory cells in passive immunity, it is not long-lasting. Because active immunity can last longer than passive immunity, it is the preferred method. However, passive immunity is preferred when immediate protection is needed.

Active Natural Immunity

Natural exposure to an antigen, such as a disease-causing microorganism, can cause the immune system to mount an adaptive immune response against the antigen and achieve **active natural immunity**. Because the individual is not immune during the first exposure, he or she usually develops the symptoms of the disease. Interestingly, exposure to an antigen does not always produce symptoms. For example, many people exposed to the poliomyelitis virus at an early age have an immune system response, produce poliomyelitis antibodies, but do not exhibit any disease symptoms.

Active Artificial Immunity

In **active artificial immunity**, an antigen is deliberately introduced into a person's body to stimulate the immune system. This process is called immunization, or **vaccination**, and the

introduced antigen is a **vaccine**. A vaccine is usually administered by injection. Examples of vaccinations are the DPT injection against diphtheria, pertussis (whooping cough), and tetanus and the MMR injection against mumps, measles, and rubella (German measles).

A vaccine usually consists of a part of a microorganism, a dead microorganism, or a live, altered microorganism. The antigen has been changed so that it will stimulate an immune response but will not cause the disease symptoms. Because active artificial immunity produces long-lasting immunity without disease symptoms, it is the preferred method of acquiring adaptive immunity.

➤ Predict 8

Some vaccination procedures require a booster shot, another dose of the original vaccine given sometime after the original dose was administered. Why are booster shots administered?

Passive Natural Immunity

Passive natural immunity results when antibodies are transferred from a mother to her child across the placenta before birth or through the mother's milk after the child is born. During her life, the mother has been exposed to many antigens, either naturally or artificially, and she has antibodies against many of these antigens that protect her and the developing fetus against disease. Some of the antibodies (IgG) can cross the placenta and enter the fetal blood. Following birth, the antibodies protect the baby for the first few months. Eventually, the antibodies break down, and the baby must rely on his or her own immune system. If the mother nurses her baby, antibodies (IgA) in the mother's milk may also provide some protection for the baby.

FUNDAMENTAL Figure

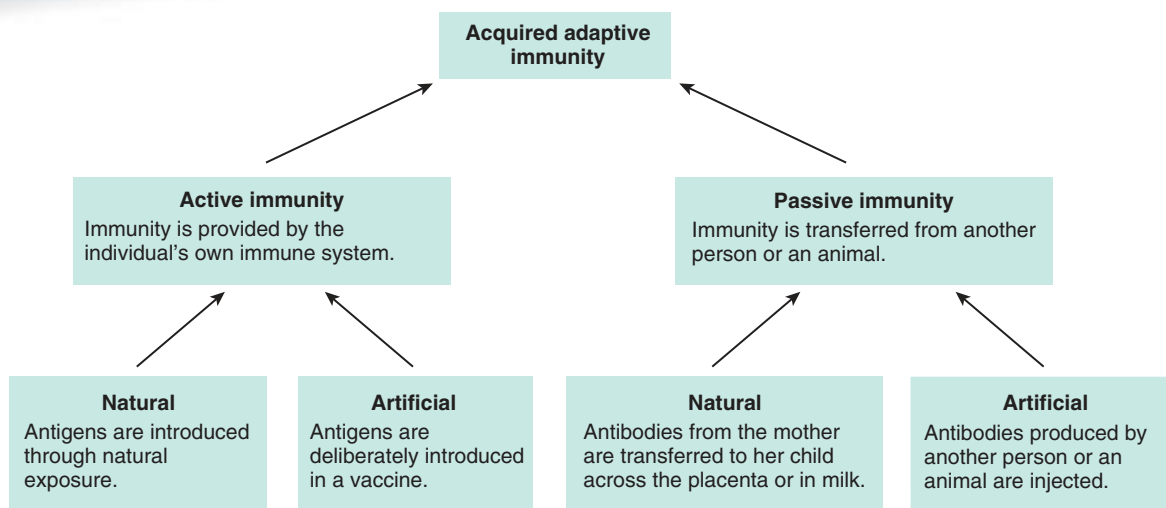

FIGURE 22.24 Ways to Acquire Adaptive Immunity

Passive Artificial Immunity

Achieving **passive artificial immunity** usually begins with vaccinating an animal, such as a horse. After the animal's immune system responds to the antigen, antibodies (and sometimes T cells) are removed from the animal and injected into the human requiring immunity. In some cases, a human who has developed immunity through natural exposure or vaccination can serve as a source of antibodies. Passive artificial immunity provides immediate protection for the individual receiving the antibodies and is therefore

preferred when time might not be available for the individual to develop his or her own immunity. However, this technique provides only temporary immunity because the antibodies are used or eliminated by the recipient.

Antiserum is the general term for the injection that contains antibodies responsible for passive artificial immunity. Antiserum is essentially blood serum, which is plasma minus the clotting factors. Antisera are available against microorganisms that cause diseases, such as rabies, hepatitis, and

Clinical IMPACT

Acquired Immunodeficiency Syndrome

Aquired immunodeficiency syndrome (AIDS) is a life-threatening disease caused by the **human immunodeficiency virus (HIV)**. HIV is transmitted from an infected person to a noninfected person in body fluids, such as blood, semen, or vaginal secretions. The major methods of transmission are through unprotected sexual contact, through contaminated needles used by intravenous drug users, through tainted blood products, and from a pregnant woman to her fetus. Evidence indicates that household, school, and work contacts do not result in transmission. Reduced exposure to HIV is the best prevention for its transmission. Practices such as abstinence, the use of latex condoms, monogamy, and avoiding sharing needles are effective ways to reduce exposure to HIV. Medical professionals should also use care when handling body fluids, such as wearing latex gloves.

HIV infection begins when a protein on the surface of the virus, called gp120, binds to a CD4 molecule on the surface of a cell. The CD4 molecule is found primarily on helper T cells, and it normally enables helper T cells to adhere to other lymphocytes—for example, during antigen presentation. Certain monocytes, macrophages, neurons, and glial cells also have CD4 molecules. Once attached to the CD4 molecules, the virus injects its genetic material (RNA) and enzymes into the cell and begins to replicate. Copies of the virus are manufactured using the organelles and materials within the cell. Replicated viruses escape from the cell and infect other cells.

Following infection by HIV, within 3 weeks to 3 months, many patients develop mononucleosis-like symptoms, such as fever, sweats, fatigue, muscle and joint aches, headache, sore throat, diarrhea, rash, and swollen lymph nodes. Within 1–3 weeks, these symptoms disappear as the immune system responds to the virus by producing antibodies and

activating cytotoxic T cells that kill HIV-infected cells. However, the immune system is not able to eliminate HIV completely, and by about 6 months a kind of “set point” is achieved in which the virus continues to replicate at a low but steady rate. This chronic stage of infection lasts, on average, 8–10 years, and the infected person feels good and exhibits few, if any, symptoms.

Although helper T cells are infected and destroyed during the chronic stage of HIV infection, the body responds by producing large numbers of helper T cells. Nonetheless, over a period of years the HIV numbers gradually increase, and helper T cell numbers decrease. Normally, approximately 1200 helper T cells are present per cubic millimeter of blood. An HIV-infected person is diagnosed with AIDS when one or more of the following conditions appear: The helper T cell count falls below 200 cells/mm³, an opportunistic infection occurs, or Kaposi sarcoma develops.

Opportunistic infections involve organisms that normally do not cause disease but do so when the immune system is depressed. Without helper T cells, cytotoxic T- and B-cell activation is impaired, and adaptive resistance is suppressed. Examples of opportunistic infections include pneumocystis (noo-mō-sis'tis) pneumonia (caused by an intracellular fungus, *Pneumocystis carinii*), tuberculosis (caused by an intracellular bacterium, *Mycobacterium tuberculosis*), syphilis (caused by a sexually transmitted bacterium, *Treponema pallidum*), candidiasis (kan-di-dī'ā-sis; a yeast infection of the mouth or vagina caused by *Candida albicans*), and protozoans that cause severe, persistent diarrhea. Kaposi sarcoma is a type of cancer that produces lesions in the skin, lymph nodes, and visceral organs. AIDS symptoms resulting from the effects of HIV on the nervous system include loss of motor activity, behavioral changes, progressive dementia, and possibly psychosis.

A cure for AIDS has yet to be discovered. Management of AIDS can be divided into two categories: (1) management of secondary infections or malignancies associated with AIDS and (2) control of HIV replication.

The first effective treatment of AIDS was the drug azidothymidine (AZT; az'i-dō-thī'mi-dēn), also called zidovudine (zī-dō'voo-dēn), which prevents HIV replication. AZT can delay the onset of AIDS but does not appear to increase the survival time of AIDS patients. However, the number of babies who contract AIDS from their HIV-infected mothers can be dramatically reduced by giving AZT to the mothers during pregnancy and to the babies following birth.

The current treatment for suppressing HIV replication is **highly active antiretroviral therapy (HAART)**. This therapy uses multiple drugs from at least two classes of antivirals. Treatment involves combining multiple drugs, because HIV is unlikely to develop resistance to all drugs. This strategy has proven very effective in reducing the death rate from AIDS and partially restoring health in some individuals.

Effective treatment for AIDS is not the same as a cure. Even if viral load decreases to the point that the virus is undetected in the blood, the virus still remains in cells throughout the body. The virus may eventually mutate and escape drug suppression. The long-term goal for deterring AIDS is to develop a vaccine that prevents HIV infection.

Because of improved treatment, people with HIV/AIDS can now live for many years. Thus, HIV/AIDS is being viewed increasingly as a chronic disease, not a death sentence. Working together, a multidisciplinary team of occupational therapists, physical therapists, nutritionists/dieticians, psychologists, infectious disease physicians, and others can help patients with HIV/AIDS have a better quality of life.

measles; bacterial toxins, such as those that cause tetanus, diphtheria, and botulism; and venoms from poisonous snakes and black widow spiders.

ASSESS YOUR PROGRESS

57. Distinguish between active and passive immunity.
58. State four general ways of acquiring adaptive immunity. Which two provide the longest-lasting immunity?
59. What type of immunity occurs when a child is given the chickenpox vaccine? What type of immunity does a nursing baby obtain?
60. What type of immunity occurs when a person is given the rabies antisera? What type of immunity occurs if a person had the chickenpox as a child?

22.7 Overview of Immune Interactions

LEARNING OUTCOME

After reading this section, you should be able to

- A. Explain how innate, antibody-mediated, and cell-mediated immunity can function together to eliminate an antigen.

Although the immune system can be described in terms of innate, antibody-mediated, and cell-mediated immunity, these categories are artificial divisions used to emphasize particular aspects of immunity. Actually, there is only one immune system, but its responses often involve components of more than one type of immunity (figure 22.25). For example, although adaptive immunity can recognize and remember specific antigens, once recognition has occurred the antigen is destroyed with the help of many innate immunity activities, including inflammation and phagocytosis.

ASSESS YOUR PROGRESS

61. Describe how interactions among innate, antibody-mediated, and cell-mediated immunity can protect the body from an antigen.

22.8 Immunotherapy

LEARNING OUTCOME

After reading this section, you should be able to

- A. Define and give examples of immunotherapy.

Knowledge of how the immune system operates has produced two fundamental benefits: (1) an understanding of the cause and

progression of many diseases and (2) the development or proposed development of methods to prevent, stop, or even reverse diseases. In this section, we discuss the second benefit, **immunotherapy**, which treats disease by altering immune system function or by directly attacking harmful cells. Some types of immunotherapy attempt to boost immune system function in general. For example, administering cytokines or other agents can promote inflammation and activate immune cells, which can help destroy tumor cells. On the other hand, sometimes inhibiting the immune system is helpful. For example, multiple sclerosis is an autoimmune disease in which the immune system treats self-antigens as foreign antigens, thereby destroying the myelin that covers axons. The cytokine interferon beta (IFN β) blocks the expression of MHC molecules that display self-antigens and is used to treat multiple sclerosis.

Some immunotherapy methods take a more specific approach. For example, vaccination can prevent many diseases (see section 22.6). The ability to produce monoclonal antibodies may result in effective treatments for tumors. If an antigen unique to tumor cells can be found, monoclonal antibodies can deliver radioactive isotopes, drugs, toxins, enzymes, or cytokines that kill the tumor cell directly or activate the immune system to kill the cell. Unfortunately, so far researchers have found no antigen on tumor cells that is not also present on normal cells. Nonetheless, this approach may be useful if damage to normal cells is minimal. For example, tumor cells may have more surface antigens of a particular type than normal cells, resulting in greater treatment delivery. Tumor cells may also be more susceptible to damage, or normal cells may be better able to recover from the treatment.

One problem with monoclonal antibody delivery systems is that the immune system recognizes the monoclonal antibody as a foreign antigen. After the first exposure, a memory response quickly destroys the monoclonal antibodies, rendering the treatment ineffective. In a process called **humanization**, the monoclonal antibodies are modified to resemble human antibodies. This approach has allowed monoclonal antibodies to sneak past the immune system.

Some uses of monoclonal antibodies to treat tumors are yielding promising results. For example, monoclonal antibodies with radioactive iodine (^{131}I) have caused the regression of B-cell lymphomas with few side effects. Herceptin, a monoclonal antibody, binds to a growth factor that is overexpressed in 25–30% of primary breast cancers. The antibodies “tag” cancer cells, which are then lysed by natural killer cells. Herceptin slows disease progression and increases survival time, but it is not a cure for breast cancer.

Many other immunotherapy approaches are being studied, and more treatments that use the immune system are sure to be developed.

Systems PATHOLOGY

Systemic Lupus Erythematosus

Background Information

Systemic lupus erythematosus (SLE) is an autoimmune disease, meaning that tissues and cells are damaged by the body's own immune system. The name describes the skin rash that is characteristic of the disease (figure 22A). The term *lupus* means "wolf" and originally referred to eroded (as if gnawed by a wolf) lesions of the skin. *Erythematosus* refers to redness of the skin resulting from inflammation.

In SLE, a large variety of antibodies are produced that recognize self-antigens, such as nucleic acids, phospholipids, coagulation factors, red blood cells, and platelets. The combination of the antibodies with self-antigens forms immune complexes that circulate throughout the body and are deposited in various tissues, where they stimulate inflammation and tissue destruction. Thus, SLE can affect many body systems, as the term *systemic* implies. For example, the most common antibodies act against DNA released from damaged cells. Normally, the liver removes the DNA, but sometimes DNA and antibodies form immune complexes that tend to be deposited in the kidneys and other tissues. Approximately 40–50% of individuals with SLE develop renal disease. In some cases, the antibodies can bind to antigens on cells, causing the cells to lyse. For example, antibodies binding to red blood cells cause hemolysis and anemia.

The cause of SLE is unknown. The most popular hypothesis suggests that a viral infection disrupts the function of regulatory T cells, resulting in loss of tolerance to self-antigens. The picture is probably more complicated, however, because not all SLE patients have reduced numbers of regulatory T cells. In addition, some patients have decreased numbers of the helper T cells that normally stimulate regulatory T-cell activity.

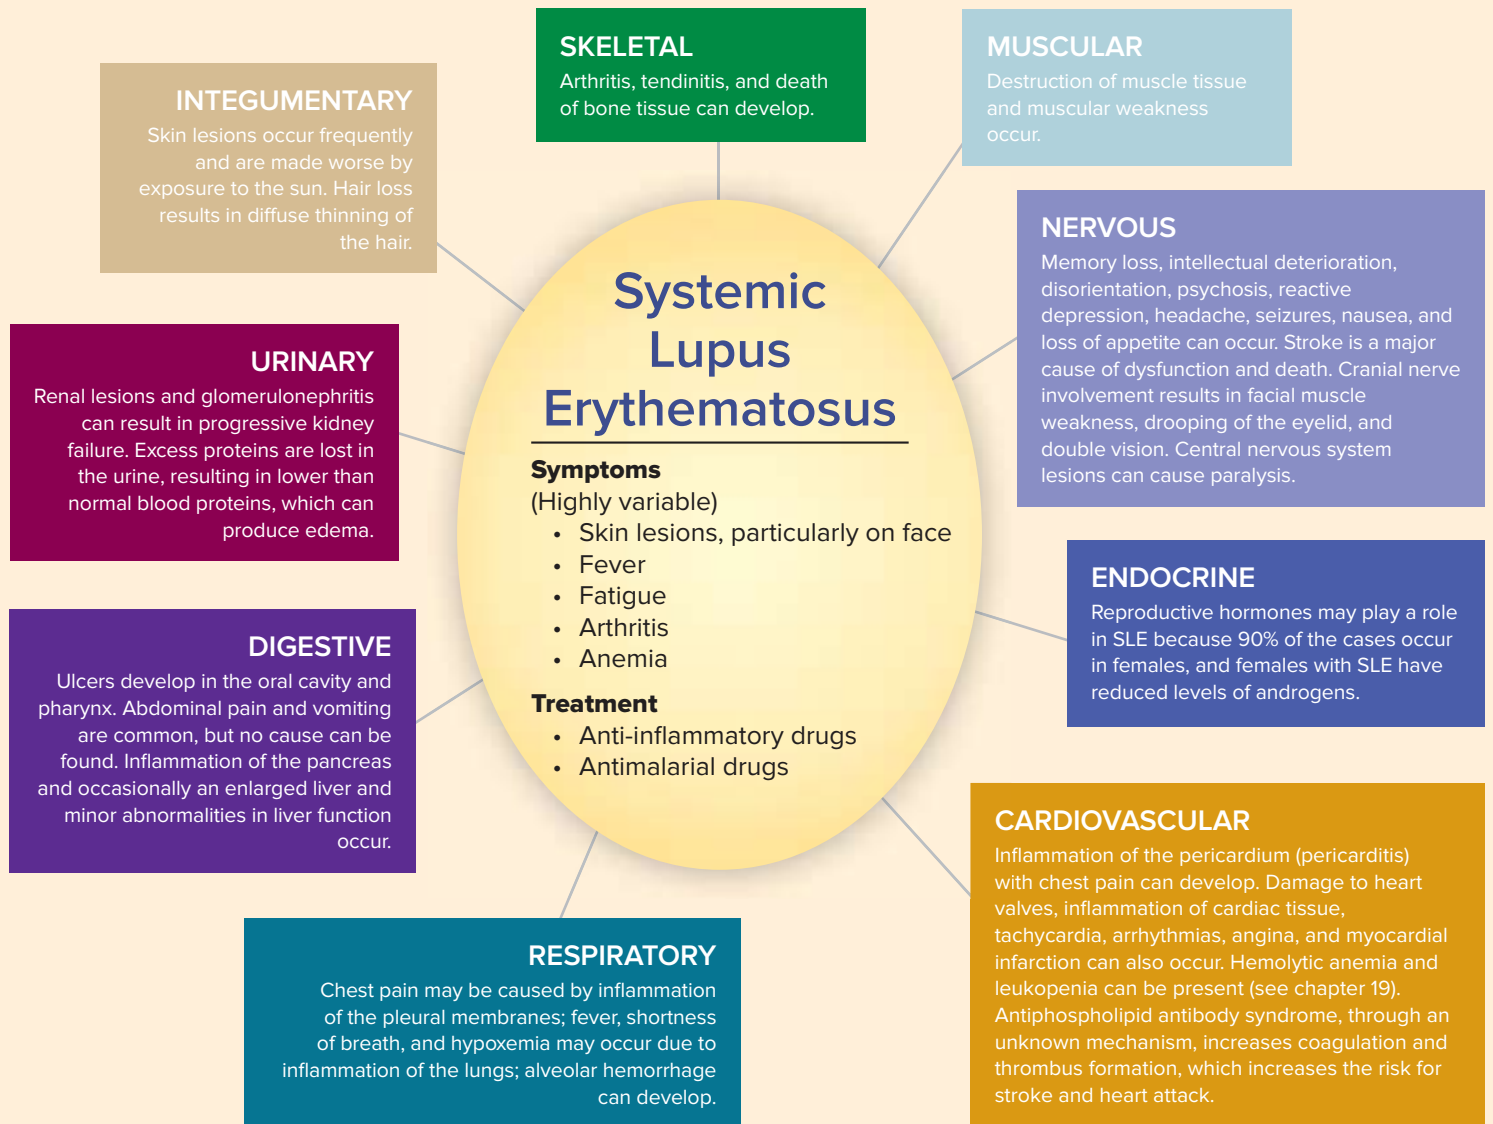

Genetic factors probably contribute to the development of the disease. The likelihood of developing SLE is much higher if a family member also has it. In addition, family members of SLE patients who do not have SLE are much more likely to have DNA antibodies than the general population does. Approximately 1 of every 2000 individuals in the United States has SLE. The first symptoms usually appear between 15 and 25 years of age and affect women approximately nine times as often as men. A low-grade fever is present in most cases of active SLE. The progress of the disease is unpredictable, with flare-ups followed by periods of remission. The survival after diagnosis is greater than 90% after 10 years. The most frequent causes of death are kidney failure, central nervous system dysfunction, infections, and cardiovascular disease.

No cure for SLE exists, nor is there one standard of treatment, because the course of the disease is highly variable and patient histories differ

Figure 22A Systemic Lupus Erythematosus

The butterfly rash results from inflammation in the skin.

widely. Treatment usually begins with mild medications and proceeds to increasingly potent therapies as conditions warrant. Aspirin and nonsteroidal anti-inflammatory drugs are used to suppress inflammation. Antimalarial drugs are prescribed to treat skin rash and arthritis in SLE, but the mechanism of action is unknown. Patients who do not respond to these drugs and those who have severe SLE are helped by glucocorticoids. Although glucocorticoids effectively treat inflammation, they can produce undesirable side effects, including suppression of normal adrenal

gland functions. In patients with life-threatening SLE, very high doses of glucocorticoids are used.

► Predict 9

The red lesion Lucy developed on her arm is called purpura (pūr'poo-ră), and it is caused by bleeding into the skin. The lesions gradually change color and disappear in 2–3 weeks. Explain how SLE produces purpura.

Diseases and Disorders

TABLE 22.6 Lymphatic System and Immunity

Condition	Description
LYMPHATIC SYSTEM	
Infections	
Lymphadenitis (lim-fad'ē-nī'tis)	Inflammation of the lymph nodes; lymph nodes become enlarged and tender as microorganisms are trapped and destroyed
Lymphangitis (lim-fan-jī'tis)	Inflammation of the lymphatic vessels; often results in visible red streaks in the skin that extend from the site of infection
Bubonic (bū-bon'ik) plague	Enlarged lymph nodes caused by bacterial infection (transferred by flea bites from rats); without treatment, bacteria enter the blood, and death occurs rapidly due to septicemia; known as the Black Death in the Middle Ages
Lymphedema (limf'e-dē'ma)	
Abnormal accumulation of lymph in tissues, often the limbs; 70–90% of cases in women; can be inherited or caused by developmental defects (primary lymphedema), disease, or damage to the lymphatic system (secondary lymphedema)	
Elephantiasis (el-ē-fan-tī'ā-sis)	Caused by long, slender roundworms transferred to humans by mosquito bites; adult worms lodge in lymphatic vessels and block lymph flow, so that a limb can become permanently swollen and enlarged; major cause of lymphedema worldwide
Lymphedema following cancer treatment	Caused by removal of lymph nodes near a tumor by surgery or radiation therapy; sentinel lymph nodes (those nearest the tumor) are first examined for cancer cells
Lymphoma (lim-fō'mā)	Cancer of lymphocytes that often begins in lymph nodes; immune system becomes depressed, with increased susceptibility to infections
IMMUNITY	
Immediate Hypersensitivities	
Symptoms occur within a few minutes of exposure to an antigen because antibodies are already present from prior exposure.	
Hay fever	Often caused by inhalation of plant pollen antigens
Asthma (az'mā)	Antigen combines with antibodies on mast cells or basophils in the lungs, which then release inflammatory chemicals that cause constriction of the air tubes, so that the patient has trouble breathing
Immune complex disease	Caused by excessive formation of immune complexes (combinations of antigens and IgG or IgM), which activate too much complement; results in acute inflammatory response and tissue damage; examples include serum sickness, some autoimmune diseases, chronic graft rejection, and Arthus reactions (localized reactions)
Urticaria (er'ti-kar'i-ā)	Skin rash or localized swelling; can be caused by an ingested antigen; also called hives
Anaphylaxis (an'ā-fī-lak'sis)	Systemic allergic reaction, often resulting from insect sting or drugs, such as penicillin; chemicals released from mast cells and basophils cause systemic vasodilation, increased vascular permeability, drop in blood pressure, and possibly death
Delayed Allergic Reactions	
Symptoms occur in hours to days following exposure to the antigen because these types of reactions involve migration of T cells to the antigen, followed by release of cytokines.	
Poison ivy and poison oak	Antigen absorbed by epithelial cells, which are then destroyed by T cells, causing inflammation and tissue destruction; itching can be intense
Autoimmune Diseases	
Similar to allergic reactions, except that the immune system incorrectly treats self-antigens as foreign antigens. Many types of autoimmune diseases exist, including type 1 diabetes, gluten-sensitive enteropathy, rheumatoid arthritis, multiple sclerosis, systemic lupus erythematosus, and Graves disease.	
Congenital Immunodeficiencies	
They usually involve failure of the fetus to form adequate numbers of B cells, T cells, or both.	
Severe combined immunodeficiency (SCID)	Both B cells and T cells fail to form; unless patient is kept in a sterile environment or provided with a compatible bone marrow transplant, death from infection results
Acquired Immunodeficiencies	
They have many causes—for example, diseases, stress, and drugs.	
Acquired immunodeficiency syndrome (AIDS)	Life-threatening disease caused by the human immunodeficiency virus (HIV); HIV is transmitted in body fluids; infection begins when the virus binds to the CD4 protein found primarily on helper T cells; without helper T cells, cytotoxic T-cell and B-cell activation is impaired, and adaptive immunity is suppressed; course of HIV infection varies, with most people surviving 10 or more years
Transplanted tissue rejection	Caused by a normal immune response to foreign antigens encoded by the major histocompatibility complex genes, also called human leukocyte antigen (HLA) genes; drugs that suppress the immune system must be administered for life to prevent graft rejection

22.9 Effects of Aging on the Lymphatic System and Immunity

LEARNING OUTCOME

After reading this section, you should be able to

A. Describe how aging affects the lymphatic system and immunity.

Aging appears to have little effect on the lymphatic system's ability to remove fluid from tissues, absorb lipids from the digestive tract, or remove defective red blood cells from the blood. However, aging has a severe impact on the adaptive immune system.

The thymus atrophies as a person ages, so it loses the ability to produce new T cells. By the age of 40, much of the thymus has been replaced with adipose tissue and, after age 60, the thymus decreases in size to the point that it can be difficult to detect. Although the number of T cells remains stable in most individuals due to the replication (not maturation) of T cells in secondary lymphatic tissues, the T cells are less functional. In many individuals, the ability of helper T cells to proliferate in response to antigens decreases. Thus, antigen exposure produces fewer helper T cells, which results in less stimulation of B cells and cytotoxic T cells. Consequently, both antibody-mediated immunity and cell-mediated immunity responses to antigens decrease.

Both primary and secondary antibody responses decrease with age. More antigen is required to produce a response, the response is slower, less antibody is produced, and fewer memory cells result. Thus, a person's ability to resist infections and

develop immunity decreases. Because these declines are most evident after age 60, it is recommended that regular vaccinations be given well before that age. However, vaccinations can be beneficial at any age, especially if the individual has reduced resistance to infection. For example, the elderly are more susceptible to influenza (flu) and should be vaccinated every year.

The ability of cell-mediated immunity to resist intracellular pathogens also decreases with age. Some pathogens cause disease but are not eliminated from the body; with age, decreased immunity can lead to reactivation of the pathogen. An example is the virus that causes chickenpox in children, which can remain latent within neurons, even if the disease seems to have disappeared. Later in life, the virus can leave the neurons and infect skin cells, causing painful lesions known as herpes zoster, or shingles.

Autoimmune disease occurs when immune responses destroy otherwise healthy tissue. There is very little increase in the number of new-onset autoimmune diseases in the elderly. However, the chronic inflammation and immune responses that begin earlier in life have a cumulative, damaging effect. Likewise, the increased incidence of cancer is likely to be caused primarily by repeated exposure to and damage from cancer-causing agents rather than by decreased immunity.

ASSESS YOUR PROGRESS

63. What effect does aging have on the major functions of the lymphatic system?
64. Describe the effects of aging on B cells and T cells. Give examples of how they affect antibody-mediated and cell-mediated immune responses.

Answer

Learn to Predict ◀ From page 779

Maddie was correct; she was having an allergic, or hypersensitivity, reaction to one of the chemicals sprayed on the trees. After reviewing the Diseases and Disorders table in this chapter, we can conclude that her symptoms are most consistent with a delayed hypersensitivity response, since the itching and swelling did not occur until a day after she had been exposed to the chemicals. The chemicals on the leaves acted as haptens and combined with proteins, which were processed by the MHC class I processing

system in the skin cells of her hands. In this chapter we learned that cytotoxic T cells can combine with MHC class I molecules on the surface of skin cells, destroying the cells. In addition, cytokines are released that attract macrophages to the area, thereby enhancing phagocytosis and inflammation.

Answers to the rest of this chapter's Predict questions appear in appendix G.

Summary

22.1 Functions of the Lymphatic System (p. 780)

The lymphatic system maintains fluid balance in tissues, absorbs lipids from the small intestine, and defends against microorganisms and foreign substances.

22.2 Anatomy of the Lymphatic System (p. 780)

The lymphatic system consists of lymph, lymphatic vessels, lymphatic tissue, lymphatic nodules, lymph nodes, the tonsils, the spleen, and the thymus.

Lymphatic Vessels

- Lymphatic vessels carry lymph away from tissues.
- Lymphatic capillaries lack a basement membrane and have loosely overlapping epithelial cells. Fluids and other substances easily enter lymphatic capillaries.
- Lymphatic capillaries join to form lymphatic vessels.
 - Lymphatic vessels have valves that ensure a one-way flow of lymph.
 - Contraction of lymphatic vessel smooth muscle, contraction of skeletal muscle, and thoracic pressure changes move the lymph.
- Lymph nodes are found along the lymphatic vessels. After passing through lymph nodes, lymphatic vessels form lymphatic trunks and lymphatic ducts.
- Lymphatic trunks and ducts empty into the blood at thoracic veins (junctions of the internal jugular and subclavian veins).
 - Lymph from the right thorax, the right-upper limb, and the right side of the head and the neck enters the right thoracic veins.
 - Lymph from the lower limbs, pelvis, and abdomen; the left thorax; the left-upper limb; and the left side of the head and the neck enters the left thoracic veins.
- The jugular, subclavian, and bronchomediastinal trunks may unite to form the right lymphatic duct.
- The thoracic duct is the largest lymphatic vessel.
- The intestinal and lumbar trunks may converge on the cisterna chyli, a sac that joins the inferior end of the thoracic duct.

Lymphatic Tissue and Organs

- Lymphatic tissue is reticular connective tissue that contains lymphocytes and other cells.
- Lymphatic tissue can be surrounded by a capsule (lymph nodes, spleen, thymus).
- Lymphatic tissue can be nonencapsulated (diffuse lymphatic tissue, lymphatic nodules, tonsils). Mucosa-associated lymphoid tissue (MALT) is nonencapsulated lymphatic tissue located in and below the mucous membranes of the digestive, respiratory, urinary, and reproductive tracts.
- Diffuse lymphatic tissue consists of dispersed lymphocytes and has no clear boundaries.
- Lymphatic nodules are small aggregates of lymphatic tissue (e.g., Peyer patches in the small intestine).
- The tonsils
 - The tonsils are large groups of lymphatic nodules in the oral cavity and nasopharynx.
 - The three groups of tonsils are the palatine, pharyngeal, and lingual tonsils.
- Lymph nodes
 - Lymphatic tissue in the lymph node is organized into the cortex and the medulla. Lymphatic sinuses extend through the lymphatic tissue.
 - Substances in lymph are removed by phagocytosis, or they stimulate lymphocytes (or both).
 - Lymphocytes leave the lymph nodes and circulate to other tissues.
- The spleen
 - The spleen is in the left superior side of the abdomen.
 - Foreign substances stimulate lymphocytes in the white pulp of the spleen (periarterial lymphatic sheath and lymphatic nodules).
 - Foreign substances and defective red blood cells are removed from the blood by phagocytes in the red pulp of the spleen (splenic cords and venous sinuses).
 - The spleen is a limited reservoir for blood.

- The thymus
 - The thymus is a gland in the superior mediastinum and is divided into a cortex and a medulla.
 - Lymphocytes in the cortex are separated from the blood by reticular cells.
 - Lymphocytes produced in the cortex migrate through the medulla, enter the blood, and travel to other lymphatic tissues, where they can proliferate.

Overview of the Lymphatic System

See figure 22.9.

22.3 Immunity (p. 788)

Immunity is the ability to resist the harmful effects of microorganisms and other foreign substances.

22.4 Innate Immunity (p. 790)

Physical Barriers

Physical barriers prevent the entry of microbes (skin and mucous membranes) or remove them (tears, saliva, and mucus).

Chemical Mediators

- Chemical mediators promote phagocytosis and inflammation.
- Complement can be activated by either the alternative or the classical pathway. Complement lyses cells, increases phagocytosis, attracts immune system cells, and promotes inflammation.
- Interferons prevent viral replication. Interferons are produced by virally infected cells and move to other cells, which are then protected.

White Blood Cells

- Chemotactic factors are parts of microorganisms or chemicals that are released by damaged tissues. Chemotaxis is the ability of white blood cells to move to tissues that release chemotactic factors.
- Phagocytosis is the ingestion and destruction of materials.
- Neutrophils are small phagocytic white blood cells.
- Macrophages are large phagocytic white blood cells.
 - Macrophages can engulf more than neutrophils can.
 - Macrophages in connective tissue protect the body at locations where microbes are likely to enter, and macrophages clean blood and lymph.
- Basophils and mast cells release chemicals that promote inflammation.
- Eosinophils defend against parasitic worms.
- Natural killer cells lyse tumor cells and virus-infected cells.

Inflammatory Response

- The inflammatory response can be initiated in many ways.
 - Chemical mediators cause vasodilation and increase vascular permeability, which allows the entry of other chemical mediators.
 - Chemical mediators attract phagocytes.
 - The numbers of chemical mediators and phagocytes increase until the cause of the inflammation is destroyed. Then the tissue undergoes repair.
- Local inflammation produces redness, heat, swelling, pain, and loss of function. Symptoms of systemic inflammation include an increase in neutrophil numbers, fever, and shock.

22.5 Adaptive Immunity (p. 794)

1. Antigens are large molecules that stimulate an adaptive immune response.
2. B cells are responsible for antibody-mediated immunity. T cells are involved with cell-mediated immunity.

Origin and Development of Lymphocytes

1. B cells and T cells originate in red bone marrow. T cells are processed in the thymus, and B cells are processed in bone marrow.
2. Positive selection ensures the survival of lymphocytes that can react against antigens, and negative selection eliminates lymphocytes that react against self-antigens.
3. A clone is a group of identical lymphocytes that can respond to a specific antigen.
4. B cells and T cells move to lymphatic tissue from their processing sites. They continually circulate from one lymphatic tissue to another.
5. The primary lymphatic organs (red bone marrow and the thymus) are where lymphocytes mature into functional cells. Secondary lymphatic organs and tissues are where lymphocytes produce an immune response.

Activation of Lymphocytes

1. The antigenic determinant is the specific part of the antigen to which the lymphocyte responds. The antigen receptor (T-cell receptor or B-cell receptor) on the surface of lymphocytes combines with the antigenic determinant.
2. MHC class I molecules display antigens on the surface of nucleated cells, resulting in the destruction of the cells.
3. MHC class II molecules display antigens on the surface of antigen-presenting cells, resulting in the activation of immune cells.
4. MHC-antigen complex and costimulation are usually necessary to activate lymphocytes. Costimulation involves cytokines and certain surface molecules.
5. Antigen-presenting cells stimulate the proliferation of helper T cells, which stimulate the proliferation of B cells or cytotoxic T cells.

Inhibition of Lymphocytes

1. Tolerance is suppression of the immune system's response to an antigen.
2. Tolerance is produced by the deletion of self-reactive cells, by the prevention of lymphocyte activation, and by the activation of regulatory T cells.

Antibody-Mediated Immunity

1. Antibodies are proteins.
 - The variable region of an antibody combines with the antigen. The constant region activates complement or binds to cells.
 - Five classes of antibodies exist: IgG, IgM, IgA, IgE, and IgD.
2. Antibodies affect the antigen in many ways.
 - Antibodies bind to the antigen and interfere with antigen activity or bind the antigens together.
 - Antibodies act as opsonins (substances that increase phagocytosis) by binding to the antigen and to macrophages.

- Antibodies can activate complement through the classical pathway.
 - Antibodies attach to mast cells or basophils and cause the release of inflammatory chemicals when the antibody combines with the antigen.
3. The primary response results from the first exposure to an antigen. B cells form plasma cells, which produce antibodies, and memory B cells.
 4. The secondary response results from exposure to an antigen after a primary response, and memory B cells quickly form plasma cells and additional memory B cells.

Cell-Mediated Immunity

1. Cells infected with intracellular microorganisms process antigens that combine with MHC class I molecules.
2. Cytotoxic T cells are stimulated to divide, producing more cytotoxic T cells and memory T cells, when MHC class I/antigen complexes are presented to T-cell receptors. Cytokines released from helper T cells also stimulate cytotoxic T cells.
3. Cytotoxic T cells lyse virus-infected cells, tumor cells, and tissue transplants.
4. Cytotoxic T cells produce cytokines, which promote phagocytosis and inflammation.

22.6 Acquired Adaptive Immunity (p. 808)

1. Active natural immunity results from natural exposure to an antigen.
2. Active artificial immunity results from deliberate exposure to an antigen.
3. Passive natural immunity results from the transfer of antibodies from a mother to her fetus or baby.
4. Passive artificial immunity results from the transfer of antibodies (or cells) from an immune animal to a nonimmune animal.

22.7 Overview of Immune Interactions (p. 812)

Innate immunity, antibody-mediated immunity, and cell-mediated immunity can function together to eliminate an antigen.

22.8 Immunotherapy (p. 812)

Immunotherapy treats diseases by stimulating or inhibiting the immune system.

22.9 Effects of Aging on the Lymphatic System and Immunity (p. 817)

1. Aging has little effect on the lymphatic system's ability to remove fluid from tissues, absorb lipids from the digestive tract, or remove defective red blood cells from the blood.
2. Decreased helper T-cell proliferation results in decreased antibody-mediated and cell-mediated immune responses to antigens.
3. Primary and secondary antibody responses decrease with age.
4. The ability to resist intracellular pathogens decreases with age.

REVIEW AND COMPREHENSION

1. The lymphatic system
 - a. removes excess fluid from tissues.
 - b. absorbs lipids from the digestive tract.
 - c. defends the body against microorganisms and other foreign substances.
 - d. All of these are correct.
2. Which of the following statements is correct?
 - a. Lymphatic vessels do not have valves.
 - b. Lymphatic vessels empty into lymph nodes.
 - c. Lymph from the right-lower limb passes into the right jugular or subclavian vein.

- d. Lymph from the jugular and subclavian trunks empties into the cisterna chyli.
e. All of these are correct.
3. The tonsils
a. consist of large groups of lymphatic nodules.
b. protect against bacteria.
c. can become chronically infected.
d. decrease in size in adults.
e. All of these are correct.
4. Lymph nodes
a. filter lymph.
b. are where lymphocytes divide and increase in number.
c. contain a network of reticular fibers.
d. contain lymphatic sinuses.
e. All of these are correct.
5. Which of these statements about the spleen is *not* correct?
a. The spleen has white pulp associated with the arteries.
b. The spleen has red pulp associated with the veins.
c. The spleen destroys defective red blood cells.
d. The spleen is surrounded by trabeculae located outside the capsule.
e. The spleen is a limited reservoir for blood.
6. The thymus
a. increases in size in adults.
b. produces lymphocytes that move to other lymphatic tissue.
c. is located in the abdominal cavity.
d. All of these are correct.
7. Which of these is an example of innate immunity?
a. Tears and saliva wash away microorganisms.
b. Basophils release histamine and leukotrienes.
c. Neutrophils phagocytize a microorganism.
d. The complement cascade is activated.
e. All of these are correct.
8. Neutrophils
a. enlarge to become macrophages.
b. account for most of the dead cells in pus.
c. are usually the last cell type to enter infected tissues.
d. are usually located in lymphatic and blood sinuses.
9. Macrophages
a. are large, phagocytic cells that outlive neutrophils.
b. develop from mast cells.
c. often die after a single phagocytic event.
d. have the same function as eosinophils.
e. All of these are correct.
10. Which of these cells is the most important in the release of histamine, which promotes inflammation?
a. monocyte
b. macrophage
c. eosinophil
d. mast cell
e. natural killer cell
11. Which of these conditions does *not* occur during the inflammatory response?
a. release of histamine and other chemical mediators
b. chemotaxis of phagocytes
c. entry of fibrinogen into tissues from the blood
d. vasoconstriction of blood vessels
e. increased permeability of blood vessels
12. Antigens
a. are foreign substances introduced into the body.
b. are molecules produced by the body.
c. stimulate an adaptive immune system response.
d. All of these are correct.
13. B cells
a. are processed in the thymus.
b. originate in red bone marrow.
c. once released into the blood remain in the blood.
d. are responsible for cell-mediated immunity.
e. All of these are correct.
14. MHC molecules
a. are glycoproteins.
b. attach to the plasma membrane.
c. have a variable region that can bind to foreign antigens and self-antigens.
d. may form an MHC-antigen complex that activates T cells.
e. All of these are correct.
15. Antigen-presenting cells can
a. take in foreign antigens.
b. process antigens.
c. use MHC class II molecules to display the antigens.
d. stimulate other immune system cells.
e. All of these are correct.
16. Which of these participates in costimulation?
a. cytokines d. histamine
b. complement e. natural killer cells
c. antibodies
17. Helper T cells
a. respond to antigens from macrophages.
b. respond to cytokines from macrophages.
c. stimulate B cells with cytokines.
d. All of these are correct.
18. The most important function of tolerance is to
a. increase lymphocyte activity.
b. increase complement activation.
c. prevent the immune system from responding to self-antigens.
d. prevent excessive immune response to foreign antigens.
e. process antigens.
19. Variable amino acid sequences on the arms of the antibody molecule
a. make the antibody specific for a given antigen.
b. enable the antibody to activate complement.
c. enable the antibody to attach to basophils and mast cells.
d. are part of the constant region.
e. All of these are correct.
20. Antibodies
a. prevent antigens from binding together.
b. promote phagocytosis.
c. inhibit inflammation.
d. block complement activation.
e. block the function of opsonins.
21. The secondary antibody response
a. is slower than the primary response.
b. produces fewer antibodies than the primary response.
c. prevents disease symptoms from occurring.
d. occurs because of cytotoxic T cells.

22. The type of lymphocyte responsible for the secondary antibody response is the
- memory B cell.
 - B cell.
 - T cell.
 - helper T cell.
23. The largest percentage of antibodies in the blood are
- IgA.
 - IgD.
 - IgE.
 - IgG.
 - IgM.
24. Antibody-mediated immunity
- works best against intracellular antigens.
 - regulates the activity of T cells.
 - cannot be transferred from one person to another.
 - is responsible for immediate hypersensitivity reactions.
25. The activation of cytotoxic T cells can result in
- lysis of virus-infected cells.
 - production of cytokines.
 - production of memory T cells.
 - All of these are correct.

Answers in appendix E

CRITICAL THINKING

- A patient is suffering from edema in the right-lower limb. Explain why elevating and massaging the limb help remove the excess fluid.
- If the thymus of an experimental animal is removed immediately after its birth, the animal exhibits the following characteristics: (a) an increased susceptibility to infections, (b) decreased numbers of lymphocytes in lymphatic tissue, and (c) a greatly decreased ability to reject grafts. Explain these observations.
- If the thymus of an adult experimental animal is removed, the following observations can be made: (a) No immediate effect occurs, and (b) after 1 year, decreases occur in the number of lymphocytes in the blood, the ability to reject grafts, and the ability to produce antibodies. Explain these observations.
- Adjuvants are substances that slow but do not stop the release of an antigen from an injection site into the blood. Suppose injection A is given without an adjuvant and injection B of the same amount of antigen is given with an adjuvant that causes antigen to be released over a period of 2–3 weeks. Does injection A or injection B result in the greater amount of antibody production? Explain.
- Tetanus is caused by bacteria that enter the body through wounds in the skin. The bacteria produce a toxin that causes spastic muscle contractions. Death often results from failure of the respiratory muscles. A patient goes to the emergency room after stepping on a nail. If the patient has been vaccinated against tetanus, he or she is given a tetanus booster shot, which consists of the toxin altered so that it is harmless. A patient who has never been vaccinated against tetanus is given an antiserum shot against tetanus. Explain the rationale for this treatment strategy. Sometimes both a booster and an antiserum shot are given, but at different locations on the body. Explain why both vaccinations are given and why they are injected in different locations.
- An infant appears healthy until about 9 months of age, when he develops severe bacterial infections, one after another. Fortunately, the infections are treated successfully with antibiotics. When infected with the measles and other viral diseases, the infant recovers without unusual difficulty. Explain the different immune responses to these infections. Why did it take so long for this disorder to become apparent? (*Hint: Consider IgG.*)
- A patient has many allergic reactions. As part of the treatment scheme, doctors try to identify the allergen that stimulates the immune system's response. A series of solutions, each containing an allergen that commonly causes a reaction, is composed. Each solution is injected into the skin at different locations on the patient's back. The following results are obtained: (a) At one location, the injection site becomes red and swollen within a few minutes; (b) at another injection site, swelling and redness appear 2 days later; and (c) no redness or swelling develops at the other sites. Explain what happened for each observation by describing what part of the immune system was involved and what caused the redness and swelling.
- Ivy Hurtt developed a poison ivy rash after a camping trip. Her doctor prescribed a cortisone ointment to relieve the inflammation. A few weeks later, Ivy scraped her elbow, which became inflamed. Because she had some of the cortisone ointment left over, she applied it to the scrape. Was the ointment an effective treatment for the poison ivy? Was the ointment an appropriate treatment for the scrape?
- Billie Boards was riding her skateboard down a newly paved road from the top of a hill. Part of the way down, she fell and skinned her knees on the asphalt. From the following list, choose the immune response(s) that occurred in the next several hours.
 - increased capillary permeability
 - chemotaxis of neutrophils
 - coagulation
 - release of mediators of inflammation
 - increased mitosis of B lymphocytes

a. 1,2,3,4,5 b. 1,2,3,4 c. 1,2,3 d. 1,2
- Upon first exposure to an antigen, a sequence of events results in antigen processing and an increase in the number of helper T cells. Given the following list of events, select the sequence that results in an increased number of helper T cells.
 - Unprocessed extracellular antigen is ingested by a macrophage.
 - The MHC II complex is presented at the cell surface.
 - Costimulation occurs.
 - Interleukin-1 is released from macrophages, and interleukin-2 is released from T lymphocytes.
 - A specific helper T cell recognizes and binds to the MHC II complex.
 - Mitosis of helper T cells takes place.
 - The ingested antigen is broken down to fragments.
 - The processed antigen and MHC II molecules are joined and transported to the cell surface.

Learn to Predict

Flashing lights at 2 a.m. alerted the neighbors that something was wrong at the Theron home. Mr. Theron, who has moderate emphysema, could not stop coughing, so his wife called 911. In the emergency room, a physician listened to Mr. Theron's respiratory sounds and concluded that his left lung had collapsed. **By using some information about the peripheral circulation from chapter 21 and reading this chapter, explain how emphysema affected Mr. Theron's breathing, what caused his lung to collapse, and how the physician was able to detect the collapsed lung.**

Respiratory System

If you've ever had a severe chest cold, bronchitis, or pneumonia, you might be able to relate to what Mr. Theron of this chapter's "Learn to Predict" experienced when his left lung collapsed. If we stop breathing, or breathing becomes difficult, within seconds we feel a strong need for air. From our first breath at birth, the rate and depth of our breathing are unconsciously matched to our activities, whether studying, sleeping, talking, eating, or exercising. Breathing is so characteristic of life that, along with the pulse, it is one of the first vital signs checked to determine whether an unconscious person is alive.

Breathing is necessary because all living cells of the body require oxygen and produce carbon dioxide. The respiratory system exchanges these gases between the air and the blood, and the cardiovascular system transports them between the lungs and the body cells. Without healthy respiratory and cardiovascular systems, the capacity to carry out normal activity is reduced.

Photo: Colorized scanning electron micrograph of the lung, showing alveoli, which are small air chambers where gas exchange takes place between the air and the blood.

23.1 Functions of the Respiratory System

LEARNING OUTCOME

After reading this section, you should be able to

A. Describe the functions of the respiratory system.

Breathing is critical for homeostasis. It provides our bodies with crucial oxygen and expels carbon dioxide, a potentially toxic waste product. Our respiratory system helps us breathe. Breathing is formally called **respiration**. For complete exchange of oxygen (O_2) and carbon dioxide (CO_2) in respiration, four steps occur simultaneously:

1. *Ventilation*. This is what most of us think of as breathing. It is the movements of the thorax and certain muscles that cause air to go into and out of our lungs.
2. *External respiration*. Oxygen enters the blood in the lungs and CO_2 exits the blood in the lungs.
3. *Gas transport*. Carbon dioxide and O_2 are circulated in the blood to and from tissues.
4. *Internal respiration*. Gas exchange with the tissues involves the exit of O_2 from blood to move into the tissues, while CO_2 exits the tissues to enter the blood.

It can be confusing to hear the term *respiration* alone because sometimes it also refers to cellular metabolism, or **cellular respiration** (discussed in chapter 25); in fact, the two processes are related. Breathing provides the O_2 needed in cellular respiration to make ATP from glucose. Breathing also rids the body of potentially toxic CO_2 , the waste produced during cellular respiration.

In addition to respiration, the respiratory system performs the following functions:

1. *Regulation of blood pH*. The respiratory system can alter blood pH by changing blood CO_2 levels.
2. *Production of chemical mediators*. The lungs produce an enzyme called angiotensin-converting enzyme (ACE), which is an important component of blood pressure regulation (discussed in chapter 26).
3. *Voice production*. Air moving past the vocal folds makes sound and speech possible.
4. *Olfaction*. The sensation of smell occurs when airborne molecules are drawn into the nasal cavity (discussed in chapter 15).
5. *Protection*. The respiratory system provides protection against some microorganisms by preventing them from entering the body and removing them from respiratory surfaces.

ASSESS YOUR PROGRESS

1. What are the four steps of respiration?
2. Explain the functions of the respiratory system.

23.2 Anatomy and Histology of the Respiratory System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the anatomy of the respiratory passages, beginning at the nose and ending with the alveoli.
- B. Describe the structural and functional anatomy of the respiratory system.
- C. State the parts of the respiratory membrane.
- D. Describe the structure of the lungs, including the blood and lymphatic supply.
- E. Explain the roles of the thoracic wall and the pleura in respiration.
- F. Explain how contraction of the muscles of respiration causes changes in thoracic volume during quiet breathing and during labored breathing.

There are seven structures that make up the respiratory system: the external nose, the nasal cavity, the pharynx (the throat), the larynx (the voicebox), the trachea (the windpipe), the bronchi (branches of the trachea), and the lungs (figure 23.1). The diaphragm and the muscles of the thoracic and abdominal walls are responsible for respiratory movements. (Although air frequently passes through it, the oral cavity is considered part of the digestive system rather than the respiratory system.) The respiratory system can be

FIGURE 23.1 Respiratory System

The upper respiratory tract consists of the external nose, the nasal cavity, the pharynx (throat) and its associated structures, and the larynx. The lower respiratory tract consists of the trachea, the bronchi and smaller bronchioles, and the lungs. **APR**

classified in two ways: structurally and functionally. Structurally, the respiratory system is divided into the upper respiratory tract and the lower respiratory tract. The **upper respiratory tract** includes the external nose, the nasal cavity, the pharynx with its associated structures, and the larynx; the **lower respiratory tract** includes the trachea, the bronchi and smaller bronchioles, and the lungs. However, these are not official anatomical terms, and they have several alternate definitions. For example, one classification system places the larynx in the lower respiratory tract.

Functionally, the respiratory system is divided into two regions. The **conducting zone** is exclusively for air movement and extends from the nose to the bronchioles. The **respiratory zone** is within the lungs and is where gas exchange between air and blood takes place.

Conducting Zone

The conducting zone structures are well adapted for the movement, cleaning, warming, and humidification of air. Air is simply moved from the external environment to areas deep inside the lungs, which are in contact with blood capillaries.

Nose

The **nose**, or *nasus* (nā'sūs), consists of the external nose and the nasal cavity. The **external nose** is the visible structure that forms a prominent feature of the face. The largest part of the external nose is composed of hyaline cartilage plates (see figure 7.9b). The nasal bones plus extensions of the frontal and maxillary bones constitute the *bridge* of the nose, which is where eyeglasses would rest.

The **nasal cavity** is the open chamber inside the nose where air first enters the respiratory system. It extends from the anterior structures called the **nares** (nā'res; sing. naris), or *nostrils*, to the posterior structures called **choanae** (kō'an-ē; figure 23.2). The nares are the external openings of the nasal cavity. Just inside each naris, in the anterior part of the nasal cavity, is the region called the **vestibule** (ves'ti-bool; entry room). The vestibule is lined with stratified squamous epithelium, which is continuous with the stratified squamous epithelium of the skin. The choanae in the posterior part of the nasal cavity are the openings into the pharynx. The **hard palate** (pal'ăt) is the anterior portion of the roof of the mouth. It is formed by the palatine process of the maxillae and the palatine bone. It is covered by a highly vascular mucous membrane that forms the floor of the nasal cavity. It separates the nasal cavity from the oral cavity. The nasal cavity is divided into right and left halves by a partition called the **nasal septum**. The anterior part of the nasal septum is composed of cartilage, while the posterior part consists of the vomer bone and the perpendicular plate of the ethmoid bone. A deviated nasal septum occurs when the septum bulges to one side (see figure 7.9a).

There are three lateral bony ridges called **conchae** (kon'kē; resembling a conch shell) on each side of the nasal cavity. The conchae used to be named the turbinate bones because they act as “wind turbines,” helping the air churn through the nasal cavity. The air passes through tunnels beneath each concha. Each of these tunnels is called a **meatus** (mē-ā'tūs; tunnel or passageway). Within the superior and middle meatuses are openings from the various **paranasal sinuses** (see figure 7.10). Each inferior meatus also contains the opening of a **nasolacrimal** (nā-zō-lak'ri-māl) **duct** for tear drainage from the surface of the eye (see figure 15.10).

In addition to air movement into the respiratory system, the nasal cavity has several other functions. The five functions of the nasal cavity are the following:

1. *Serves as a passageway for air.* The nasal cavity remains open even when the mouth is full of food.
2. *Cleans the air.* The vestibule is lined with hairs, which trap some of the large particles of dust in the air. The nasal septum and nasal conchae increase the surface area of the nasal cavity and make airflow within the cavity more turbulent, thereby increasing the likelihood that air will come into contact with the mucous membrane lining the nasal cavity. This mucous membrane consists of pseudostratified ciliated columnar epithelium with goblet cells. The goblet cells secrete mucus, which traps debris in the air. The cilia on the surface of the mucous membrane sweep the mucus posteriorly to the pharynx, where it is swallowed and eliminated by the acidic stomach of the digestive system.
3. *Humidifies and warms the air.* Moisture from the mucous epithelium and from excess tears that drain into the nasal cavity through the nasolacrimal duct is added to the air as it passes through the nasal cavity. Warm blood flowing through the mucous membrane warms the air within the nasal cavity before it passes into the pharynx, thus preventing damage to the rest of the respiratory passages due to cold air.
4. *Contains the olfactory epithelium.* The olfactory epithelium, the sensory organ for smell, is located in the most superior part of the nasal cavity (see figure 15.1).
5. *Helps determine voice sound.* The nasal cavity and paranasal sinuses are resonating chambers for speech. For example, most people know immediately when you have a cold because your voice sounds different.

Pharynx

The **pharynx** (far'ingks; throat) is the common opening of both the digestive and the respiratory systems. It receives air from the nasal cavity and receives air, food, and drink from the oral cavity. Inferiorly, the pharynx is connected to the respiratory system at

Clinical IMPACT

Sinusitis

Sinusitis (sī-nū-sī'tis) is inflammation of sinus mucous membranes, especially those of the paranasal sinuses. Viral infections, such as the common cold, can cause mucous membranes to become inflamed and swollen and to produce excess mucus. As a result, the sinus opening into the nasal cavity is partially or completely blocked, allowing mucus to accumulate within the sinus, which can promote a bacterial infection. Treatments include taking antibiotics and using decongestants, hydration, and steam inhalation to promote sinus drainage. Sinusitis can also result from swelling caused by allergies or by polyps that obstruct the sinus opening into the nasal cavity.

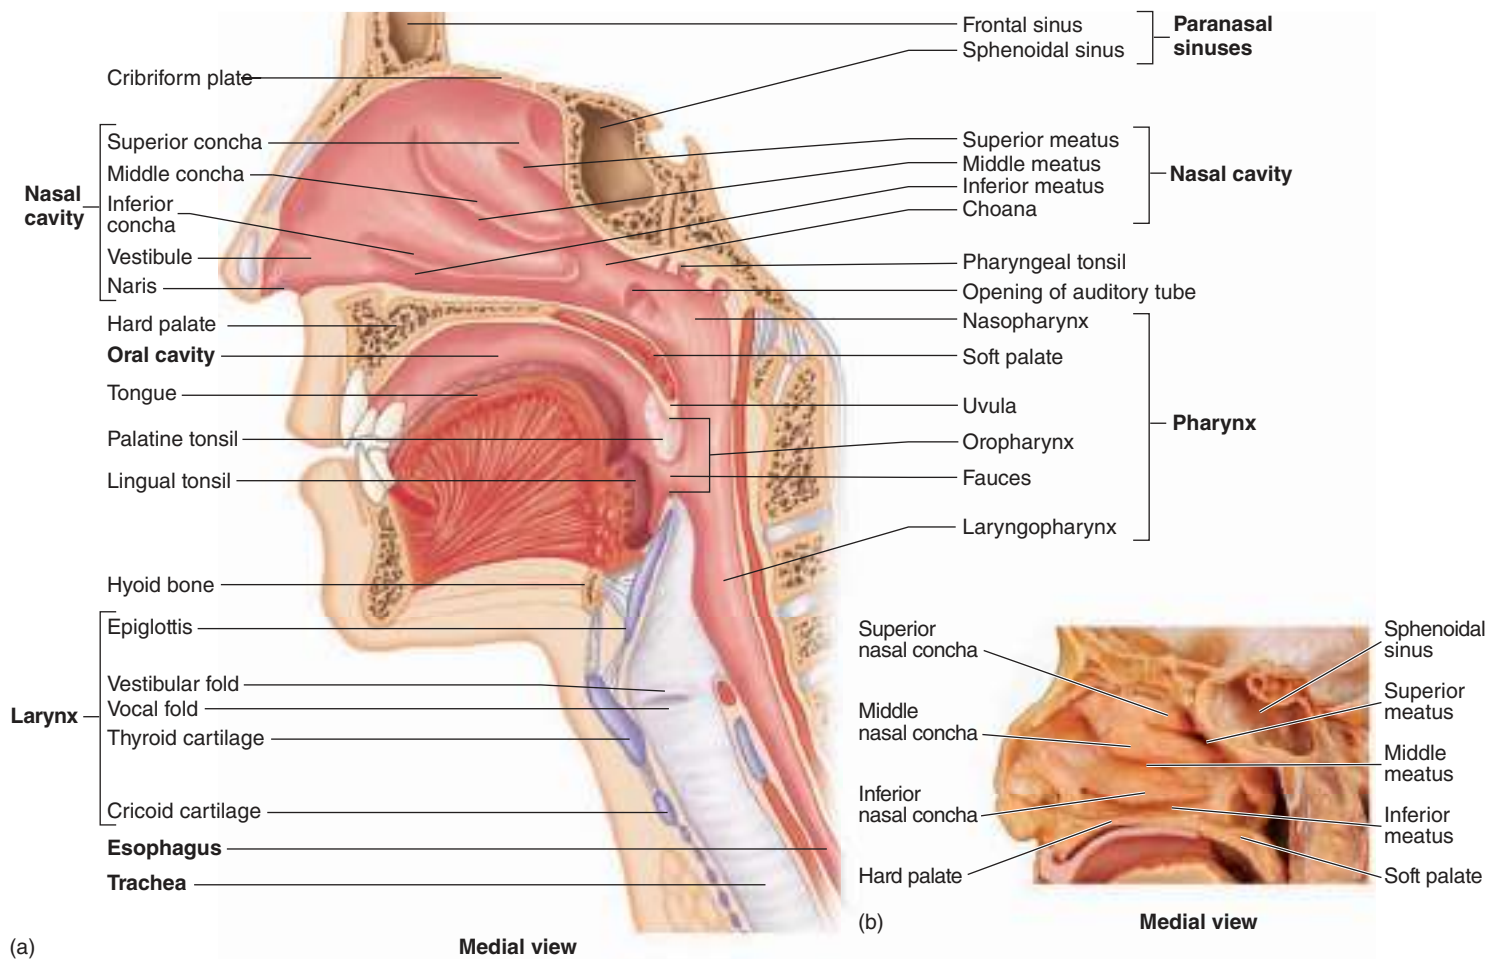

FIGURE 23.2 Nasal Cavity and Pharynx

(a) Sagittal section through the nasal cavity and pharynx. (b) Photograph of sagittal section of the head. **AP R**

the larynx and to the digestive system at the esophagus. From superior to inferior, there are three regions of the pharynx: the nasopharynx, the oropharynx, and the laryngopharynx (figure 23.2a).

The **nasopharynx** (nā'zō-far'ingks) is immediately posterior to the nasal cavity. Specifically, it is posterior to the choanae and superior to the **soft palate**. The soft palate is an incomplete partition composed of muscle and connective tissue. It separates the nasopharynx from the oropharynx. The posterior extension of the soft palate is called the **uvula** (ū'vū-lă; grape). The soft palate blocks swallowed materials away from the nasopharynx and nasal cavity toward the back of the pharynx. The nasopharynx is lined with a mucous membrane that traps debris. This debris-laden mucus from the nasal cavity is moved through the nasopharynx and swallowed. Any swallowed pathogens are killed by the acid in the stomach. The nasopharynx also contains openings on each side from the auditory tubes that are continuous with the middle ear. (figure 23.2a; see figure 15.24). Air passes through the auditory tubes to equalize air pressure between the atmosphere and the tympanic membrane. The posterior wall of the nasopharynx houses the pharyngeal tonsil, or **adenoids** (ad'ě-noydz), which helps defend the body against infection (see chapter 22). An enlarged pharyngeal tonsil can interfere with normal breathing and airflow through the auditory tubes.

The nasopharynx is continuous with the **oropharynx** (ōr'ō-far'ingks). The oropharynx is the middle portion of the pharynx. It is immediately posterior to the mouth and begins at the soft palate.

From there, it descends to the superior portion of the larynx. A region called the **fauces** (faw'sēz) joins the mouth's oral cavity and the oropharynx. Thus, air, food, and drink all pass through the oropharynx. Moist stratified squamous epithelium lines the oropharynx and protects it against abrasion. Two sets of tonsils, called the palatine tonsils and the lingual tonsils, are located near the fauces.

The oropharynx is continuous with the **laryngopharynx** (lă-ring'gō-far-ingks). The laryngopharynx spans the posterior length of the larynx: from the most superior larynx structure, the epiglottis, to the esophagus. Food and drink pass through the laryngopharynx to the esophagus. Although most air passes from the laryngopharynx into the larynx, a small amount of air may be swallowed with food and drink. The laryngopharynx is lined with moist stratified squamous epithelium.

ASSESS YOUR PROGRESS

3. Name the parts of the upper and lower respiratory tracts.
4. Explain how the conducting zone differs from the respiratory zone.
5. Describe the structures of the nasal cavity.
6. What are the five functions of the nasal cavity?
7. Name the three regions of the pharynx. With what other structures does each part communicate?

Larynx

The **larynx** (lar'ingks) is commonly known as the voicebox. It is located in the anterior part of the laryngopharynx and extends from the base of the tongue to the trachea (figure 23.2a). Because it is a passageway for air between the pharynx and the trachea it must remain open and be strongly constructed. The larynx is held in place by membranes and/or muscles superior to the hyoid bone. Its rigidity is due to an outer casing of nine cartilages connected to one another by muscles and ligaments (figure 23.3). Six of the nine cartilages are paired, and three are unpaired. The largest of the cartilages is the single **thyroid** (shield; refers to the shape of the cartilage) **cartilage**, or *Adam's apple*.

The base of the larynx is formed by the single **cricoid** (krī'koyd; ring-shaped) **cartilage**, the most inferior cartilage of the larynx. The other cartilages rest upon the cricoid cartilage.

The third single cartilage is the **epiglottis** (ep-i-glot'is; on the glottis). It is attached to the thyroid cartilage and projects superiorly as a free flap toward the tongue. The epiglottis differs from the other cartilages in that it consists of elastic rather than hyaline cartilage.

The paired **arytenoid** (ar-i-tē'noyd; ladle-shaped) **cartilages** articulate with the posterior, superior border of the cricoid

cartilage, and the paired **corniculate** (kōr-nik'ū-lāt; horn-shaped) **cartilages** are attached to the superior tips of the arytenoid cartilages. The paired **cuneiform** (kū'nē-i-fōrm; wedge-shaped) **cartilages** are contained in a mucous membrane anterior to the corniculate cartilages (figure 23.3b).

Two pairs of ligaments extend from the anterior surface of the arytenoid cartilages to the posterior surface of the thyroid cartilage. The superior ligaments are covered by a mucous membrane and are called the **vestibular folds**, or *false vocal cords* (figures 23.3c and 23.4a,b).

The inferior ligaments are covered by a mucous membrane and are called the **vocal folds**, or *true vocal cords* (figure 23.4). The **glottis** (glot'is) is the combination of the vocal folds and the opening between them (figure 23.4). The vestibular folds and the vocal folds are lined with stratified squamous epithelium. The remainder of the larynx is lined with pseudostratified ciliated columnar epithelium. An inflammation of the vocal folds is called **laryngitis** (lar-in-jī'tis).

The larynx performs four important functions:

1. The rigid nature of the thyroid and cricoid cartilages maintains an open passageway for air movement.
2. The larynx prevents swallowed materials from entering the lower respiratory tract and regulates the passage of air into

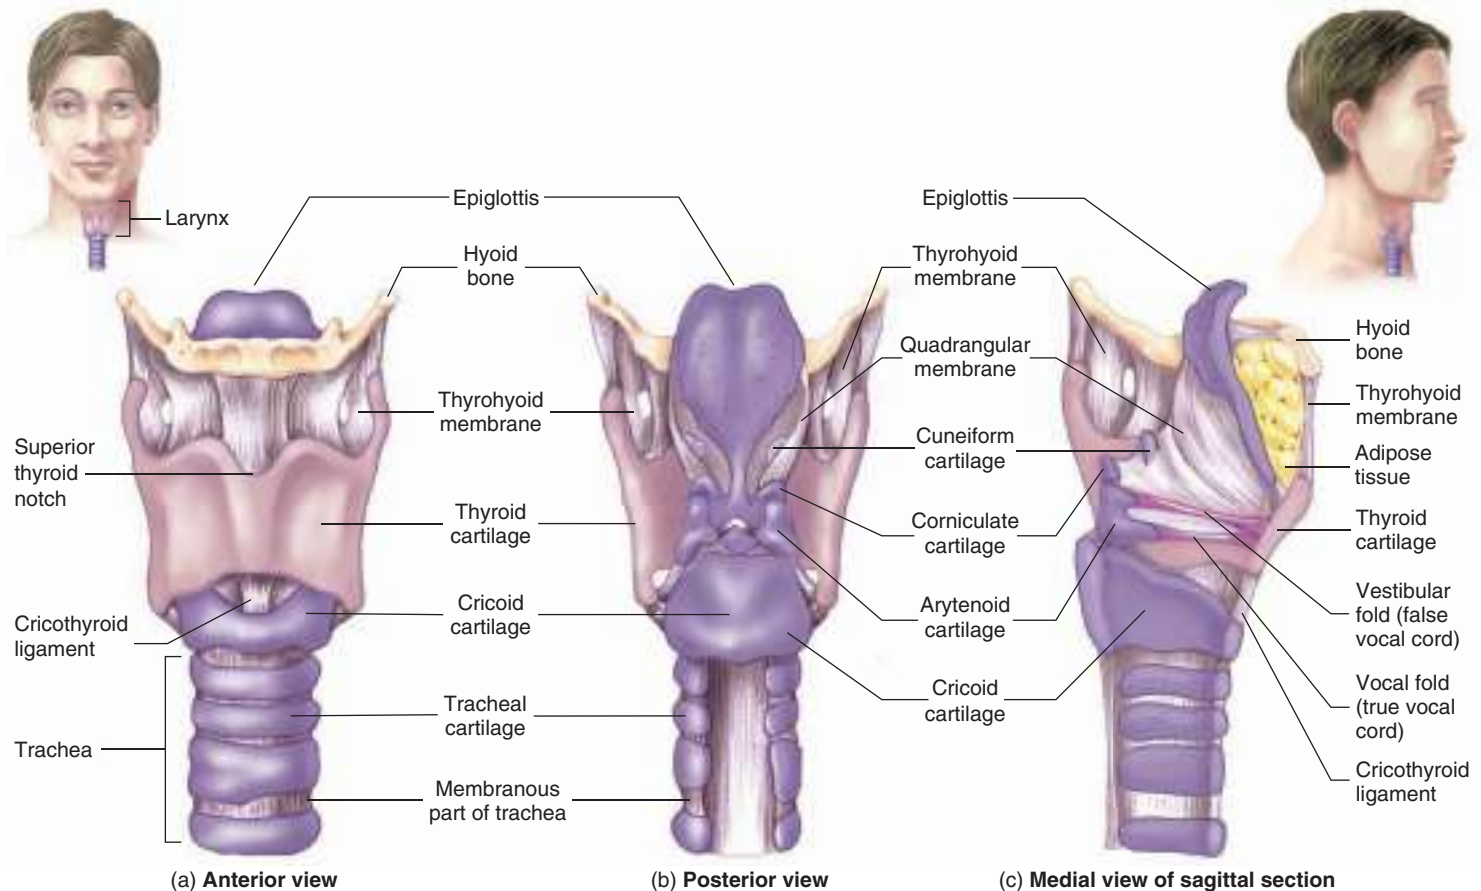

FIGURE 23.3 Anatomy of the Larynx **AP R**

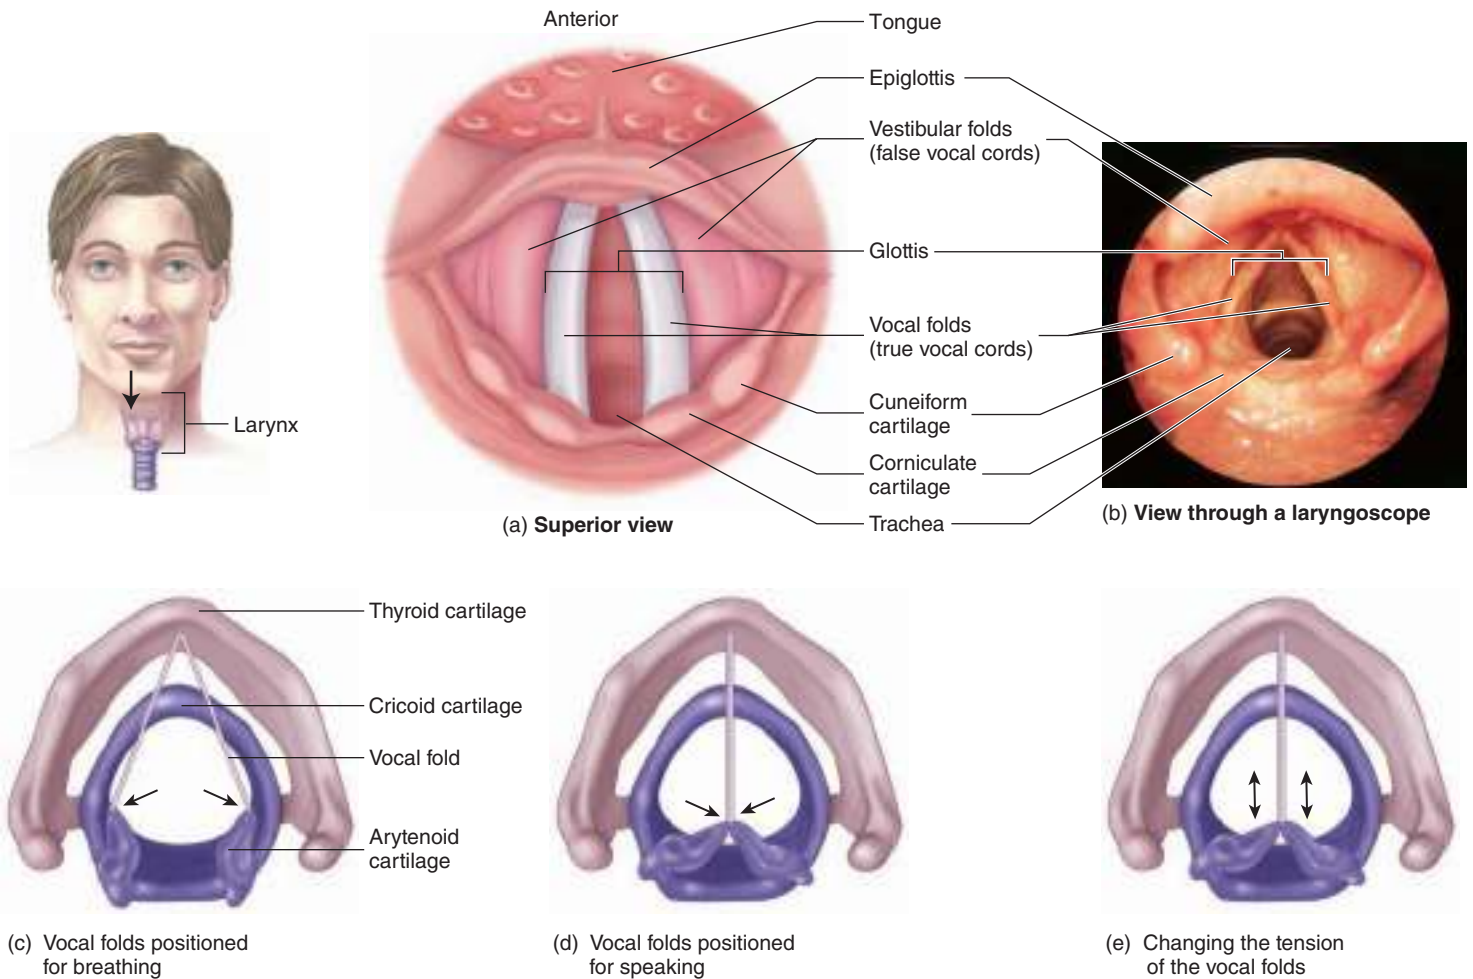

FIGURE 23.4 Vestibular Vocal Folds

(a) Relationship of the vestibular folds to the vocal folds and the laryngeal cartilages. (b) Laryngoscopic view of the vestibular and vocal folds. (c) Lateral rotation of the arytenoid cartilages moves the vocal folds laterally for breathing. (d) Medial rotation of the arytenoid cartilages moves the vocal folds medially for speaking. (e) Anterior/posterior movement of the arytenoid cartilages changes the length and tension of the vocal folds, altering the pitch of sounds. Arrows show the direction of viewing the vestibular and vocal folds.

and out of the lower respiratory tract. During swallowing, the larynx elevates to meet the epiglottis, which is pushed backward by food to cover the opening into the larynx (see “Swallowing Phases,” section 24.7). Thus, food and liquid slide over the epiglottis toward the esophagus. However, the most important method for preventing materials from entering the larynx is closure of the vestibular and vocal folds, which move medially and come together. The closure of the vestibular and vocal folds can also prevent the passage of air, as when a person holds his or her breath or increases air pressure within the lungs prior to coughing or sneezing.

3. The vocal folds are the primary source of sound production. Air moving past the vocal folds causes them to vibrate and produce sound. The force of air moving past the vocal folds determines the amplitude of the vibration and the loudness of the sound. The greater the amplitude of the vibration, the louder the sound. The frequency of vibrations determines pitch, with higher-frequency vibrations producing higher-pitched

sounds and lower-frequency vibrations producing lower-pitched sounds. Variations in the length of the vibrating segments of the vocal folds affect the frequency of the vibrations. Higher-pitched tones are produced when only the anterior parts of the folds vibrate, and progressively lower tones result when longer sections of the folds vibrate. Because males usually have longer vocal folds than females, most males have lower-pitched voices. The sound produced by the vibrating vocal folds is modified by the tongue, lips, teeth, and other structures to form words. Interestingly, a person whose larynx has been removed because of carcinoma of the larynx can produce sound by swallowing air and causing the esophagus to vibrate.

Movement of the arytenoid and other cartilages is controlled by skeletal muscles, thereby changing the position and length of the vocal folds. When a person is simply breathing, lateral rotation of the arytenoid cartilages opens the vocal folds, which allows greater movement of air (figure 23.4c). Medial rotation of the arytenoid cartilages closes the vocal

folds, places them in position for producing sounds, and changes the tension on them (figure 23.4d). Anterior movement of the arytenoid cartilages decreases the length and tension of the vocal folds, lowering pitch. Posterior movement of the arytenoid cartilages increases the length and tension of the vocal folds, increasing pitch (figure 23.4e).

- The pseudostratified ciliated columnar epithelium lining the larynx produces mucus, which traps debris in air. The cilia move the mucus and debris into the pharynx.

› Predict 2

Jake told his girlfriend that the rollercoaster did not bother him, but during the ride he let loose with a long, high-pitched scream. Explain how the muscles of respiration, the muscles that control the vocal folds, and the muscles that move the epiglottis produced Jake's scream.

ASSESS YOUR PROGRESS

- Name and describe the three single cartilages of the larynx. What are their functions?
- Distinguish between the vestibular and vocal folds. How are sounds of different loudness and pitch produced by the vocal folds?
- How does the position of the arytenoid cartilages change when a person is simply breathing versus making low-pitched and high-pitched sounds?
- What are the four functions of the larynx?

Trachea

The **trachea** (trā'kē-ă), or windpipe, allows air to flow into the lungs. It is a membranous tube attached to the larynx. It consists of dense regular connective tissue and smooth muscle (see figure 23.2). Reinforcing the trachea are 15–20 C-shaped pieces of hyaline cartilage. The cartilages support the anterior and lateral sides of the trachea to protect the trachea and maintain an open passageway for air (figure 23.5a). Because the tracheal rings do not completely surround the entire trachea, the posterior wall of the trachea is devoid of cartilage. Instead, it contains an elastic ligamentous membrane and bundles of smooth muscle called the **trachealis** (trā'kē-ā-lis) **muscle**. Contraction of this smooth muscle can narrow the diameter of the trachea, which aids in coughing. Narrowing the trachea's diameter causes air to move more forcefully through the trachea, helping to expel mucus and foreign objects during coughing. The esophagus lies immediately posterior to the cartilage-free posterior wall of the trachea.

› Predict 3

Explain what happens to the shape of the trachea when a person swallows a large mouthful of food. Why is this change of shape advantageous?

A mucous membrane lines the trachea (figure 23.5b). The membrane's goblet cells produce mucus, which traps inhaled dust, bacteria, and other foreign matter. The ciliated epithelium then moves the mucus and foreign matter into the larynx. From the larynx the foreign matter enters the pharynx and is swallowed

Establishing Airflow

In cases of extreme emergency when the upper air passageway is blocked by a foreign object so that the person cannot breathe, quick reaction is required to save the person's life. **Abdominal thrusts**, or the *Heimlich maneuver*, are designed to force an object out of the air passage by the sudden application of pressure to the abdomen. The person who performs the technique stands behind the patient, with his or her arms under the patient's arms and hands over the patient's abdomen between the navel and the rib cage. With one hand formed into a fist and the other hand over it, the rescuer suddenly pulls both hands toward the abdomen with an upward motion. This technique, if done properly, forces air up the trachea and dislodges most foreign objects.

There are other ways to establish airflow, but they should be performed only by trained medical personnel. In **intubation**, a tube is passed through the mouth or nose into the pharynx and then through the larynx to the trachea. Sometimes it is necessary to make an opening through which to pass the tube. The preferred point of entry in emergency cases is through the membrane between the cricoid and thyroid cartilages, a procedure called a **cricothyrotomy** (krī'kō-thī-rot'ō-mē).

A **tracheostomy** (trā'kē-os'tō-mē; *tracheo-* + *stoma*, mouth) is an operation performed to make an opening into the trachea, commonly between the second and third cartilage rings. Usually, the opening is intended to be permanent, and a tube is inserted into the trachea to allow airflow and provide a way to remove secretions. The term **tracheotomy** (trā'kē-ot'ō-mē; *tracheo-* + *tome*, incision) refers to the actual cutting into the trachea, but sometimes the terms *tracheostomy* and *tracheotomy* are used interchangeably. In emergencies, opening the air passageway through the trachea is not advisable because it may disturb the arteries, nerves, and thyroid gland overlying the anterior surface of the trachea.

(figure 23.5b,c). Constant, long-term irritation to the trachea, as occurs in smokers, can cause the tracheal epithelium to become moist stratified squamous epithelium that lacks cilia and goblet cells. This transition prevents the normal function of the tracheal epithelium.

The trachea has an inside diameter of 12 mm and a length of 10–12 cm, descending from the larynx to the level of the fifth thoracic vertebra (figure 23.6). The trachea divides to form two smaller tubes called **main bronchi**, or *primary bronchi* (brong'kī; sing. bronchus, brong'kūs; windpipe), each of which extends to a lung. The tracheal cartilage separating the openings into the main bronchi forms a ridge called the **carina** (kā-rī'nă). The carina is an important landmark for reading x-rays. In addition, the mucous membrane of the carina is very sensitive to mechanical stimulation. If foreign matter is inhaled to the level of the carina, it stimulates a powerful cough reflex. Materials in the air passageways beyond the carina do not usually stimulate a cough reflex.

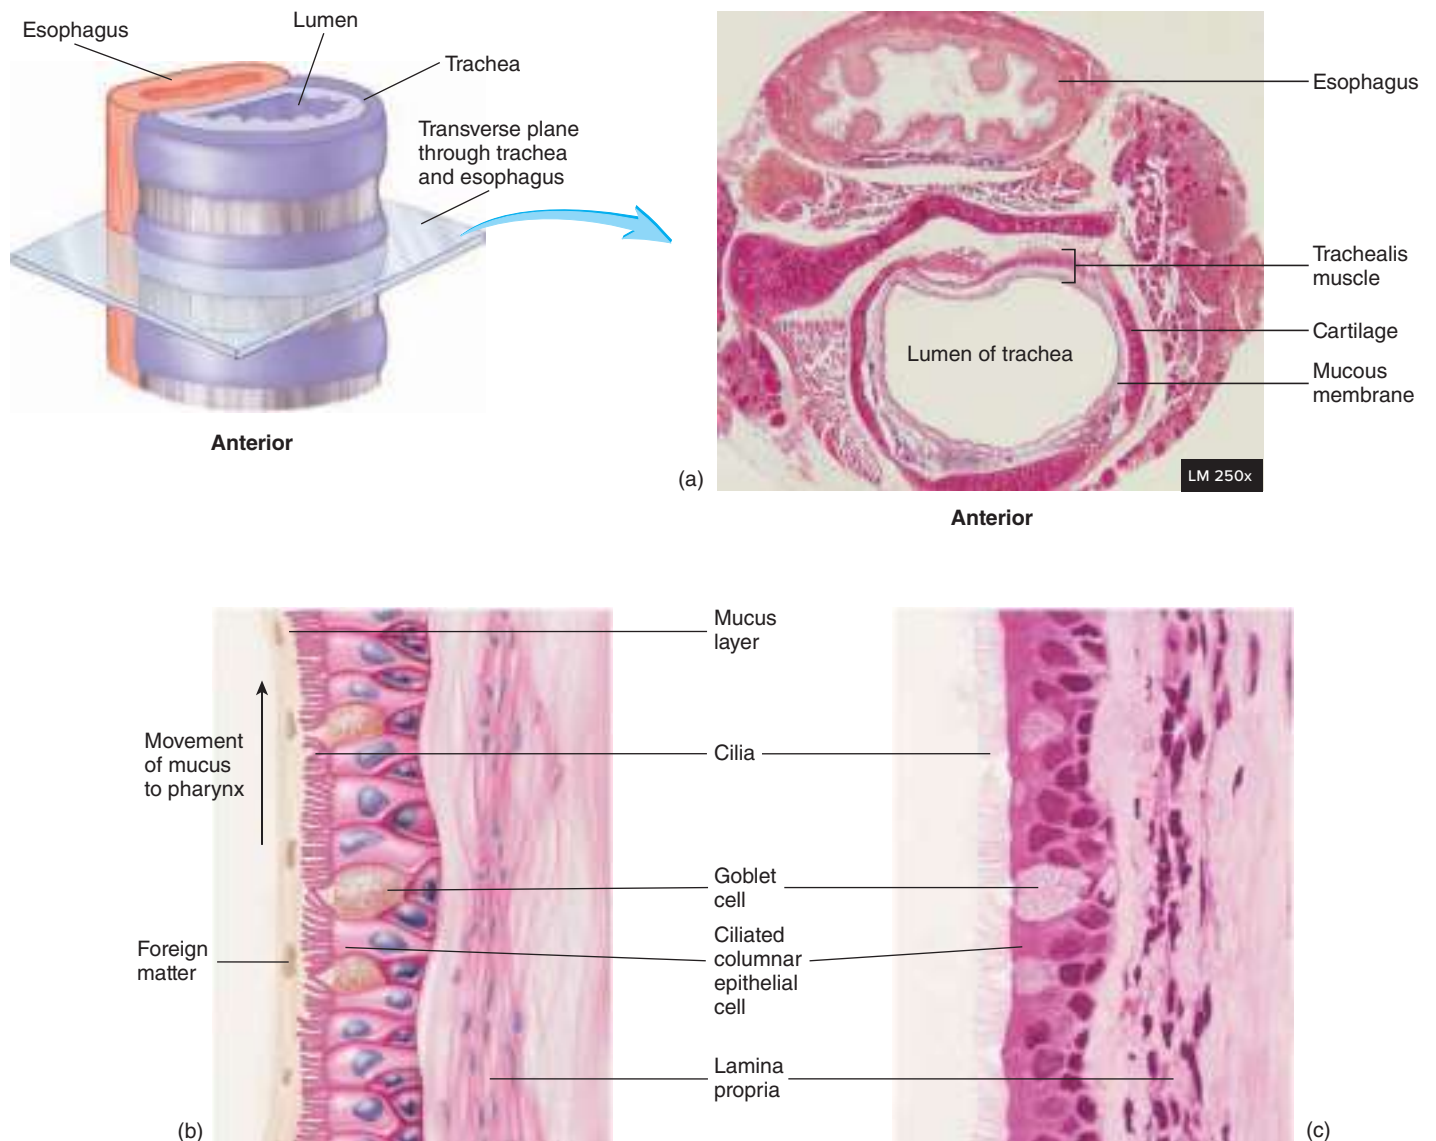

FIGURE 23.5 Trachea

(a) Light micrograph of a transverse section of the trachea. The esophagus is posterior to the trachea, next to the smooth muscle connecting the ends of the C-shaped cartilages of the trachea. (b) Mucus, produced by the goblet cells, traps foreign matter in the air. Movement of the cilia moves the mucus and foreign matter to the laryngopharynx. (c) Light micrograph of the surface of the mucous membrane lining the trachea. Goblet cells are interspersed between ciliated cells. **APR**

Tracheobronchial Tree

The **tracheobronchial** (trā'kē-ō-brong'kē-āl) **tree** consists of the trachea and all other respiratory passageways in the lungs (figure 23.6). The trachea divides to form a left and right bronchus, each of which divides to form smaller and smaller bronchi. Eventually, the tracheobronchial tree consists of many microscopic tubes and sacs. The right main bronchus is larger in diameter and more directly in line with the trachea than the left main bronchus. As a result, swallowed objects that accidentally enter the lower respiratory tract are more likely to become lodged in the right main bronchus.

Within each lung the main bronchi divide into **lobar bronchi**, or *secondary bronchi*. There are two lobar bronchi in the left lung and three lobar bronchi in the right lung. The lobar

bronchi, in turn, give rise to **segmental bronchi**, or *tertiary bronchi*. The bronchi continue to branch, finally giving rise to **bronchioles** (brong'kē-ōlz), which are less than 1 mm in diameter. The bronchioles also subdivide several times to become even smaller **terminal bronchioles**. Approximately 16 generations of branching occur from the trachea to the terminal bronchioles.

As the air passageways of the lungs become smaller, the structure of their walls changes. Like the trachea, the main bronchi are supported by C-shaped cartilage connected by smooth muscle. In the lobar bronchi, the C-shaped cartilages are replaced with cartilage plates, and smooth muscle forms a layer between the cartilage and the mucous membrane. As the bronchi become smaller, the cartilage becomes more sparse, and smooth muscle becomes more

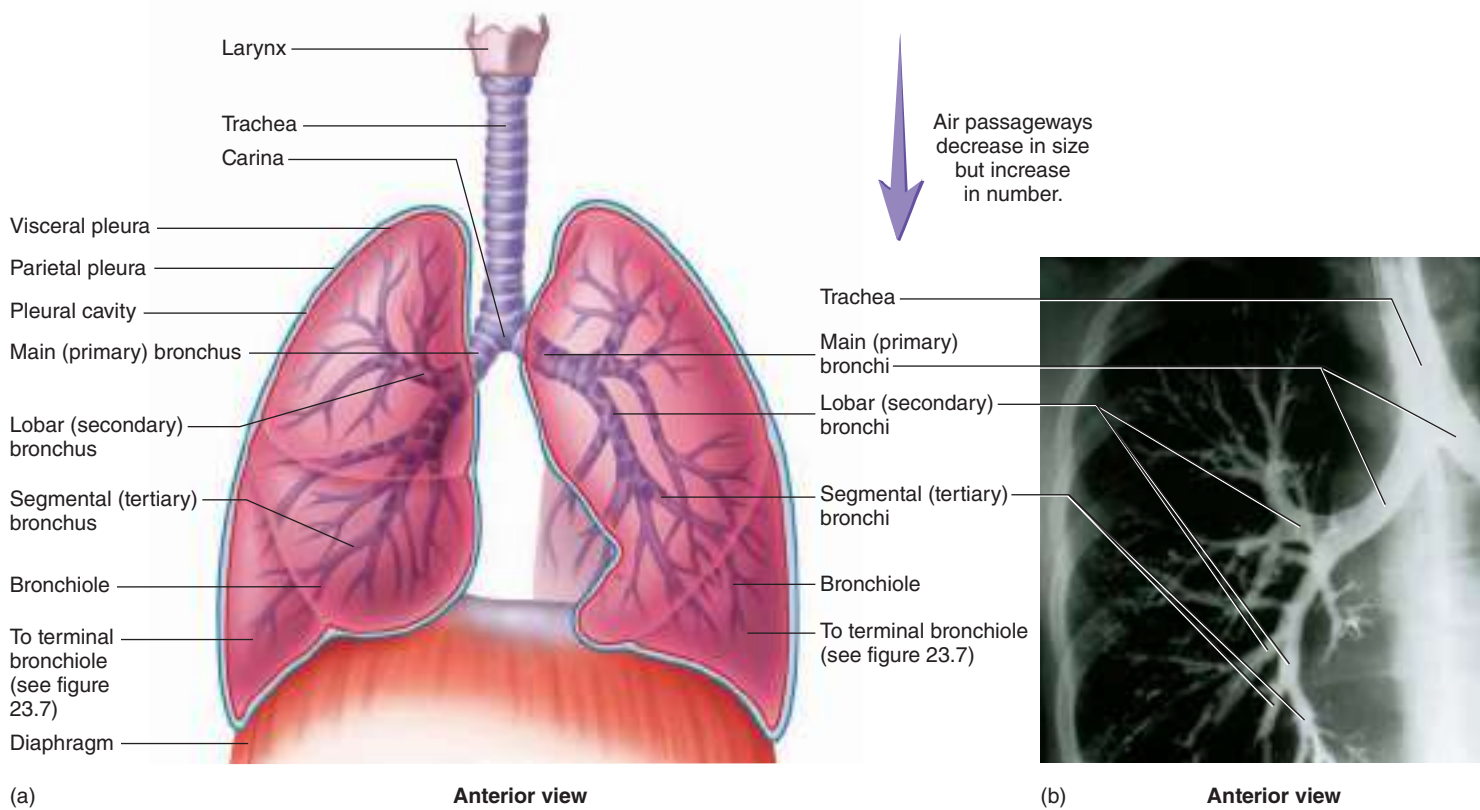

FIGURE 23.6 Tracheobronchial Tree

(a) The conducting zone of the tracheobronchial tree begins at the trachea and ends at the terminal bronchioles. (b) A bronchogram is a radiograph of the tracheobronchial tree. A contrast medium, which makes the passageways visible, is injected through a catheter after a topical anesthetic is applied to the mucous membranes of the nose, pharynx, larynx, and trachea. **APR**

abundant. The terminal bronchioles have no cartilage, and the smooth muscle layer is prominent. The smooth muscle within the bronchi and bronchioles relaxes and contracts, changing the diameter of the air passageways. **Bronchodilation** occurs when the smooth muscle relaxes, making the bronchiole diameter larger. **Bronchoconstriction** occurs when the smooth muscle contracts, making the bronchiole diameter smaller. This works in the same way as vasoconstriction and vasodilation (see chapter 21). Changes in the diameter of the airways affect the air movement through them. For example, during exercise bronchodilation occurs, reducing the resistance to airflow, which increases air movement. However, during an **asthma attack**, bronchoconstriction decreases the diameter of the airways, which increases resistance to airflow and greatly reduces air movement. In severe cases, air movement can be so restricted that the patient dies. Fortunately, medications, such as albuterol (al-bū'ter-ol), help counteract the effects of an asthma attack by promoting smooth muscle relaxation in the walls of terminal bronchioles, so that air can flow more freely.

The bronchi are lined with pseudostratified ciliated columnar epithelium. The larger bronchioles are lined with ciliated simple columnar epithelium, which changes to ciliated simple cuboidal epithelium in the terminal bronchioles. The ciliated epithelium functions as a mucus-cilia escalator, trapping debris in the air and moving it to the larynx.

Respiratory Zone

Alveoli

The respiratory zone begins once gas exchange between inspired air and blood is possible. This occurs where alveoli start to form. **Alveoli** (al-vē'ō-lī; hollow cavities) are small, air-filled chambers where the air and the blood come into close contact with each other. Terminal bronchioles divide to form **respiratory bronchioles**, which have a few attached alveoli (figure 23.7a). As the respiratory bronchioles divide to form smaller respiratory bronchioles, the number of attached alveoli increases. The respiratory bronchioles give rise to **alveolar** (al-vē'ō-lār) **ducts**, which are like long, branching hallways with many open doorways. The “doorways” open into alveoli, which become so numerous that the alveolar duct wall is little more than a series of alveoli. The alveolar ducts end as two or three **alveolar sacs**, which are chambers connected to two or more alveoli (figure 23.7b). Approximately seven generations of branching occur from the terminal bronchioles to the alveolar ducts.

The tissue surrounding the alveoli contains elastic fibers, which allow the alveoli to expand during inspiration and recoil during expiration. The lungs are very elastic and, when inflated, are capable of expelling air and returning to their original, uninflated state. Even when not inflated, however, the lungs retain some air, which gives them a spongy quality.

MICROBES In Your Body

Whooping Cough

Whooping cough, or pertussis, is a serious bacterial infection of the tracheobronchial tree, caused by the bacterium *Bordetella pertussis* (*B. pertussis*; -tussis, cough). Whooping cough is highly contagious and spreads through inhalation of airborne droplets or contact with droplet-covered surfaces. It is estimated that each newly infected person will pass the disease on to over 10 other people. This is primarily because the incubation period is 7–10 days compared to only 1–3 days for the common cold. In addition, the first 2 weeks of symptoms are similar to those of a mild cold, and the patient may be less cautious around others, making it more likely that he or she will spread the infection. After the incubation phase, a severe cough develops that consists of bouts of intense coughing, which can cause vomiting, lack of sufficient gas exchange during the coughing episode, followed by a loud inspiratory high-pitched sound, or “whoop.” The coughing stage can last 10 weeks or more, but full recovery does not occur for another 2–3 months. The most severely affected patients are infants under 6 months of age, 50% of whom will require hospitalization. Infants and children under 6–7 years of age are also the most likely to develop serious side effects, which include development of pneumonia, apnea (interrupted breathing), seizures, brain hemorrhage, and even death by asphyxiation (suffocation).

B. pertussis affects both the respiratory and the immune systems simultaneously in two major ways: (1) by directly attacking the ciliated epithelium in the tracheobronchial tree and (2) by avoiding the effects of complement. In chapter 22, you learned that the tracheobronchial tree contributes to innate immunity by providing both a mechanical and a chemical barrier to invading pathogens. The mechanical barrier is formed by a mucus-producing, ciliated epithelium. The cilia constantly sweep

debris and bacteria-laden mucus toward the pharynx to be swallowed. The chemical barrier is provided by activation of the complement system by roaming macrophages in the mucosal lining of the tracheobronchial tree. The complement system consists of a group of proteins that, when activated, initiates a series of reactions, resulting in lysis of bacterial cells. Upon first entering the trachea, *B. pertussis* begins secreting chemicals called virulence factors. Some of these virulence factors are attachment proteins that allow the bacteria to bind to the plasma membrane of each cilium and the plasma membrane of the epithelial cells. This is similar to the way adjacent stratified squamous cells in the epidermis of the skin adhere to each other using attachment proteins (see chapter 4). Once attached, the bacteria secrete another virulence factor, called tracheal cytotoxin, that causes stasis (nonmovement) of the cilia. This stasis is what induces the intense coughing fits, which benefit the bacteria by clearing mucus that could trap and kill the bacteria. Other virulence factors produced by *B. pertussis* include numerous polysaccharides and proteins that prevent binding of complement proteins to the bacterium. Without the actions of complement, the bacteria are able to survive. Unfortunately, antibiotic treatment does not prevent the clinical symptoms from developing, shorten the disease time, or prevent any serious side effects of whooping cough. The primary reason clinicians are encouraged to prescribe antibiotics is to kill the bacteria in the nasopharynx, which aids in reducing the rate of transmission to other people.

The most effective method to avoid whooping cough is vaccination. Prior to the 1940s and 1950s, whooping cough was a leading cause of infant death. Then in the 1940s, development of a universal vaccine caused a sharp drop in the number of U.S. whooping cough incidences and outbreaks. However, starting in the 1980s, the

number of whooping cough cases began rising to levels not seen in over 60 years. Research has shown that the increase in whooping cough incidence is most likely due to several factors, all of which center around vaccination. These factors prompted the Centers for Disease Control and Prevention (CDC) to recommend a T_{dap} booster (a vaccine for tetanus, diphtheria, and acellular pertussis given to adolescents and adults) for all pregnant women past the 20th week of gestation. Even though the United States’ average vaccination rate is 95%, several states have rates that are lower, with the lowest rate at about 80%. High numbers of intentionally unvaccinated or undervaccinated people in a given region increase the likelihood of pertussis outbreaks. In addition, it seems that the efficacy of the early childhood DTaP vaccine (a five-dose vaccine for diphtheria, tetanus, and acellular pertussis for children younger than 7 years) may fade by the time a child is 11 or 12. This can be addressed by giving a T_{dap} booster at that time. Both the failure to vaccinate and the decreased vaccination rate (completion of all recommended doses) of infants and children have allowed *B. pertussis* to circulate freely throughout the population. Now *B. pertussis* has genetically adapted, so that it can avoid attack by our immune system even more effectively. In other words, the relatively recent increased number of cases has led to a decreased sensitivity of *B. pertussis* to the current vaccine. Development of a new, more effective vaccine to be given to all unvaccinated people may help eradicate this horrible disease.

➤ Predict 4

Predict how identifying and then purifying the complement system avoidance virulence factors that are produced by *B. pertussis* could help create a new, more effective pertussis vaccine.

The walls of respiratory bronchioles consist of collagenous and elastic connective tissue with bundles of smooth muscle. The epithelium in the respiratory bronchioles is a simple cuboidal epithelium. The alveolar ducts and alveoli consist of simple squamous epithelium. Although the epithelium of the alveoli and respiratory bronchioles is not ciliated, debris from the air can be removed by macrophages that move over the surfaces of the cells. The macrophages do not accumulate in the respiratory zone

because they either move into nearby lymphatic vessels or enter terminal bronchioles, thereby becoming entrapped in mucus that is swept to the pharynx.

Approximately 300 million alveoli are in the two lungs. The average diameter of an alveolus is approximately 250 μm , and its wall is extremely thin. Two types of cells form the alveolar wall (figure 23.8a). **Type I pneumocytes** are thin squamous epithelial cells that form 90% of the alveolar surface. Most of the gas

exchange between alveolar air and the blood takes place through these cells. **Type II pneumocytes** are round or cube-shaped secretory cells that produce surfactant, which makes it easier for the alveoli to expand during inspiration (see “Lung Recoil” in section 23.3).

Clinical GENETICS

Emphysema

Emphysema (em-fi-zē'mă) is a condition in which lung alveoli become progressively enlarged as the walls between them are destroyed. Individuals who have emphysema experience shortness of breath and coughing.

Cigarette smoking is the major risk factor for emphysema. Chemicals in cigarette smoke damage lung tissues and stimulate inflammation. As part of the inflammatory response, neutrophils and macrophages release **proteases**, which are enzymes that break down proteins. Proteases in the lungs protect against some bacteria and foreign substances, but too much protease activity can result in the breakdown of lung tissue proteins, especially elastin in elastic fibers. **Alpha-1 anti-trypsin (AAT)**, which is synthesized in

the liver, is a **protease inhibitor (Pi)**. Normally, AAT inhibits protease activity, preventing the destruction of lung tissue. However, excess protease production stimulated by cigarette smoke can cause lung damage, leading to emphysema.

Approximately 1–2% of emphysema cases are due to a deficiency of AAT caused by defects in the AAT gene. The mutated gene reduces the amount of secreted AAT. Multiple alleles for AAT have been identified. Individuals who are homozygous for the normal allele produce normal levels of AAT. Individuals with one copy of the normal allele and one copy of the most common abnormal allele have about 60% of normal levels of AAT. This is sufficient activity to prevent protease damage. However, individuals with two copies of

the *abnormal* allele produce only about 15–20% of normal AAT levels. If these individuals smoke, the development of emphysema is accelerated by 10–15 years. Other variant alleles cause different levels of AAT. The most severe form results in no AAT and the development of emphysema by age 30, even in nonsmokers.

Treatment of AAT deficiency follows the normal course of treatment for emphysema. Stopping smoking reduces the destruction of lung tissue by removing the stimulus for excess protease activity. Drugs, such as danazol and tamoxifen, can stimulate increased AAT production in the liver. In addition, patients may receive intravenous infusions of AAT, a process called **alpha-1 antitrypsin augmentation**.

14. How is debris removed from the tracheobronchial tree?
15. Name the two types of cells in the alveolar wall, and state their functions.

The Respiratory Membrane

The **respiratory membrane** in the lungs is where O₂ enters the blood and CO₂ exits the blood. It is formed mainly by the alveolar walls and surrounding pulmonary capillaries (figure 23.8b). To facilitate diffusion of gases, the respiratory membrane is extremely thin; it is thinner than a sheet of tissue paper. The respiratory membrane consists of two layers of simple squamous epithelium, including secreted fluids and separating spaces. The individual layers are the following:

1. A thin layer of alveolar fluid
2. The alveolar epithelium, which is a single layer of simple squamous epithelium
3. The basement membrane of the alveolar epithelium
4. A thin interstitial space
5. The basement membrane of the capillary endothelium
6. The capillary endothelium, which is a single layer of simple squamous epithelium

Lungs

The **lungs** are the principal organs of respiration, and on a volume basis they are among the largest organs of the body. Each lung is conical in shape, with its base resting on the diaphragm and its apex extending to a point approximately 2.5 cm superior to the clavicle. The right lung is larger than the left and weighs an average of 620 g, whereas the left lung weighs an average of 560 g.

The **hilum** (hī'lŭm) is a region on the medial surface of the lung where structures, such as the main bronchus, blood vessels, nerves, and lymphatic vessels, enter or exit the lung. All the structures passing through the hilum are referred to as the **root of the lung**.

The right lung has three **lobes**, and the left lung has two. The left lung also has an indentation called the **cardiac notch** (figure 23.9). This structural arrangement allows the heart to lie between the lungs. The lung lobes are separated by deep, prominent **fissures** on the surface of the lung. Each lung lobe is supplied by a lobar bronchus. The lung lobes are further subdivided into **bronchopulmonary segments**, each of which is supplied by the segmental bronchi. There are 9 bronchopulmonary segments in the left lung and 10 in the right lung. The bronchopulmonary segments are separated from each other by connective tissue partitions, which are not visible as surface fissures. Because major blood vessels and bronchi do not cross the connective tissue partitions, individual diseased bronchopulmonary segments can be surgically removed, leaving the rest of the lung relatively intact. The bronchopulmonary segments are even further subdivided into **lobules** by partial walls of connective tissue. The bronchioles supply the lobules.

Thoracic Wall and Muscles of Respiration

The **thoracic wall** consists of the thoracic vertebrae, ribs, costal cartilages, sternum, and associated muscles (see chapters 7 and 10). The **thoracic cavity** is the space enclosed by the thoracic wall and the **diaphragm** (dī'ă-fram; partition). Recall from chapter 10 that the diaphragm is a sheet of skeletal muscle separating the thoracic cavity from the abdominal cavity. The diaphragm and other skeletal muscles associated with the thoracic wall are responsible

for **ventilation** (air movement; figure 23.10). There are several **muscles of inspiration** that increase thoracic volume. Downward movement of the diaphragm upon contraction is responsible for approximately two-thirds of the increase in thoracic volume during inspiration. The remaining muscles of inspiration include the external intercostals, pectoralis minor, and scalene muscles. These muscles also increase thoracic volume, but they do so by elevating the ribs. The **muscles of expiration** are the muscles that decrease thoracic volume by depressing the ribs and sternum. These are the internal intercostals and transverse thoracis, with assistance from the abdominal muscles. Although the internal intercostals and the transverse thoracis are most active during expiration, and the external intercostals are most active during inspiration, the primary function of these muscles is to stiffen the thoracic wall by contracting at the same time. In this way, they prevent the thoracic cage from collapsing inward during inspiration.

The diaphragm is dome-shaped, and the base of the dome attaches to the inner circumference of the inferior thoracic cage (see figure 10.18). The top of the dome is a flat sheet of connective tissue called the **central tendon**. In normal, quiet inspiration, contraction of the diaphragm causes the central tendon to move downward. There is very little change in the overall shape of the diaphragm. This downward movement is facilitated by relaxation of the abdominal muscles, which moves the abdominal organs out of the way. This is noticeable when your hands rest on your stomach. However, as the depth of inspiration increases, the abdominal organs prevent the central tendon from moving inferiorly. Continued contraction of the diaphragm causes it to flatten as the lower ribs are elevated. In addition, other muscles of inspiration can elevate the ribs. As the ribs are elevated, the costal cartilages allow lateral rib movement and lateral expansion of the thoracic cavity (figure 23.11). The ribs slope inferiorly from the vertebrae to the

sternum, and elevation of the ribs also increases the anterior-posterior dimension of the thoracic cavity.

Expiration during quiet breathing is a passive process. Because the thorax and lungs contain significant amounts of elastic tissue, when tension is removed, they spring back into their smaller, relaxed state. In addition, the diaphragm and external intercostals relax and thoracic volume decreases. Thoracic volume also decreases when the abdominal muscles contract, pushing the abdominal organs and the diaphragm in a superior direction.

Several differences can be recognized between normal, quiet breathing and labored breathing. During labored inspiration, more air moves into the lungs because all of the inspiratory muscles are active. They contract more forcefully than during quiet breathing, which causes a greater increase in thoracic volume (see figure 23.10*b*). During labored expiration, more air moves out of the lungs due to the forceful contraction of the internal intercostals and the abdominal muscles. This produces a more rapid and greater decrease in thoracic volume than would be produced by the passive recoil of the thorax and lungs.

FIGURE 23.10 Effect of the Respiratory Muscles on Thoracic Volume

(a) Muscles of respiration at the end of expiration. (b) Muscles of respiration at the end of inspiration.

Pleura

The lungs are contained within the thoracic cavity, but each lung is contained within its own **pleural** (ploor’äl; relating to the ribs) **cavity** formed by the pleural serous membrane (figure 23.12). Separating the two pleural cavities is a central region called the **mediastinum** (mē’dē-as-tī’nūm). The mediastinum houses the heart, trachea, esophagus, and other structures,

such as blood vessels and the thymus. The **parietal pleura** covers the inner thoracic wall, the superior surface of the diaphragm, and the mediastinum. At the hilum, the parietal pleura is continuous with the **visceral pleura**, which covers the surface of the lung.

The pleural cavity is filled with pleural fluid, which is produced by the pleural membranes. The pleural fluid has two functions: (1) It

Clinical IMPACT

Effect of Spinal Cord Injury on Ventilation

The diaphragm is supplied by the phrenic nerves, which arise from spinal nerves C3–C5 (see figure 12.16), descend along each side of the neck to enter the thorax, and pass to the diaphragm. The intercostal muscles are supplied by the intercostal nerves (see figure 12.15), which arise from spinal nerves T1–T11 and extend along the spaces between the ribs.

Spinal cord injury superior to the origin of the phrenic nerves causes paralysis of the diaphragm and intercostal muscles and results in death unless artificial respiration is provided.

A spinal cord injury inferior to the origin of the phrenic nerves causes paralysis of the intercostal muscles. Even though the diaphragm can function maximally, ventilation is drastically reduced because the intercostal muscles no longer prevent the thoracic wall from collapsing inward. Vital capacity is reduced to about 300 mL. If the spinal cord is injured inferior to the origin of the intercostal nerves, both the diaphragm and the intercostal muscles function normally.

The importance of the abdominal muscles in breathing can be observed in a person with a spinal cord injury that causes flaccid paralysis

of the abdominal muscles. In the upright position, the abdominal wall muscles sag, which allows the abdominal organs to protrude anteriorly. Picture letting your stomach wall “pooch” outward. Without the force of the abdominal organs pushing upward on the diaphragm and lungs, the thoracic cavity volume does not decrease sufficiently. Passive recoil of the thorax and lungs is inadequate for normal expiration. An elastic binder around the abdomen can help such patients. When a person is lying down, the weight of the abdominal organs can assist in expiration.

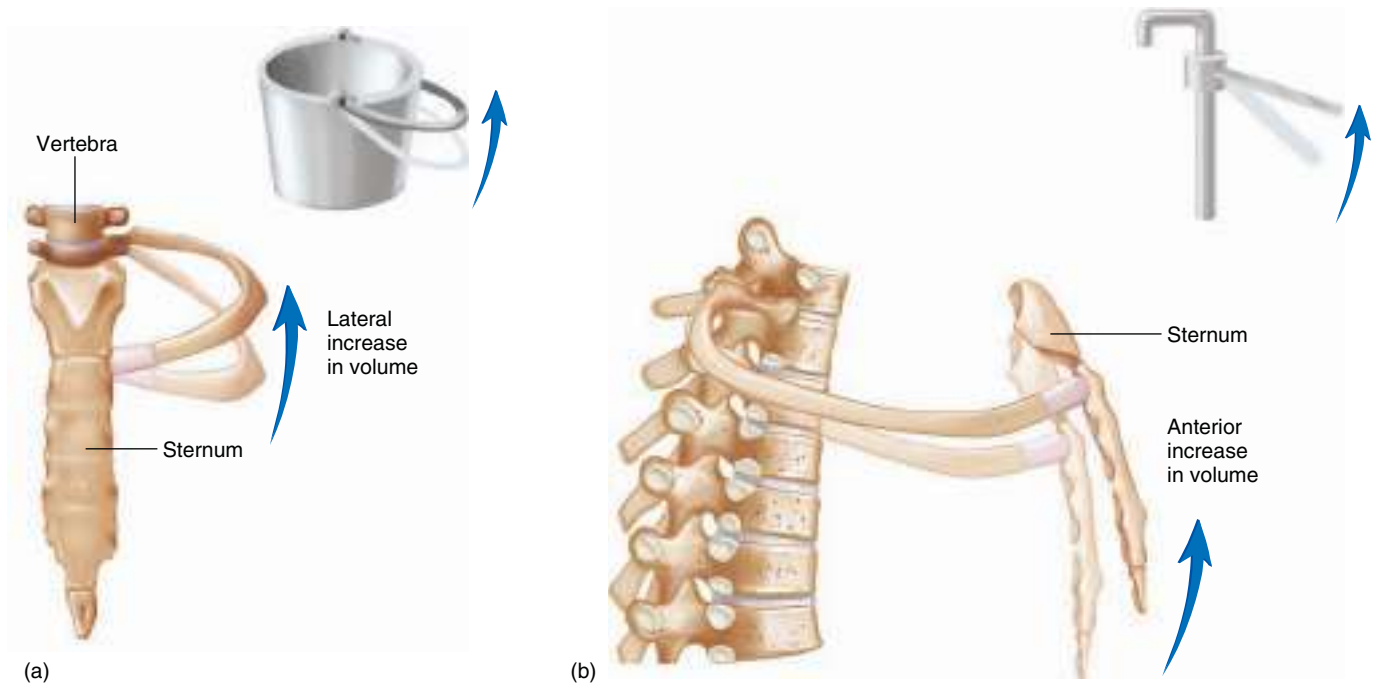

FIGURE 23.11 Effect of Rib and Sternum Movement on Thoracic Volume

(a) Elevation of the rib in the “bucket-handle” movement increases thoracic volume laterally. (b) As the rib is elevated, rotation of the rib in the “pump-handle” movement increases thoracic volume anteriorly. **APR**

FIGURE 23.12 Pleural Cavities and Membranes

Transverse section of the thorax, showing the relationship of the pleural cavities to the thoracic organs. Each lung is surrounded by a pleural cavity. The parietal pleura lines the wall of each pleural cavity, and the visceral pleura covers the surface of the lungs. The space between the parietal and visceral pleurae is small and filled with pleural fluid.

acts as a lubricant, allowing the parietal and visceral pleural membranes to slide past each other during ventilation, and (2) it causes the parietal pleura to cling to the visceral pleura around the lungs. Thus, the lungs “stick” to the thoracic wall, so that when the wall of the thorax expands during inspiration, the lungs also expand. The parietal pleura “pulls” the visceral pleura outward. The pleural fluid is analogous to a thin film of water between two sheets of glass (the visceral and parietal pleurae); the glass sheets can easily slide over each other, but it is difficult to separate them.

Blood Supply

Blood that has passed through the lungs and picked up O₂ is called **oxygenated blood**, and blood that has passed through the tissues and released some of its O₂ is called **deoxygenated blood**. There are two blood flow routes to the lungs. The major route takes deoxygenated blood to the lungs, where it is oxygenated (see chapter 21). To get to the alveoli, the deoxygenated blood flows through pulmonary arteries to pulmonary capillaries. In the capillaries, the blood becomes oxygenated and returns to the heart through pulmonary veins. The other route takes oxygenated blood to the tissues of the bronchi down to the respiratory bronchioles. The oxygenated blood flows from the thoracic aorta through bronchial arteries to capillaries, where O₂ is released. Deoxygenated blood from the proximal part of the bronchi returns to the heart through the bronchial veins and the azygos venous system (see chapter 21). More distally, the venous drainage from the bronchi enters the pulmonary veins. Thus, the oxygenated blood returning from the alveoli in the pulmonary veins is mixed with a small amount of deoxygenated blood returning from the bronchi.

Lymphatic Supply

The lungs have two lymphatic supplies. The **superficial lymphatic vessels** are deep to the visceral pleura; they drain lymph from the superficial lung tissue and the visceral pleura. The **deep lymphatic vessels** follow the bronchi; they drain lymph from the bronchi and associated connective tissues. No lymphatic vessels are located in the walls of the alveoli. Both the superficial and deep lymphatic vessels exit the lung at the hilum.

Phagocytic cells within the lungs phagocytize carbon particles and other debris from inspired air and move them to the lymphatic vessels. In an older person, especially one who smokes or has lived most of his or her life in a city with air pollution, these particles accumulate and cause the surface of the lungs to become gray or black. In addition, cancer cells from the lungs can sometimes spread to other parts of the body through the lymphatic vessels.

Clinical IMPACT

Cough and Sneeze Reflexes

Both the cough reflex and the sneeze reflex dislodge foreign matter or irritating material from the respiratory passages. The bronchi and trachea contain sensory receptors that detect such substances and initiate action potentials that pass along the vagus nerves to the medulla oblongata, where the cough reflex is triggered.

The movements resulting in a cough occur as follows: Approximately 2.5 L of air are inspired; the vestibular and vocal folds close tightly to trap the inspired air in the lungs; the abdominal muscles contract to force the abdominal organs up against the diaphragm; and the muscles of expiration contract forcefully. As a consequence, the pressure in the lungs increases to 100 mm Hg or more. Then the vestibular and vocal folds open suddenly, the soft palate

is elevated, and air rushes from the lungs and out the oral cavity at a high velocity, carrying foreign matter with it.

The sneeze reflex is similar to the cough reflex in that air is forcefully expelled from the lungs, but it differs in several ways. The irritation that initiates the sneeze reflex occurs in the nasal passages instead of in the trachea and bronchi, and the action potentials travel along the trigeminal nerves to the medulla oblongata, where the reflex is triggered. During the sneeze reflex, the soft palate is depressed, so that air is directed primarily through the nasal passages, although a considerable amount passes through the oral cavity. The rapidly flowing air dislodges particulate matter from the nasal passages and can propel it a considerable distance from the nose.

About 17–25% of people have a photic sneeze reflex, which is stimulated by exposure to bright light, such as the sun. The sneeze reflex may be connected to the pupillary reflex, which causes the pupils to constrict in response to bright light. Researchers speculate that the complicated “wiring” of the pupillary and sneeze reflexes are intermixed in some people, so that, when bright light activates a pupillary reflex, it also activates a sneeze reflex. Sometimes the photic sneeze reflex is fancifully called ACHOO, which stands for autosomal dominant compelling helio-ophthalmic outburst. As the name suggests, the reflex is inherited as an autosomal dominant trait. A person needs to inherit only one copy of the gene to have a photic sneeze reflex.

21. What are the two major routes of blood flow to and from the lungs? What is the function of each route?
22. Describe the lymphatic supply of the lungs.

23.3 Ventilation

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the changes in alveolar pressure that are responsible for the movement of air into and out of the lungs.**
- B. Explain how surfactant and pleural pressure prevent the collapse of the lungs and how changes in pleural pressure cause changes in alveolar volume.**

Pressure Differences and Airflow

Ventilation is what we call breathing; it is the process of moving air into and out of the lungs. Airflow into the lungs requires a pressure gradient from the outside of the body to the alveoli. This pressure gradient is provided by atmospheric pressure—the combined force of all the gases that make up the air we breathe. Airflow from the lungs requires a pressure gradient in the opposite direction, which is created by the components of the respiratory system. The physics of airflow in tubes, such as the ones that make up the respiratory passages, is the same as that of the flow of blood in blood vessels (see chapter 21). Thus, the following relationships hold:

$$F = \frac{P_1 - P_2}{R}$$

where F is airflow (milliliters per minute) in a tube, P_1 is pressure at point 1, P_2 is pressure at point 2, and R is resistance to airflow.

Air moves through tubes because of a pressure difference: Air moves from areas of higher pressure to areas of lower pressure. Thus, when P_1 is greater than P_2 , gas flows from P_1 to P_2 . The greater the pressure difference, the faster the flow rate. If the pressure difference decreases, the flow rate also decreases. For example, during inspiration, air pressure outside the body is greater than air pressure in the alveoli, and air flows into the body through the trachea and bronchi to the alveoli.

Pressure and Volume

The pressure of a gas in a container at a constant temperature follows **Boyle's law**:

$$P = k/V$$

where P is gas pressure, k is a constant for a given temperature, and V is the volume of the container. Body temperature in humans can be considered a constant. Thus, Boyle's law states that, in a container, such as the thoracic cavity or an alveolus, pressure is inversely proportional to volume. As volume increases, pressure decreases; as volume decreases, pressure increases (table 23.1).

TABLE 23.1

Gas Laws

Description	Importance
<p>Boyle's Law</p> <p>The pressure of a gas is inversely proportional to its volume at a given temperature.</p>	<p>Air flows from areas of higher to lower pressure. When alveolar volume increases, causing pleural pressure to decrease below atmospheric pressure, air moves into the lungs. When alveolar volume decreases, causing pleural pressure to increase above atmospheric pressure, air moves out of the lungs.</p>
<p>Dalton's Law</p> <p>The partial pressure of a gas in a mixture of gases is the percentage of the gas in the mixture.</p>	<p>Gases move from areas of higher to lower partial pressure. The greater the difference in partial pressure between two points, the greater the rate of gas movement. Maintaining partial pressure differences ensures gas movement.</p>
<p>Henry's Law</p> <p>The concentration of a gas dissolved in a liquid is equal to the partial pressure of the gas times the solubility coefficient of the gas.</p>	<p>Only a small amount of the gases in air dissolves in the fluid lining the alveoli. Carbon dioxide, however, is 24 times more soluble than O_2; therefore, CO_2 exits through the respiratory membrane more readily than O_2 enters.</p>

Clinical IMPACT

Disorders That Decrease the Diameter of Air Passageways

The flow of air decreases when the resistance to airflow is increased by conditions that reduce the diameter of the respiratory passageways. According to Poiseuille's law (see chapter 21), the resistance to airflow is proportional to the diameter (D) of a tube. Thus, a small change in diameter results in a large change in resistance, which greatly decreases airflow. For example, asthma results in the release of inflammatory chemicals, such as leukotrienes, that cause severe constriction of the bronchioles. Emphysema produces increased airway resistance because the bronchioles are obstructed as a result of inflammation and because damaged bronchioles collapse during expiration, thus trapping air within the alveoli. Cancer can also occlude respiratory passages as the tumor replaces lung tissue.

When there is increased resistance, increasing the pressure difference between alveoli and the atmosphere can help maintain airflow. Within limits, this can be accomplished by increased contraction of the muscles of respiration.

Airflow Into and Out of Alveoli

Because air movement is dependent on pressure gradients between the external environment and the lungs, pressure is measured with respiration-specific units. These measurements are used to describe

airflow into and out of the lungs. Respiratory physiologists express different pressures within the respiratory system in the following ways:

1. **Barometric air pressure (P_B)**, which is simply atmospheric air pressure outside the body, is designated as zero. Thus, whether at sea level with a pressure of 760 mm Hg or at 10,000 feet above sea level on a mountaintop with a pressure of 523 mm Hg, P_B is always designated as zero.
2. Respiratory pressures are measured relative to barometric air pressure. For example, **intra-alveolar pressure (P_{alv})** is the air pressure inside an alveolus. Because the pressure inside the alveolus measures approximately 759 mm Hg upon inhalation, P_{alv} is usually expressed as -1 mm Hg. This is because it has decreased by 1 mm Hg below P_B . Then, when you exhale, the P_{alv} increases to about 761 mm Hg, so it is usually designated as $+1$ mm Hg. Thus, for simplicity, P_{alv} is always given as its difference from P_B —either 1 mm Hg above P_B or 1 mm Hg below P_B .

The movement of air into and out of the lungs results from changes in thoracic volume, which cause changes in alveolar volume. The changes in alveolar volume produce changes in intra-alveolar pressure. The pressure difference between barometric air pressure and intra-alveolar pressure ($P_B - P_{alv}$) results in air movement. The details of this process during quiet resting breathing are as follows:

1. *End of expiration* (figure 23.13, *step 1*). By the end of expiration, barometric air pressure and intra-alveolar pressure are equal. Therefore, no air moves into or out of the lungs.
2. *During inspiration* (figure 23.13, *step 2*). As inspiration begins, contraction of inspiratory muscles increases thoracic volume, which results in expansion of the lungs and an increase in alveolar volume (see the section “Changing Alveolar Volume”). The increased alveolar volume causes a decrease in intra-alveolar pressure below barometric air pressure to approximately -1 mm Hg. Air flows into the lungs because barometric air pressure is greater than intra-alveolar pressure.
3. *End of inspiration* (figure 23.13, *step 3*). At the end of inspiration, the thorax stops expanding, the alveoli stop expanding, and intra-alveolar pressure becomes equal to barometric air pressure because of airflow into the lungs. No movement of air occurs after intra-alveolar pressure becomes equal to barometric pressure, but the volume of the lungs is larger than at the end of expiration.
4. *During expiration* (figure 23.13, *step 4*). During expiration, the volume of the thorax decreases as the diaphragm relaxes, and the thorax and lungs recoil. Because thoracic volume determines alveolar volume, the smaller thoracic volume results in a corresponding decrease in alveolar volume. Thus, intra-alveolar pressure rises over barometric air pressure to approximately $+1$ mm Hg. Because intra-alveolar pressure is greater than barometric air pressure, air flows out of the lungs. As expiration ends, the decrease in thoracic volume stops, and the alveoli stop changing size. The process repeats, beginning at step 1.

ASSESS YOUR PROGRESS

23. What is ventilation?
24. How do pressure differences and resistance affect airflow through a tube?
25. What happens to the pressure within a container when the volume of the container increases? Whose law describes this relationship?
26. What are the assigned values for barometric air pressure and for intra-alveolar pressure?
27. Describe the process of making intra-alveolar pressure changes that occurs during quiet resting breathing.

Changing Alveolar Volume

It is important to understand that lung recoil and changes in pleural pressure cause changes in alveolar volume. When alveolar volume changes, it causes the pressure differences between the environment and the alveoli, resulting in ventilation.

Lung Recoil

One factor that changes alveolar volume is **lung recoil**. This is the tendency for the lungs to decrease in size after they are stretched. Imagine a stretched rubber band snapping back to its original size when released. Similarly, upon expiration, the tension on the lungs is released and they shrink. This compresses the alveoli and reduces their volume. Expanded alveoli decrease in size for two reasons: (1) elastic recoil caused by the elastic fibers in the alveolar walls and (2) surface tension of the film of fluid that lines the alveoli. Surface tension occurs due to the tendency of hydrogen bonding of water molecules with each other. Water molecules are all attracted to the center of an alveolus and form a drop of water. Because the alveolar fluid water molecules are also attracted to the surface of the alveoli, formation of a drop of water causes the alveoli to collapse, thus producing fluid-filled alveoli with smaller volumes than air-filled alveoli.

A molecule called **surfactant** (ser-fak'tānt; surface acting agent) forms a one-molecule-thick layer over the alveolar fluid, which reduces the surface tension in the alveoli. Surfactant is a mixture of lipoprotein molecules produced by the type II pneumocytes of the alveolar epithelium. With surfactant, the force produced by surface tension is approximately 3 mm Hg; without surfactant, the force can be as high as 30 mm Hg. Thus, surfactant greatly reduces the tendency of the lungs to collapse. Premature infants do not produce enough surfactant. This is what is meant by the idea that “their lungs are immature” (see Clinical Impact, “Infant Respiratory Distress Syndrome”).

Pleural Pressure

Another factor important in air movement into and out of the lungs is the pressure within the pleural cavity, called **pleural pressure (P_{pl})**. Recall that the visceral pleura and the parietal pleura are adhered to each other, so that when the thoracic cavity expands, the lungs are “pulled” outward. This creates a negative pressure in the pleural cavity. Because pleural pressure is normally less than intra-alveolar pressure, alveoli can expand. In order for the lungs to function normally, alveoli at rest need to be partially expanded. If not, the alveoli completely collapse, making it very difficult to re-expand them.

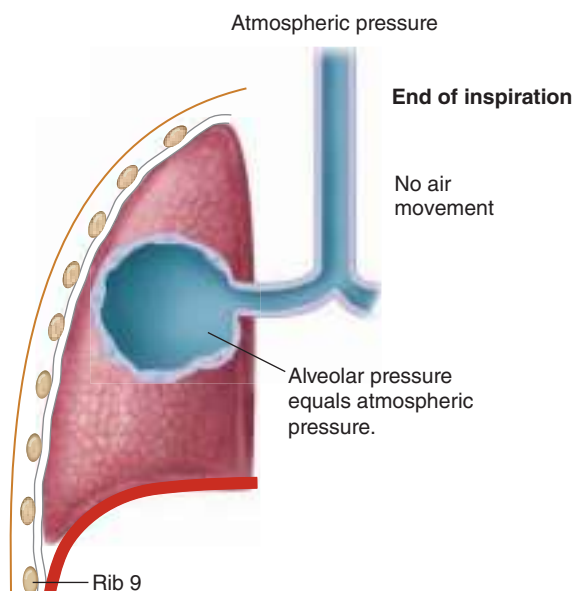

FUNDAMENTAL Figure

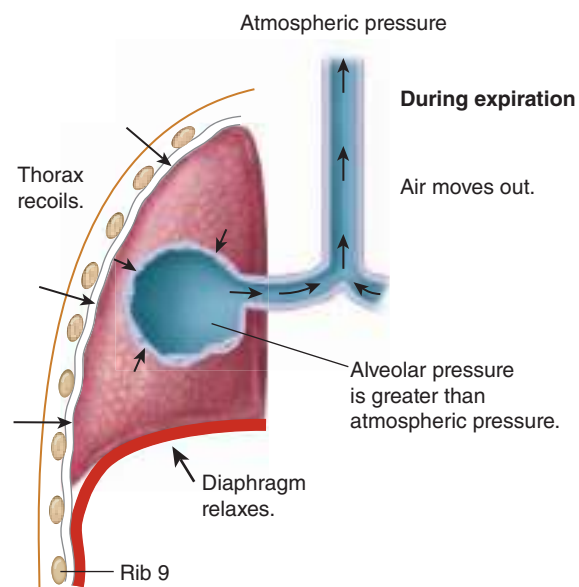

1 At the end of expiration, alveolar pressure is equal to atmospheric pressure, and there is no air movement.

2 During inspiration, increased thoracic volume results in increased alveolar volume and decreased alveolar pressure. Atmospheric pressure is greater than alveolar pressure, and air moves into the lungs.

3 At the end of inspiration, alveolar pressure is equal to atmospheric pressure, and there is no air movement.

4 During expiration, decreased thoracic volume results in decreased alveolar volume and increased alveolar pressure. Alveolar pressure is greater than atmospheric pressure, and air moves out of the lungs.

PROCESS FIGURE 23.13 Intra-alveolar Pressure Changes During Inspiration and Expiration

The combined space of all the alveoli is represented by a large “bubble” (blue). The alveoli are actually microscopic and would not be visible at the scale of this illustration. **APR**

Clinical IMPACT

Infant Respiratory Distress Syndrome

Infant respiratory distress syndrome is common in premature infants, especially those with a gestation age of less than 7 months. This condition occurs because surfactant is not produced in adequate quantities until approximately 7 months of development. Thereafter, the amount produced increases as the fetus matures. Pregnant women who are likely to deliver prematurely can be given cortisol, which crosses the placenta into the fetus and stimulates surfactant synthesis.

If a newborn produces insufficient surfactant, the lungs tend to collapse. Thus, the muscles of respiration must exert a great deal of energy to keep the lungs inflated, and even then ventilation is inadequate. Without specialized treatment, most babies with this disease die soon after birth as a result of inadequate ventilation of the lungs and fatigued respiratory muscles. Infants with infant respiratory distress syndrome are treated with pressurized air, which delivers oxygen-rich air to the lungs. The pressure helps keep the alveoli inflated. In addition, surfactant administered with the pressurized air can reduce surface tension in the alveoli. Surfactant can be obtained from cow, pig, and human lungs; from human amniotic fluid; or from genetically modified bacteria. Synthetic surfactant is also available.

If you have flown on a plane, or have been to the mountains, you may have experienced a situation similar to that which keeps the alveoli expanded. At higher altitudes, the atmospheric pressure is much lower than at sea level. If a bottle of liquid (such as shampoo), normally kept at sea level, is rapidly taken to a high altitude, it will “explode.” Because there is not as much force on the outside of the bottle at high altitude, it expands. Similarly, because the pleural pressure pulls the pleura away from the outside of the alveoli, the pressure on the alveoli is lower. The lower pressure allows the alveoli to expand.

Even after exhaling, pleural pressure is lower than intra-alveolar pressure. At the end of a normal expiration, pleural pressure is -4 mm Hg, and intra-alveolar pressure is 0 mm Hg. This is due to a suction effect caused by fluid removal by the lymphatic system and by lung recoil. As the lungs recoil, the visceral pleura is pulled against the parietal pleura. Normally, the visceral pleura will not pull away from the parietal pleura because pleural fluid holds them together. Nonetheless, this pull decreases pressure in the pleural cavity, an effect that can be appreciated by putting water on the palms of your hands and then placing them together. As you gently pull your hands apart, you will feel a sensation of negative pressure.

Transpulmonary pressure is the difference between intra-alveolar pressure and pleural pressure. When pleural pressure is lower than intra-alveolar pressure, the alveoli tend to expand. However, they do not expand to the point of bursting because the lungs’ tendency to recoil places an opposite force on alveolar expansion. Therefore, the alveoli expand when the pull of the visceral pleura against the parietal pleura is stronger than the

opposite pull of lung recoil. In other words, when the transpulmonary pressure is around 4 mm Hg, the alveoli are expanded.

However, if the transpulmonary pressure decreases, the alveoli collapse. This happens when the two pleural membranes become separated and the force from lung recoil is strong enough to pull the visceral pleura away from the parietal pleura. Specifically, pleural pressure increases and becomes equal to barometric air pressure. This happens when the thoracic wall or lung is pierced, and the pleural cavity opens to the outside. Therefore, the alveoli collapse, lung recoil is unopposed, and the entire lung collapses and pulls away from the thoracic wall. Because the two pleural cavities are independent, one lung can collapse while the other remains inflated.

This pleural pressure increase is called a **pneumothorax**. A pneumothorax occurs when the parietal pleura is pierced or torn. Air then enters the pleural cavity through the damaged parietal pleura. A pneumothorax has two major possible causes: penetrating trauma and nonpenetrating trauma. Types of penetrating traumas include being stabbed, getting shot by a gun, and breaking a rib. Types of nonpenetrating traumas include a blow to the chest; a medical procedure, such as insertion of a catheter to withdraw pleural fluid; disease, such as an infection or emphysema; and severe, spastic coughing.

The most common symptoms of a pneumothorax are chest pain and shortness of breath. Treatment depends on the cause and severity. In patients with mild symptoms, the pneumothorax may resolve on its own. In other cases, a chest tube that aspirates the pleural cavity and restores a negative pressure can cause reexpansion of the lung. Surgery may also be necessary to close the opening into the pleural cavity.

In a **tension pneumothorax**, the pressure within the pleural cavity is always higher than barometric air pressure. Any situation where a pneumothorax occurred can lead to a tension pneumothorax. If a tear in the pleural cavity forms a tissue flap that acts as a flutter valve, it will allow air to enter the pleural cavity during inspiration but will not allow it to exit during expiration. The result is an increase in air and pressure within the pleural cavity, which can compress blood vessels returning blood to the heart, causing decreased venous return, low blood pressure, and inadequate delivery of O_2 to tissues. The insertion of a large-bore needle into the pleural cavity allows air to escape and releases the pressure.

Pressure Changes During Inspiration and Expiration

At the end of a normal expiration, pleural pressure is -4 mm Hg, and intra-alveolar pressure is equal to barometric pressure (0 mm Hg). During normal, quiet inspiration, pleural pressure decreases to -7 mm Hg (figure 23.14, *step 1*). Consequently, the alveolar volume increases, intra-alveolar pressure decreases below barometric air pressure, and air flows into the lungs. As air flows into the lungs, intra-alveolar pressure increases and becomes equal to barometric pressure at the end of inspiration (figure 23.14, *steps 2 and 3*).

The decrease in pleural pressure during inspiration occurs for two reasons. First, because changing volume affects pressure (Boyle’s law), the increased volume of the thoracic cavity causes decreased pleural pressure. Second, as the thoracic cavity expands, the lungs expand because they adhere to the inner thoracic wall through the pleurae. As the lungs expand, their tendency to recoil

Changes during inspiration

1 Pleural pressure decreases because thoracic volume increases.

2 As inspiration begins, intra-alveolar pressure decreases below barometric air pressure (0 on the graph) because the decreased pleural pressure causes alveolar volume to increase. By the end of inspiration, intra-alveolar and barometric air pressure are equal.

3 During inspiration, air flows into the lungs because intra-alveolar pressure is lower than barometric air pressure.

Inspiration

Expiration

Changes during expiration

4 Pleural pressure increases because thoracic volume decreases.

5 As expiration begins, intra-alveolar pressure increases above barometric air pressure (0 on the graph) because the increased pleural pressure causes alveolar volume to decrease. By the end of expiration, intra-alveolar and barometric air pressure are equal.

6 During expiration, air flows out of the lungs because intra-alveolar pressure is greater than barometric air pressure.

PROCESS FIGURE 23.14 Dynamics of a Normal Breathing Cycle

increases, resulting in an increased suction effect and a lowering of pleural pressure. The tendency for the lungs to recoil increases as the lungs are stretched, similar to the increased force generated in a stretched rubber band.

During expiration, pleural pressure increases because of decreased thoracic volume and decreased lung recoil (figure 23.14, *step 4*). As pleural pressure increases, alveolar volume decreases, intra-alveolar pressure increases above barometric air pressure, and air flows out of the lungs. As air flows out of the lungs, intra-alveolar pressure decreases and becomes equal to barometric pressure at the end of expiration (figure 23.14, *steps 5 and 6*).

28. What is lung recoil, and what two factors cause it?
29. How does surfactant reduce lung recoil? What happens if the alveoli have insufficient surfactant?
30. What is pleural pressure? What happens to alveolar volume when pleural pressure decreases? What causes pleural pressure to be lower than intra-alveolar pressure?
31. How does a pneumothorax cause a lung to collapse? How does a pneumothorax affect the chest cavity?

32. During inspiration, what causes pleural pressure to decrease? What effect does this have on intra-alveolar pressure and air movement?
33. During expiration, what causes pleural pressure to increase? What effect does this have on intra-alveolar pressure and air movement?

23.4 Measurement of Lung Function

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Define compliance, minute volume, and alveolar ventilation.
- B. List the pulmonary volumes and capacities, and define each of them.
- C. Distinguish between anatomical dead space and physiological dead space.

Sometimes, the amount of air a person's lungs are capable of moving is not sufficient to support normal activities. In that case, several types of medical tests can be performed to determine what

FIGURE 23.15 Lung Volumes and Lung Capacities

The tidal volume during resting conditions is represented.

might be causing the lung malfunction. The patient's measurements are then used to diagnose specific diseases and to track recovery.

Compliance of the Lungs and Thorax

Compliance is a measure of the ease with which the lungs and thorax expand. The compliance of the lungs and thorax is the volume by which they increase for each unit of change in intra-alveolar pressure. It is usually expressed in liters (volume of air) per mm Hg (pressure), and for a normal person the compliance of the lungs and thorax is 0.18 L/mm Hg. That is, for every 1 mm Hg change in intra-alveolar pressure, the volume changes by 0.18 L.

A lower than normal compliance means that it is harder to expand the lungs and thorax. There are many conditions that could decrease compliance. These include the deposition of inelastic fibers in lung tissue (pulmonary fibrosis), the collapse of the alveoli (infant respiratory distress syndrome and pulmonary edema), increased resistance to airflow caused by airway obstruction (asthma, bronchitis, and lung cancer), and deformities of the thoracic wall that reduce its ability to expand and allow the thoracic volume to increase (kyphosis and scoliosis). Pulmonary diseases that result in decreased compliance can markedly affect the total amount of energy required

for ventilation and increase the total amount of energy expended by the body by up to 30%.

On the other hand, if the lungs and thorax have lost some of their elasticity, the compliance will be greater. If this becomes the case, it is easier to expand the lungs and thorax. For example, emphysema sometimes causes the destruction of elastic lung tissue. This reduces the elastic recoil force of the lungs, thereby making expansion of the lungs easier and resulting in a higher than normal compliance.

Pulmonary Volumes and Capacities

Spirometry (spī-rom'ě-trē) is the process of measuring volumes of air that move into and out of the respiratory system, and a **spirometer** (spī-rom'ě-ter) is the device used to measure these pulmonary volumes. The four pulmonary volumes and representative values for a young adult male are graphed in figure 23.15 and listed here:

1. **Tidal volume** is the normal volume of air inspired and expired with each breath. At rest, quiet breathing results in a tidal volume of approximately 500 mL.
2. **Inspiratory reserve volume** is the amount of air that can be inspired forcefully after a normal inspiration (approximately 3000 mL at rest).
3. **Expiratory reserve volume** is the amount of air that can be forcefully expired after a normal expiration (approximately 1100 mL at rest).
4. **Residual volume** is the volume of air still remaining in the respiratory passages and lungs after the most forceful expiration (approximately 1200 mL).

The tidal volume increases when a person is more active. Because the maximum volume of the respiratory system does not change from moment to moment, an increase in tidal volume causes a decrease in the inspiratory and expiratory reserve volumes.

Pulmonary capacities are the sum of two or more pulmonary volumes (figure 23.15). Some pulmonary capacities follow:

1. **Inspiratory capacity** is the tidal volume plus the inspiratory reserve volume. It is the amount of air a person can inspire maximally after a normal expiration (approximately 3500 mL at rest).
2. **Functional residual capacity** is the expiratory reserve volume plus the residual volume. It is the amount of air remaining

in the lungs at the end of a normal expiration (approximately 2300 mL at rest).

- Vital capacity** is the sum of the inspiratory reserve volume, the tidal volume, and the expiratory reserve volume. It is the maximum volume of air a person can expel from the respiratory tract after a maximum inspiration (approximately 4600 mL).
- Total lung capacity** is the sum of the inspiratory and expiratory reserve volumes plus the tidal volume and the residual volume (approximately 5800 mL).

Factors such as gender, age, body size, and physical conditioning cause variations in respiratory volumes and capacities from one individual to another. For example, the vital capacity of adult females is usually 20–25% less than that of adult males. The vital capacity reaches its maximum amount in young adults and gradually decreases in the elderly. Tall people usually have a greater vital capacity than short people, and thin people have a greater vital capacity than obese people. Well-trained athletes can have a vital capacity 30–40% above that of untrained people. In patients whose respiratory muscles are paralyzed by spinal cord injury or diseases such as poliomyelitis or muscular dystrophy, vital capacity can be reduced to values not consistent with survival (less than 500–1000 mL). Factors that reduce compliance also reduce vital capacity.

The **forced expiratory vital capacity** is a simple and clinically important pulmonary test. The patient inspires maximally and then exhales maximally into a spirometer as rapidly as possible. The volume of air expired at the end of the test is the vital capacity. The spirometer also records the volume of air expired per second. The **forced expiratory volume in 1 second (FEV₁)** is the amount of air expired within the first second of the test. In some conditions, the vital capacity may not be dramatically affected, but how rapidly air is expired can be greatly decreased. Airway obstruction, caused by asthma, the collapse of bronchi in emphysema, or a tumor, as well as disorders that reduce the ability of the lungs or chest wall to deflate, such as pulmonary fibrosis, silicosis, kyphosis, and scoliosis, can cause a decreased FEV₁.

Minute Volume and Alveolar Ventilation

A common vital sign measured in clinics and hospitals is the **respiratory rate**, or number of breaths per minute. The *volume* of air moved through the respiratory system per minute is the **minute volume**. The minute volume equals the tidal volume times the respiratory rate. Using approximate numbers, we can calculate the average minute volume. With a resting tidal volume of 500 mL and a respiratory rate of 12 breaths per minute, minute volume averages approximately 6 L/min (500 mL x 12 breaths/min = 6000 mL/min, or 6 L/min).

Although minute volume measures the amount of air moving into and out of the respiratory system per minute, it is not a measure of the amount of air available for gas exchange. However, minute volume is clinically important because it is an indication of CO₂ levels, an important physiological parameter (see section 23.6).

A more accurate measure of the amount of air available for gas exchange per minute is **alveolar ventilation**. In order to

calculate alveolar ventilation, we must first account for a parameter called the dead space. The structures of the respiratory system where gas exchange does not take place are collectively called the dead space: anatomical dead space and physiological dead space. **Anatomical dead space** is generally about 1 mL of dead space per pound of an individual's "ideal" body weight. It includes the nasal cavity, pharynx, larynx, trachea, bronchi, bronchioles, and terminal bronchioles. **Physiological dead space** is the anatomical dead space plus the volume of any alveoli in which gas exchange is less than normal. In a healthy person, anatomical and physiological dead spaces are nearly the same, meaning that most alveoli are functional. However, in patients with emphysema, alveolar walls degenerate, and small alveoli combine to form larger alveoli. The result is not only fewer alveoli but also alveoli with an increased volume and decreased surface area. Although the enlarged alveoli are still ventilated, their surface area is inadequate for complete gas exchange, and the physiological dead space increases.

During inspiration, much of the inspired air fills the dead space first before reaching the alveoli and, thus, is unavailable for gas exchange. The volume of air available for gas exchange per minute is called alveolar ventilation (\dot{V}_A), and it is calculated as follows:

$$\dot{V}_A = f(V_T - V_D)$$

where \dot{V}_A is alveolar ventilation (milliliters per minute), f is respiratory rate (frequency; breaths per minute), V_T is tidal volume (milliliters per respiration), and V_D is dead space (milliliters per respiration). The dot over the letter V means that this is a *per minute* measure. Thus, for each breath, physiologically relevant air is only that volume inside healthy alveoli.

Predict 5

What is the alveolar ventilation of a resting person with a tidal volume of 500 mL, a dead space of 150 mL, and a respiratory rate of 12 breaths per minute? Suppose the person exercises, so that tidal volume increases to 4000 mL, dead space increases to 300 mL due to dilation of the respiratory passageways, and respiratory rate increases to 24 breaths per minute. What is the alveolar ventilation then? How is the change in alveolar ventilation beneficial for doing exercise?

ASSESS YOUR PROGRESS

- What is compliance? What is the effect on lung expansion when compliance increases or decreases?
- Distinguish among tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume.
- Differentiate among inspiratory capacity, functional residual capacity, vital capacity, and total lung capacity.
- What is forced expiratory volume in 1 second, and why it is clinically important?
- What is the difference between minute volume and alveolar ventilation?
- What is dead space? Contrast anatomical dead space with physiological dead space.

23.5 Physical Principles of Gas Exchange

LEARNING OUTCOMES

After reading this section, you should be able to

- Explain partial pressure and its relationship to the concentration of gases in the body. Describe the partial pressure gradients for O₂ and CO₂.
- Explain the factors that affect gas movement through the respiratory membrane.
- Describe the relationship between alveolar ventilation and pulmonary capillary perfusion.

Ventilation supplies atmospheric air to the alveoli. The next step in the process of respiration (external respiration) is the diffusion of gases between the alveoli and the blood in the pulmonary capillaries. The molecules of gas move randomly down their partial pressure gradient from the air into the blood for O₂ and from the blood into the air for CO₂. Partial pressure is one measurement to express the amount a gas that is present in a mixture.

Partial Pressure

Atmospheric pressure is due to a mixture of gases, each of which is present in a different amount. The term *pressure* is used to express the amount of each gas in a mixture. This is comparable to using the term *concentration* for solutes. According to **Dalton's law**, the total pressure of a gas is the sum of the individual pressures of each gas. For example, at sea level, the pressure of all the gases in the air, or atmospheric pressure, is approximately 760 mm Hg. The major components of atmospheric air are nitrogen (approximately 79%) and O₂ (approximately 21%). If the individual gas pressures are equivalent to the percentage each gas represents in the mixture, we can easily determine these values (table 23.1). These values are referred to as **partial pressures**. For example, using the values in table 23.1, we can calculate the partial pressure for nitrogen. Because nitrogen makes up 79% of the volume of atmospheric air, the partial pressure resulting from nitrogen (P_{N₂}) is 0.79 times 760 mm Hg, or 600 mm Hg. Because O₂ is 21% of the volume of atmospheric air, the partial pressure resulting from O₂ (P_{O₂}) is 0.21 times 760 mm Hg, or 160 mm Hg. Because CO₂ is 0.04% of atmospheric air, its partial pressure (P_{CO₂}) is 0.3 mm Hg.

When air comes in contact with water, some of the water turns into a gas and evaporates into the air. Water molecules in gaseous form also exert a partial pressure. This partial pressure (P_{H₂O}) is sometimes referred to as **water vapor pressure** (table 23.2). In other words, atmospheric air can be represented by the following equation:

$$P_{O_2} + P_{CO_2} + P_{N_2} + P_{H_2O} = 760 \text{ mm Hg}$$

A common misconception is that at higher altitudes there is “less” O₂ in the air. However, this is not the case. Rather, it is total atmospheric pressure that is lower at higher altitudes than at sea level. For example, the atmospheric pressure at an elevation of 14,000 ft above sea level, the elevation of Pike's Peak in Colorado, is about 430 mm Hg. The percentage of the air that is O₂ remains at 21%. Thus, 0.21 times 430 mm Hg is 90 mm Hg. Therefore, at high altitudes your body does, in fact, react as if there were “less” O₂. However, it is the O₂ partial pressure gradient that has reduced, causing less O₂ to enter the lungs per breath. The normal initial adaptation to high altitudes is an increased breathing rate per minute, thereby allowing a sufficient amount of O₂ delivery to the lungs.

Three factors cause differences in the composition among alveolar air, expired air, and atmospheric air. (1) Air entering the respiratory system is humidified. (2) O₂ diffuses from the alveoli into the blood, while CO₂ diffuses from the blood into the alveoli. (3) The alveolar air is only partially replaced with atmospheric air during each inspiration.

Diffusion of Gases Into and Out of Liquids

Gas molecules move from the air into a liquid, or from a liquid into the air, down their partial pressure gradients. Gases move from a higher partial pressure to a lower partial pressure. When partial pressures of gases are equal between the air and a liquid, they are in equilibrium. However, to calculate the amount of a gas in a liquid, the partial pressure alone is not sufficient. The amount of the gas is also dependent on how readily a gas dissolves in the liquid, which is called the solubility coefficient. Thus, at a given temperature, **Henry's law** describes the concentration of a gas at equilibrium in a liquid (see table 23.1):

$$\text{Concentration of dissolved gas} = \text{Pressure of gas} \times \text{Solubility coefficient}$$

In water, the solubility coefficient for O₂ is 0.024; for CO₂ it is 0.57. Thus, CO₂ is approximately 24 times more soluble in water than O₂ is.

TABLE 23.2 Partial Pressures of Gases at Sea Level

Gases	Dry Air		Humidified Air		Alveolar Air		Expired Air	
	mm Hg	%	mm Hg	%	mm Hg	%	mm Hg	%
Nitrogen	600	79	562.4	74	569	74.9	566	74.5
Oxygen	160	21	152	20	104	13.6	120	15.7
Carbon dioxide	0.3	0.04	0.3	0.04	40	5.3	27	3.6
Water vapor	0.0	0.00	47	6.20	47	6.2	47	6.2

Predict 6

As a scuba diver descends, the pressure of the water on the body prevents normal expansion of the lungs. To compensate, the diver breathes pressurized air, which has a greater pressure than air at sea level. What effect does the increased pressure have on the amount of gas dissolved in the diver's body fluids? A scuba diver who suddenly ascends to the surface from a great depth can develop decompression sickness (the bends), in which bubbles of nitrogen gas form. The expanding bubbles damage tissues or block blood flow through small blood vessels. Explain why the bubbles develop.

ASSESS YOUR PROGRESS

40. According to Dalton's law, what is the partial pressure of a mixture of gases? What is water vapor pressure?
41. Why are the compositions of inspired, alveolar, and expired air different?
42. According to Henry's law, how do partial pressure and solubility of a gas affect its concentration in a liquid?

Diffusion of Gases Through the Respiratory Membrane

In order for humans to utilize O_2 in the air we breathe, O_2 must be able to diffuse across the respiratory membrane into the blood. Four major factors influence the rate of gas diffusion through the respiratory membrane: (1) the thickness of the membrane, (2) the diffusion coefficient of the gas across the membrane, (3) the surface area of the membrane, and (4) the partial pressure gradient of the gas across the membrane.

Respiratory Membrane Thickness

Increasing the thickness of the respiratory membrane decreases the rate of gas diffusion. The thickness of the respiratory membrane normally averages $0.6 \mu\text{m}$, but diseases increase its thickness. A two- or three-fold thickness increase markedly decreases the rate of gas exchange. The most common cause of increased respiratory membrane thickness is an accumulation of fluid in the alveoli, known as *pulmonary edema*. Alveolar fluid accumulation is usually caused by failure of the left side of the heart. Left side heart failure increases venous pressure in the pulmonary capillaries and causes fluid to accumulate in the alveoli. Conditions that result in inflammation of the lung tissues, such as tuberculosis, pneumonia, or advanced silicosis, can also cause fluid accumulation within the alveoli.

Diffusion Coefficient

The **diffusion coefficient** is a measure of how easily a gas diffuses into and out of a liquid or tissue. The diffusion coefficient accounts for both the solubility of the gas in the liquid and the size of the gas molecule (molecular weight). For example, if the diffusion coefficient of O_2 is assigned a value of 1, the relative diffusion coefficient of CO_2 is 20, which means CO_2 diffuses through the respiratory membrane about 20 times more readily than O_2 does. In other words, CO_2 is 24 times more soluble in water than O_2 is; when the chemical characteristics of the two molecules are also considered, the diffusion *rate* is calculated to be 20:1 of CO_2 to O_2 .

When the respiratory membrane becomes progressively damaged as a result of disease, its capacity for allowing O_2 to move into the blood is often so impaired that death from O_2 deprivation results before the diffusion of CO_2 can be reduced. If life is being maintained by extensive O_2 therapy, which increases the concentration of O_2 in the lung alveoli, the reduced capacity for the diffusion of CO_2 across the respiratory membrane can result in substantial increases in CO_2 in the blood.

Surface Area

In a healthy adult, the total surface area of the respiratory membrane is approximately 70 m^2 (approximately the floor area of a 25- × 30-foot room). Several respiratory diseases, including emphysema and lung cancer, cause a decrease in the surface area of the respiratory membrane. Even small decreases in this surface area adversely affect the respiratory exchange of gases during strenuous exercise. When the total surface area of the respiratory membrane is decreased to one-third or one-fourth of normal, the exchange of gases is significantly restricted, even under resting conditions.

A decreased surface area for gas exchange can also result from the surgical removal of lung tissue, the destruction of lung tissue by cancer, the degeneration of the alveolar walls by emphysema, or the replacement of lung tissue by connective tissue due to tuberculosis. More acute conditions that cause the alveoli to fill with fluid also reduce the surface area for gas exchange because the increased thickness of the respiratory membrane caused by the fluid accumulation makes the alveoli nonfunctional. This may occur in pneumonia or in pulmonary edema resulting from failure of the left ventricle.

Partial Pressure Gradient

The determining factor of gas movement direction is the partial pressure gradient for each gas. If the partial pressure gradient of a gas is higher in the alveolus, it will diffuse into the blood. On the other hand, if the partial pressure of a gas is higher in the blood, it will diffuse into the alveolus. When the partial pressure of a gas is greater on one side of the respiratory membrane than on the other side, net diffusion occurs from the higher to the lower partial pressure (see figure 23.8b). Normally, the partial pressure of oxygen (PO_2) is greater in the alveoli than in the blood of the pulmonary capillaries, and the partial pressure of carbon dioxide (PCO_2) is greater in the blood than in the alveolar air.

If faster gas exchange is needed, increasing alveolar ventilation will create a steeper partial pressure gradient for both O_2 and CO_2 . The greater volume of atmospheric air exchanged with the residual volume raises alveolar PO_2 and lowers alveolar PCO_2 . This promotes gas exchange. Conversely, inadequate ventilation causes a lower than normal partial pressure gradient for both O_2 and CO_2 , which causes inadequate gas exchange.

Relationship Between Alveolar Ventilation and Pulmonary Capillary Perfusion

Under normal conditions, effective gas exchange occurs between the air and the blood. This is because the alveoli supplied with air (alveolar ventilation) also have an ample blood supply, referred to as **pulmonary capillary perfusion**. During exercise,

effective gas exchange is maintained because both ventilation and cardiac output increase.

The normal relationship between alveolar ventilation and pulmonary capillary perfusion can be disrupted in two ways. First, alveolar ventilation may exceed the blood's ability to pick up O_2 , which can happen because of inadequate cardiac output after a heart attack. Second, alveolar ventilation may not be great enough to provide the O_2 needed to oxygenate the blood flowing through the pulmonary capillaries. For example, constriction of the bronchioles in asthma can decrease air delivery to the alveoli.

Blood that is not completely oxygenated is called shunted blood. There are two sources of shunted blood in the lungs. An **anatomical shunt** results when deoxygenated blood from the bronchi and bronchioles mixes with blood in the pulmonary veins (see “Blood Supply” in section 23.2). The other source of shunted blood is blood that passes through pulmonary capillaries but does not become fully oxygenated. The combination of these two shunts is called the **physiological shunt**. Normally, 1–2% of cardiac output makes up the physiological shunt.

Any condition that decreases gas exchange between the alveoli and the blood can increase the amount of shunted blood. For example, obstruction of the bronchioles in conditions such as asthma can decrease ventilation beyond the obstructed areas. The result is a large increase in shunted blood because the blood flowing through the pulmonary capillaries in the obstructed area is not able to pick up O_2 . In pneumonia or pulmonary edema, a buildup of fluid in the alveoli results in poor gas diffusion and less oxygenated blood.

When a person is standing, greater blood flow and ventilation occur in the base of the lung than in the top of the lung because gravity tends to pull the blood down toward the base of the lungs. Arterial pressure at the base of the lung is 22 mm Hg greater than at the top of the lung because of hydrostatic pressure caused by gravity (see chapter 21). This greater pressure increases blood flow and distends blood vessels. The decreased pressure at the top of the lung results in less blood flow and less distension in blood vessels, some of which are even collapsed during diastole.

During exercise, cardiac output and ventilation increase. The increased cardiac output raises pulmonary blood pressure throughout the lung, which increases blood flow. However, blood flow increases most at the top of the lung, because the increased pressure expands the less distended vessels and opens the collapsed vessels. Thus, gas exchange at the top of the lung is more effective because of greater blood flow.

Although gravity is the major factor affecting regional blood flow in the lung, under certain circumstances alveolar PO_2 can also have an effect. In most tissues, low PO_2 results in increased blood flow through the tissues (see chapter 21). However, in the lung, low PO_2 has the opposite effect. Low PO_2 causes arterioles to constrict, which reduces blood flow. This response helps keep gas exchange in the lungs efficient. Blood is routed away from areas of low O_2 toward parts of the lung that are better oxygenated. Because the function of the lungs is to acquire O_2 for the body, it is more efficient to avoid low O_2 areas in the lungs. For example, if a bronchus becomes partially blocked, ventilation of alveoli past the blockage site decreases, which in turn decreases gas exchange between the air

and blood. The effect of this decreased gas exchange is diminished by rerouting the blood to better-ventilated alveoli.

Predict 7

Even people in “good shape” may have trouble breathing at high altitudes. Explain how this can happen, even when ventilation of the lungs increases.

ASSESS YOUR PROGRESS

43. Describe the four factors that affect the diffusion of gases through the respiratory membrane. Give examples of diseases that decrease diffusion by altering these factors.
44. Does O_2 or CO_2 diffuse more easily through the respiratory membrane?
45. What effect do alveolar ventilation and pulmonary capillary perfusion have on gas exchange?
46. What are the anatomical shunt and the physiological shunt?
47. What are the effects of gravity and alveolar PO_2 on blood flow in the lung?

23.6 Oxygen and Carbon Dioxide Transport in the Blood

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the partial pressure gradients of O_2 and CO_2 .
- B. Explain how O_2 and CO_2 are transported in the blood.
- C. Discuss the factors that affect O_2 and CO_2 transport in the blood.
- D. Explain the CO_2 exchange in the lungs and at the tissues.
- E. Contrast fetal hemoglobin with maternal hemoglobin.

Once O_2 diffuses through the respiratory membrane into the blood, it is transported to all the cells of the body. The primary mode of O_2 transport in the blood is the red blood cell protein, hemoglobin. Most O_2 combines reversibly with hemoglobin, while a smaller amount dissolves in the plasma. Hemoglobin binds O_2 in the pulmonary capillaries and delivers it to the tissue capillaries, where some of the O_2 is released. The O_2 diffuses out of the blood and into the cells of the tissue. There O_2 is used in aerobic respiration to synthesize ATP (see chapter 25).

Cells produce CO_2 during aerobic respiration. The CO_2 diffuses out of the cells into the blood. Once CO_2 enters the blood, it is transported in three ways: dissolved in the plasma, in combination with hemoglobin, or as bicarbonate ions (HCO_3^-).

Oxygen Partial Pressure Gradients

The PO_2 of alveolar air averages approximately 104 mm Hg, whereas the PO_2 in blood returning to the lungs is approximately 40 mm Hg (figure 23.16, *step 1*). Consequently, O_2 diffuses down its partial pressure gradient from the alveoli into the pulmonary

PROCESS FIGURE 23.16 Gas Exchange

Partial pressure gradients of O_2 and CO_2 between the alveoli and the pulmonary capillaries and between the tissues and the tissue capillaries are responsible for gas exchange. All partial pressures shown are expressed in mm Hg. **APR**

capillary blood. By the time blood flows through the first third of the pulmonary capillary beds, an equilibrium has been achieved, and the PO_2 in the blood is 104 mm Hg, which is equivalent to the PO_2 in the alveoli. Even with the greater velocity of blood flow associated with exercise, by the time blood reaches the venous ends of the pulmonary capillaries, the PO_2 in the capillaries has achieved the same value as that in the alveoli (figure 23.16, *step 2*).

Blood leaving the pulmonary capillaries has a PO_2 of 104 mm Hg, but blood leaving the lungs in the pulmonary veins has a PO_2 of approximately 95 mm Hg. This decrease in the PO_2 occurs because the newly oxygenated blood mixes with deoxygenated (shunted) blood from the bronchial veins (figure 23.16, *step 3*).

The blood that enters the arterial end of the tissue capillaries has a PO_2 of approximately 95 mm Hg. The PO_2 of the interstitial fluid, in contrast, is close to 40 mm Hg and is probably near 20 mm Hg in the individual cells. Oxygen diffuses from the tissue capillaries to the interstitial fluid and from the interstitial fluid into the body's cells, where it is used in aerobic respiration. Because the cells use O_2 continuously, a constant partial pressure gradient exists for O_2 from the tissue capillaries to the cells (figure 23.16, *steps 4 and 5*).

Carbon Dioxide Partial Pressure Gradients

When cells use aerobic respiration to synthesize ATP, they continuously produce CO_2 as a by-product. This creates a partial pressure gradient from the cells of the tissue to the blood. The intracellular PCO_2 is approximately 46 mm Hg, and the interstitial fluid PCO_2 is approximately 45 mm Hg. At the arterial end of the tissue capillaries, the PCO_2 is close to 40 mm Hg. As blood flows through the tissue capillaries, CO_2 diffuses from a higher PCO_2 to a lower PCO_2 until an equilibrium in PCO_2 is established. By the venous end of the capillaries, blood PCO_2 has increased to 45 mm Hg (figure 23.16, *step 5*).

After blood leaves the venous end of the capillaries, it is transported through the cardiovascular system to the lungs. At the arterial end of the pulmonary capillaries, the PCO_2 is 45 mm Hg. Because the PCO_2 is approximately 40 mm Hg in the alveoli, CO_2 diffuses from the blood into the alveoli. At the venous end of the pulmonary capillaries, the PCO_2 has again decreased to 40 mm Hg (figure 23.16, *steps 1 and 2*).

Hemoglobin and Oxygen Transport

Approximately 98.5% of the O_2 transported in the blood from the lungs to the tissues is transported bound to hemoglobin in red blood cells, and the remaining 1.5% is dissolved in the plasma. The binding of O_2 to hemoglobin is reversible. In the lungs, O_2 binds to hemoglobin inside red blood cells; in the tissues, O_2 dissociates from hemoglobin and diffuses out of the red blood cells to supply the cells of the tissues.

Effect of PO_2

The relationship between O_2 and hemoglobin is similar to that of a ligand and its receptor in that hemoglobin has specific binding sites for O_2 . These binding sites are the heme groups of the hemoglobin, each of which binds to one O_2 (see chapter 19). Hemoglobin is 100% saturated with O_2 when four O_2 molecules are bound to each hemoglobin molecule in the red blood cells. When there is an average of two O_2 molecules bound to each hemoglobin molecule,

hemoglobin is 50% saturated. The **oxygen-hemoglobin dissociation curve** describes the percent saturation of hemoglobin in the blood at different blood PO_2 values. The degree of hemoglobin saturation is determined by many factors that affect the “attraction” of hemoglobin for O_2 . This attraction is called affinity. The first factor we will consider is the effect of PO_2 on hemoglobin's affinity for O_2 .

Normally, the PO_2 in the blood leaving the lungs is 104 mm Hg. At that partial pressure, hemoglobin is 98% saturated (figure 23.17a). Decreases in the PO_2 in the pulmonary capillaries have a relatively small effect on hemoglobin saturation, as shown by the fairly flat shape of the upper part of the oxygen-hemoglobin dissociation curve. Even if the blood PO_2 decreases from 104 mm Hg to 60 mm Hg, hemoglobin is still 90% saturated. Because the affinity of hemoglobin for O_2 is stable over a wide range of PO_2 levels, hemoglobin is effective at picking up O_2 in the lungs even if the PO_2 drops significantly.

In a resting person, the normal blood PO_2 leaving the tissues is 40 mm Hg, which correlates to 75% hemoglobin saturation. Thus, 23% ($98 - 75 = 23$) of the O_2 picked up in the lungs is released from hemoglobin. Oxygen then diffuses into the cells of the tissues (figure 23.17b). The 75% of O_2 still bound to the hemoglobin is an O_2 reserve, which can be released if blood PO_2 decreases further. In the tissues, at lower PO_2 levels, a relatively small change in blood PO_2 results in a relatively large change in hemoglobin saturation. This is shown by the steep slope of the oxygen-hemoglobin dissociation curve (figure 23.17b). For example, during vigorous exercise, the PO_2 in skeletal muscle capillaries can decline to levels as low as 15 mm Hg. Skeletal muscle cells use a significant amount of O_2 for aerobic respiration (see chapter 9). At a PO_2 of 15 mm Hg, hemoglobin is only 25% saturated, resulting in the release of 73% ($98 - 25 = 73$) of the O_2 picked up in the lungs (figure 23.17c). Thus, as tissues use more O_2 , hemoglobin releases more O_2 to those tissues.

ASSESS YOUR PROGRESS

48. Describe the partial pressure of O_2 and CO_2 in the alveoli, lung capillaries, tissue capillaries, and tissues.
49. How do these pressures account for the movement of O_2 and CO_2 between air and blood, and between blood and tissues?
50. Name the two ways O_2 is transported in the blood, and state the percentage of total O_2 transport for which each method is responsible.
51. How does the oxygen-hemoglobin dissociation curve explain the uptake of O_2 in the lungs and the release of O_2 in tissues?

Effect of pH, PCO_2 , and Temperature

In addition to PO_2 , three other factors influence the saturation of hemoglobin: blood pH, PCO_2 , and temperature (figure 23.18). As the pH of the blood drops (due to higher H^+ levels), the affinity of hemoglobin for O_2 at any given PO_2 is much lower. The higher H^+ levels bind to non-heme portions of hemoglobin, which changes its overall shape. Following the concept of form following function, changing the shape of hemoglobin would change its affinity for O_2 . Conversely, an increase in blood pH results in an increased affinity of hemoglobin for O_2 . This effect of pH on the

oxygen-hemoglobin dissociation curve is called the **Bohr effect**, after its discoverer, Christian Bohr.

An increase in P_{CO_2} also decreases hemoglobin's ability to bind O_2 due to the effect of CO_2 on pH. Within red blood cells, an enzyme called **carbonic anhydrase** catalyzes a reversible reaction that results in carbonic acid formation when CO_2 and H_2O mix. This reaction is shown by the following equation:

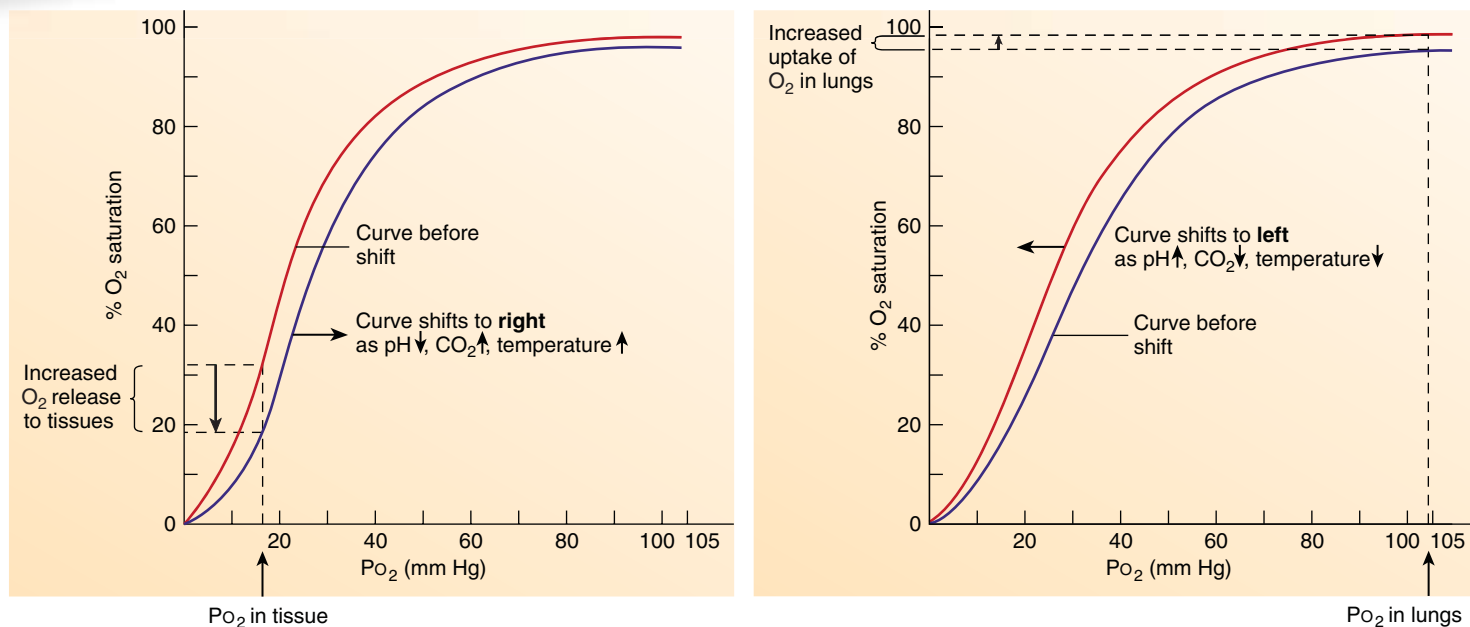

As CO_2 levels increase, more H^+ is produced, and the pH drops. As CO_2 levels decline, the reaction proceeds in the opposite direction, resulting in a lower H^+ concentration and an increase in pH. Thus, changes in CO_2 levels indirectly produce a Bohr effect by altering pH. In addition, CO_2 can directly affect hemoglobin's ability to bind O_2 . When CO_2 binds to the α - and β -globin chains of hemoglobin (see chapter 19), hemoglobin's affinity for O_2 is reduced.

As blood passes through tissue capillaries, CO_2 enters the blood from the tissues. As a consequence, blood CO_2 levels increase, pH decreases, and hemoglobin has less affinity for O_2 in the tissue capillaries. Therefore, a greater amount of O_2 is released in the tissue capillaries than would be released if CO_2 were not present. When blood is returned to the lungs and passes through the pulmonary capillaries, CO_2 leaves the capillaries and enters the alveoli. As a result, CO_2 levels in the pulmonary capillaries are reduced, pH increases, and hemoglobin's affinity for O_2 increases.

An increase in temperature also decreases O_2 's tendency to remain bound to hemoglobin. Therefore, elevated temperatures resulting from increased metabolism increase the amount of O_2 released into the tissues by hemoglobin. In less metabolically active tissues in which the temperature is lower, less O_2 is released from hemoglobin.

When hemoglobin's affinity for O_2 decreases, the oxygen-hemoglobin dissociation curve is shifted to the right, and hemoglobin releases more O_2 (figure 23.18a). During exercise, when CO_2 and acidic substances accumulate and the temperature increases in the tissue spaces, the oxygen-hemoglobin curve shifts

FUNDAMENTAL Figure

(a) In the tissues, the oxygen-hemoglobin dissociation curve shifts to the right. As pH decreases, PCO_2 increases, or temperature increases, the curve (red) shifts to the right (blue), resulting in an increased release of O_2 .

(b) In the lungs, the oxygen-hemoglobin dissociation curve shifts to the left. As pH increases, PCO_2 decreases, or temperature decreases, the curve (blue) shifts to the left (red), resulting in an increased ability of hemoglobin to pick up O_2 .

FIGURE 23.18 Effects of Shifting the Oxygen-Hemoglobin Dissociation Curve

to the right. Under these conditions, as much as 75–85% of the O_2 is released from the hemoglobin. In the lungs, however, the curve shifts to the left because of the lower CO_2 levels, lower temperature, and lower acid levels. Therefore, hemoglobin's affinity for O_2 increases, and it becomes easily saturated (figure 23.18b).

During resting conditions, approximately 5 mL of O_2 are transported to the tissues in each 100 mL of blood, and cardiac output is approximately 5000 mL/min. Consequently, 250 mL of O_2 are delivered to the tissues each minute. During exercise, this value can increase up to 15 times. Oxygen transport can be increased threefold because of a greater degree of O_2 release from hemoglobin in the tissue capillaries, and the rate of O_2 transport is increased another five times because of the increase in cardiac output. Consequently, the volume of O_2 delivered to the tissues can be as high as 3750 mL/min (15×250 mL/min). Highly trained athletes can increase this volume to as high as 5000 mL/min.

➤ Predict 8

In carbon monoxide (CO) poisoning, CO binds to hemoglobin, thereby decreasing the uptake of O_2 by hemoglobin. In addition, when CO binds to hemoglobin, the oxygen-hemoglobin dissociation curve shifts to the left. How does this shift affect the ability of tissues to get O_2 ? Explain.

Effect of BPG

As red blood cells metabolize glucose for energy, they produce a by-product called **2,3-bisphosphoglycerate (BPG;** formerly called diphosphoglycerate). BPG binds to hemoglobin, which reduces its

affinity for O_2 . Thus, hemoglobin releases more O_2 . A potent trigger for increased BPG production is low blood O_2 . For example, barometric pressure is lower at high altitudes than at sea level, causing both the partial pressure of O_2 in the alveoli and the percent saturation of blood with O_2 in the pulmonary capillaries to be lower. Consequently, the blood holds less O_2 for delivery to tissues. BPG helps increase O_2 delivery to tissues because higher levels of BPG increase the release of O_2 in tissues (the oxygen-hemoglobin dissociation curve shifts to the right). On the other hand, when blood is removed from the body and stored in a blood bank, the BPG levels in the stored blood decrease. As BPG levels decrease, the blood becomes unsuitable for transfusion after approximately 6 weeks because the hemoglobin releases less O_2 to the tissues. Banked blood is, therefore, discarded after 6 weeks of storage.

➤ Predict 9

If a person lacks the enzyme necessary for BPG synthesis, do he or she exhibit anemia (a lower than normal number of red blood cells) or erythrocytosis (a higher than normal number of red blood cells)? Explain.

Fetal Hemoglobin

Fetal hemoglobin is a unique type of hemoglobin found in fetuses only (see chapter 19). As fetal blood circulates through the placenta, O_2 is released from the mother's blood into the fetal blood, and CO_2 is released from fetal blood into the mother's blood. Fetal hemoglobin is very efficient at binding O_2 for several reasons:

1. The concentration of fetal hemoglobin is approximately 50% greater than the concentration of maternal hemoglobin.
2. Fetal hemoglobin is different from maternal hemoglobin. Its oxygen-hemoglobin dissociation curve is to the left of the maternal oxygen-hemoglobin dissociation curve. Thus, for a given PO_2 , fetal hemoglobin has a higher affinity for O_2 than maternal hemoglobin does.
3. BPG has little effect on fetal hemoglobin. That is, BPG does not cause fetal hemoglobin to release O_2 .

Predict 10

How does the movement of CO_2 from fetal blood into maternal blood increase the movement of O_2 from maternal blood into fetal blood? (*Hint:* Consider the shift of the oxygen-hemoglobin dissociation curve.)

ASSESS YOUR PROGRESS

52. What is the Bohr effect? How is it related to blood CO_2 ?
53. Why is it advantageous for the oxygen-hemoglobin dissociation curve to shift to the left in the lungs and to the right in tissues?
54. How does temperature affect O_2 's tendency to bind to hemoglobin?
55. How does BPG affect the release of O_2 from hemoglobin?
56. Why is fetal hemoglobin's affinity for O_2 greater than that of maternal hemoglobin?

Transport of Carbon Dioxide

Because blood concentration of CO_2 affects blood pH, its transport must be carefully controlled. There are three possible transport forms of CO_2 , each contributing with differing degrees to blood pH: as HCO_3^- dissolved in the plasma or the red blood cells, as CO_2 dissolved in the plasma, or as CO_2 bound to hemoglobin.

Carbon Dioxide Exchange in Tissues

As tissue cells produce CO_2 , it diffuses out of the cells and into the plasma of blood (figure 23.19a). Most of the CO_2 diffuses from tissues into red blood cells. Inside the red blood cells, the CO_2 reacts with water to form carbonic acid, a reaction catalyzed by carbonic anhydrase. Carbonic acid then dissociates to form bicarbonate ions (HCO_3^-). About 70% of blood CO_2 is transported in the form of HCO_3^- dissolved in either the red blood cells or the plasma. Another 7% is transported as CO_2 dissolved in the plasma, and approximately 23% is transported bound to hemoglobin.

Removing HCO_3^- from inside the red blood cells promotes CO_2 transport because, as the HCO_3^- concentration decreases, more CO_2 combines with water to form additional HCO_3^- and H^+ (see “Reversible Reactions,” chapter 2). In a process called the **chloride shift** (figure 23.19a, step 4), antiporters exchange Cl^- for HCO_3^- : HCO_3^- diffuses out of the red blood cells; Cl^- diffuses into the red blood cells. This exchange maintains electrical balance in the red blood cells and plasma.

Although elevated H^+ levels usually create an acidic environment, there are mechanisms in place that dampen the H^+ effect. The effectiveness of these mechanisms is due to the fact that hemoglobin

binds H^+ (figure 23.19a, step 6). These mechanisms are as follows: (1) The pH inside the red blood cells does not decrease because hemoglobin is a buffer that prevents an increase in H^+ concentration. (2) In red blood cells, H^+ concentration decreases due to H^+ binding to hemoglobin. This lowering of H^+ triggers further reaction of CO_2 and H_2O . Thus, more CO_2 is transported. (3) The affinity of hemoglobin for O_2 decreases. Hemoglobin releases O_2 in tissue capillaries because of decreased pH. Hemoglobin's decreased affinity for O_2 shifts the oxygen-hemoglobin dissociation curve to the right (the Bohr effect; see figure 23.18a) and results in an increase in the release of O_2 from hemoglobin.

Approximately 23% of blood CO_2 is transported bound to hemoglobin. Many CO_2 molecules bind in a reversible fashion to the α - and β -globin chains of hemoglobin molecules (figure 23.19a, step 7). Carbon dioxide's ability to bind to hemoglobin is affected by the amount of O_2 bound to hemoglobin. The smaller the amount of O_2 bound to hemoglobin, the greater the amount of CO_2 able to bind to it, and vice versa. This relationship is called the **Haldane effect**. In tissues, as hemoglobin binds CO_2 , the affinity of hemoglobin for O_2 is reduced. Remember that when the affinity of hemoglobin for O_2 is lower, more O_2 is released. This is beneficial because tissues with higher levels of CO_2 demand more O_2 in order to continue aerobic respiration, our cells' most efficient means of producing ATP.

Carbon Dioxide Exchange in the Lungs

Carbon dioxide leaves the body when it diffuses out of red blood cells and plasma into the alveoli (figure 23.19b). As CO_2 levels in the red blood cells decrease, carbonic acid is converted to CO_2 and water. In response, HCO_3^- joins with H^+ to form carbonic acid. As HCO_3^- and H^+ concentrations decrease because of this reaction, HCO_3^- enters red blood cells in exchange for Cl^- , and H^+ is released from hemoglobin. Hemoglobin picks up O_2 in pulmonary capillaries because of increased PO_2 (see figure 23.17). The release of H^+ from hemoglobin increases hemoglobin's affinity for O_2 , shifting the oxygen-hemoglobin curve to the left (Bohr effect; see figure 23.18b). Oxygen from the alveoli diffuses into the pulmonary capillaries and into the red blood cells, where it binds with hemoglobin. Carbon dioxide is released from hemoglobin and diffuses out of the red blood cells into the alveoli. As hemoglobin binds to O_2 , it more readily releases CO_2 (Haldane effect). This is beneficial in preventing the buildup of CO_2 in the blood.

Carbon Dioxide and Blood pH

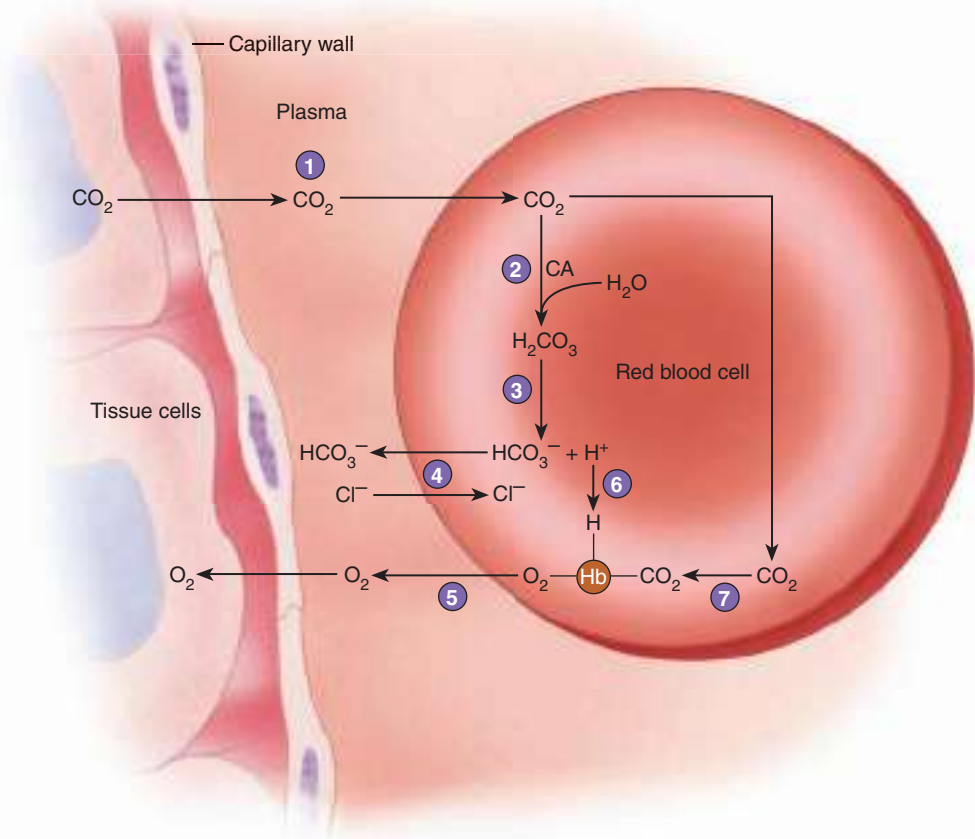

Blood pH refers to the pH in plasma, not inside red blood cells. As plasma CO_2 levels increase, H^+ levels increase, and blood pH decreases. An important function of the respiratory system is to regulate blood pH by changing plasma CO_2 levels (see chapter 27). Increased breathing rate, or hyperventilation, decreases plasma CO_2 , whereas decreased breathing rate, or hypoventilation, increases it.

Predict 11

Explain the effect of (1) hyperventilation and (2) holding one's breath on blood pH.

FUNDAMENTAL Figure

- 1 In the tissues, CO_2 diffuses into the plasma and into red blood cells. Some of the CO_2 remains in the plasma.
- 2 In red blood cells, CO_2 reacts with water (H_2O) to form carbonic acid (H_2CO_3) in a reaction catalyzed by the enzyme carbonic anhydrase (CA).
- 3 Carbonic acid dissociates to form bicarbonate ions (HCO_3^-) and hydrogen ions (H^+).
- 4 In the chloride shift, as HCO_3^- diffuse out of the red blood cells, electrical neutrality is maintained by the diffusion of chloride ions (Cl^-) into them.
- 5 Oxygen is released from hemoglobin (Hb). Oxygen diffuses out of red blood cells and plasma into the tissue.
- 6 Hydrogen ions combine with hemoglobin, which promotes the release of O_2 from hemoglobin (Bohr effect).
- 7 Carbon dioxide combines with hemoglobin. Hemoglobin that has released O_2 readily combines with CO_2 (Haldane effect).

(a) Gas exchange in the tissues

- 1 In the lungs, CO_2 diffuses from red blood cells and plasma into the alveoli.
- 2 Carbonic anhydrase catalyzes the formation of CO_2 and H_2O from H_2CO_3 .
- 3 Bicarbonate ions and H^+ combine to replace H_2CO_3 .
- 4 In the chloride shift, as HCO_3^- diffuse into red blood cells, electrical neutrality is maintained by the diffusion of chloride ions (Cl^-) out of them.
- 5 Oxygen diffuses into the plasma and into red blood cells. Some of the O_2 remains in the plasma. Oxygen binds to hemoglobin.
- 6 Hydrogen ions are released from hemoglobin, which promotes the uptake of O_2 by hemoglobin (Bohr effect).
- 7 Carbon dioxide is released from hemoglobin. Hemoglobin that is bound to O_2 readily releases CO_2 (Haldane effect).

(b) Gas exchange in the lungs

PROCESS FIGURE 23.19 Gas Exchange

ASSESS YOUR PROGRESS

57. How does the lowering HCO_3^- concentrations inside red blood cells affect CO_2 transport?
58. What is the chloride shift, and what does it accomplish?
59. Name three effects produced by H^+ binding to hemoglobin.
60. What is the Haldane effect?
61. What effect does blood CO_2 level have on blood pH?

23.7 Regulation of Ventilation

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the respiratory areas of the brainstem and how they produce a rhythmic pattern of ventilation.
- B. Explain how the cerebral cortex and limbic system can affect ventilation.
- C. Explain how blood pH, CO_2 , and O_2 levels affect ventilation.
- D. Discuss the Hering-Breuer reflex and its importance.
- E. Describe the effect of exercise on ventilation.

Neurons within the medulla oblongata that stimulate the muscles of respiration control the basic rhythm of ventilation. The recruitment of muscle fibers and the more frequent stimulation of muscle fibers result in stronger muscle contractions and increased depth of respiration. The rate of respiration is determined by how frequently the respiratory muscles are stimulated.

Respiratory Areas in the Brainstem

Neurons involved with respiration are aggregated in certain parts of the brainstem. Scientists have learned that neurons that are active during inspiration are intermingled with those that are active during expiration.

The **medullary respiratory center** in the medulla oblongata consists of two **dorsal respiratory groups**, each forming a longitudinal column of cells located bilaterally in the dorsal part of the medulla oblongata, and two **ventral respiratory groups**, each forming a longitudinal column of cells located bilaterally in the ventral part of the medulla oblongata (figure 23.20). Although the dorsal and ventral respiratory groups are bilaterally paired, cross-communication takes place between the pairs, so respiratory movements are symmetrical. In addition, communication occurs between the dorsal and ventral respiratory groups.

Each dorsal respiratory group is a collection of neurons that are most active during inspiration, but some are active during expiration. The dorsal respiratory groups are primarily responsible for stimulating contraction of the diaphragm. They receive input from other parts of the brain and peripheral receptors, which allows the modification of respiration.

Each ventral respiratory group is a collection of neurons that are active during both inspiration and expiration. These neurons primarily stimulate the external intercostal, internal intercostal, and abdominal muscles. A part of the ventral respiratory group,

FIGURE 23.20 Respiratory Structures in the Brainstem

This figure shows the relationship of respiratory structures to each other and to the nerves innervating the muscles of respiration on the left side of the body.

the **pre-Bötzinger complex**, is believed to establish the basic rhythm of respiration.

The **pontine respiratory group**, formerly called the pneumotaxic center, is a collection of neurons in the pons (figure 23.20). Some of the neurons are active only during inspiration, some

only during expiration, and others during both inspiration and expiration. The precise function of the pontine respiratory group is unknown, but it has connections with the medullary respiratory center and appears to play a role in switching between inspiration and expiration, thus fine-tuning the breathing pattern. It is not considered essential for the generation of the respiratory rhythm.

Generation of Rhythmic Ventilation

One explanation for the generation of rhythmic ventilation involves the integration of stimuli that start and stop inspiration:

1. *Starting inspiration.* Neurons in the medullary respiratory center spontaneously establish the basic rhythm of ventilation. The medullary respiratory center constantly receives stimulation from receptors that monitor blood gas levels, blood temperature, and the movements of muscles and joints. In addition, stimulation from the parts of the brain concerned with voluntary respiratory movements and emotions can occur. Inspiration starts when the combined input from all these sources causes the production of action potentials in the neurons that stimulate respiratory muscles.
2. *Increasing inspiration.* Once inspiration begins, more and more neurons are gradually activated. The result is progressively stronger stimulation of the respiratory muscles, which lasts for approximately 2 seconds.
3. *Stopping inspiration.* The neurons stimulating the muscles of respiration also stimulate the neurons in the medullary respiratory center that are responsible for stopping inspiration. The neurons responsible for stopping inspiration also receive input from the pontine respiratory group, stretch receptors in the lungs, and probably other sources. When these inhibitory neurons are activated, they inhibit the neurons that stimulate respiratory muscles. Relaxation of respiratory muscles results in expiration, which lasts approximately 3 seconds. The next inspiration begins again at step 1.

Although the medullary neurons establish the basic rate and depth of ventilation, their activities can be influenced by input from other parts of the brain and by input from peripherally located receptors.

Cerebral and Limbic System Control

Through the cerebral cortex, it is possible to consciously or unconsciously increase or decrease the rate and depth of the respiratory movements (figure 23.21a). For example, during talking or singing, air movement is controlled to produce sounds, as well as to facilitate gas exchange.

Apnea (ap'nē-ă) is the absence of breathing. A person may stop breathing voluntarily. As the period of voluntary apnea increases, a greater and greater urge to breathe develops. That urge is primarily due to higher PCO_2 levels in the arterial blood. Finally, the PCO_2 reaches levels that cause the respiratory center to override the conscious influence from the cerebrum. Occasionally, people are able to hold their breath until the blood PO_2 declines to a level low enough that they lose consciousness. After consciousness is lost, the respiratory center resumes its normal automatic control of respiration.

On the other hand, voluntary hyperventilation decreases blood PCO_2 levels far enough, which causes vasodilation of the peripheral blood vessels and a corresponding drop in blood pressure (see chapter 21). Dizziness or a giddy feeling can result because the decreased blood pressure results in a decreased rate of blood flow to the brain, and therefore less O_2 is delivered to the brain.

Emotions acting through the limbic system of the brain can also affect the respiratory center (figure 23.21a). For example, strong emotions can cause hyperventilation or produce the sobs and gasps of crying.

ASSESS YOUR PROGRESS

62. Name the three respiratory groups, and describe their main functions.
63. How is rhythmic ventilation generated?
64. Explain how the cerebral cortex and limbic system can exert control over ventilation. What is apnea?

Chemical Control of Ventilation

The respiratory system maintains blood O_2 and CO_2 concentrations and blood pH within normal values. Changes in these levels out of their normal range has a noticeable influence on breathing rate and depth. Changes in O_2 and CO_2 concentrations and in pH are superimposed on the neural mechanisms that establish rhythmic ventilation.

Chemoreceptors

Chemoreceptors are specialized neurons that detect changes in the concentration of specific chemicals. The chemoreceptors involved in regulating respiration respond to changes in pH, changes in PO_2 , or both (figures 23.21b,c and 23.22). **Central chemoreceptors** are located bilaterally and ventrally in the **chemosensitive area** of the medulla oblongata, and they are connected to the respiratory center. **Peripheral chemoreceptors** are found in the carotid and aortic bodies. These structures are small, vascular sensory organs encapsulated in connective tissue and located near the carotid sinuses and the aortic arch (see chapter 21). The respiratory center is connected to the carotid body chemoreceptors through the glossopharyngeal nerve (IX) and to the aortic body chemoreceptors by the vagus nerve (X).

Effect of pH

The chemosensitive area of the medulla oblongata detects changes in blood pH due to changes in CO_2 , whereas the carotid and aortic bodies detect changes in H^+ concentrations. Because H^+ does not easily cross the blood-brain barrier or the blood-cerebrospinal fluid barrier (see chapter 11), the chemosensitive area detects changes in blood pH through changes in blood CO_2 . Carbon dioxide easily diffuses across the blood-brain barrier and the blood-cerebrospinal fluid barrier. The lower pH then stimulates the respiratory center, resulting in a greater rate and depth of breathing. Consequently, CO_2 levels decrease as CO_2 is eliminated from the body, and blood pH increases to normal levels.

Maintaining body pH levels within normal limits is necessary for the proper functioning of cells. Because changes in CO_2 levels can change pH, the respiratory system plays an important role in acid-base balance. For example, if blood pH decreases, the respiratory

center is stimulated, so that CO₂ is eliminated, and blood pH increases back to normal levels. Conversely, if blood pH increases, the respiratory rate decreases, and CO₂ levels increase, causing blood pH to decrease back to normal levels. The respiratory system's role in maintaining pH is considered in greater detail in chapter 27.

Effect of Carbon Dioxide

Blood CO₂ levels are a major regulator of respiration during resting conditions, as well as at times when CO₂ levels are elevated—for example, during intense exercise. Even a small increase in CO₂ in the bloodstream triggers a large increase in the rate and depth of ventilation. For example, an increase in PCO₂ of 5 mm Hg causes an increase in ventilation of 100%. A greater than normal amount of CO₂ in the blood is called **hypercapnia** (hī-per-kap'nē-ă). Conversely, a lower than normal CO₂ level, called **hypocapnia** (hī-pō-kap'nē-ă), results in periods when breathing rate is reduced or does not occur at all.

The chemoreceptors in the chemosensitive area of the medulla oblongata and in the carotid and aortic bodies respond to changes in

CO₂ because of the effects of CO₂ on blood pH (figure 23.22). The chemosensitive area in the medulla oblongata is far more important in regulating PCO₂ and pH than either the carotid or the aortic bodies. The carotid and aortic bodies are responsible for, at most, 15–20% of the total response to changes in PCO₂ or pH. During intense exercise, however, the carotid bodies respond more rapidly to changes in blood pH than does the chemosensitive area of the medulla.

Effect of Oxygen

Although PCO₂ levels are responsible for most of the changes in respiration, changes in Po₂ can also affect respiration (figure 23.22). A decrease in O₂ below its normal values is called **hypoxia** (hī-pok'sē-ă). If Po₂ levels in the arterial blood are markedly reduced while the pH and PCO₂ are held constant, an increase in ventilation rate occurs. However, within a normal range of Po₂ levels, the effect of O₂ on the regulation of respiration is small. Only after arterial Po₂ decreases to approximately 50% of its normal value does it begin to have a large stimulatory effect on respiratory movements.

HOMEOSTASIS FIGURE 23.22 Regulation of Blood pH

(1) Blood pH is in its normal range. (2) Blood pH increases outside its normal range, which disturbs homeostasis. (3) The control centers for blood pH, the medullary chemoreceptors, detect an increase in blood pH (blood becomes more basic) and respond to the increased pH by signaling a decreased breathing rate. (4) The effectors, the diaphragm and other respiratory muscles, respond by slowing their contraction rate, which lowers the rate of breathing. (5) As a result, more CO_2 is retained, which causes pH to drop (blood becomes more acidic). (6) Blood pH returns to its normal range and homeostasis is maintained. Observe the responses to a decrease in blood pH by following the red arrows.

At first, it is somewhat surprising that small changes in PO_2 do not cause changes in respiratory rate. But the reason becomes clear if we consider the oxygen-hemoglobin dissociation curve. Because of the S shape of the curve, at any PO_2 above 80 mm Hg nearly all of the hemoglobin is saturated with O_2 . Consequently, until PO_2 levels change significantly, the oxygen-carrying capacity of the blood is unaffected.

When PO_2 levels are low, the carotid and aortic body chemoreceptors stimulate the respiratory center. This keeps it active despite decreasing O_2 levels. However, if PO_2 decreases sufficiently, the respiratory center can fail to function, resulting in death.

ASSESS YOUR PROGRESS

65. Where are central chemoreceptors and peripheral chemoreceptors? Which are most important for regulating blood pH and CO_2 level? How does this change during intense exercise?
 66. Define hypercapnia and hypocapnia.
 67. How does a decrease in blood pH affect respiratory rate? How does a decrease in CO_2 affect respiratory rate?
 68. What is hypoxia? Why must arterial PO_2 change significantly before it affects respiratory rate?

Hering-Breuer Reflex

The **Hering-Breuer** (her'ing-broy'er) **reflex** limits the depth of inspiration and prevents overinflation of the lungs (see figure 23.21d). This reflex depends on stretch receptors in the walls of the bronchi and bronchioles of the lungs. Action potentials are initiated in these stretch receptors when the lungs are inflated and are passed along sensory neurons within the vagus nerves to the medulla oblongata. The action potentials have an inhibitory influence on the respiratory center and result in expiration. As expiration proceeds, the stretch receptors are no longer stimulated, and the decreased inhibitory effect on the respiratory center allows inspiration to begin again.

In infants, the Hering-Breuer reflex plays a role in regulating the basic rhythm of breathing and in preventing overinflation of the lungs. In adults, however, the reflex is important only when the tidal volume is large, such as during exercise.

Effect of Exercise on Ventilation

The mechanisms by which ventilation is regulated during exercise are controversial, and no single factor can account for all of the observed responses. Ventilation during exercise is divided into two phases:

1. *Ventilation increases abruptly.* At the onset of exercise, ventilation immediately increases. This initial increase can be as much as 50% of the total increase that occurs during exercise. The immediate increase in ventilation occurs too quickly to be explained by changes in metabolism or blood gases. As axons pass from the motor cortex of the cerebrum through the motor pathways, numerous collateral fibers project into the reticular formation of the brain. During exercise, action potentials in the motor pathways stimulate skeletal muscle contractions, and action potentials in the collateral fibers stimulate the respiratory center (see figure 23.21e).

Clinical IMPACT

Importance of Reduced PO_2

Carbon dioxide is much more important than O_2 as a regulator of normal alveolar ventilation, but under certain circumstances a reduced PO_2 in the arterial blood plays an important stimulatory role. During conditions of shock when blood pressure is very low, the PO_2 in arterial blood can drop low enough to strongly stimulate carotid and aortic body sensory receptors. At high altitudes, where barometric air pressure is low, the PO_2 in arterial blood can also drop to levels low enough to stimulate the carotid and aortic bodies. Although PO_2 levels in the blood are reduced, the respiratory system's ability to eliminate CO_2 is not greatly affected by low barometric air pressure. Thus, blood CO_2 levels become lower than normal because of the increased alveolar ventilation initiated in response to low PO_2 .

In people with emphysema, the destruction of the respiratory membrane allows less O_2 to move into the blood. The resulting low arterial PO_2 levels stimulate an increased rate and depth of respiration. At first, arterial PCO_2 levels may be unaffected by the reduced surface area of the respiratory membrane because CO_2 diffuses across the respiratory membrane 20 times more readily than does O_2 . However, if alveolar ventilation increases to the point that CO_2 exchange increases above normal, arterial CO_2 becomes lower than normal. More severe emphysema, in which the surface area of the respiratory membrane is reduced to a minimum, can decrease CO_2 exchange to the point that arterial CO_2 becomes elevated.

Furthermore, during exercise, body movements stimulate proprioceptors in the joints of the limbs. Action potentials from the proprioceptors pass along sensory nerve fibers to the spinal cord and along ascending nerve tracts (the dorsal-column/medial-lemniscal system) of the spinal cord to the brain. Collateral fibers project from these ascending pathways to the respiratory center in the medulla oblongata. Movement of the limbs has a strong stimulatory influence on the respiratory center (see figure 23.21e).

A learned component may also exist in the ventilation response during exercise. After a period of training, the brain "learns" to match ventilation with the intensity of the exercise. Well-trained athletes match their respiratory movements more efficiently with their level of physical activity than do untrained individuals. Thus, the centers of the brain involved in learning have an indirect influence on the respiratory center, but the exact mechanism for this kind of regulation is unclear.

2. *Ventilation increases gradually.* After the immediate increase in ventilation, a gradual increase occurs and levels off within 4–6 minutes after the onset of exercise. Factors responsible for the immediate increase in ventilation may play a role in the gradual increase as well.

Despite large changes in O_2 consumption and CO_2 production during exercise, the *average* arterial PO_2 , PCO_2 , and pH remain constant and close to resting levels as long as the

exercise is aerobic (see chapter 9). This suggests that changes in blood gases and pH do not play an important role in regulating ventilation during aerobic exercise. However, during exercise, the values of arterial PO_2 , PCO_2 , and pH rise and fall more than at rest. Thus, even though the average values do not change, their oscillations may be a signal for helping control ventilation.

The highest level of exercise that can be performed without causing a significant change in blood pH is called the **anaerobic threshold**. If the exercise intensity is high enough to exceed the anaerobic threshold, blood pH drops. The drop in pH stimulates the carotid bodies, which increases ventilation. In fact, ventilation can increase so much that arterial PCO_2 decreases below resting levels and arterial PO_2 increases above resting levels.

Other Modifications of Ventilation

Higher brain centers control the respiratory system when touch, thermal, or pain receptors are activated (see figure 23.21f). For example, irritants in the nasal cavity can initiate a sneeze reflex, and irritants in the lungs can stimulate a cough reflex. An increase in body temperature can stimulate increased ventilation because metabolism is elevated and more CO_2 is produced, which then needs to be expelled from the body.

Predict 12

Suppose that cold water is suddenly splashed on you. Describe your respiratory response. In the past, newborn babies were sometimes swatted on the buttocks. Explain the rationale for this procedure.

ASSESS YOUR PROGRESS

69. Describe the Hering-Breuer reflex and its function.
70. What mechanisms regulate ventilation at the onset of exercise and then during exercise? What is the anaerobic threshold?

23.8 Respiratory Adaptations to Exercise

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe the changes in the respiratory system that result from exercise training.

In response to training, athletic performance increases because the cardiovascular and respiratory systems become more efficient at delivering O_2 and picking up CO_2 . Ventilation does not limit performance in most individuals because ventilation can increase to a greater extent than does cardiovascular function.

With long-term athletic training, vital capacity increases slightly, and residual volume decreases slightly. Tidal volume at rest and during submaximal exercise does not change. At maximal exercise, however, tidal volume increases. In conditioned

athletes, the respiratory rate at rest or during submaximal exercise is slightly lower than in a non-athlete. However, athletes have higher respiratory rates at maximal exercise.

Minute volume is affected by the changes in tidal volume and respiratory rate. After training, minute volume is essentially unchanged or slightly reduced at rest and is slightly reduced during submaximal exercise. Minute volume is greatly increased at maximal exercise. For example, an untrained person's minute volume of 120 L/min can increase to 150 L/min after training. Increases to 180 L/min are typical of highly trained athletes.

Gas exchange between the alveoli and the blood increases at maximal exercise following training. The increased minute volume results in increased alveolar ventilation. In addition, increased cardiovascular efficiency allows greater blood flow through the lungs, especially the superior parts of the lungs.

ASSESS YOUR PROGRESS

71. What effect does training have on resting, submaximal, and maximal tidal volumes and on minute volume?

23.9 Effects of Aging on the Respiratory System

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe the effects of aging on the respiratory system.

Most aspects of the respiratory system are affected by aging. However, even though vital capacity, maximum ventilation rates, and gas exchange decrease with age, the elderly can engage in light to moderate exercise because the respiratory system has a large reserve capacity.

Vital capacity decreases with age because of a decreased ability to fill the lungs (decreased inspiratory reserve volume) and a decreased ability to empty the lungs (decreased expiratory reserve volume). As a result, maximum minute volume rates decrease, which in turn decreases the ability to perform intense exercise. These changes are related to weakening of respiratory muscles and to decreased compliance of the thoracic cage caused by the stiffening of cartilage and ribs. Lung compliance actually increases with age, but this effect is offset by the decreased thoracic cage compliance. Lung compliance increases because parts of the alveolar walls are lost, which reduces lung recoil. No significant age-related changes take place in lung elastic fibers or surfactant.

Alveolar ducts and many of the larger bronchioles expand in diameter with age, which increases residual volume. Larger bronchioles and alveolar ducts create more dead space, lowering the amount of air available for gas exchange (alveolar ventilation). In addition, gas exchange across the respiratory membrane is reduced because parts of the alveolar walls are lost, which decreases the surface area available for gas exchange, and the remaining walls thicken, which decreases the diffusion of gases.

Diseases and Disorders

TABLE 23.3 Respiratory System

Condition	Description
RESPIRATORY DISORDERS	
Bronchi and Lungs	
Bronchitis (brong-kī'tis)	Inflammation of the bronchi caused by irritants, such as cigarette smoke or infection; swelling impairs breathing; bronchitis can progress to emphysema
Emphysema (em-fi-sē'mă)	Destruction of alveolar walls; increased coughing increases pressure on the alveoli, causing rupture and destruction; loss of alveoli decreases surface area for gas exchange and decreases the lungs' ability to expel air; progression can be slowed, but there is no cure; in combination with bronchitis, the condition is known as chronic obstructive pulmonary disease (COPD)
Adult respiratory distress syndrome (ARDS)	Caused by damage to the respiratory membrane, which promotes inflammation; amount of surfactant is reduced, and fluid fills the alveoli, lessening gas exchange; ARDS usually develops after an injurious event, such as inhaling smoke from a fire or breathing toxic fumes
Cystic fibrosis (fi-brō'sis)	Genetic disorder that affects mucus secretions throughout the body due to an abnormal transport protein; mucus is much more viscous and accumulates in ducts and tubes, such as the bronchioles; airflow is restricted, and infections are more likely
Pulmonary fibrosis	Replacement of lung tissue with fibrous connective tissue, making the lungs less elastic; exposure to asbestos or coal dust is a common cause
Lung cancer	Occurs in the epithelium of the respiratory tract; can easily spread to other parts of the body because of the rich blood and lymphatic supply to the lungs;
Asthma	See Systems Pathology, later in this chapter
Circulatory System	
Thrombosis of the pulmonary arteries	Blood clot in lung blood vessels, causing inadequate blood flow through the pulmonary capillaries, which affects respiratory function
Anemia	Reduced hemoglobin lowers oxygen-carrying capacity of blood
Carbon monoxide poisoning	Carbon monoxide binds more strongly to hemoglobin than O ₂ does and prevents already-bound O ₂ from entering tissues
Nervous System	
Sudden infant death syndrome (SIDS)	Most frequent cause of death of infants between 2 weeks and 1 year of age; cause is still unknown, but at-risk babies can be placed on monitors that warn if breathing stops
Paralysis of the respiratory muscles	Damage to the spinal cord in the cervical or thoracic region interrupts nervous signals to the muscles of respiration
Thoracic Wall	Decreased elasticity of the thoracic wall prevents it from expanding to full capacity and reduces air movement; two spinal curvature conditions that reduce elasticity of the thoracic wall are scoliosis (skō-lē-ō'sis) and kyphosis (kī-fō'sis)
INFECTIOUS DISEASES OF THE RESPIRATORY SYSTEM	
Upper Respiratory Tract	
Strep throat	Caused by streptococcal bacteria (<i>Streptococcus pyogenes</i>); characterized by inflammation of the pharynx and fever
Diphtheria (dif-thē'r'ē-ă)	Caused by the bacterium <i>Corynebacterium diphtheriae</i> ; a grayish membrane forms in the throat and can completely block respiratory passages; DTaP immunization for children partially targets diphtheria
Common cold	Results from a viral infection
Lower Respiratory Tract	
Whooping cough (pertussis; per-tūs'is)	Caused by the bacterium <i>Bordetella pertussis</i> , which destroys cilia lining the respiratory epithelium, allowing mucus to accumulate; leads to a very severe cough; DTaP immunization for children targets pertussis
Tuberculosis (tū-ber'kyū-lō'sis)	Caused by the bacterium <i>Clostridium tuberculosis</i> , which forms small, lumplike lesions called tubercles; immune system targets tubercles and causes larger lesions; certain strains of tuberculosis are resistant to antibiotics
Pneumonia (noo-mō'nē-ă)	Can be caused by a number of bacterial or viral infections of the lungs that cause fever, difficulty in breathing, and chest pain; edema in the lungs decreases their inflation ability and reduces gas exchange
Flu (influenza; in-flū-en'ză)	Viral infection of the respiratory system; does not affect the digestive system, as is commonly misunderstood; causes chills, fever, headache, and muscle aches
Fungal diseases	Fungal spores enter the respiratory tract attached to dust particles, usually resulting in minor respiratory infections that in some cases can spread to other parts of the body; examples are histoplasmosis and coccidioidomycosis

Background Information

Asthma (az'mă; difficult breathing) is characterized by abnormally increased constriction of the trachea and bronchi in response to various stimuli, which results in narrowed air passageways and decreased ventilation efficiency. Symptoms include rapid and shallow breathing, wheezing, coughing, and shortness of breath (figure 23A). In contrast to many other respiratory disorders, the symptoms of asthma typically reverse either spontaneously or with therapy.

There is no definitive pathological feature or diagnostic test for asthma, but three important characteristics of the disease are chronic airway inflammation, airway hyperreactivity, and airflow obstruction. The inflammation results in tissue damage, edema, and mucus buildup, which can block airflow through the bronchi. Airway hyperreactivity means that the smooth muscle in the trachea and bronchi contracts greatly in response to a stimulus, thus decreasing the diameter of the airway and increasing resistance to airflow. The effects of inflammation and airway hyperreactivity combine to cause airflow obstruction (figure 23B).

Many cases of asthma appear to be associated with a chronic inflammatory response by the immune system. The number of immune cells in the bronchi, including mast cells, eosinophils, neutrophils, macrophages, and lymphocytes, increases. Inflammation appears to be linked to airway hyperreactivity by some chemical mediators released by immune cells (e.g., leukotrienes, prostaglandins, and interleukins), which increase the airway's sensitivity to stimulation and cause smooth muscle contraction.

The stimuli that prompt airflow obstruction in asthma vary from one individual to another. Some asthmatics react to particular allergens, which are foreign substances that evoke an inappropriate immune system response (see chapter 22). Examples include inhaled pollen, animal dander, and dust mites. Many cases of asthma are caused by an allergic reaction to substances in the droppings and carcasses of cockroaches, which may explain the higher rate of asthma in poor, urban areas. However, other inhaled substances, such as chemicals in the workplace or cigarette smoke, can provoke an asthma attack without stimulating an allergic reaction.

Figure 23A

Strenuous exercise is one of the many factors that can bring on an asthma attack.

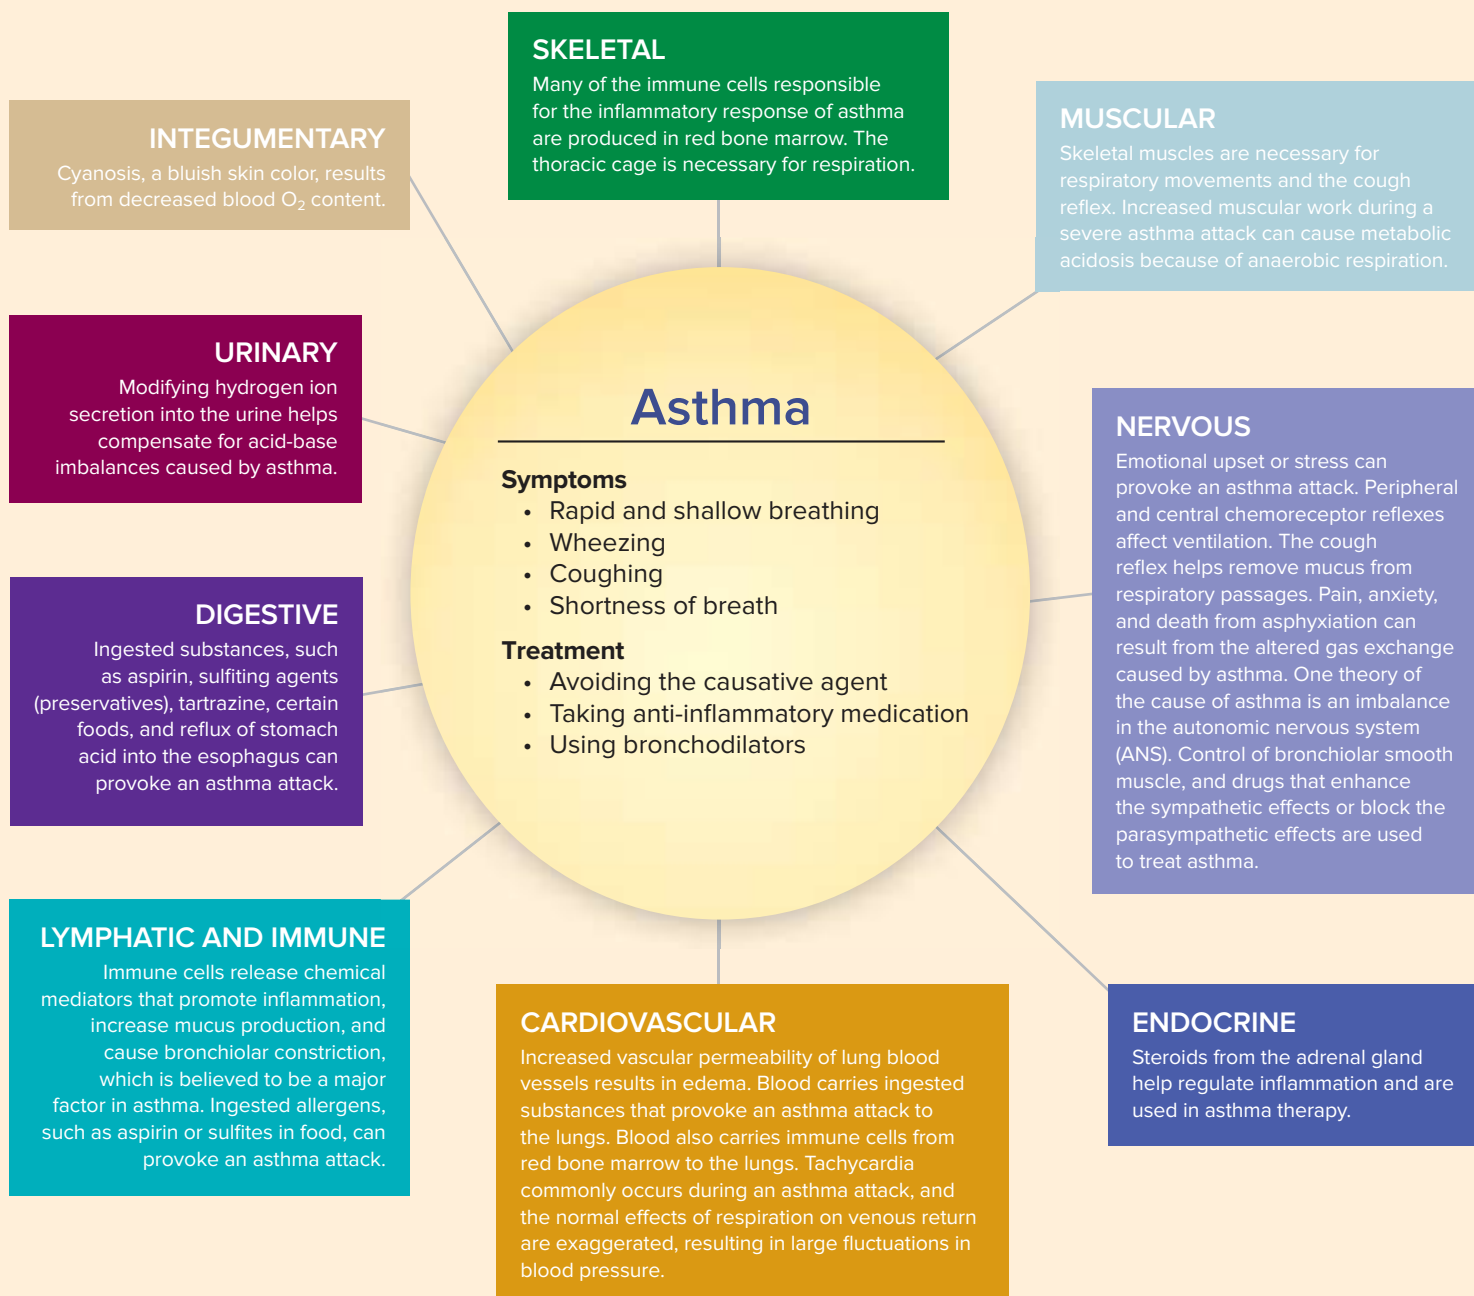

Asthmatic bronchiole:
Note how constricted it is.

Figure 23B

Normal bronchiole:
Note how clear it is.

Over 200 substances have been associated with occupational asthma. An asthma attack can also be stimulated by ingested substances, such as aspirin; nonsteroidal anti-inflammatory compounds, such as ibuprofen (ī'byōō-prō'fən); sulfites in food preservatives; and tartrazine (tar'tră-zēn) in food colorings. Asthmatics can substitute acetaminophen (as-et-ă-mē'nō-fen, a-set-ă-min'ō-fen; e.g., Tylenol) for aspirin.

Other stimuli, such as strenuous exercise (especially in cold weather) can precipitate an asthma attack. Such episodes can often be avoided by using a bronchodilator prior to exercise. Viral infections, emotional upset, stress, air pollution, and even reflux of stomach acid into the esophagus are known to elicit an asthma attack.

Treatment of asthma involves avoiding the causative stimulus and taking medications. Steroids and mast cell–stabilizing agents, which prevent the release of chemical mediators from mast cells, can reduce airway inflammation. Bronchodilators are used to increase airflow.

➤ Predict 13

It is not usually necessary to assess arterial blood gases when diagnosing and treating asthma. However, this information can sometimes be useful in severe asthma attacks. Suppose that Will had a P_{O_2} of 60 mm Hg and a P_{CO_2} of 30 mm Hg when he first went to the emergency room. Explain how that could happen.

A gradual rise in resting tidal volume with age compensates for these changes.

With age, mucus accumulates within the respiratory passageways because it becomes more viscous and because the number of cilia and their rate of movement decrease. As a consequence, the elderly are more susceptible to respiratory infections and bronchitis.

ASSESS YOUR PROGRESS

72. Why do vital capacity, alveolar ventilation, and the diffusion of gases across the respiratory membrane decrease with age?
73. Why are the elderly more likely to develop respiratory infections and bronchitis?

Answer

Learn to Predict From page 822

Mr. Theron suffers from emphysema, a respiratory disorder that results in the destruction of alveoli. This chapter explained that the alveoli form the respiratory membrane, the site of gas exchange between the atmosphere and the blood. Alveolar destruction would directly reduce the respiratory membrane surface and therefore gas exchange. As a consequence, Mr. Theron has exaggerated respiratory movements to compensate for the reduction in surface area. Blood PO_2 is an important stimulus for the respiratory center, and the increased respiratory movements keep the ventilation just adequate to maintain blood PO_2 in the low normal range. Because CO_2 diffuses across the respiratory membrane at a faster rate than O_2 , the elevated respiration required to maintain blood PO_2 causes too much CO_2 to be expired, resulting in his blood P_{CO_2} level dropping below normal.

This chapter explained that a pneumothorax, or the introduction of air into the pleural cavity through an opening in the thoracic

wall or lung, can cause a lung to collapse. Due to his emphysema, Mr. Theron's lung collapsed when alveoli near the surface of the lung ruptured, allowing air to enter the pleural space. The physician was able to diagnose Mr. Theron's collapsed lung by listening for respiratory sounds with a stethoscope. He detected respiratory sounds in the right lung but not in the left lung. We would expect Mr. Theron's respiratory movements to be even more exaggerated, since the respiratory membrane was reduced by half when his left lung collapsed. The reduction in the respiratory membrane would cause a drop in PO_2 and an increase in PCO_2 , both of which would stimulate respiratory centers to increase ventilation.

Answers to the rest of this chapter's Predict questions are in appendix G.

23.1 Functions of the Respiratory System (p. 823)

1. Respiration includes the movement of air into and out of the lungs, the exchange of gases between the air and the blood, the transport of gases in the blood, and the exchange of gases between the blood and tissues.
2. Other functions of the respiratory system are regulation of blood pH, production of chemical mediators, voice production, olfaction, and protection against some microorganisms.

23.2 Anatomy and Histology of the Respiratory System (p. 823)

Conducting Zone

Nose

1. The nose consists of the external nose and the nasal cavity.
2. The bridge of the nose is bone, and most of the external nose is cartilage.
3. Openings of the nasal cavity
 - The nares open to the outside, and the choanae lead to the pharynx.
 - The paranasal sinuses and the nasolacrimal duct open into the nasal cavity.
4. Parts of the nasal cavity
 - The nasal cavity is divided by the nasal septum.
 - The anterior vestibule contains hairs that trap debris.

Summary

- The nasal cavity is lined with pseudostratified ciliated columnar epithelium that traps debris and moves it to the pharynx.
 - The superior part of the nasal cavity contains the olfactory epithelium.
5. The nasal cavity serves as a passageway for air; cleans and humidifies air; is the location for the sense of smell; and, with the paranasal sinuses, functions as a resonating chamber for speech.

Pharynx

1. The nasopharynx joins the nasal cavity through the internal choanae and contains the openings to the auditory tube and the pharyngeal tonsils.
2. The oropharynx joins the oral cavity and contains the palatine and lingual tonsils.
3. The laryngopharynx opens into the larynx and the esophagus.

Larynx

1. Cartilage

Three of the nine cartilages are single cartilages. The thyroid cartilage and cricoid cartilage form most of the larynx. The epiglottis covers the opening of the larynx during swallowing. Six of the cartilages are paired. The vocal folds attach to the arytenoid cartilages.
2. The larynx maintains an open air passageway, regulates the passage of swallowed materials and air, produces sounds, and removes debris from the air.

3. Sounds are produced as the vocal folds vibrate when air passes through the larynx. Tightening the folds produces sounds of different pitches by controlling the length of the fold, which is allowed to vibrate.

Trachea

1. The trachea connects the larynx to the main bronchi.
2. The trachealis muscle regulates the diameter of the trachea.

Tracheobronchial Tree

1. The trachea divides to form two main bronchi, which extend to the lungs. The main bronchi divide to form lobar bronchi, which divide to form segmental bronchi, which divide to form bronchioles, which divide to form terminal bronchioles.
2. The trachea to the terminal bronchioles is a passageway for air movement.
 - The area from the trachea to the terminal bronchioles is ciliated to facilitate the removal of inhaled debris.
 - Cartilage helps hold the tube system open (from the trachea to the bronchioles).
 - Smooth muscle controls the diameter of the tubes (terminal bronchioles).

Respiratory Zone

Alveoli

1. Terminal bronchioles divide to form respiratory bronchioles, which give rise to alveolar ducts. Air-filled chambers called alveoli open into the respiratory bronchioles and alveolar ducts. The alveolar ducts end as alveolar sacs, which are chambers that connect to two or more alveoli.
2. Gas exchange occurs between the respiratory bronchioles and the alveoli.
3. The components of the respiratory membrane are a film of water, the walls of the alveolus and the capillary, and an interstitial space.

Lungs

1. The thoracic cavity contains two lungs.
2. The lungs are divided into lobes, bronchopulmonary segments, and lobules.

Thoracic Wall and Muscles of Respiration

1. The thoracic wall consists of vertebrae, ribs, the sternum, and muscles that allow expansion of the thoracic cavity.
2. Contraction of the diaphragm increases thoracic volume.
3. Muscles can elevate the ribs and increase thoracic volume or depress the ribs and decrease thoracic volume.

Pleura

The pleural membranes surround the lungs and protect against friction.

Blood Supply

1. Deoxygenated blood is transported to the lungs through the pulmonary arteries, and oxygenated blood leaves through the pulmonary veins.
2. Oxygenated blood is mixed with a small amount of deoxygenated blood from the bronchi.

Lymphatic Supply

The superficial and deep lymphatic vessels drain lymph from the lungs.

23.3 Ventilation (p. 839)

Pressure Differences and Airflow

1. Ventilation is the movement of air into and out of the lungs.
2. Air moves from an area of higher pressure to an area of lower pressure.

Pressure and Volume

Pressure is inversely related to volume.

Airflow Into and Out of Alveoli

1. Inspiration results when barometric air pressure is greater than intra-alveolar pressure.
2. Expiration results when barometric air pressure is less than intra-alveolar pressure.

Changing Alveolar Volume

1. Lung recoil causes alveoli to collapse.
 - Lung recoil results from elastic fibers and water surface tension.
 - Surfactant reduces water surface tension.
2. Pleural pressure is the pressure in the pleural cavity.
 - A negative pleural pressure can cause the alveoli to expand.
 - Pneumothorax is an opening between the pleural cavity and the air that causes a loss of pleural pressure.
3. Changes in thoracic volume cause changes in pleural pressure, resulting in changes in alveolar volume, intra-alveolar pressure, and airflow.

23.4 Measurement of Lung Function (p. 843)

Compliance of the Lungs and Thorax

1. Compliance is a measure of lung expansion caused by intra-alveolar pressure.
2. Reduced compliance means that it is more difficult than normal to expand the lungs.

Pulmonary Volumes and Capacities

1. Four pulmonary volumes exist: tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume.
2. Pulmonary capacities are the sum of two or more pulmonary volumes and include inspiratory capacity, functional residual capacity, vital capacity, and total lung capacity.
3. The forced expiratory vital capacity measures vital capacity while the individual exhales as rapidly as possible.

Minute Volume and Alveolar Ventilation

1. Minute volume is the total amount of air moved into and out of the respiratory system per minute.
2. Dead space is the part of the respiratory system where gas exchange does not take place.
3. Alveolar ventilation is how much air per minute enters the parts of the respiratory system where gas exchange takes place.

23.5 Physical Principles of Gas Exchange (p. 846)

Partial Pressure

1. Partial pressure is the contribution of a gas to the total pressure of a mixture of gases (Dalton's law).
2. Water vapor pressure is the partial pressure produced by water.
3. Atmospheric air, alveolar air, and expired air have different compositions.

Diffusion of Gases Into and Out of Liquids

The concentration of a dissolved gas in a liquid is determined by its pressure and by its solubility coefficient (Henry's law).

Diffusion of Gases Through the Respiratory Membrane

1. The respiratory membrane is thin and has a large surface area that facilitates gas exchange.
2. The rate of diffusion of gases through the respiratory membrane depends on its thickness, the diffusion coefficient of the gas, the surface area of the membrane, and the partial pressure of the gases in the alveoli and the blood.

Relationship Between Alveolar Ventilation and Pulmonary Capillary Perfusion

1. Increased alveolar ventilation or increased pulmonary capillary perfusion increases gas exchange.
2. The physiological shunt is the deoxygenated blood returning from the lungs.

23.6 Oxygen and Carbon Dioxide Transport in the Blood (p. 848)

Oxygen Partial Pressure Gradients

1. Oxygen moves from the alveoli ($PO_2 = 104$ mm Hg) into the blood ($PO_2 = 40$ mm Hg). Blood is almost completely saturated with O_2 when it leaves the capillary.
2. The PO_2 in the blood decreases ($PO_2 = 95$ mm Hg) when it mixes with deoxygenated blood.
3. Oxygen moves from the tissue capillaries ($PO_2 = 95$ mm Hg) into the tissues ($PO_2 = 40$ mm Hg).

Carbon Dioxide Partial Pressure Gradients

1. Carbon dioxide moves from the tissues ($PCO_2 = 45$ mm Hg) into tissue capillaries ($PCO_2 = 40$ mm Hg).
2. Carbon dioxide moves from the pulmonary capillaries ($PCO_2 = 45$ mm Hg) into the alveoli ($PCO_2 = 40$ mm Hg).

Hemoglobin and Oxygen Transport

1. Oxygen is transported by hemoglobin (98.5%) and is dissolved in plasma (1.5%).
2. The oxygen-hemoglobin dissociation curve shows that hemoglobin is almost completely saturated when PO_2 is 80 mm Hg or above. At lower partial pressures, the hemoglobin releases O_2 .
3. Hemoglobin's ability to hold O_2 decreases because of a shift of the oxygen-hemoglobin dissociation curve to the right due to decreased pH (Bohr effect), increased CO_2 , or increased temperature.
4. Hemoglobin's ability to hold O_2 increases because of a shift of the oxygen-hemoglobin dissociation curve to the left due to increased pH (Bohr effect), decreased CO_2 , or decreased temperature.
5. The substance 2,3-bisphosphoglycerate increases hemoglobin's ability to release O_2 .
6. Fetal hemoglobin has a higher affinity for O_2 than maternal hemoglobin does.

Transport of Carbon Dioxide

1. Carbon dioxide is transported dissolved in plasma (7%), as HCO_3^- dissolved in plasma and in red blood cells (70%), and bound to hemoglobin (23%).
2. In tissue capillaries, the following events occur:
 - Carbon dioxide combines with water inside red blood cells to form carbonic acid, which dissociates to form HCO_3^- . Decreasing HCO_3^- concentrations promote CO_2 transport.
 - Exchange of Cl^- for HCO_3^- occurs between plasma and red blood cells; this is called the chloride shift.

- Hydrogen ions binding to hemoglobin promote CO_2 transport, prevent a pH change in red blood cells, and produce a Bohr effect.
 - In the Haldane effect, the smaller the amount of O_2 bound to hemoglobin, the greater the amount of CO_2 bound to it, and vice versa.
3. In pulmonary capillaries, the events occurring in the tissue capillaries are reversed.

23.7 Regulation of Ventilation (p. 855)

Respiratory Areas in the Brainstem

1. The medullary respiratory center consists of the dorsal and ventral respiratory groups.
 - The dorsal respiratory groups stimulate the diaphragm.
 - The ventral respiratory groups stimulate the intercostal and abdominal muscles.
2. The pontine respiratory group is involved with switching between inspiration and expiration.

Generation of Rhythmic Ventilation

1. Neurons in the medullary respiratory center establish the basic rhythm of ventilation.
2. When stimuli from receptors or other parts of the brain exceed a threshold level, inspiration begins.
3. As respiratory muscles are stimulated, neurons that stop inspiration are stimulated. When the stimulation of these neurons exceeds a threshold level, inspiration is inhibited.

Cerebral and Limbic System Control

Ventilation can be voluntarily controlled and can be modified by emotions.

Chemical Control of Ventilation

1. Carbon dioxide is the major regulator of ventilation. An increase in CO_2 or a decrease in pH can stimulate the chemosensitive area, causing a greater rate and depth of ventilation.
2. Oxygen levels in the blood affect ventilation when a 50% or greater decrease from normal exists. Decreased O_2 is detected by receptors in the carotid and aortic bodies, which then stimulate the respiratory center.

Hering-Breuer Reflex

Stretch of the lungs during inspiration can inhibit the respiratory center and contribute to a cessation of inspiration.

Effect of Exercise on Ventilation

1. Collateral fibers from motor neurons and from proprioceptors stimulate the respiratory centers.
2. Chemosensitive mechanisms and learning fine-tune the effects produced through the motor neurons and proprioceptors.

Other Modifications of Ventilation

Touch, thermal, and pain sensations can modify ventilation.

23.8 Respiratory Adaptations to Exercise (p. 860)

Tidal volume, respiratory rate, minute volume, and gas exchange between the alveoli and blood remain unchanged or slightly lower at rest or during submaximal exercise but increase at maximal exercise.

23.9 Effects of Aging on the Respiratory System (p. 860)

- Vital capacity and maximum minute volume decrease with age because of weakened respiratory muscles and decreased thoracic cage compliance.
- Residual volume and dead space increase because of the enlarged

diameter of respiratory passageways. As a result, alveolar ventilation decreases.

- An increase in resting tidal volume compensates for decreased alveolar ventilation, loss of alveolar walls (surface area), and thickening of alveolar walls.
- The ability to remove mucus from the respiratory passageways decreases with age.

REVIEW AND COMPREHENSION

- The nasal cavity
 - has openings for the paranasal sinuses.
 - has a vestibule, which contains the olfactory epithelium.
 - is connected to the pharynx by the nares.
 - has passageways called conchae.
 - is lined with squamous epithelium, except for the vestibule.
- The larynx
 - connects the oropharynx to the trachea.
 - has three single and six paired cartilages.
 - contains the vocal folds.
 - contains the vestibular folds.
 - All of these are correct.
- Terminal bronchioles branch to form
 - the alveolar duct.
 - bronchioles.
 - alveoli.
 - respiratory bronchioles.
- During an asthma attack, a person has difficulty breathing because of constriction of the
 - trachea.
 - bronchi.
 - terminal bronchioles.
 - alveoli.
 - respiratory membrane.
- During quiet expiration, the
 - abdominal muscles relax.
 - diaphragm moves inferiorly.
 - external intercostal muscles contract.
 - thorax and lungs passively recoil.
 - All of these are correct.
- The parietal pleura
 - covers the surface of the lung.
 - covers the inner surface of the thoracic cavity.
 - is the connective tissue partition that divides the thoracic cavity into right and left pleural cavities.
 - covers the inner surface of the alveoli.
 - is the membrane across which gas exchange occurs.
- Contraction of the bronchiolar smooth muscle has which of these effects?
 - A smaller pressure gradient is required to get the same rate of airflow, compared with normal bronchioles.
 - It increases airflow through the bronchioles.
 - It increases resistance to airflow.
 - It increases alveolar ventilation.
- During expiration, the intra-alveolar pressure is
 - lower than the pleural pressure.
 - greater than the barometric pressure.
 - lower than the barometric pressure.
 - unchanged.
- Normally, which of the following keeps the lungs from collapsing?
 - surfactant
 - pleural pressure
 - elastic recoil
 - Both a and b are correct.
- Immediately after the creation of an opening through the thorax into the pleural cavity,
 - air flows through the hole and into the pleural cavity.
 - air flows through the hole and out of the pleural cavity.
 - air flows neither out nor in.
 - the lung protrudes through the hole.
- Compliance of the lungs and thorax
 - is the volume by which the lungs and thorax change for each unit change of intra-alveolar pressure.
 - increases in emphysema.
 - decreases because of lack of surfactant.
 - All of these are correct.
- Given these lung volumes:
 - tidal volume = 500 mL
 - residual volume = 1000 mL
 - inspiratory reserve volume = 2500 mL
 - expiratory reserve volume = 1000 mL
 - dead space = 1000 mL
 The vital capacity is
 - 3000 mL.
 - 3500 mL.
 - 4000 mL.
 - 5000 mL.
 - 6000 mL.
- Alveolar ventilation is the
 - tidal volume times the respiratory rate.
 - minute volume plus the dead space.
 - amount of air available for gas exchange in the lungs.
 - vital capacity divided by the respiratory rate.
 - inspiratory reserve volume times minute volume.
- The rate of diffusion of a gas across the respiratory membrane increases as the
 - respiratory membrane becomes thicker.
 - surface area of the respiratory membrane decreases.
 - partial pressure gradient of the gas across the respiratory membrane increases.
 - diffusion coefficient of the gas decreases.
 - All of these are correct.
- Oxygen is mostly transported in the blood
 - dissolved in plasma.
 - bound to blood proteins.
 - within HCO_3^- .
 - bound to the heme portion of hemoglobin.

16. The oxygen-hemoglobin dissociation curve is adaptive because it
 - a. shifts to the right in the pulmonary capillaries and to the left in the tissue capillaries.
 - b. shifts to the left in the pulmonary capillaries and to the right in the tissue capillaries.
 - c. does not shift.
17. Carbon dioxide is mostly transported in the blood
 - a. dissolved in plasma.
 - b. bound to blood proteins.
 - c. within HCO_3^- .
 - d. bound to the heme portion of hemoglobin.
 - e. bound to the globin portion of hemoglobin.
18. The chloride shift
 - a. promotes the transport of CO_2 in the blood.
 - b. occurs when Cl^- replaces HCO_3^- within red blood cells.
 - c. maintains electrical neutrality in red blood cells and the plasma.
 - d. All of these are correct.
19. Which of these parts of the brainstem is correctly matched with its main function?
 - a. ventral respiratory groups—stimulate the diaphragm
 - b. dorsal respiratory groups—limit inflation of the lungs
 - c. pontine respiratory group—is involved in the switch between inspiration and expiration
 - d. All of these are correct.
20. The chemosensitive area
 - a. stimulates the respiratory center when blood CO_2 levels increase.
 - b. stimulates the respiratory center when blood pH increases.
 - c. is located in the pons.
 - d. stimulates the respiratory center when blood O_2 levels increase.
 - e. All of these are correct.
21. Blood O_2 levels
 - a. are more important than CO_2 levels in the regulation of respiration.
 - b. need to change only slightly to cause a change in respiration.
 - c. are detected by sensory receptors in the carotid and aortic bodies.
 - d. All of these are correct.

Answers in appendix E

CRITICAL THINKING

1. A person's vital capacity is measured while standing and while lying down. What difference, if any, in the measurement do you predict and why?
2. Ima Diver wanted to do some underwater exploration. Instead of buying expensive SCUBA equipment, she obtained a long hose and an innertube. She attached one end of the hose to the innertube so that the end was always out of the water, and she inserted the other end of the hose in her mouth and went diving. What happened to her alveolar ventilation and why? How can she compensate for this change? How does diving affect lung compliance and the work of ventilation?
3. The bacteria that cause gangrene (*Clostridium perfringens*) are anaerobic microorganisms that do not thrive in the presence of O_2 . Hyperbaric oxygenation (HBO) treatment places a person in a chamber containing O_2 at three to four times normal atmospheric pressure. Explain how HBO helps treat gangrene.
4. One technique for artificial respiration is mouth-to-mouth resuscitation. The rescuer takes a deep breath, blows air into the patient's mouth, and then lets air flow out. The process is repeated. Explain the following: (1) Why do the patient's lungs expand? (2) Why does air move out of the patient's lungs? (3) What effect do the PO_2 and the PCO_2 of the rescuer's air have on the victim?
5. The left phrenic nerve supplies the left side of the diaphragm, and the right phrenic nerve supplies the right side. Damage to the left phrenic nerve results in paralysis of the left side of the diaphragm. During inspiration, does the left side of the diaphragm move superiorly, move inferiorly, or stay in place?
6. Suppose that the thoracic wall is punctured at the end of a normal expiration, producing a pneumothorax. Does the thoracic wall move inward, move outward, or not move at all?
7. During normal, quiet respiration, when does the maximum rate of diffusion of O_2 in the pulmonary capillaries occur? When does the maximum rate of diffusion of CO_2 occur?
8. Experimental evidence suggests that the overuse of erythropoietin (EPO; see chapter 19) reduces athletic performance. What side effects of EPO abuse reduce exercise stamina?
9. Predict what would happen to tidal volume if (a) the vagus nerves were cut, (b) the phrenic nerves were cut, or (c) the intercostal nerves were cut.
10. You and your physiology instructor are trapped in an overturned ship. To escape, you must swim under water a long distance. You tell your instructor it would be a good idea to hyperventilate before making the escape attempt. Your instructor calmly replies, "What good would that do, since your pulmonary capillaries are already 100% saturated with oxygen?" What should you do and why?
11. Ima Anxious was hysterical and hyperventilating, so a doctor made her breathe into a paper bag. An especially astute student said to the doctor, "When Ima was hyperventilating, she was reducing blood CO_2 levels; when she breathed into the paper bag, CO_2 was trapped in the bag, and she was rebreathing it, thus causing blood CO_2 levels to increase. As Ima's blood CO_2 levels increased, her urge to breathe should have increased. Instead, she began to breathe more slowly. Please explain." How do you think the doctor responded? (*Hint:* Recall that the effect of decreased blood CO_2 on the vasomotor center results in vasodilation and a sudden decrease in blood pressure.)

Digestive System

Almost everyone loves to eat, and we all must eat to stay alive. Throughout history, food and drink have provided not only nourishment but also the foundation for many social gatherings. Although it's not something we often think about while enjoying our pizza and favorite beverage, the body has an amazing digestive system that includes its own quality control and waste disposal methods.

Every cell of the body needs nourishment, yet most cells cannot leave their position in the body and travel to a food source. Therefore, the food must be converted to a usable form and delivered. To do this, the digestive system is specialized to ingest food, propel it through the digestive tract, digest it, and absorb water, electrolytes, and nutrients. The digestive process involves a choreographed mixing of food with digestive juices that include strong acids, detergent-like bile salts, and activated enzymes. The body then maximizes absorption of digested nutrients. Once these useful substances are absorbed, they are transported through the blood to cells, which use them for energy or as new molecules for building and maintaining tissues and organs. Indeed, the digestive system is the body's "meals on wheels."

Learn to Predict

Rebecca kept attributing her recurring abdominal pain to "something I ate"—and she was partly right about that. Several times during the past year, eating high-fat meals had led to episodes of serious abdominal pain. During the most recent attack, the discomfort became so intense that Rebecca went to the emergency room, where she was given medication to relieve the pain. Still, over the next few hours, her skin took on a yellowish tint, and the next morning she had diarrhea and clay-colored feces. Following lab tests and ultrasonography, a physician diagnosed gallstones and recommended the removal of Rebecca's gallbladder. **By combining your background knowledge from chapters 21 and 22 with new information about the digestive system in this chapter, explain how gallstones led to Rebecca's pain and other symptoms.**

Photo: Colorized computed tomographic (CT) scan of an axial section through the abdomen. The image shows a gallstone (*pink*) obstructing the cystic duct where it leaves the gallbladder (*green circle*). The large yellow region around the gallbladder is the liver. A vertebra (*pink*) is visible in bottom center, with C-shaped kidneys (*yellow*) on either side.

24.1 Anatomy of the Digestive System

LEARNING OUTCOME

After reading this section, you should be able to

A. List the regions of the digestive tract.

The **digestive system** (figure 24.1) consists of the digestive tract and accessory organs. The **digestive tract** is a tube extending from the mouth to the anus. It is also called the *alimentary tract*, or *alimentary canal*. Technically, the term **gastrointestinal** (gas'trō-in-tes'tin-āl; **GI**) **tract** refers only to the stomach and intestines, but it is often used as a synonym for *digestive tract*. The associated **accessory organs** are primarily glands located outside the digestive tract that secrete fluids into it.

The digestive tract and associated accessory organs include the following:

1. *Oral cavity*, or mouth, including the tongue and teeth, with the salivary glands as accessory organs
2. *Pharynx*, or throat, with the tonsils as accessory organs
3. *Esophagus*
4. *Stomach*
5. *Small intestine*, consisting of the duodenum, jejunum, and ileum, with the liver, gallbladder, and pancreas as major accessory organs
6. *Large intestine*, including the cecum, colon, rectum, and anal canal
7. *Anus*

FIGURE 24.1 Digestive System

ASSESS YOUR PROGRESS

1. List the regions of the digestive tract, from beginning to end.

24.2 Functions of the Digestive System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the major functions of the digestive system.
- B. State which digestive functions occur in the different regions of the digestive tract.

The major functions of the digestive system are listed in table 24.1 and described here:

1. *Ingestion* is the intake of solid or liquid food into the stomach. The normal route of ingestion is through the oral cavity.
2. *Mastication* is the process by which the teeth chew food in the mouth. Digestive enzymes cannot easily penetrate solid food particles and can work effectively only on particle surfaces. It is vital, therefore, that solid foods be mechanically broken down by mastication into smaller particles to increase the total surface area of food for digestion.
3. *Propulsion* is the movement of food from one end of the digestive tract to the other. The total time it takes food to travel the length of the digestive tract is usually about 24–36 hours. Each segment of the digestive tract is specialized to assist in moving its contents from the oral end to the anal end. These movements begin with swallowing, followed by peristalsis, and finally mass movements. Characteristics of these propulsive movements are
 - a. **Swallowing**, or *deglutition* (dē'gloo-tish'ŭn), moves liquids or a soft mass of food and liquid, called a **bolus** (bō'lŭs), from the oral cavity into the esophagus.
 - b. **Peristalsis** (per-i-stal'sis; figure 24.2) propels material through most of the digestive tract. **Peristaltic** (per-i-stal'tik) **waves** are muscular contractions consisting of a wave of relaxation of the circular muscles in front of the bolus, followed by a wave of strong contraction of the circular muscles behind the bolus, which force the bolus along the digestive tube. Each peristaltic wave travels the length of the esophagus in about 10 seconds. Peristaltic waves in the small and large intestines usually travel only short distances.
 - c. **Mass movements** are contractions that move material in the distal parts of the large intestine to the anus.
4. *Mixing*. Some contractions do not propel food from one end of the digestive tract to the other but, rather, move it back and forth within the digestive tract to *mix* it with digestive secretions and help break it into smaller pieces. **Segmental contractions** are mixing contractions that occur in the small intestine (figure 24.3).
5. *Secretion*. As food moves through the digestive tract, secretions are added to lubricate, liquefy, buffer, and digest the food. **Mucus**, secreted along the entire digestive tract,

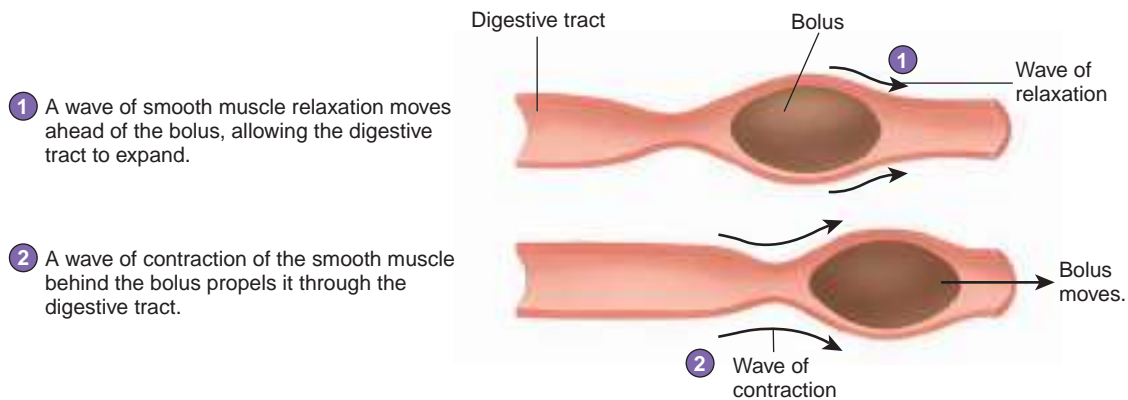

TABLE 24.1 Functions of the Digestive System

Organ	Functions
Oral cavity	<p><i>Ingestion.</i> Solid food and fluids are taken into the digestive tract through the oral cavity.</p> <p><i>Taste.</i> Tastants dissolved in saliva stimulate taste buds in the tongue.</p> <p><i>Mastication.</i> Movement of the mandible by the muscles of mastication causes the teeth to break food into smaller pieces. The tongue and cheeks help place the food between the teeth.</p> <p><i>Digestion.</i> Amylase in saliva begins carbohydrate (starch) digestion.</p> <p><i>Swallowing.</i> The tongue forms food into a bolus and pushes the bolus into the pharynx.</p> <p><i>Communication.</i> The lips, cheeks, teeth, and tongue are involved in speech. The lips change shape as part of facial expressions.</p> <p><i>Protection.</i> Mucin and water in saliva provide lubrication, and lysozyme (an enzyme that lyses cells) kills microorganisms. Nonkeratinized stratified squamous epithelium prevents abrasion.</p>
Pharynx	<p><i>Swallowing.</i> The involuntary phase of swallowing moves the bolus from the oral cavity to the esophagus. Materials are prevented from entering the nasal cavity by the soft palate and kept out of the lower respiratory tract by the epiglottis and vestibular folds.</p> <p><i>Breathing.</i> Air passes from the nasal or oral cavity through the pharynx to the lower respiratory tract.</p> <p><i>Protection.</i> Mucus provides lubrication. Nonkeratinized stratified squamous epithelium prevents abrasion.</p>
Esophagus	<p><i>Propulsion.</i> Peristaltic contractions move the bolus from the pharynx to the stomach. The lower esophageal sphincter limits reflux of the stomach contents into the esophagus.</p> <p><i>Protection.</i> Glands produce mucus, which provides lubrication and protects the inferior esophagus from stomach acid.</p>
Stomach	<p><i>Storage.</i> Rugae allow the stomach to expand and hold food until it can be digested.</p> <p><i>Digestion.</i> Protein digestion begins as a result of the actions of hydrochloric acid and pepsin.</p> <p><i>Absorption.</i> Absorption of a few substances (e.g., water, alcohol, aspirin) takes place in the stomach.</p> <p><i>Mixing and propulsion.</i> Mixing waves churn ingested materials and stomach secretions into chyme. Peristaltic waves move the chyme into the small intestine.</p> <p><i>Protection.</i> Mucus provides lubrication and prevents digestion of the stomach wall. Stomach acid kills most microorganisms.</p>
Small intestine	<p><i>Neutralization.</i> Bicarbonate ions from the pancreas and bile from the liver neutralize stomach acid to form a pH environment suitable for pancreatic and intestinal enzymes.</p> <p><i>Digestion.</i> Enzymes from the pancreas and the lining of the small intestine complete the breakdown of food molecules. Bile salts from the liver emulsify lipids.</p> <p><i>Absorption.</i> The circular folds, villi, and microvilli increase surface area. Most nutrients are actively or passively absorbed. Most of the ingested water or the water in digestive tract secretions is absorbed.</p> <p><i>Mixing and propulsion.</i> Segmental contractions mix the chyme, and peristaltic contractions move the chyme into the large intestine.</p> <p><i>Excretion.</i> Bile from the liver contains bilirubin and excess cholesterol.</p> <p><i>Protection.</i> Mucus provides lubrication, prevents digestion of the intestinal wall, and protects the small intestine from stomach acid. Peyer patches protect against microorganisms.</p>
Large intestine	<p><i>Absorption.</i> The proximal half of the colon absorbs salts (e.g., sodium chloride), water, and vitamins (e.g., K) produced by bacteria.</p> <p><i>Storage.</i> The distal half of the colon holds feces until they are eliminated.</p> <p><i>Mixing and propulsion.</i> Slight segmental mixing occurs. Mass movements propel feces toward the anus, and defecation eliminates the feces.</p> <p><i>Protection.</i> Mucus provides lubrication; mucus and bicarbonate ions protect against acids produced by bacteria.</p>

lubricates the food and the lining of the tract. The mucus coats and protects the epithelial cells of the digestive tract from mechanical abrasion, stomach acid, and digestive enzymes. The secretions also contain large amounts of **water**, which liquefies the food, making it easier to digest and absorb. Water also moves into the intestine by osmosis. Liver secretions break large lipid droplets into much smaller droplets,

which makes the digestion and absorption of lipids possible. **Enzymes** secreted by the oral cavity, stomach, small intestine, and pancreas break down large food molecules into smaller molecules that can be absorbed by the intestinal wall.

- Digestion* is the breakdown of large organic molecules into their component parts: carbohydrates into monosaccharides, proteins into amino acids, and triglycerides into fatty acids

1 A wave of smooth muscle relaxation moves ahead of the bolus, allowing the digestive tract to expand.

2 A wave of contraction of the smooth muscle behind the bolus propels it through the digestive tract.

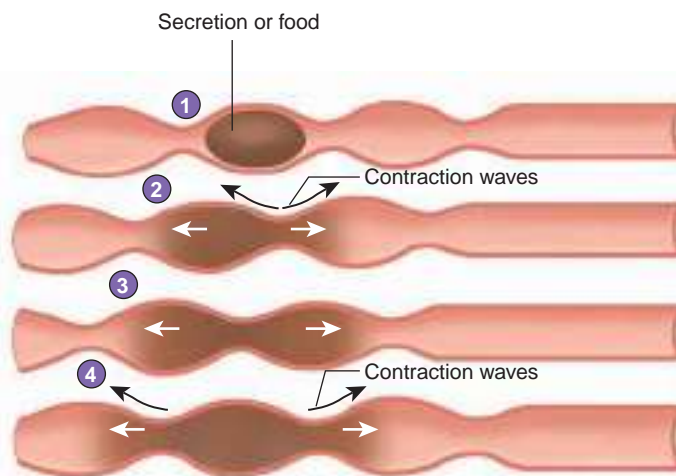

PROCESS FIGURE 24.2 Peristalsis

1 A secretion introduced into the digestive tract or food within the tract begins in one location.

2 Segments of the digestive tract alternate between contraction and relaxation.

3 Material (*brown*) in the intestine is spread out in both directions from the site of introduction.

4 The secretion or food is spread out in the digestive tract and becomes more diffuse (*lighter color*) through time.

PROCESS FIGURE 24.3 Segmental Contractions

and glycerol. Digestion consists of **mechanical digestion**, which involves the mastication and mixing of food, and **chemical digestion**, which is accomplished by digestive enzymes secreted along the digestive tract. Large organic molecules must be digested into their component parts before they can be absorbed by the digestive tract. Minerals and water are not broken down before being absorbed. Vitamins are also absorbed without digestion; in fact, they lose their function if their structure is altered by digestion.

7. *Absorption* is the movement of molecules out of the digestive tract and into the blood or into the lymphatic system. The mechanism by which absorption occurs depends on the type of molecule involved. Molecules pass out of the digestive tract by diffusion, facilitated diffusion, active transport, symport, or endocytosis (see chapter 3).

8. *Elimination* is the process by which the waste products of digestion are removed from the body. During this process, which occurs primarily in the large intestine, water and salts are absorbed, changing the material in the digestive tract from liquefied to semisolid. These semisolid waste products, called **feces**, are then eliminated from the digestive tract by the process of **defecation**.

ASSESS YOUR PROGRESS

- Describe each of the functions involved in the normal functions of the digestive system.
- Explain the three types of propulsion through the digestive tract.
- What is the difference between mechanical digestion and chemical digestion?
- What digestive functions occur in the stomach? In the small intestine?

24.3 Histology of the Digestive Tract

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the histology of the digestive tract.
- List the types of glands associated with the digestive tract.

FIGURE 24.4 Digestive Tract Histology

The four tunics are the mucosa, the submucosa, the muscularis, and a serosa or an adventitia. Glands may exist along the digestive tract as part of the epithelium, as glands within the submucosa, or as large glands outside the digestive tract.

The digestive tube consists of four major tunics, or layers: (1) the internal mucosa, (2) the submucosa, (3) the muscularis, and (4) the external serosa or adventitia. These four tunics are present in all areas of the digestive tract, from the esophagus to the anus. These tunics are shown in a generalized view of digestive tract histology in figure 24.4. Three major types of glands are associated with the intestinal tract: (1) unicellular mucous glands in the mucosa, (2) multicellular glands in the mucosa and submucosa, and (3) multicellular glands (accessory glands) outside the digestive tract.

Mucosa

The innermost tunic, the **mucosa** (mū-kō'să), or *mucous membrane*, consists of three layers: (1) the inner **mucous epithelium**, which is moist stratified squamous epithelium in the mouth, oropharynx, esophagus, and anal canal and simple columnar epithelium in the remainder of the digestive tract; (2) a loose connective tissue called the **lamina propria** (lam'i-nă prō'prē-ă); and (3) a thin outer layer of smooth muscle, the **muscularis mucosae**. The epithelium extends deep into the lamina propria in many places to form **intestinal glands** and **crypts**. Two types of specialized cells in the mucosa are mechanoreceptors involved in peristaltic reflexes and chemoreceptors that detect the chemical composition of food.

Submucosa

Beneath the mucosa lies the **submucosa**, a thick connective tissue layer. This tunic contains nerves, blood vessels, lymphatic vessels, and small glands. A network of nerve cells in the submucosa forms the **submucosal plexus** (plek'sūs), or *Meissner plexus*, consisting of axons, many scattered neuron cell bodies, and glial cells. Axons from the submucosal plexus extend to cells in epithelial intestinal glands, stimulating their secretion. The esophagus and stomach lack a submucosal plexus, but the plexus is extensive throughout the rest of the digestive tract.

Muscularis

The next tunic is the **muscularis**, a muscular layer. The muscularis consists of an inner layer of circular smooth muscle and an outer layer of longitudinal smooth muscle. Two exceptions are the upper esophagus, where the muscles are striated, and the stomach, which has three layers of smooth muscle. Between the two muscle layers is the **myenteric** (mī-en-ter'ik) **plexus**, or *Auerbach plexus* (figure 24.4). The myenteric plexus controls the motility of the intestinal tract. This function is in contrast with the submucosal plexus, which controls secretions. Both the myenteric plexus and the submucosal plexus consist of axons, many scattered neuron cell bodies, and glial cells, although the myenteric plexus is much more extensive than the submucosal plexus.

Within the myenteric plexus, specialized **interstitial cells** form a network of pacemakers, which promote rhythmic contractions of smooth muscle along the digestive tract. These cells also help transmit signals from neurons to muscles to regulate movement. Dysfunction of these pacemakers decreases motility in the digestive tract.

Together, the submucosal and myenteric plexuses constitute the **enteric nervous system (ENS)**, or the *enteric* (en-tě'rik) *plexus*, which is extremely important in controlling secretion and movement (see section 24.4).

Serosa or Adventitia

The fourth layer of the digestive tract is either a **serosa** or an **adventitia** (ad-ven-tish'ă; foreign or coming from outside), depending on the structure of the layer. Parts of the digestive tract that protrude into the peritoneal cavity have a serosa as the outermost layer. This serosa, or serous membrane, is called the visceral peritoneum. It consists of a thin layer of connective tissue and a simple squamous epithelium. When the outer layer of the digestive tract is derived from adjacent connective tissue, the tunic is called the adventitia and consists of a connective tissue covering that blends with the surrounding connective tissue. These areas include the esophagus and the retroperitoneal organs (see section 24.5).

ASSESS YOUR PROGRESS

6. What are the major tunics of the digestive tract wall, listed from inside to outside?
7. What types of tissue are found in each tunic?
8. In what tunics of the digestive tract are the submucosal and myenteric plexuses found? What are their functions?
9. How do the serosa and adventitia differ?

24.4 Regulation of the Digestive System

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe the overall neural and chemical regulation of the digestive system.

The digestive system is controlled by elaborate nervous and chemical mechanisms that regulate the movement, secretion, absorption, and elimination processes.

Nervous Regulation of the Digestive System

Most of the nervous regulation of the digestive tract is under local control by the enteric nervous system. The **enteric nervous system (ENS)** is an extensive network of the submucosal and myenteric plexuses within the walls of the digestive tract (figure 24.4). This network of neurons and associated glial cells is a division of the autonomic nervous system (see chapter 16). The ENS contains more neurons than the spinal cord. In addition to local

reflexes within the ENS, there is also control mediated by autonomic innervation from the CNS. This innervation is largely by the parasympathetic division of the ANS through the vagus nerves and to a lesser extent by sympathetic nerves (see chapter 16).

There are three major types of enteric neurons: (1) Enteric sensory neurons detect changes in the chemical composition of digestive tract contents or detect mechanical changes, such as stretch of the digestive tract wall; (2) enteric motor neurons stimulate or inhibit smooth muscle contraction and glandular secretion in the digestive system; and (3) enteric interneurons connect enteric sensory and motor neurons. The ENS functions through **local reflexes** to control activities within specific, short regions of the digestive tract. The ENS is capable of controlling the complex peristaltic and mixing movements, as well as blood flow to the digestive tract, without any outside influences. The importance of the ENS is highlighted by the poor intestinal motility observed in patients with **Hirschsprung disease**, or *megacolon*, who lack a subset of enteric neurons.

Although the ENS can control the activities of the digestive tract independent of the CNS, the two systems normally work together. Autonomic innervation from the CNS can increase or decrease ENS activity.

Control of the digestive system by the CNS occurs when reflexes are activated by stimuli originating either in the digestive tract or in the CNS. From within the digestive system, action potentials are carried by sensory neurons in the vagus and sympathetic nerves to the CNS, where the reflexes are integrated. Reflexes within the CNS can be activated by the sight, smell, or taste of food. An example is increased salivation and pancreatic secretions when food is seen or smelled. All of these reflexes influence activity in parasympathetic neurons of the CNS. Parasympathetic neurons extend to the digestive tract through the vagus nerves to control responses or alter the activity of the ENS and local reflexes. Some sympathetic neurons inhibit muscle contraction and secretion in the digestive system and decrease blood flow to the digestive system.

Chemical Regulation of the Digestive System

Over 30 neurotransmitters are associated with the ENS. Two major ENS neurotransmitters are acetylcholine and norepinephrine. In general, acetylcholine stimulates and norepinephrine inhibits digestive tract motility and secretions. Another major ENS neurotransmitter is serotonin, which stimulates digestive tract motility.

In addition to neural release, serotonin is also produced by endocrine cells within the digestive tract wall. Over 95% of the serotonin in the body is found in the digestive tract, so drugs that increase serotonin levels and function, such as antidepressants (see chapter 11) and chemotherapeutics used for cancer treatment, can also affect digestive tract activity. An unintended consequence of many cancer therapies is nausea, due to increased serotonin release from endocrine cells in the digestive tract. Serotonin binds to a subset of serotonin receptors, called 5HT₃ receptors, on sensory terminals of the vagus nerve, which stimulates the vomiting center in the brain. This results in the nausea and vomiting associated with chemotherapy and radiotherapy. 5HT₃ receptor blockers, such as ondansetron (ōn-dan'sē-tron), are commonly used to alleviate nausea.

Clinical IMPACT

Enteric Neurons

Hirschprung disease, also called *megacolon*, is a painful developmental disorder caused by the absence of enteric neurons in the distal large intestine. Mutations in the *RET* gene have been identified in patients with Hirschprung disease. The *RET* gene encodes a receptor that is normally activated by the growth factors required for the survival and differentiation of a subset of enteric neurons. The mutations in *RET* that lead to loss of receptor function result in loss of enteric neurons, which results in poor intestinal motility and severe constipation. Conversely, a different set of mutations in the *RET* gene is linked to an inherited cancer called **multiple endocrine neoplasia type 2 (MEN2)**. In contrast to the loss of function due to Hirschprung mutations, the MEN2 mutations cause a gain of RET receptor function, so that it is active even in the absence of growth factors. Hence, two types of mutations in the same gene result in two very different syndromes. Rapid DNA tests are used to screen patients and family members for suspected Hirschprung and MEN2 mutations.

A number of hormones, such as gastrin and secretin, are secreted by endocrine cells in the digestive system and are carried through the blood to target organs of the digestive system or to target tissues in other systems. These hormones help regulate many digestive tract functions, as well as the secretions of associated glands, such as the liver and pancreas.

In addition to the hormones produced by the digestive system that enter the blood other paracrine chemicals, such as histamine, are released locally within the digestive tract, where they influence the activity of nearby cells. These localized chemical regulators help local reflexes within the ENS control local digestive tract environments, such as pH levels.

ASSESS YOUR PROGRESS

- Describe the roles of the ENS, CNS, and ANS in controlling the digestive system.
- What chemical mechanisms regulate the digestive system?

24.5 Peritoneum

LEARNING OUTCOME

After reading this section, you should be able to

A. Describe the peritoneum and its function.

The walls and organs of the abdominal cavity are lined with **serous membranes**. These membranes are called the **peritoneum** (per'i-tō-nē'ūm; to stretch over; figure 24.5). Serous membranes are very smooth and secrete a serous fluid, which provides a

lubricating film between the layers of membranes. The membranes and fluid reduce friction as organs move within the abdomen. The serous membrane that covers the organs is the **visceral peritoneum**, and the one that covers the interior surface of the wall of the abdominal cavity is the **parietal peritoneum** (figure 24.5). Serous membranes also line other organs of the body.

Peritonitis is a potentially life-threatening inflammation of the peritoneal membranes. The inflammation can result from chemical irritation by substances, such as bile, that have escaped from a damaged digestive tract or from infection originating in the digestive tract, as when the appendix ruptures. The main symptoms of peritonitis are acute abdominal pain and tenderness that are worsened by movement. An accumulation of excess serous fluid in the peritoneal cavity, called **ascites** (ă-sī'tēz), can occur in peritonitis. Ascites can also accompany starvation, alcoholism, or liver cancer.

Many organs within the abdominal cavity are held in place by connective tissue sheets called **mesenteries** (mes'en-ter'ēz; middle intestine). The mesenteries consist of two layers of serous membranes with a thin layer of loose connective tissue between them. They provide a route by which vessels and nerves can pass from the abdominal wall to the organs. Although *mesentery* is a general term referring to the serous membranes attached to the abdominal organs, it is also applied specifically to the mesentery associated with the small intestine, sometimes called the **mesentery proper**. The mesenteries of parts of the colon are the **transverse mesocolon**, which extends from the transverse colon to the posterior body wall, and the **sigmoid mesocolon**. The vermiform appendix has its own little mesentery, called the **mesoappendix**.

The mesentery connecting the lesser curvature of the stomach and the proximal end of the duodenum to the liver and diaphragm is called the **lesser omentum** (ō-men'tūm; membrane of the bowels), and the mesentery extending as a fold from the greater curvature and then to the transverse colon is called the **greater omentum** (figure 24.5). The greater omentum forms a long, double fold of mesentery that extends inferiorly from the stomach over the surface of the small intestine. Because of this folding, a cavity called the **omental bursa** (ber'să; pocket) forms between the two layers of mesentery. A large amount of adipose tissue accumulates in the greater omentum, and it is sometimes referred to as the “fatty apron.” The greater omentum has considerable mobility in the abdomen.

Predict 2

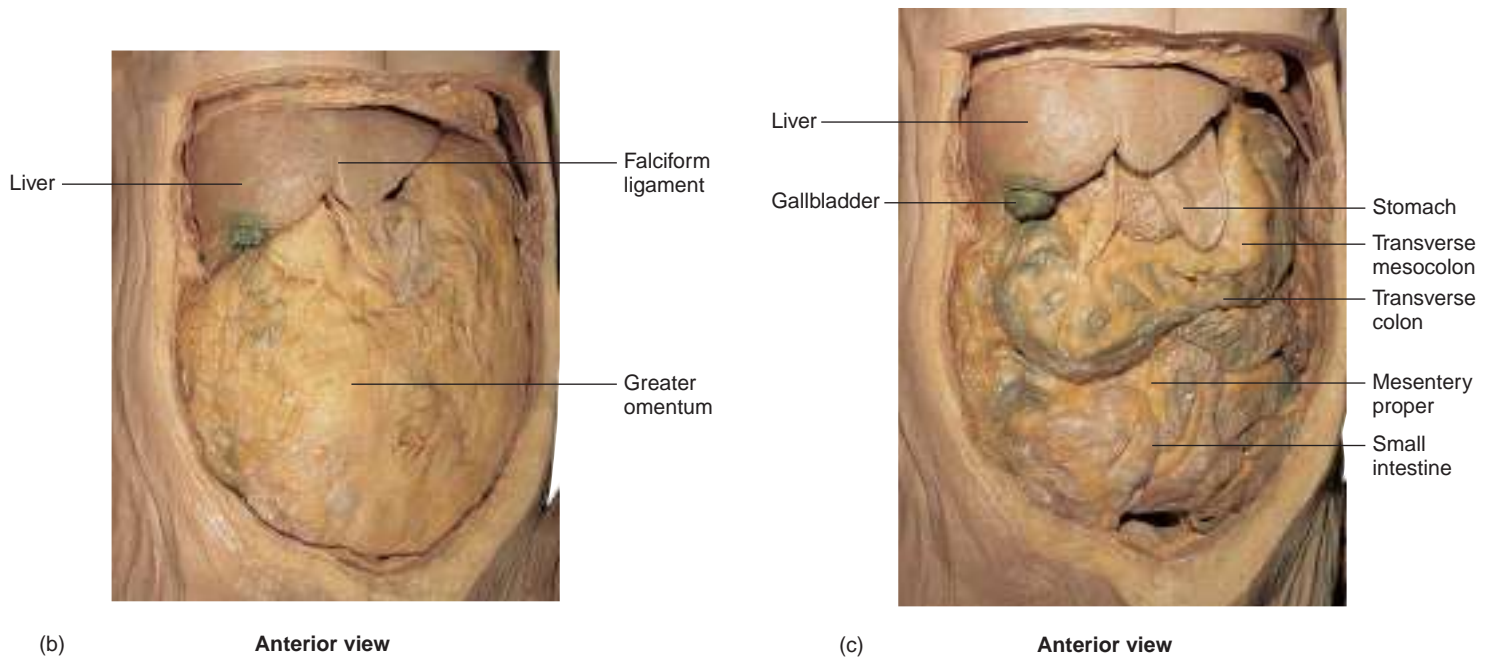

If you placed a pin through the greater omentum, through how many layers of simple squamous epithelium would the pin pass?

The **coronary ligament** attaches the liver to the diaphragm. Unlike other mesenteries, the coronary ligament has a wide space in the center, the bare area of the liver, where no peritoneum exists. The **falciform ligament** attaches the liver to the anterior abdominal wall (figure 24.5b).

Other abdominal organs that have no mesenteries are referred to as **retroperitoneal** (re'trō-per'i-tō-nē'ăl; behind the peritoneum; see chapter 1). The retroperitoneal organs lie along the abdominal wall and include the duodenum, pancreas, ascending colon, descending colon, rectum, kidneys, adrenal glands, and urinary bladder.

ASSESS YOUR PROGRESS

12. Where are the visceral peritoneum and parietal peritoneum found? Define and give examples of retroperitoneal organs.
13. What is the function of the peritoneum?
14. What are the mesenteries? Name and describe the location of the mesenteries in the abdominal cavity.

24.6 Oral Cavity

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the oral cavity and the structure and function of the lips, cheeks, palate, and tongue.
- B. Outline the structure and types of adult teeth and describe the process of mastication.
- C. Compare the structures and locations of the major salivary glands and describe the composition and functions of saliva and the control of its release.

The **oral cavity** (figure 24.6), or *mouth*, is divided into two regions: (1) The **vestibule** (ves'ti-bool; entry) is the space between the lips or cheeks and the teeth, and (2) the **oral cavity proper** lies medial to the teeth. The oral cavity is lined with moist stratified squamous epithelium, which protects against abrasion.

Lips, Cheeks, and Palate

The **lips**, or *labia* (lā'bē-ă; figure 24.6), are muscular structures formed mostly by the **orbicularis oris** (ōr-bik'ū-lā'ris ōr'is) muscle (see figure 10.9) and connective tissue. The outer surfaces of the lips are covered by skin. The keratinized stratified epithelium of the skin is thin at the margin of the lips and is not as highly keratinized as the epithelium of the surrounding skin (see chapter 5); consequently, it is more transparent than the epithelium over the rest of the body. The color from the underlying blood vessels shows through the relatively transparent epithelium, giving the lips a reddish-pink to dark red appearance, depending on the overlying pigment. At the internal margin of the lips, the epithelium is continuous with the moist stratified squamous epithelium of the mucosa in the oral cavity.

One or more **labial frenula** (fren'ū-lă; sing. *frenulum*), which are mucosal folds, extend from the alveolar process of the maxilla to the upper lip and from the alveolar process of the mandible to the lower lip.

The **cheeks** form the lateral walls of the oral cavity. They consist of an interior lining of moist stratified squamous epithelium and an exterior covering of skin. The substance of the cheek includes the **buccinator muscle** (see chapter 10), which flattens the cheek against the teeth, and the **buccal fat pad**, which rounds out the profile on the side of the face.

The lips and cheeks are important in mastication and speech. They help manipulate food within the oral cavity and hold it in place while the teeth crush or tear it. They also help form words when we speak. A large number of the muscles of facial expression are involved in moving the cheeks and lips (see chapter 10).

FIGURE 24.6 Oral Cavity **APR**

The roof of the oral cavity is called the **palate**. The palate separates the oral and nasal cavities and prevents food from passing into the nasal cavity during chewing and swallowing. The palate consists of two parts (figure 24.6). The anterior, bony part is the **hard palate** (see chapter 7). The posterior, nonbony part is the **soft palate**, which consists of skeletal muscle and connective tissue. The **uvula** (ū'vū-lă; a grape) is a posterior projection from the soft palate. The posterior boundary of the oral cavity is the **fauces** (faw'sēz), which is the opening into the pharynx, or *throat*. The **palatine tonsils** are in the lateral wall of the fauces (see chapter 22).

Tongue

The **tongue** is a large, muscular organ that occupies most of the oral cavity proper when the mouth is closed. Its major attachment in the oral cavity is through its posterior part. The anterior part of the tongue is relatively free, except for attachment to the floor of the mouth by a thin fold of tissue called the **lingual** (tongue) **frenulum**. The muscles associated with the tongue are divided into two categories: **Intrinsic muscles** are within the tongue itself, and **extrinsic muscles** are outside the tongue but attached to it. The intrinsic muscles are largely responsible for changing the shape of the tongue,

such as flattening and elevating it during drinking and swallowing. The extrinsic tongue muscles protrude and retract the tongue, move it from side to side, and change its shape (see chapter 10).

A groove called the **terminal sulcus** divides the tongue into two parts. The part anterior to the terminal sulcus accounts for about two-thirds of the surface area and is covered by papillae, some of which contain taste buds (see chapter 15). The posterior one-third of the tongue is devoid of papillae and has only a few scattered taste buds. Instead, it has a few small glands and a large amount of lymphatic tissue, which form the **lingual tonsil** (see chapter 22). Moist stratified squamous epithelium covers the tongue.

The tongue moves food in the mouth and, in cooperation with the lips and gums, holds the food in place during mastication. It also plays a major role in swallowing. In addition, the tongue is a major sensory organ for taste (see chapter 15) and one of the primary organs of speech. Patients with cancer of the tongue often have part or all of their tongue removed. These patients can learn to speak fairly well but have difficulty chewing and swallowing.

Teeth

The teeth play an important role in mastication and assist in speech. Adults normally have 32 **teeth**, which are distributed in two **dental arches**: the maxillary arch and the mandibular arch. The teeth in the right and left halves of each dental arch are roughly mirror images of

each other. As a result, the teeth are apportioned into four quadrants: right-upper, left-upper, right-lower, and left-lower. The teeth in each quadrant include one central and one lateral **incisor**, one **canine**, first and second **premolars**, and first, second, and third **molars** (figure 24.7a). The third molars are often called *wisdom teeth* because they usually appear in the late teens or early twenties, when a person is old enough to have acquired some wisdom. In people with small dental arches, the third molars may not have room to erupt into the oral cavity and remain embedded within the jaw. Embedded wisdom teeth are referred to as impacted and may cause pain or irritation. Usually, the impacted wisdom teeth are surgically removed.

The teeth of the adult mouth are called **permanent teeth**, or *secondary teeth*. Most of them are replacements for **deciduous** (dē-sid'ū-ŭs) **teeth**, or *primary teeth*, also called *milk teeth*, which are lost during childhood (figure 24.7b). The deciduous teeth erupt (the crowns appear within the oral cavity) between about 6 months and 24 months of age (figure 24.7b). The permanent teeth begin replacing the deciduous teeth at about 5 years, and the process is completed by about 11 years.

Each tooth consists of a **crown** with one or more **cusps** (points), a **neck**, and a **root** (figure 24.8). The *clinical crown* is the part of the tooth exposed in the oral cavity. The *anatomical crown* is the entire enamel-covered part of the tooth. The neck is the small region between the crown and root. The root is the largest region of the

FIGURE 24.7 Teeth

(a) Permanent teeth. (b) Deciduous teeth. Dental professionals have developed a “universal” numbering and lettering system for convenience in identifying individual teeth.

FIGURE 24.8 Molar Tooth in Place in the Alveolar Bone

A tooth consists of a crown (anatomical and clinical), a neck, and a root. The root is covered with cementum, and the tooth is held in the socket by periodontal ligaments. Nerves and vessels enter and exit the tooth through the apical foramen.

tooth. It anchors the tooth in the jawbone. Within the center of the tooth is a **pulp cavity**, which is filled with blood vessels, nerves, and connective tissue called **pulp**. The pulp cavity within the root is called the **root canal**. The nerves and blood vessels of the tooth enter and exit the pulp through a hole at the point of each root called the **apical foramen**. The pulp cavity is surrounded by living, cellular, calcified tissue called **dentin**. The dentin of the tooth crown is covered by an extremely hard, nonliving, acellular substance called **enamel**, which protects the tooth against abrasion and acids produced by bacteria in the mouth. The surface of the dentin in the root is covered with a bonelike substance called **cementum**, which helps anchor the tooth to the periodontal ligament in the jaw.

The teeth are set in **alveoli** (al-vē'ō-lī; sockets) along the alveolar processes of the mandible and maxilla. Dense fibrous connective tissue and stratified squamous epithelium, referred to as the **gingiva** (jin'ji-vă; gums), cover the alveolar processes (see figure 24.6). **Periodontal** (per'ē-ō-don'täl; around a tooth) **ligaments** secure the teeth in the alveoli.

Several conditions can affect the health of the tooth and the structures associated with it, such as the periodontal ligament and gingiva. **Dental caries**, or tooth decay, is a breakdown of enamel by bacterial acids on the tooth surface. Because the enamel is nonliving and cannot repair itself, a dental filling is necessary to prevent further damage. If the decay reaches the pulp cavity, with its rich supply of nerves, a toothache may result. Sometimes, when decay has reached the pulp cavity, a dentist must perform a procedure called a root canal, which consists of removing the pulp from the tooth. **Periodontal disease** is the inflammation and degradation of the periodontal ligaments, gingiva, and alveolar bone. This disease is the most common cause of tooth loss in adults. **Gingivitis** (jin-ji-vī'tis) is an inflammation of the gingiva, often caused by food deposited in gingival crevices and not promptly

removed by brushing and flossing. Gingivitis may eventually lead to periodontal disease. Halitosis (hal-i-tō'sis), or bad breath, often occurs with periodontal disease.

ASSESS YOUR PROGRESS

15. What is the difference between the vestibule and the oral cavity proper?
16. What are the functions of the lips and cheeks? What muscle forms the substance of the lips? The cheeks?
17. What are the hard and soft palates? Where is the uvula located?
18. List the functions of the tongue. Distinguish between intrinsic and extrinsic tongue muscles.
19. What are permanent and deciduous teeth? Name the types of teeth.
20. List the three parts of a tooth. What are dentin, enamel, cementum, and pulp?

Mastication

Food taken into the mouth is **masticated**, or *chewed*, by the teeth. The anterior teeth (the incisors and the canines) primarily cut and tear food, whereas the premolars and molars primarily crush and grind it. Mastication breaks large food particles into smaller ones, creating a much larger total surface area. Because digestive enzymes digest food molecules only at the surface of the particles, mastication increases the efficiency of digestion.

Four pairs of muscles move the mandible during mastication: **temporalis**, **masseter**, **medial pterygoid**, and **lateral pterygoid** muscles (see chapter 10). All four close the jaw, while the lateral pterygoid muscle opens it. The medial and lateral pterygoids and the masseter muscles accomplish protraction and lateral and medial excursion of the jaw. The temporalis retracts the jaw. All these movements are involved in tearing, crushing, and grinding food.

The **mastication reflex**, or *chewing reflex*, is integrated in the medulla oblongata and controls the basic movements of chewing. The presence of food in the mouth stimulates sensory receptors, which activate a reflex that relaxes the muscles of mastication. As the mandible is lowered, the muscles stretch and activate a reflex that causes the muscles of mastication to contract. Once the mouth is closed, the food again stimulates the muscles of mastication to relax, and the cycle repeats. Descending pathways from the cerebrum strongly influence the mastication reflex, so that chewing can be consciously initiated or stopped. The rate and intensity of chewing movements can also be influenced by the cerebrum.

Salivary Glands

A considerable number of **salivary glands** are scattered throughout the oral cavity. There are three pairs of large, multicellular salivary glands: the parotid glands, the submandibular glands, and the sublingual glands (figure 24.9). In addition to these large salivary glands, numerous small, coiled, tubular salivary glands are located deep to the epithelium of the tongue (lingual glands), the palate (palatine glands), the cheeks (buccal glands), and the lips (labial glands).

All of the major large salivary glands are compound **acinar glands**, which are branching glands with clusters of acini

FIGURE 24.9 Salivary Glands

(a) The large salivary glands are the parotid glands, the submandibular glands, and the sublingual glands. The parotid duct extends anteriorly from the parotid gland. (b) An idealized schematic illustrates the histology of the large salivary glands. The figure is representative of all the glands and does not depict any specific salivary gland. (c) Photomicrograph of the parotid gland.

resembling grapes (see chapter 4). They produce thin serous secretions or thicker mucous secretions. **Saliva** is a combination of serous and mucous secretions from the various salivary glands.

The largest salivary glands, the **parotid** (pă-rot'id; beside the ear) **glands**, are serous glands, which produce mostly watery saliva; they are located just anterior to the ear on each side of the head. Each **parotid duct** exits the gland on its anterior margin, crosses the lateral surface of the masseter muscle, pierces the buccinator muscle, and enters the oral cavity adjacent to the second upper molar (figure 24.9a). A viral infection can cause the parotid glands to become inflamed and swollen, making the cheeks quite large. Before the measles/mumps/rubella (MMR) vaccination program was begun in the United States, **mumps** was a common childhood disease caused by the mumps virus. Now mumps is very rare in the United States. The virus causing mumps can also infect other tissues, including the testes, which can result in sterility in an adult male.

The **submandibular** (below the mandible) **glands** are mixed glands with more serous than mucous acini. Each gland can be felt as a soft lump along the inferior border of the posterior half of the mandible. A submandibular duct exits each gland, passes

anteriorly deep to the mucous membrane on the floor of the oral cavity, and opens into the oral cavity beside the frenulum of the tongue (see figure 24.6).

The **sublingual** (below the tongue) **glands**, the smallest of the three large, paired salivary glands, are mixed glands containing some serous acini but consisting primarily of mucous acini. They lie immediately below the mucous membrane in the floor of the oral cavity. These glands do not have single, well-defined ducts like those of the submandibular and parotid glands. Instead, each sublingual gland opens into the floor of the oral cavity through 10–12 small ducts.

Saliva has multiple roles: It helps keep the oral cavity moist, which is needed for normal speech and for the suspension of food molecules in solution so they can be tasted; it has protective functions; and it begins the process of digestion. The moistening and protective functions are aided by the large volume of serous saliva, 1–1.5 L/day, secreted primarily by the parotid and submandibular glands. In addition, the mucous secretions of the submandibular and sublingual glands contain a large amount of **mucin** (mū'sin), a proteoglycan that gives a lubricating quality to the secretions of the salivary glands.

Saliva has important protective functions. It prevents bacterial infection in the mouth by continually washing the oral surface. In addition, the bicarbonate ions in saliva act as a buffer to neutralize the acids produced by oral bacteria. This reduces the harmful effects of bacterial acids on tooth enamel. Saliva also contains **lysozyme**, an enzyme that has a weak antibacterial action, and immunoglobulin A, which helps prevent bacterial infection. Any lack of salivary gland secretion increases the risk for ulceration and infection of the oral mucosa and for caries (cavities) in the teeth.

The digestive functions of saliva are relatively minor compared to digestion later in the tract. The serous part of saliva contains a digestive enzyme called **salivary amylase** (am'il-ās; starch-splitting enzyme), which breaks the covalent bonds between glucose molecules in starch and other polysaccharides to produce the disaccharides maltose and isomaltose (table 24.2). The release of maltose and isomaltose gives starches a sweet taste. However, food spends very little time in the mouth, so only about 3–5% of the total carbohydrates are digested there. In addition, most starchy foods come from plants and are therefore covered by cellulose, making them inaccessible to salivary amylase. Cooking and thoroughly chewing food destroy the cellulose covering and increase the efficiency of the digestive process.

Salivary gland secretion is stimulated by both the parasympathetic and the sympathetic nervous systems, but the parasympathetic system is the more important. Salivary nuclei in the brainstem increase salivary secretions by sending action potentials through parasympathetic fibers of the facial (VII) and glossopharyngeal (IX) cranial nerves in response to a variety of stimuli, such as tactile stimulation in the oral cavity or certain tastes, especially sour. Higher centers of the brain also affect salivary gland activity. Odors that trigger thoughts of food or the sensation of hunger can increase saliva secretion as well.

ASSESS YOUR PROGRESS

- List the muscles of mastication and the actions they produce. Describe the mastication reflex.
- Name and give the location of the three largest salivary glands. What are the other types of salivary glands called?
- What are the functions of saliva? What substances are contained in saliva?
- What is the difference between serous and mucous saliva?
- Describe the stimuli that stimulate the release of saliva. What nerves are involved?

24.7 Swallowing

LEARNING OUTCOMES

After reading this section, you should be able to

- List the parts of the pharynx involved with digestion.
- Describe the structure of the esophagus.
- Explain the three phases of swallowing.

Swallowing involves distinct phases in the pharynx and esophagus (figure 24.10).

Pharynx

The **pharynx**, described in detail in chapter 23, consists of three parts: the nasopharynx, oropharynx, and laryngopharynx. Normally, only the oropharynx and laryngopharynx transmit food. The **oropharynx** communicates with the nasopharynx superiorly, with the larynx and **laryngopharynx** inferiorly, and with the mouth anteriorly. The laryngopharynx extends from the oropharynx to the esophagus and is posterior to the larynx. The epiglottis covers the opening of the larynx and keeps food and drink from entering the larynx. The posterior walls of the oropharynx and laryngopharynx consist of three muscles: the superior, middle, and inferior **pharyngeal constrictors**, which are arranged like three stacked flowerpots, one inside the other. The oropharynx and the laryngopharynx are lined with moist stratified squamous epithelium, and the nasopharynx is lined with ciliated pseudostratified columnar epithelium.

Esophagus

The **esophagus** is the part of the digestive tract that extends between the pharynx and the stomach. It is about 25 cm long and lies in the mediastinum, anterior to the vertebrae and posterior to the trachea. It passes through the esophageal hiatus (opening) of the diaphragm and ends at the stomach. The esophagus transports food from the pharynx to the stomach.

The esophagus has thick walls consisting of the four tunics common to the digestive tract: mucosa, submucosa, muscularis, and adventitia. The muscular tunic has an outer longitudinal layer and an inner circular layer, as is true of most parts of the digestive tract, but it differs by having skeletal muscle in the superior part of the esophagus and smooth muscle in the inferior part. An **upper esophageal sphincter** and a **lower esophageal sphincter**, at the upper and lower ends of the esophagus, respectively, regulate the movement of materials into and out of the esophagus. The mucosal lining of the esophagus is moist stratified squamous epithelium. Numerous mucous glands in the submucosal layer produce a thick, lubricating mucus, which passes through ducts to the surface of the esophageal mucosa.

Swallowing Phases

Swallowing, or *deglutition*, is divided into three phases: voluntary, pharyngeal, and esophageal. During the **voluntary phase** (figure 24.10, *step 1*), a bolus of food is formed in the mouth and pushed by the tongue against the hard palate, until it is forced toward the posterior part of the mouth and into the oropharynx.

The **pharyngeal phase** of swallowing (figure 24.10, *steps 2–4*) is a reflex initiated by the stimulation of tactile receptors in the area of the oropharynx. Afferent action potentials travel through the trigeminal (V) and glossopharyngeal (IX) nerves to the **swallowing center** in the medulla oblongata. There, they initiate action potentials in motor neurons, which pass through the trigeminal (V), glossopharyngeal (IX), vagus (X), and accessory (XI) nerves to the soft palate

TABLE 24.2 **Functions of Major Digestive Secretions**

Fluid or Enzyme	Function
Oral Cavity Secretions	
Serous saliva (mostly water, bicarbonate ions)	Moistens food and mucous membrane; neutralizes bacterial acids; flushes bacteria from oral cavity; has weak antibacterial activity
Salivary amylase	Digests carbohydrates
Mucus	Lubricates food; protects digestive tract from digestion by enzymes
Lingual lipase	Digests a minor amount of lipids
Esophagus Secretions	
Mucus	Lubricates esophagus; protects lining of esophagus from abrasion and allows food to move more smoothly through esophagus
Gastric Secretions	
Hydrochloric acid	Antibacterial; decreases stomach pH to activate pepsinogen to pepsin
Pepsin*	Digests protein into smaller peptide chains; activates pepsinogen
Mucus	Protects stomach lining from digestion
Intrinsic factor	Binds to vitamin B ₁₂ and aids in its absorption in the small intestine
Gastric lipase	Digests a minor amount of lipids
Liver Secretions	
Bile	Bile salts in bile emulsify lipids, making them available to lipases, and help make end products soluble and available for absorption by the intestinal mucosa; many of the other bile contents are waste products, such as bile pigments, that are transported to the intestines for disposal
Pancreas Secretions	
Trypsin*	Digests proteins (cleaves at arginine or lysine amino acids); activates trypsinogen and other digestive enzymes
Chymotrypsin*	Digests proteins (cleaves at hydrophobic amino acids)
Carboxypeptidase*	Digests proteins (removes amino acids from the carboxyl end of proteins)
Pancreatic amylase	Digests carbohydrates (hydrolyzes starches and glycogen to form maltose and isomaltose)
Pancreatic lipase	Digests lipids (breaks down triglycerides into monoglycerides and free fatty acids)
Ribonuclease	Digests ribonucleic acid (hydrolyzes phosphodiester bonds)
Deoxyribonuclease	Digests deoxyribonucleic acid (hydrolyzes phosphodiester bonds)
Bicarbonate ions	Neutralize acid from stomach; provide appropriate pH for pancreatic enzymes
Small Intestine Secretions	
Mucus	Protects duodenum from stomach acid, gastric enzymes, and intestinal enzymes; provides adhesion for fecal matter; protects intestinal wall from bacterial action and acid produced in the feces
Peptidases†	Split amino acids from polypeptides
Enterokinase†	Activates trypsin from trypsinogen
Sucrase†	Splits sucrose into glucose and fructose
Maltase†	Splits maltose into two glucose molecules
Isomaltase†	Splits isomaltose into two glucose molecules
Lactase†	Splits lactose into glucose and galactose

*These enzymes are secreted as inactive forms and then activated.

†These enzymes remain in the microvilli.

and pharynx. This phase of swallowing begins with the elevation of the soft palate, which closes the passage between the nasopharynx and oropharynx. The pharynx elevates to receive the bolus of food from the mouth and moves the bolus down the pharynx into the esophagus. The superior, middle, and inferior pharyngeal constrictor muscles contract in succession, forcing the food through the pharynx. At the same time, the upper esophageal sphincter relaxes, the

elevated pharynx opens the esophagus, and food is pushed into the esophagus. This phase of swallowing is unconscious and is controlled automatically, even though the muscles involved are skeletal. The pharyngeal phase of swallowing lasts about 1–2 seconds.

During the pharyngeal phase, the vestibular folds and vocal cords close, and the **epiglottis** (ep-i-glot'is; on the glottis) is tipped posteriorly, so that the epiglottic cartilage covers the opening into

1 During the **voluntary phase**, a bolus of food (yellow) is pushed by the tongue against the hard and soft palates and posteriorly toward the oropharynx (blue arrow indicates tongue movement; black arrow indicates movement of the bolus). Tan: bone; purple: cartilage; red: muscle.

2 During the **pharyngeal phase**, the soft palate is elevated, closing off the nasopharynx. The pharynx and larynx are elevated (blue arrows indicate muscle movement; green arrow indicates elevation of the larynx).

3 Successive constriction of the pharyngeal constrictors from superior to inferior (blue arrows) forces the bolus through the pharynx and into the esophagus. As this occurs, the vestibular and vocal folds expand medially to close the passage of the larynx. The epiglottis (green arrow) is bent down over the opening of the larynx largely by the force of the bolus pressing against it.

4 As the inferior pharyngeal constrictor contracts, the upper esophageal sphincter relaxes (outwardly directed blue arrows), allowing the bolus to enter the esophagus.

5 During the **esophageal phase**, the bolus is moved by peristaltic contractions of the esophagus toward the stomach (inwardly directed blue arrows).

PROCESS FIGURE 24.10 Three Phases of Swallowing (Deglutition)

the larynx, and the larynx is elevated. These movements prevent food from passing into the larynx.

➤ Predict 3

Why is it important to close the opening between the nasopharynx and the oropharynx during swallowing? What may happen if a person emits an explosive burst of laughter while trying to swallow a liquid? Predict the consequences of trying to swallow and speak at the same time.

The **esophageal phase** of swallowing (figure 24.10, *step 5*), which takes about 5–8 seconds, is responsible for moving food from the pharynx to the stomach. Muscular contractions in the wall of the esophagus occur in peristaltic waves. Gravity helps move liquids and watery food through the esophagus. However, the peristaltic contractions in the esophagus are forceful enough to allow a person to swallow even while doing a headstand or floating in the zero-gravity environment of space.

As the peristaltic waves and the food bolus approach the stomach, the lower esophageal sphincter in the esophagus relaxes. This sphincter is not anatomically distinct from the rest of the esophagus, but it can be identified physiologically because it remains tonically constricted to prevent the reflux of stomach contents into the lower part of the esophagus.

The presence of food in the esophagus stimulates the myenteric plexus, which controls the peristaltic waves. Food in the esophagus also stimulates tactile receptors, which send afferent impulses to the medulla oblongata through the vagus nerves. Motor impulses, in turn, pass along the vagal efferent fibers to the striated and smooth muscles within the esophagus, thereby stimulating their contractions and reinforcing the peristaltic contractions.

ASSESS YOUR PROGRESS

26. Name the parts of the pharynx involved with digestion. What are pharyngeal constrictors?
27. Where is the esophagus located? Describe the tunics of the esophageal wall and the esophageal sphincters.
28. What are the three phases of swallowing? Sequentially list the processes involved in the last two phases and describe how they are regulated.

24.8 Stomach

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Outline the anatomical and histological characteristics of the stomach.
- B. Describe stomach secretions, their function, and their regulation.
- C. Describe gastric movements and their regulation.

The **stomach** is an enlarged segment of the digestive tract that primarily functions as a storage and mixing chamber. It is located in

the left superior part of the abdomen (see figure 24.1). Its shape and size vary from person to person, even within the same individual from time to time, depending on food content and body posture. Nonetheless, several general anatomical features can be described.

Anatomy of the Stomach

The opening from the esophagus into the stomach is the **gastro-esophageal opening**, or **cardiac opening** (located near the heart), and the region of the stomach around the cardiac opening is the **cardiac part** (figure 24.11). The **lower esophageal sphincter**, also called the **cardiac sphincter**, surrounds the cardiac opening. Recall that, although this is an important structure in the normal function of the stomach, it is a physiological constrictor only and cannot be seen anatomically. The part of the stomach to the left of the cardiac part, the **fundus** (fün'dūs), is actually superior to the cardiac opening. The largest part of the stomach is the **body**, which turns to the right, creating a **greater curvature** and a **lesser curvature**. The body narrows to form the funnel-shaped **pyloric part** of the stomach. The wider part of the funnel, toward the body of the stomach, is the **pyloric antrum**. The narrow part of the funnel is the **pyloric canal**. The pyloric canal opens through the **pyloric orifice** into the small intestine. The pyloric orifice is surrounded by the **pyloric sphincter**, or **pylorus**, a relatively thick ring of smooth muscle, which helps regulate the movement of gastric contents into the small intestine. **Hypertrophic pyloric stenosis** is a common defect of the stomach in infants, in which the pyloric sphincter is greatly thickened and thus interferes with normal stomach emptying.

Histology of the Stomach

The **serosa**, or **visceral peritoneum**, is the outermost tunic of the stomach. It consists of an outer layer of simple squamous epithelium and an inner layer of connective tissue. The **muscularis** of the stomach consists of three layers: an outer longitudinal layer, a middle circular layer, and an inner oblique layer (figure 24.11a). The inner oblique layer is unique to the stomach wall. This layer helps generate the strong stomach contractions that physically break down ingested food into smaller particles. In some areas of the stomach, such as the fundus, the three layers blend with one another and cannot be separated. Deep to the muscular layer are the submucosa and the mucosa, which are thrown into large folds called **rugae** (roo'gē; wrinkles) when the stomach is empty. These folds allow the mucosa and submucosa to stretch, and the folds disappear as the stomach volume increases as it is filled.

The stomach has a mucous lining of simple columnar epithelium. The epithelium forms numerous, tubelike **gastric pits**, which are the openings for the **gastric glands** (figure 24.11b). There are five types of epithelial cells of the stomach: (1) surface mucous cells, (2) mucous neck cells, (3) parietal cells, (4) chief cells, and (5) endocrine cells.

Surface mucous cells are found on the surface around the gastric pit. These cells protect the stomach wall from being damaged by acid and digestive enzymes. The cells produce an alkaline mucus on their surface that neutralizes the acid and is a barrier to the digestive enzymes. The surface mucous cells are connected by

FIGURE 24.11 Anatomy and Histology of the Stomach

tight junctions, which provide an additional barrier that prevents acids and enzymes from reaching deeper tissues. In addition, when surface mucous cells are damaged, they are rapidly replaced.

The remaining four cell types are in the gastric glands. The **mucous neck cells** are located near the openings of the glands and produce mucus. The parietal, chief, and endocrine cells are interspersed in the deeper parts of the glands. **Parietal cells** produce hydrochloric acid and intrinsic factor. **Chief cells** produce the enzyme pepsinogen. **Endocrine cells** produce regulatory hormones and paracrine factors. There are several types of endocrine cells. Enterochromaffin-like cells produce histamine, which stimulates acid secretion by parietal cells. Gastrin-containing cells secrete gastrin, and somatostatin-containing cells secrete somatostatin, which inhibits gastrin and insulin secretion.

Secretions of the Stomach

Once food enters the stomach, it is mixed with stomach secretions to form a semifluid material called **chyme** (kīm; juice). The primary function of the stomach is to store and mix the chyme. Although some digestion and absorption occur in the stomach, they are not its major functions.

Stomach secretions include mucus, hydrochloric acid, gastrin, histamine, intrinsic factor, and pepsinogen. Pepsinogen is the inactive form of the protein-digesting enzyme pepsin.

The surface mucous cells and mucous neck cells secrete a viscous, alkaline mucus that covers the surface of the epithelial cells, forming a layer 1–1.5 mm thick. The thick layer of mucus lubricates and protects the epithelial cells of the stomach wall from the damaging effect of the acidic chyme and pepsin. Irritation of the stomach mucosa stimulates the secretion of a greater volume of mucus.

Parietal cells in the gastric glands of the pyloric region secrete intrinsic factor and a concentrated solution of hydrochloric acid. **Intrinsic factor** is a glycoprotein that binds with vitamin B₁₂, making the vitamin more readily absorbed in the ileum. Vitamin B₁₂ is important in deoxyribonucleic acid (DNA) synthesis, which is especially important for continual red blood cell production. A lack of vitamin B₁₂ absorption leads to pernicious anemia (see chapter 19).

Hydrochloric acid produces the low pH of the stomach's contents, which is normally between 1 and 3. Although the hydrochloric acid secreted into the stomach has a minor digestive effect on ingested food, one of its main functions is to kill bacteria that are ingested with essentially everything humans put into their mouths. However, some pathogenic bacteria may avoid digestion in the stomach, because they have an outer coat that resists stomach acids.

The low pH of the stomach's contents has additional functions. Stomach acid denatures many proteins, so that proteolytic enzymes can reach internal peptide bonds. The acid environment provides the proper pH for the activation and function of pepsin. The acid also stops carbohydrate digestion by inactivating salivary amylase.

Hydrogen ions are actively transported across the mucosal surface of the parietal cell into the lumen of the stomach by a H⁺–K⁺ exchange pump called a **proton pump** (figure 24.12). The process begins with H⁺ ions derived from carbon dioxide and water, which enter the parietal cell from its serosal surface (the side

opposite the lumen of the gastric pit). Inside the cell the enzyme carbonic anhydrase catalyzes the reaction between carbon dioxide and water to form carbonic acid. Some of the carbonic acid molecules then dissociate to form H⁺ and HCO₃[–] (bicarbonate). Drugs that block the proton pump are used to lower gastric acid levels. The pump moves H⁺ by active transport against a steep concentration gradient, and Cl[–] diffuses from the cell through ion channels in the plasma membrane. Diffusion of Cl[–] into the gastric gland duct balances the positively charged H⁺ to reduce the amount of energy needed to transport the H⁺ against both a concentration gradient and an electrical gradient.

While H⁺ is pumped into the stomach lumen, bicarbonate ions move down their concentration gradient from the parietal cell into the extracellular fluid. During this process, HCO₃[–] is exchanged for Cl[–] through an antiporter, which is located in the plasma membrane, and the Cl[–] subsequently moves into the cell. This results in an elevated blood pH in the veins that carry blood away from the stomach, called the **alkaline tide**.

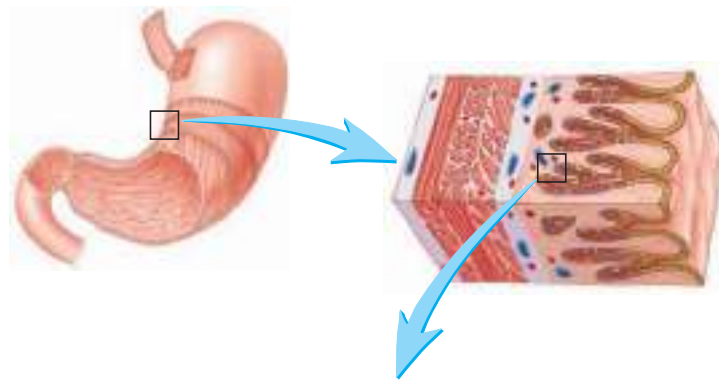

Chief cells within the gastric glands secrete **pepsinogen** (pep-sin'ō-jen). Pepsinogen is packaged in **zymogen** (zī-mō-jen) **granules**, which are released by exocytosis when pepsinogen secretion is stimulated. *Zymogen* is the term for an inactive enzyme. Once pepsinogen enters the lumen of the stomach, hydrochloric acid and previously formed pepsin molecules convert it to **pepsin**. Pepsin exhibits optimal enzymatic activity at a pH of 3 or less. Pepsin catalyzes the cleavage of some covalent bonds in proteins, thus breaking them into smaller peptide chains.

Regulation of Stomach Secretion

Approximately 2–3 L of gastric secretions (gastric juice) are produced each day. The amount and type of food entering the stomach and small intestine dramatically affect the quantity of gastric secretions, but up to 700 mL are secreted as a result of a typical meal. Both nervous and hormonal mechanisms regulate gastric secretions. The neural mechanisms involve reflexes integrated within the medulla oblongata and local reflexes integrated within the ENS. In addition, higher brain centers influence the reflexes. The chemical messengers that regulate stomach secretions include the hormones gastrin, secretin, and cholecystokinin (table 24.3), as well as the paracrine chemical messenger histamine.

The regulation of stomach secretion is divided into three phases: cephalic, gastric, and intestinal. The cephalic phase can be viewed as the “get started” phase, when stomach secretions are increased in anticipation of incoming food. This is followed by the “go for it” gastric phase, when most of the stimulation of secretion occurs. Finally, the intestinal phase is the “slow down” phase, during which stomach secretion decreases.

1. **Cephalic phase.** The cephalic phase is controlled by the CNS. It begins even before the bolus of food enters the stomach. Several types of stimuli act on the centers within the medulla oblongata to influence gastric secretions (figure 24.13). These stimuli include the taste and smell of food, the stimulation of tactile receptors during the process of chewing and swallowing, and pleasant thoughts of food. Action potentials

- 1 Carbon dioxide (CO_2) diffuses into the parietal cell.
- 2 Carbon dioxide combines with water (H_2O) in an enzymatic reaction that is catalyzed by carbonic anhydrase (CA) to form carbonic acid (H_2CO_3).
- 3 Carbonic acid dissociates into a bicarbonate ion (HCO_3^-) and a hydrogen ion (H^+).
- 4 Bicarbonate ions are transported back into the bloodstream. An antiporter in the plasma membrane exchanges HCO_3^- for a chloride ion (Cl^-).
- 5 A H^+ - K^+ pump moves H^+ into the duct of the gastric gland and K^+ into the parietal cell.
- 6 Chloride ions diffuse into the gastric gland duct.

PROCESS FIGURE 24.12 Hydrochloric Acid Production by Parietal Cells in the Gastric Glands of the Stomach **APR**

TABLE 24.3 Functions of the Gastrointestinal Hormones

Site of Production	Method of Stimulation	Secretory Effects	Motility Effects
Gastrin Stomach	Distension; partially digested proteins, autonomic stimulation, ingestion of alcohol or caffeine	Increases gastric secretion	Causes a minor increase in gastric motility
Secretin Duodenum	Acidity of chyme	Decreases gastric secretion; stimulates pancreatic and bile secretions high in bicarbonate ions	Decreases gastric motility
Cholecystokinin Duodenum	Fatty acids and peptides	Slightly decreases gastric secretion; stimulates pancreatic secretions high in digestive enzymes; causes contraction of the gallbladder and relaxation of the hepatopancreatic ampullar sphincter	Strongly decreases gastric motility

are sent from the medulla oblongata along parasympathetic neurons within the vagus (X) nerves to the stomach. Within the stomach wall, the preganglionic neurons stimulate the

postganglionic neurons in the ENS. The postganglionic neurons, which are primarily cholinergic, stimulate secretory activity in the cells of the stomach mucosa.

Cephalic Phase

- 1 The taste, smell, or thought of food or tactile sensations of food in the mouth stimulate the medulla oblongata (*light green arrows*).
- 2 Vagus nerves carry parasympathetic action potentials to the stomach (*pink arrow*), where enteric plexus neurons are activated.
- 3 Postganglionic neurons stimulate secretion by parietal and chief cells and stimulate gastrin and histamine secretion by endocrine cells.
- 4 Gastrin is carried through the blood back to the stomach (*dark green arrow*), where, along with histamine, it stimulates secretion.

Gastric Phase

- 1 Distension of the stomach stimulates mechanoreceptors (stretch receptors) and activates a parasympathetic reflex. Action potentials generated by the mechanoreceptors are carried by the vagus nerves to the medulla oblongata (*light green arrow*).
- 2 The medulla oblongata increases action potentials in the vagus nerves that stimulate secretions by parietal and chief cells and stimulate gastrin and histamine secretion by endocrine cells (*pink arrow*).
- 3 Distension of the stomach also activates local reflexes that increase stomach secretions (*orange arrow*).
- 4 Gastrin is carried through the blood back to the stomach (*dark green arrow*), where they inhibit parasympathetic action potentials (*pink arrow*), thereby decreasing gastric secretions.

Intestinal Phase

- 1 Chyme in the duodenum with a pH less than 2 or containing lipids inhibits gastric secretions by three mechanisms (2–4).
- 2 Chemoreceptors in the duodenum are stimulated by H⁺ (low pH) or lipids. Action potentials generated by the chemoreceptors are carried by the vagus nerves to the medulla oblongata (*light green arrow*), where they inhibit parasympathetic action potentials (*pink arrow*), thereby decreasing gastric secretions.
- 3 Local reflexes activated by H⁺ or lipids also inhibit gastric secretion (*orange arrows*).
- 4 Secretin and cholecystokinin produced by the duodenum (*dark red arrows*) decrease gastric secretions in the stomach.

PROCESS FIGURE 24.13 Phases of Stomach Secretion

Clinical IMPACT

Peptic Ulcer

Approximately 10% of people in the United States will develop a **peptic ulcer** during their lifetime. Peptic ulcers are caused when the gastric juices (acid and pepsin) digest the mucosal lining of the digestive tract. Approximately 80% of peptic ulcers occur on the duodenal side of the pyloric sphincter, but peptic ulcers can also occur in the stomach (gastric ulcers) or esophagus (esophageal ulcers).

Nearly all peptic ulcers are due to infection by a specific bacterium, *Helicobacter pylori*, which is also linked to gastritis and gastric cancer. Because stress, diet, smoking, and alcohol cause excess acid secretion in the stomach, these lifestyle patterns were deemed responsible for ulcers for many years. Although these factors can contribute to ulcers, it is now clear that the root cause is *H. pylori*.

The presence of bacteria in the stomach mucosa was first discovered in 1892, but the finding was met with severe skepticism. In 1982, an Australian doctor, Barry Marshall, was finally able to culture an unusual bacterium, *H. pylori*, from stomach biopsies. To prove his belief that

this bacterium can cause gastritis and ulcers, Marshall did something that no one should do at home. He drank a solution of *H. pylori* and subsequently developed gastric inflammation. Luckily, antibiotic treatment was able to cure him. In 2005, along with his colleague, Dr. Robin Warren, he received the Nobel Prize in Physiology or Medicine for his discovery.

Antibiotic treatment to eradicate *H. pylori* is the best therapy for ulcers. A combination of antibiotics and antacids cures 95% of gastric and 74% of duodenal ulcers within 2 months, with less than a 10% recurrence rate. By contrast, the previous conventional treatment using antacids yields only temporary relief, with about 90% recurrence within a year. Other treatments involve drugs that prevent histamine-stimulated acid secretion or that directly inhibit the proton pumps that secrete the acid. Such treatments are effective only for short-term relief, not for long-term treatment.

Most bacteria cannot survive in the stomach. Hence, *H. pylori* is one of the most pervasive of human pathogens because it inhabits a niche without competition. Estimates suggest

that well over half of the world's population is infected with *H. pylori*. The infection rate in the United States is about 1% per year of age—for example, 30% of all 30-year-olds are infected. In developing countries, nearly all people over age 25 are infected. This may contribute to the high rates of stomach cancer in some of those countries.

Analyses of the *H. pylori* DNA sequences from various ethnic and geographic populations suggest that *H. pylori* infection has been present in humans for over 150,000 years, yet only about 15–20% exhibit gastric problems attributed to *H. pylori*. What triggers the development of ulcers is a major unanswered question. It seems likely that both *H. pylori* infection and conditions that elevate acid secretion or damage the stomach wall, such as stress or the excessive ingestion of alcohol or aspirin, contribute to the development of an ulcer. For example, if a person is highly stressed, elevated sympathetic activity may inhibit duodenal gland secretion and increase the person's susceptibility to ulcers in the duodenum by reducing the protective coating of mucus on the duodenal wall.

Parasympathetic stimulation of the stomach mucosa results in the release of the neurotransmitter acetylcholine, which increases the secretory activity of both the parietal and the chief cells and stimulates the secretion of **gastrin** (gas'trin) and **histamine** from endocrine cells. The gastrin released into the circulation travels to the parietal cells, where it stimulates additional hydrochloric acid and pepsinogen secretion. In addition, gastrin stimulates enterochromaffin-like cells to release histamine, which stimulates parietal cells to secrete hydrochloric acid. Histamine acts as both a local paracrine chemical messenger and a hormone in the blood to stimulate gastric gland secretory activity. Acetylcholine, histamine, and gastrin working together cause a greater secretion of hydrochloric acid than any of them does separately. Of the three, histamine has the greatest stimulatory effect. Drugs that block the actions of histamine are used to lower acid levels.

2. **Gastric phase.** The greatest volume of gastric secretions is produced during the gastric phase of gastric regulation. The presence of food in the stomach initiates the gastric phase (figure 24.13). The primary stimuli are distension of the stomach and the presence of amino acids and peptides in the stomach.

Distension of the stomach wall, especially in the body or fundus, stimulates mechanoreceptors. Action potentials generated by these receptors initiate reflexes that involve both the

CNS and the ENS. These reflexes result in acetylcholine release and the cascade of events that increase secretion, as in the cephalic phase. The presence of partially digested proteins or moderate amounts of alcohol or caffeine in the stomach also stimulates gastrin secretion.

When the pH of the stomach contents falls below 2, increased gastric secretion produced by distension of the stomach is blocked. This negative-feedback mechanism limits the secretion of gastric juice.

3. **Intestinal phase.** The intestinal phase of gastric secretion primarily inhibits gastric secretions (figure 24.13). It is initiated by the entrance of acidic chyme into the duodenum of the small intestine, which activates both neural and hormonal mechanisms. Secretions are inhibited when the pH of the chyme entering the duodenum drops to 2 or below. In addition, when the chyme contains lipid digestion products, gastric secretions are inhibited.

Acidic solutions in the duodenum cause the release of the hormone **secretin** (se-krē'tin) into the bloodstream. Secretin inhibits gastric secretion by inhibiting both parietal and chief cells.

Fatty acids, other lipids, and to a lesser degree protein digestion products in the duodenum and the proximal jejunum initiate the release of the hormone **cholecystokinin** (kō'lē-sis-tō-kī'nin), which inhibits gastric secretion.

Clinical IMPACT

Gastroesophageal Reflux

Gastroesophageal reflux is the reflux of acidic chyme from the stomach into the esophagus. Gastroesophageal reflux is commonly called *heartburn* because the refluxed acid causes a painful, burning sensation in the chest. The pain is usually short-lived but may be confused with the pain of an ulcer or a heart attack. The lower esophageal sphincter normally prevents acid reflux. Overeating (especially fatty and fried foods), lying down immediately after a meal, consuming too much alcohol or caffeine, smoking, and wearing extremely tight clothing can all cause gastroesophageal reflux. Gastroesophageal reflux commonly occurs in infants, but they usually outgrow it by their first birthday.

Chronic reflux more than twice a week in infants or adults is more serious and is called **gastroesophageal reflux disease (GERD)**. GERD in young infants can be difficult to diagnose. Women commonly experience GERD during pregnancy because of increased abdominal pressure from the fetus and higher levels of the hormone progesterone, which relaxes the lower esophageal sphincter.

For most adults, lifestyle changes and medications that decrease gastric acid secretion are sufficient to relieve the symptoms of GERD. Antacids that buffer gastric acid can also alleviate minor discomfort. One class of drugs acts by blocking the H_2 histamine receptors on parietal cells. H_2 receptors are different from the H_1 receptors involved in allergic reactions. Drugs that block allergic reactions do not affect histamine-mediated stomach acid secretion, and vice versa. Cimetidine (Tagamet[®]) and ranitidine (Zantac[®]) are histamine receptor antagonists that prevent histamine from binding to receptors on parietal cells. These chemicals are extremely effective inhibitors of gastric acid secretion. Cimetidine, one of the most commonly prescribed drugs, is also used to treat gastric acid hypersecretion associated with gastritis and gastric ulcers. The most effective inhibitors of gastric acid secretion are the proton pump inhibitors, such as omeprazole (Prilosec[®]) and lansoprazole (Prevacid[®]). These drugs inhibit the proton pumps on parietal cells, thus preventing acid secretion into the stomach. If not treated, GERD can lead to serious complications, including esophageal ulcers, scarring that constricts the esophagus, and esophageal cancer.

The inhibition of gastric secretion is also under nervous control. The **enterogastric reflex** consists of a local reflex and a reflex integrated within the medulla oblongata that reduce gastric secretion. Distension of the duodenal wall, the presence of irritating substances in the duodenum, reduced pH, and hypertonic or hypotonic solutions in the duodenum activate the enterogastric reflex.

To summarize, gastric acid secretion is controlled by negative-feedback loops involving nerves and hormones. During the gastric phase, high acid levels in the stomach trigger a decrease in additional acid secretion. Then, during the intestinal phase, acidic chyme entering the duodenum triggers a decrease in stomach acid secretion. These negative-feedback loops ensure that the acidic chyme entering the duodenum is neutralized, which is required for

the digestion of food by pancreatic enzymes and for the prevention of peptic ulcer formation.

► Predict 4

Alice, age 85, reported periods of laryngitis that began when she awakened in the morning and lasted a few days. Alice's physician used a laryngoscope to examine her vocal folds and upper trachea, which appeared inflamed. He prescribed an antacid and a drug to decrease H^+ secretion and told her to take the medications prior to going to bed at night. He also advised Alice to avoid eating just before bedtime. Explain the cause of her laryngitis and why the medications should relieve the symptoms.

Movements of the Stomach

Stomach Filling

As food enters the stomach, the rugae flatten and the stomach volume increases up to 20-fold. This expansion allows the stomach to accommodate a large amount of food with very little increased pressure, until the stomach nears maximum capacity. Relaxation of the rugae is mediated by a reflex integrated within the medulla oblongata that inhibits muscle tone and pressure is further minimized by the ability of smooth muscle to stretch without an increase in tension (see chapter 9).

Mixing of Stomach Contents

Ingested food is thoroughly mixed with stomach gland secretions to form chyme. This mixing is accomplished by gentle **mixing waves**, which are contractions that occur about every 20 seconds. They proceed from the body of the stomach toward the pyloric sphincter. **Peristaltic waves** occur less frequently, are significantly more powerful than mixing waves, and force the chyme near the periphery of the stomach toward the pyloric sphincter. The more solid material near the center of the stomach is pushed superiorly toward the cardiac part for further digestion (figure 24.14). Roughly 80% of the contractions are mixing waves, and 20% are peristaltic waves. The back-and-forth movement of the chyme effectively mixes the ingested food with gastric juice.

Stomach Emptying

The amount of time food remains in the stomach depends on a number of factors, including the type and volume of food. Liquids exit the stomach within $1\frac{1}{2}$ – $2\frac{1}{2}$ hours after ingestion. After a typical meal, the stomach is usually empty within 3–4 hours. The pyloric sphincter normally remains partially closed because of mild tonic contraction. Each peristaltic contraction is strong enough to force a small amount of chyme through the pyloric opening and into the duodenum. The peristaltic contractions responsible for moving chyme through the partially closed pyloric opening are called the **pyloric pump**. In general, increased motility leads to increased emptying. In an empty stomach, peristaltic contractions that approach tetanic contractions can occur for about 2–3 minutes. The contractions are increased by low blood glucose levels and are strong enough to create uncomfortable sensations called **hunger pangs**. Hunger pangs usually begin 12–24 hours after a meal, in less time for some people. If nothing is ingested, hunger pangs reach their maximum intensity within 3–4 days and then become progressively weaker.

- 1 A mixing wave initiated in the body of the stomach progresses toward the pyloric sphincter (*pink arrows directed inward*).
- 2 The more fluid part of the chyme is pushed toward the pyloric sphincter (*blue arrows*), whereas the more solid center of the chyme squeezes past the peristaltic constriction back toward the body of the stomach (*orange arrow*).
- 3 Peristaltic waves (*purple arrows*) move in the same direction and in the same way as the mixing waves but are stronger.
- 4 Again, the more fluid part of the chyme is pushed toward the pyloric region (*blue arrows*), whereas the more solid center of the chyme squeezes past the peristaltic constriction back toward the body of the stomach (*orange arrow*).
- 5 Peristaltic contractions force a few milliliters of the mostly fluid chyme through the pyloric opening into the duodenum (*small red arrows*). Most of the chyme, including the more solid portion, is forced back toward the body of the stomach for further mixing (*yellow arrow*).

PROCESS FIGURE 24.14 Movements in the Stomach

Regulation of Stomach Emptying

If the stomach empties too fast, the efficiency of digestion and absorption is reduced, and acidic gastric contents dumped into the duodenum may damage its lining. However, if the rate of emptying is too slow, the highly acidic contents of the stomach may damage the stomach wall and reduce the rate at which nutrients are digested and absorbed.

To prevent these two extremes, stomach emptying is regulated. The neural mechanisms that stimulate stomach secretions are also involved with increasing stomach motility. The major stimulus for both motility and secretion is distension of the stomach wall. Increased stomach motility increases stomach emptying. Conversely, the hormonal and neural mechanisms associated with the duodenum that decrease gastric secretions also decrease gastric motility and increase constriction of the pyloric sphincter. The enterogastric reflex and the hormone cholecystinin are major inhibitors of gastric motility. The result is a decrease in the rate of stomach emptying.

A meal of polysaccharide carbohydrates (starch and glycogen) has the fastest clearance time from the stomach, typically 1 hour.

For comparison, a meal heavy with dietary fats and proteins takes up to 6 hours to clear from the stomach. A major reason for this difference is that a fatty meal increases the release of cholecystinin, which is a major inhibitor of stomach emptying.

Vomiting is usually a protective mechanism against the ingestion of toxic or harmful substances. Vomiting can result from irritation (e.g., overdistension or overexcitation) anywhere along the digestive tract. Action potentials travel through the vagus nerve and spinal visceral afferent nerves to the vomiting center in the medulla oblongata. Once the vomiting center is stimulated and the reflex is initiated, the following events occur: (1) A deep breath is taken; (2) the hyoid bone and larynx are elevated, opening the upper esophageal sphincter; (3) the opening of the larynx is closed; (4) the soft palate is elevated, closing the connection between the oropharynx and the nasopharynx; (5) the diaphragm and abdominal muscles are forcefully contracted, strongly compressing the stomach and increasing the intragastric pressure; (6) the lower esophageal sphincter is relaxed; and (7) the gastric contents are forced out of the stomach, through the esophagus and oral cavity, to the outside.

ASSESS YOUR PROGRESS

29. Describe the parts of the stomach. List the tunics of the stomach wall. How is the stomach wall different from the esophagus wall?
30. What are gastric pits and gastric glands?
31. Name the types of cells in the stomach and the secretions they produce. What are the functions of the secretions?
32. Describe the three phases of regulation of stomach secretion.
33. How are gastric secretions inhibited? Why is this inhibition necessary?
34. As the stomach fills, why does the pressure not greatly increase until maximum volume is reached?
35. Name the two kinds of stomach movements. How are stomach movements regulated by hormones and nervous control?

24.9 Small Intestine

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the sections of the small intestine and describe the characteristics that account for its large surface area.
- B. Name the four major cell types of the duodenal mucosa and describe their functions.
- C. Describe the secretions and movements of the small intestine.

The **small intestine** consists of three parts: the duodenum, the jejunum, and the ileum (figure 24.15). The entire small intestine is about 6 m long (range: 4.6–9 m). The duodenum is about 25 cm long (*duodenum* means 12, suggesting that it is 12 inches long). The jejunum, constituting about two-fifths of the total length of the small intestine, is about 2.5 m long. The ileum, constituting three-fifths of the small intestine, is about 3.5 m long. Two major accessory glands, the liver and the pancreas, are associated with the duodenum.

The small intestine is where the greatest amount of digestion and absorption occurs. Each day, about 9 L of water enter the digestive system. This includes water that is ingested and fluid secretions produced by glands along the length of the digestive tract. Most of the water (8–8.5 L) moves by osmosis, along with the absorbed solutes, out of the small intestine. A small part (0.5–1 L) enters the colon.

Anatomy and Histology of the Small Intestine

Duodenum

The **duodenum** (doo-ō-dē'nūm, doo-od'ē-nūm) nearly completes a 180-degree arc as it curves around the head of the pancreas within the abdominal cavity (figure 24.16a). The structure of the duodenum begins with a short, superior part and ends in a sharp bend,

FIGURE 24.15 Small Intestine **APR**

where it joins the jejunum. Within the duodenum, about two-thirds of the way down the descending part, are two small mounds: the **major duodenal papilla** and the **minor duodenal papilla**. Ducts from the liver and/or pancreas open at these papillae.

The surface of the duodenum has three modifications that increase its area about 600-fold to allow for more efficient digestion and absorption of food. (1) The mucosa and submucosa form a series of folds called the **circular folds**, or *plicae (plī'sē) circulares* (figure 24.16a), which run perpendicular to the long axis of the digestive tract. (2) Tiny, fingerlike projections of the mucosa form numerous **villi** (vil'ī), which are 0.5–1.5 mm in length (figure 24.16c). Each villus is covered by simple columnar epithelium and contains a blood capillary network and a lymphatic capillary called a **lacteal** (lak'tē-āl; figure 24.16d). (3) Most of the cells that make up the surface of the villi have numerous cytoplasmic extensions (about 1 μm long) called **microvilli**, which further increase the surface area (figure 24.16e). The combined microvilli on the entire epithelial surface form the **brush border**. All three of these modifications increase the surface area of the small intestine, which greatly enhances absorption.

The mucosa of the duodenum is simple columnar epithelium with four major cell types: (1) absorptive cells, (2) goblet cells, (3) granular cells, and (4) endocrine cells. **Absorptive cells** are cells with microvilli that produce digestive enzymes and absorb digested food. **Goblet cells** produce a protective mucus. **Granular cells**, or *Paneth cells*, may help protect the intestinal epithelium from bacteria. **Endocrine cells** produce regulatory hormones. The epithelial cells are produced within tubular invaginations of the mucosa, called **intestinal glands**, or *crypts of Lieberkühn*, at the base of the villi. The absorptive and goblet cells migrate from the intestinal glands to cover the surface of the villi and are eventually shed from its tip. The granular and endocrine cells remain in

FIGURE 24.16 Anatomy and Histology of the Duodenum

the bottom of the glands. The submucosa of the duodenum contains coiled, tubular mucous glands called **duodenal glands**, or *Brunner glands*, which open into the base of the intestinal glands.

Jejunum and Ileum

The **jejunum** (jĕ-joo'nŭm) and **ileum** (il'ē-ŭm) are similar in structure to the duodenum (see figure 24.15). However, progressing from the duodenum through the ileum, there are gradual decreases in the diameter of the small intestine, the thickness of the intestinal wall, the number of circular folds, and the number of villi. The duodenum and jejunum are the major sites of nutrient absorption, although some absorption occurs in the ileum.

Lymphatic nodules called **Peyer patches** are numerous in the mucosa and submucosa of the ileum. Peyer patches and other mucosa-associated lymphoid tissue in the digestive tract initiate immune responses against microorganisms that enter the mucosa from ingested food (see chapter 22).

The site where the ileum connects to the large intestine is the **ileocecal junction**. It has a ring of smooth muscle, the **ileocecal sphincter**, and a one-way **ileocecal valve**. Together, the sphincter and valve allow intestinal contents to move from the ileum to the large intestine, but not in the opposite direction (see figures 24.15 and 24.25).

Secretions of the Small Intestine

The mucosa of the small intestine produces secretions that contain primarily mucus, electrolytes, and water. Intestinal secretions lubricate and protect the intestinal wall from the acidic chyme and the action of digestive enzymes. They also keep the chyme in the small intestine in a liquid form to facilitate the digestive process (see table 24.2). The intestinal mucosa produces most of the secretions that enter the small intestine, but the secretions of the liver and the pancreas also enter the small intestine and play essential roles in digestion. The pancreas secretes most of the digestive enzymes entering the small intestine. The intestinal mucosa also produces enzymes, but these remain associated with the intestinal epithelial surface.

The duodenal glands, intestinal glands, and goblet cells secrete large amounts of mucus. This mucus protects the wall of the intestine from the irritating effects of acidic chyme and from the digestive enzymes that enter the duodenum from the pancreas. The intestinal mucosa releases secretin and cholecystokinin, which stimulate hepatic and pancreatic secretions (see figures 24.21 and 24.24).

Intestinal secretions from the duodenal glands are stimulated by the vagus nerve, secretin, and chemical or tactile irritation of the duodenal mucosa. Chemical and tactile irritation of the mucosa also stimulate goblet cells to produce mucus.

Enzymes of the intestinal mucosa are bound to the membranes of the absorptive cell microvilli. These surface-bound enzymes include **disaccharidases**, which break down disaccharides to monosaccharides, and **peptidases**, which hydrolyze the peptide bonds between small amino acid chains (see table 24.2). Although these enzymes are not secreted into the intestine, they influence the digestive process significantly, and the large surface area of the intestinal epithelium brings these enzymes into contact with the intestinal contents. Small molecules, which are

breakdown products of digestion, are absorbed through the microvilli and enter the circulatory or lymphatic system.

Movement in the Small Intestine

The mixing and propulsion of chyme are the primary mechanical functions of the small intestine. These functions are performed with the aid of segmental and peristaltic contractions accomplished by the smooth muscle in the wall of the small intestine and propagated for short distances. Segmental contractions (see figure 24.3) mix the intestinal contents, and peristaltic contractions propel the intestinal contents along the digestive tract. A few peristaltic contractions may proceed the entire length of the intestine. Frequently, intestinal peristaltic contractions are continuations of peristaltic contractions that begin in the stomach. These contractions both mix and propel substances through the small intestine as the wave of contraction proceeds. The contractions move at a rate of about 1 cm/min. The movements are slightly faster at the proximal end of the small intestine and slightly slower at the distal end. It usually takes 3–5 hours for chyme to move from the pyloric region to the ileocecal junction.

Local mechanical and chemical stimuli are especially important in regulating the motility of the small intestine. Smooth muscle contraction increases in response to distension of the intestinal wall. Solutions that are either hypertonic or hypotonic, solutions with a low pH, and certain products of digestion, such as amino acids and peptides, also stimulate contractions of the small intestine. Local reflexes, which are integrated within the ENS of the small intestine, mediate the intestine's response to these mechanical and chemical stimuli. Stimulation through parasympathetic nerve fibers may also increase the intestine's motility, but the parasympathetic influences in the intestine are not as important as those in the stomach.

The ileocecal sphincter at the juncture between the ileum and the large intestine remains mildly contracted most of the time, but peristaltic waves reaching it from the small intestine cause it to relax and allow the chyme to move from the small intestine into the cecum. Cecal distension, however, initiates a local reflex that causes more intense constriction of the ileocecal sphincter. Closure of the sphincter facilitates digestion and absorption in the small intestine by slowing the rate of chyme movement from the small intestine into the large intestine and prevents material from returning to the ileum from the cecum.

➤ Predict 5

Amos suffers from intermittent pain in the epigastric area that begins about 2 or 3 hours after eating. The pain is relieved by taking an antacid. An endoscopic exam identified duodenal ulcers and Amos's physician recommended antacids and an antibiotic. Amos wondered why he could not control the condition with antacids alone, but his physician was worried about perforation of the duodenum. Explain why Amos's physician prescribed both antacids and antibiotics. How could the lack of antibiotics lead to perforation of the duodenum?

24.10 Liver

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the anatomy, histology, and ducts of the liver.
- B. Describe the major functions of the liver and explain how they are regulated.

Anatomy of the Liver

The **liver** is the largest internal organ of the body, weighing about 1.36 kg (3 pounds). It is in the right-upper quadrant of the abdomen, tucked against the inferior surface of the diaphragm (figure 24.17; see figure 24.1). The liver consists of two major lobes, the **right lobe** and **left lobe**, which are separated by a connective tissue septum, the falciform ligament. Two minor lobes, the **caudate lobe** and the **quadrate lobe**, can be seen from an inferior view, along with the porta.

The **porta** (gate) is on the inferior surface of the liver, where the various vessels, ducts, and nerves enter and exit the liver (figure 24.17*b*). Blood flows into the liver via the **hepatic** (he-pat'ik) **portal vein** and the **hepatic artery**. A small hepatic nerve plexus enter the liver through the porta. Lymphatic vessels and two hepatic ducts, one each from the right and left lobes, exit the liver at the porta. The hepatic ducts transport bile out of the liver. The right and left hepatic ducts unite to form a single **common hepatic duct** (figure 24.18). The **cystic duct** from the gallbladder joins the common hepatic duct to form the **common bile duct**, which joins the pancreatic duct at the **hepatopancreatic ampulla** (hě-pat'ō-pan-crē-at'ik am-pul'lă), an enlargement where the hepatic and pancreatic ducts come together. The hepatopancreatic ampulla empties into the duodenum at the major duodenal papilla (figure 24.18). A smooth muscle sphincter surrounds the common bile duct where it enters the hepatopancreatic ampulla.

The gallbladder is a small sac on the inferior surface of the liver that stores bile. Bile can flow from the gallbladder through the cystic duct into the common bile duct, or it can flow back up the cystic duct into the gallbladder.

Histology of the Liver

A connective tissue capsule and visceral peritoneum cover the liver, except for the **bare area**, a small area on the diaphragmatic surface that lacks a visceral peritoneum and is surrounded by the coronary

ligament (see figure 24.17*c*). At the porta, the connective tissue capsule sends a branching network of septa (walls) into the substance of the liver to provide its main support. Vessels, nerves, and ducts follow the connective tissue branches throughout the liver.

The liver is divided into hexagon-shaped **hepatic lobules** by connective tissue septa with a **portal triad** at each corner (figure 24.19). The triads are so named because three structures—the hepatic portal vein, hepatic artery, and hepatic duct—are located in them. Hepatic nerves and lymphatic vessels, often too small to be seen easily in light micrographs, are also located in these areas. A **central vein** is in the center of each lobule. Central veins of the lobules unite to form **hepatic veins**, which exit the liver on its posterior and superior surfaces and empty into the inferior vena cava (figure 24.19).

Hepatic cords are strings of cells that radiate out from the central vein of each lobule like the spokes of a wheel. The hepatic cords are composed of **hepatocytes**, the functional cells of the liver. The spaces between the hepatic cords are blood channels called **hepatic sinusoids**. The sinusoids are lined with a very thin, irregular squamous endothelium consisting of two cell populations: (1) extremely thin, sparse **endothelial cells** and (2) **hepatic phagocytic cells** called Kupffer cells. A cleftlike lumen, the **bile canaliculus** (kan-ă-lik'ū-lūs; little canal), lies between the cells within each cord (figure 24.19).

Hepatocytes have six major functions: (1) bile production, (2) storage, (3) interconversion of nutrients, (4) detoxification, (5) phagocytosis, and (6) synthesis of blood components. Nutrient-rich, deoxygenated blood from the viscera enters the hepatic sinusoids from branches of the hepatic portal vein and mixes with nutrient-depleted, oxygenated blood from the hepatic arteries (figure 24.20). From the blood, the hepatocytes can take up the oxygen and nutrients, which are stored, detoxified, used for energy, or used to synthesize new molecules. Molecules produced by or modified in the hepatocytes are released into the hepatic sinusoids or into the bile canaliculi.

Mixed blood in the hepatic sinusoids flows to the central vein, where it exits the lobule and then exits the liver through the hepatic veins. **Bile** produced by the hepatocytes flows through the bile canaliculi toward the hepatic triad and exits the liver through the hepatic ducts. Blood, therefore, flows from the triad toward the center of each lobule, whereas bile flows away from the center of the lobule toward the triad.

In the fetus, special blood vessels bypass the liver sinusoids. The remnants of fetal blood vessels can be seen in the adult as the round ligament (ligamentum teres) and the ligamentum venosum (see chapter 29).

Functions of the Liver

The liver performs important digestive and excretory functions, stores and processes nutrients, detoxifies harmful chemicals, and synthesizes new molecules.

Bile Production for Digestion and Excretion

The liver produces and secretes about 600–1000 mL of bile each day (see table 24.2). Bile contains bile salts, bile pigments,

(a) Anterior view

(b) Inferior view

(c) Superior view

FIGURE 24.17 Liver **APR**

cholesterol, lipids, lipid-soluble hormones, and lecithin (a mixture of phospholipids). Bile contains no digestive enzymes, but it plays a role in digestion because it neutralizes stomach acid and emulsifies lipids. The relative alkaline pH of bile helps neutralize the acidic chyme entering the duodenum. This is important because the pancreatic enzymes cannot function at the acidic pH of the chyme leaving the stomach. **Bile salts** emulsify lipids, which is necessary for subsequent digestion by lipase. Bile pigments are not required for any digestive function but rather are excretory products. Bile pigments have greenish-yellow to brown colors and give feces their characteristic color. One common bile pigment is

bilirubin, which results from the breakdown of hemoglobin (see chapter 19).

Neural and hormonal signals stimulate the secretion and release of bile (figure 24.21). Bile secretion by the liver is increased by parasympathetic stimulation through the vagus nerve. Secretin, which is released from the duodenum, also stimulates bile secretion, primarily by increasing the water and bicarbonate ion content of bile. Cholecystokinin stimulates gallbladder contractions to release bile into the duodenum.

Bile salts increase bile secretion through a positive-feedback system. Over 90% of bile salts are reabsorbed in the ileum and

- 1 The hepatic ducts, which carry bile from the liver lobes, combine to form the common hepatic duct.
- 2 The common hepatic duct combines with the cystic duct from the gallbladder to form the common bile duct.
- 3 The common bile duct and the pancreatic duct combine to form the hepatopancreatic ampulla.
- 4 The hepatopancreatic ampulla empties bile and pancreatic secretions into the duodenum at the major duodenal papilla.
- 5 The accessory pancreatic duct empties pancreatic secretions into the duodenum at the minor duodenal papilla.

PROCESS FIGURE 24.18 Flow of Bile and Pancreatic Secretions Through the Duct System of the Liver, Gallbladder, and Pancreas

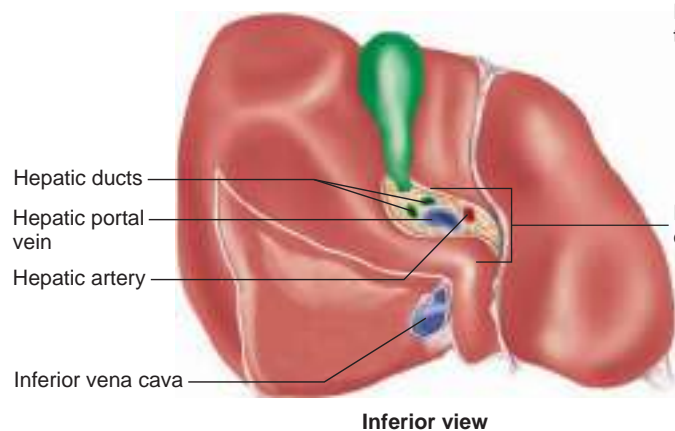

FIGURE 24.19 Histology of Hepatic Lobules in the Liver

The liver consists of hexagon-shaped lobules with a portal triad at each corner. A central vein is located in the center of each lobule.

- 1 The hepatic artery carries oxygenated blood from the aorta through the porta of the liver. Hepatic artery branches become part of the portal triads. Blood from the hepatic artery branches enters the hepatic sinusoids and supplies hepatocytes in the hepatic cords with oxygen.
- 2 The hepatic portal vein carries nutrient-rich, deoxygenated blood from the intestines through the porta of the liver. Hepatic portal vein branches become part of the portal triads. Blood from the hepatic portal vein branches enters the hepatic sinusoids and supplies hepatocytes in the hepatic cords with nutrients.
- 3 Blood in the hepatic sinusoids that comes from the hepatic artery and hepatic portal vein picks up plasma proteins, processed molecules, and waste products produced by the hepatocytes of the hepatic cords. The hepatic sinusoids empty into central veins. The central veins connect to hepatic veins, which connect to the inferior vena cava.
- 4 Bile produced by hepatocytes in the hepatic cords enters bile canaliculi, which connect to hepatic duct branches that are part of the portal triads.
- 5 The hepatic duct branches converge to form the left and right hepatic ducts, which carry bile out the porta of the liver.

PROCESS FIGURE 24.20 Blood and Bile Flow Through the Liver

carried in the blood by the hepatic portal circulation. Upon their return to the liver, the bile salts stimulate further bile secretion and are once again secreted into the bile. This recycling process reduces the loss of bile salts in the feces. Bile secretion into the duodenum continues until the duodenum empties.

Storage of Nutrients

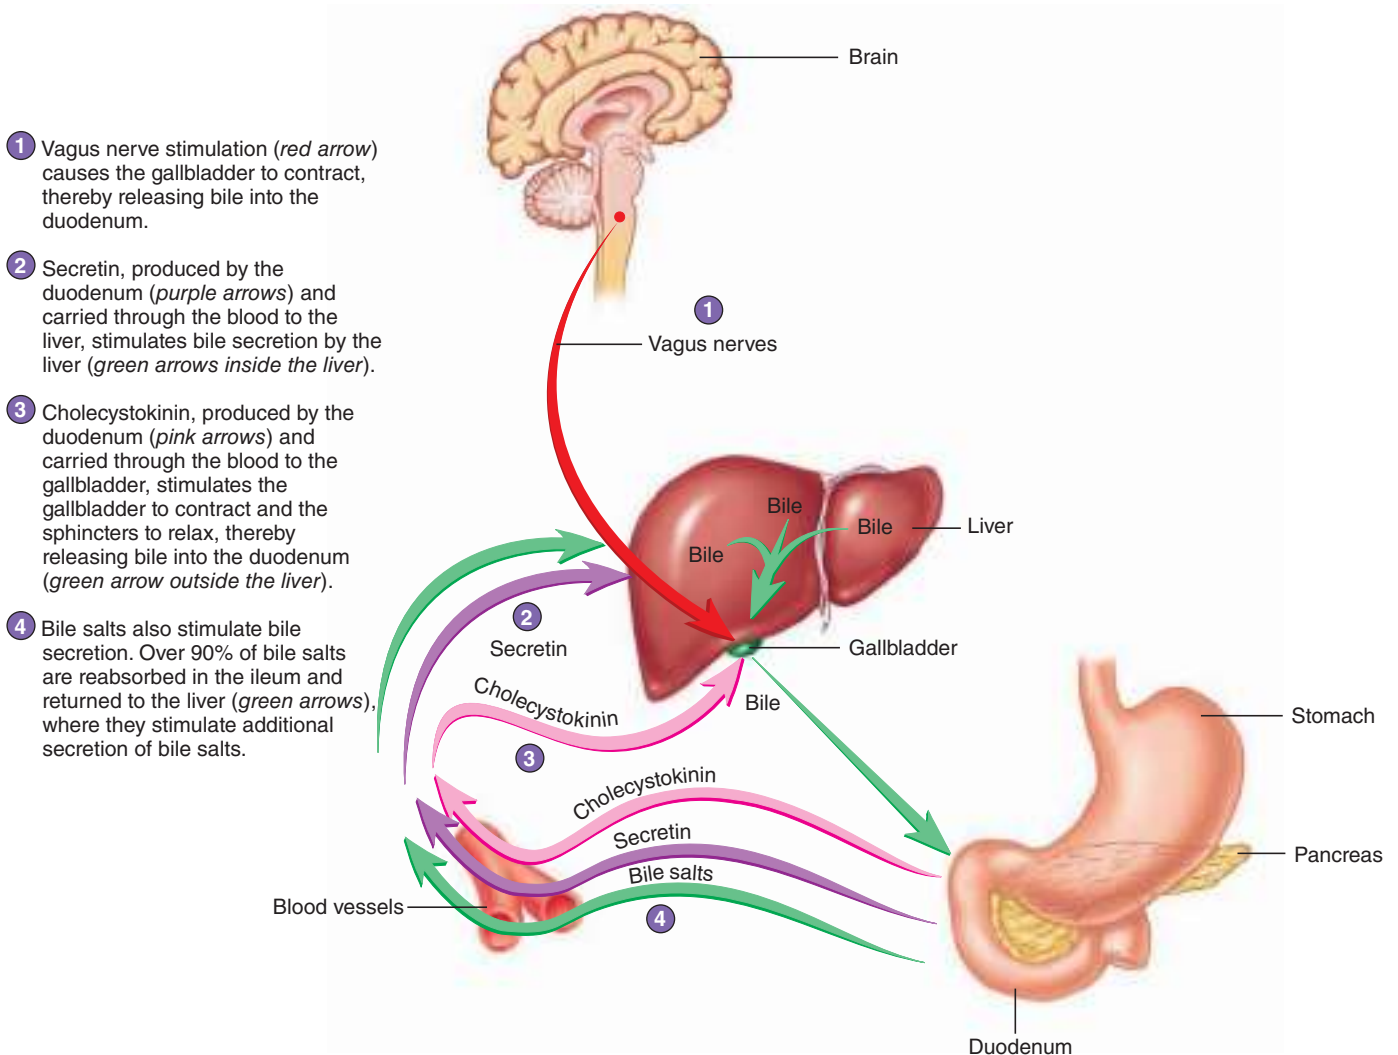

Hepatocytes can remove sugar from the blood and store it in the form of **glycogen**. They can also store lipids, vitamins (A, B₁₂, D, E, and K), copper, and iron. This storage function is usually short-term, and the amount of stored material in the hepatocytes—hence their size—fluctuates during the day.

Hepatocytes help maintain blood sugar levels within very narrow limits. If a large amount of sugar enters the general circulation after a meal, the blood osmolality will increase, resulting in hyperglycemia. Under normal conditions, this is prevented because the blood from the small intestine passes through the hepatic portal vein to the liver, where hepatocytes remove glucose and other substances from the blood, store them, and then secrete them back into the circulation when needed.

Nutrient Processing

The processing, or interconversion, of nutrients is another important function of the liver. Ingested nutrients are not always present in the proportion needed by the tissues. In this case, the liver can convert some nutrients into others. For example, if a person is on a diet that is excessively high in protein, an oversupply of amino acids and an undersupply of lipids and carbohydrates may be delivered to the liver. The hepatocytes break down the amino acids and cycle many of them through metabolic pathways, so that they can be used to produce adenosine triphosphate, lipids, and glucose (see chapter 25).

Hepatocytes also transform substances that cannot be used by most cells into more readily usable substances. For example, they combine ingested dietary fats with choline and phosphorus in the liver to produce phospholipids, which are essential components of plasma membranes. In addition, vitamin D is hydroxylated in the liver hepatocytes. The hydroxylated form of vitamin D, which is the major circulating form of vitamin D, is transported through the blood to the kidneys, where it is again hydroxylated. The double-hydroxylated vitamin D is the active form of the vitamin, which functions in calcium maintenance.

PROCESS FIGURE 24.21 Control of Bile Secretion and Release

Clinical IMPACT

Hepatitis, Cirrhosis, and Liver Damage

Hepatitis is an inflammation of the liver that can be caused by alcohol consumption or a viral infection. Hepatitis A, also called infectious hepatitis, is responsible for about 30% of all hepatitis cases in the United States. Hepatitis B, also called serum hepatitis, is a more chronic infection and is responsible for half the hepatitis cases in the United States. The remainder of U.S. cases (about 20%) are hepatitis C, also called non-A and non-B hepatitis. Hepatitis C is caused by one or more virus types that cannot be identified in blood tests, and it is spread by blood transfusions or sexual intercourse. If hepatitis is not treated, liver cells die and are replaced by scar tissue, resulting in loss of liver function. Liver failure and death can occur.

Cirrhosis (sir-rō'sis) of the liver involves the death of hepatocytes and their replacement by fibrous connective tissue. The liver becomes pale in color (the term *cirrhosis* means “a tawny or orange condition”) because of the presence of excess white connective tissue. It also becomes firmer, and the surface becomes nodular. The buildup of connective tissue can impede blood flow through the liver. The loss of hepatocytes eliminates the function of the liver, often resulting in jaundice, in which the skin and eyes appear yellowish due to buildup of bile pigments in the blood and interstitial fluid. Cirrhosis develops in many alcoholics and may result from biliary obstruction, hepatitis, or nutritional deficiencies.

Under most conditions, mature hepatocytes can proliferate and replace lost parts of the liver. However, if the liver is severely damaged, the hepatocytes may not have enough regenerative power to replace the lost parts. In this case, a liver transplant may be necessary. The liver also maintains an undifferentiated stem cell population, called “oval” cells, which gives rise to two cell lines, one forming bile duct epithelium and one producing hepatocytes. Researchers hope that these stem cells can one day be used to reconstitute a severely damaged liver. It may even become possible to remove stem cells from a person with hemophilia, genetically engineer the cells to produce the missing clotting factors, and then reintroduce the altered stem cells into the person's liver.

Detoxification

Many ingested substances are harmful to body cells. In addition, the body itself produces many by-products of metabolism that, if accumulated, are toxic. The liver forms a major line of defense by altering the structure of many of these harmful substances to make them less toxic or to make their elimination easier. Ammonia, for example, a by-product of amino acid metabolism, is toxic and not readily removed from the blood by the kidneys. Hepatocytes remove ammonia from the blood and convert it to urea, which is less toxic than ammonia. Urea is then secreted into the blood and eliminated by the kidneys in the urine. The liver hepatocytes also remove other substances from the blood and excrete them into the bile.

Hepatic phagocytic cells (Kupffer cells), which lie along the sinusoid walls of the liver, phagocytize “worn-out” and dying red

and white blood cells, some bacteria, and other debris that enters the liver through the blood vessels.

Synthesis of New Molecules

The liver can produce its own new compounds, including plasma proteins such as albumins, fibrinogen, globulins, heparin, and clotting factors, which are released into the blood (see chapter 19).

ASSESS YOUR PROGRESS

43. Describe the lobes of the liver. What is the porta?
44. Diagram the duct system from the liver, gallbladder, and pancreas that empties into the major duodenal papilla.
45. Describe the flow of blood to and through the liver. Describe the flow of bile away from the liver.
46. Explain and give examples of the major functions of the liver.
47. What stimulates bile secretion from the liver?

24.11 Gallbladder

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Discuss the structure and function of the gallbladder.
- B. State what stimulates the release of bile.

The **gallbladder** is a saclike structure for bile storage. It is on the inferior surface of the liver; it is about 8 cm long and 4 cm wide (see figure 24.18). Three tunics form the gallbladder wall: (1) an inner mucosa folded into rugae that allow the gallbladder to expand; (2) a muscularis, which is a layer of smooth muscle that allows the gallbladder to contract; and (3) an outer covering of serosa. The cystic duct connects the gallbladder to the common bile duct.

The liver continually secretes bile, which flows to the gallbladder, where 40–70 mL of bile is stored. While the bile is in the gallbladder, water and electrolytes are absorbed. Thus, bile salts and pigments become as much as 5–10 times more concentrated than when secreted by the liver. Bile is released from the gallbladder by contractions stimulated by cholecystikinin and, to a lesser degree, by vagal stimulation. In this way, large amounts of concentrated bile are dumped into the small intestine shortly after a meal (figure 24.21).

Gallstones are insoluble aggregates formed in the gallbladder. They are often caused by precipitation of excess cholesterol, which can be the result of a high-cholesterol diet or other causes. Cholesterol is not soluble in water and is ordinarily kept in solution by bile salts. Occasionally, a gallstone passes out of the gallbladder and enters the cystic duct, blocking the release of bile. This condition interferes with normal digestion, and often the gallstone must be surgically removed. If the gallstone moves far enough down the duct, it can also block the pancreatic duct, resulting in pancreatitis.

ASSESS YOUR PROGRESS

48. Describe the three tunics of the gallbladder wall.
49. What is the function of the gallbladder? What stimulates the release of bile from the gallbladder?

24.12 Pancreas

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the anatomy, histology, and ducts of the pancreas.
- List the secretions of the pancreas, their functions, and their regulation.

Anatomy of the Pancreas

The **pancreas** is a complex organ composed of both endocrine and exocrine tissues that perform several functions. The pancreas consists of a head, located within the curvature of the duodenum (figure 24.22a), a body, and a tail, which extends to the spleen.

The endocrine part of the pancreas consists of **pancreatic islets**, or *islets of Langerhans* (figure 24.22b). The islet cells produce insulin and glucagon, which are very important in controlling the blood levels of nutrients, such as glucose and amino acids, and somatostatin, which regulates insulin and glucagon secretion and may inhibit growth hormone secretion (see chapter 18).

The exocrine part of the pancreas is a compound acinar gland (see chapter 4). Acinar cells within the **acini** (as'i-nī; figure 24.22b) produce digestive enzymes. Clusters of acini form lobules that are separated by thin septa. Exocrine secretions flow from the acini via small **intercalated ducts** to **intralobular ducts**, which leave the lobules to join **interlobular ducts** between the lobules. The interlobular ducts attach to the main **pancreatic duct**, which joins the common bile duct at the hepatopancreatic ampulla, or *Vater's ampulla* (figure 24.22a; see figure 24.18). The hepatopancreatic ampulla empties into the duodenum at the major duodenal papilla. A smooth muscle sphincter, the **hepatopancreatic ampullar sphincter**, or *sphincter of Oddi*, regulates the opening of the ampulla. In most people, an accessory pancreatic duct opens at the minor duodenal papilla. The ducts are lined with simple cuboidal epithelium, and the epithelial cells of the acini are pyramid-shaped. A smooth muscle sphincter surrounds the pancreatic duct where it enters the hepatopancreatic ampulla.

Pancreatic Secretions

The exocrine secretions of the pancreas, called **pancreatic juice**, have an aqueous component and an enzymatic component. Pancreatic juice is delivered to the small intestine through the pancreatic ducts, where it functions in digestion.

The **aqueous pancreatic juice** is bicarbonate-rich. It is produced principally by columnar epithelial cells that line the smaller ducts of the pancreas. It contains Na^+ and K^+ in about the same concentration found in extracellular fluid. Bicarbonate ions (HCO_3^-) are a major part of the aqueous component. They neutralize the acidic chyme that enters the small intestine from the stomach. The increased pH caused by pancreatic secretions in the duodenum stops pepsin digestion. Importantly, the neutralized pH is required for the functions of pancreatic and brush-border enzymes. The neutralized pH also prevents damage to the

duodenum by the acid from the stomach. Bicarbonate ions are actively secreted by the duct epithelium, and water follows passively to make the pancreatic juice isotonic.

The cellular mechanism responsible for the secretion of HCO_3^- is diagrammed in figure 24.23. The production of HCO_3^- in the pancreas is similar to the production of H^+ in the gastric gland (see figure 24.12). Both processes require the enzyme carbonic anhydrase and the exchange of HCO_3^- and Cl^- , but the final products are different. An alkaline solution is produced in the pancreas, whereas an acidic solution is produced in the stomach.

The acinar cells of the pancreas produce the **enzyme-rich pancreatic juice**. The enzymes are important in digesting all major classes of food. Without the enzymes produced by the pancreas, lipids, proteins, and carbohydrates cannot be adequately digested (see tables 24.1 and 24.2).

The major proteolytic enzymes are **trypsin**, **chymotrypsin**, and **carboxypeptidase**. These enzymes, which digest proteins, are secreted in inactive forms, whereas many of the other enzymes are secreted in active form. The inactive forms are called trypsinogen, chymotrypsinogen, and procarboxypeptidase. They are activated by proteolytic removal of certain peptides from the precursor proteins. The proteolytic enzyme **enterokinase** (en'tēr-ō-kī'nās), which is attached to the brush border of the small intestine, activates trypsinogen. Trypsin then activates more trypsinogen, as well as chymotrypsinogen and procarboxypeptidase. This process of releasing inactive enzymes is necessary because if the enzymes were produced in their active forms, they would start to digest the pancreas itself. Inappropriate activation causes **pancreatitis**, which is a painful inflammation of the pancreas. Pancreatitis can result from alcoholism, the use of certain drugs, pancreatic duct blockage, cystic fibrosis, viral infection, or pancreatic cancer. Symptoms can range from mild abdominal pain to systemic shock and coma.

Pancreatic juice also contains **pancreatic amylase**, which continues the polysaccharide digestion initiated in the oral cavity. In addition, pancreatic juice contains a lipid-digesting enzyme called **pancreatic lipase**, which breaks down lipids into monoglycerides and free fatty acids. Also present in pancreatic juice are deoxyribonucleases and ribonucleases, which are enzymes that degrade DNA and RNA, respectively.

Regulation of Pancreatic Secretion

Both hormonal and neural mechanisms control the exocrine secretions of the pancreas (figure 24.24). Secretion of the bicarbonate-rich aqueous juice is stimulated by secretin. An acidic chyme in the duodenum stimulates the release of secretin.

Predict 6

Explain why secretin production in response to acidic chyme and its stimulation of bicarbonate ion secretion constitute a negative-feedback mechanism.

Secretion of the enzyme-rich pancreatic juice is stimulated by cholecystokinin and the vagus nerve. Cholecystokinin also stimulates the release of bile from the gallbladder, which aids in the digestion of lipids. As mentioned earlier, the major stimulus

FIGURE 24.22 Anatomy and Histology of the Duodenum and Pancreas

(a) The head of the pancreas lies within the duodenal curvature, with the pancreatic duct emptying into the duodenum. (b) Histology of the pancreas, showing both the acinar cells and the pancreatic duct system. **AP R**

for the release of cholecystokinin is the presence of fatty acids and other lipids in the duodenum. Parasympathetic stimulation through the vagus (X) nerves also stimulates the secretion of enzyme-rich pancreatic juices, and sympathetic impulses inhibit secretion. The effect of vagal stimulation on pancreatic juice secretion is greatest during the cephalic and gastric phases of stomach secretion.

ASSESS YOUR PROGRESS

50. Describe the parts of the pancreas responsible for endocrine and exocrine secretions. Diagram the duct system of the pancreas.
51. Name the two kinds of exocrine secretions produced by the pancreas. What stimulates their production, and what is their function?
52. What enzymes are present in pancreatic juice? Explain the function of each.

24.13 Large Intestine

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the parts of the large intestine and describe its anatomy and histology.**
- B. Describe the major functions of the large intestine and explain how defecation is regulated.**

The **large intestine** is the portion of the digestive tract extending from the ileocecal junction to the anus. It consists of the cecum, colon, rectum, and anal canal. Normally, 18–24 hours are required for material to pass through the large intestine, in contrast to the 3–5 hours required for chyme to move through the small intestine. Thus, the movements of the colon are more sluggish than those of the small intestine. While in the colon,

- 1 Water (H_2O) and carbon dioxide (CO_2) combine under the influence of carbonic anhydrase (CA) to form carbonic acid (H_2CO_3).
- 2 Carbonic acid dissociates to form hydrogen ions (H^+) and bicarbonate ions (HCO_3^-).
- 3 The H^+ is exchanged for sodium ions (Na^+) by an antiporter. Sodium ions are removed by the Na^+-K^+ pump.
- 4 The HCO_3^- is transported into the intercalated ducts in exchange for Cl^- , which returns to the lumen by a channel. Sodium ions and H_2O follow the HCO_3^- into the ducts.
- 5 The ions and H_2O move through the intercalated duct toward the interlobular duct.

PROCESS FIGURE 24.23 Bicarbonate Ion Production in the Pancreas

- 1 Parasympathetic stimulation from the vagus nerve (*red arrow*) causes the release of enzyme-rich pancreatic juice.
- 2 Secretin (*purple arrows*), released from the duodenum stimulates, release of aqueous pancreatic juice rich in bicarbonate ions.
- 3 Cholecystikinin (*pink arrows*), released from the duodenum, causes the release of enzyme-rich pancreatic juice.

PROCESS FIGURE 24.24 Control of Pancreatic Secretion

chyme is converted to feces. The formation of feces involves the absorption of water and salts, secretion of mucus, and extensive action of microorganisms. The colon stores the feces until they are eliminated by defecation. About 1500 mL of chyme enter the cecum each day, but more than 90% of the volume is reabsorbed, so that only 80–150 mL of feces are normally eliminated by defecation.

Anatomy of the Large Intestine

Cecum

The **cecum** (sē'kūm) is the proximal end of the large intestine, where it meets the small intestine at the ileocecal junction. The cecum extends inferiorly about 6 cm past the ileocecal junction in the form of a blind sac (figure 24.25). The **vermiform** (ver'mi-fōrm; worm-shaped) **appendix** is a smaller, blind tube about 9 cm long attached to the cecum. The walls of the appendix contain many lymphatic nodules, which contribute to immune functions.

Colon

The **colon** (kō'lon), about 1.5–1.8 m long, consists of four parts: the ascending colon, transverse colon, descending colon, and sigmoid colon (figure 24.25). The **ascending colon** extends superiorly from the cecum and ends at the right colic flexure (hepatic flexure) near the right inferior margin of the liver. The **transverse colon** extends from the right colic flexure to the left colic flexure (splenic flexure), and the **descending colon**

Clinical IMPACT

Appendicitis

Appendicitis is an inflammation of the vermiform appendix that usually occurs because of an obstruction of the appendix. Secretions from the appendix cannot pass the obstruction and accumulate, resulting in enlargement and pain. Bacteria in the area can cause infection of the appendix. Symptoms include sudden abdominal pain, particularly in the right-lower portion of the abdomen; slight fever; loss of appetite; constipation or diarrhea; nausea; and vomiting. In the right-lower quadrant of the abdomen, about one-third the distance along a line from the right anterior superior iliac spine to the umbilicus, is an area called the McBurney point. This area of the body surface becomes very tender in patients with acute appendicitis because of pain referred from the inflamed appendix. Each year, 500,000 people in the United States experience appendicitis. The usual treatment is surgical removal of the appendix, called an appendectomy. If the appendix bursts, the infection can spread throughout the peritoneal cavity, causing peritonitis, with life-threatening results.

extends from the left colic flexure to the superior opening of the true pelvis, where it becomes the sigmoid colon. The **sigmoid colon** forms an S-shaped tube that extends into the pelvis and ends at the rectum.

MICROBES In Your Body

Fecal Transplants

Would you be shocked if your doctor said the one thing that could save your life is feces? Unfortunately, we are in the midst of a global, hospital-acquired diarrhea epidemic. The cause of this epidemic is a bacterium called *Clostridium difficile* (commonly referred to as *C. diff*), a pathogen that is normally found in the colon, but is controlled by the normal microbiota. One of the most critical functions of the normal gut microbiota is prevention of infections through competition with pathogens. As a consequence, when a patient takes antibiotics, *C. diff* can flourish and cause life-threatening diarrhea. Treatment of *C. diff* infections with specific antibiotics will often stop the diarrhea initially. However, *C. diff* are spore-forming bacteria. Spores are very stable structures that allow bacteria to withstand harsh conditions until favorable conditions return and the bacteria can regrow. Thus, antibiotics kill only the *C. diff* cells, not the spores. Hence, it is very common for patients to suffer multiple recurrences of diarrhea for months, which can lead to death in some patients. Additionally, a more virulent, resistant strain of *C. diff* has emerged.

This strain is resistant to certain antibiotics and makes a greater number of spores and more of the toxins responsible for the diarrhea.

So, where do feces come into play? Because antibiotic treatments are not effective (65% infection recurrence), physicians are considering an old treatment: fecal transplants. The first documented case of transplanting feces from a healthy donor into a diseased recipient was in 1958. Fecal transplantation has since been used successfully in veterinary medicine for decades. However, due to the unappealing nature of this treatment, it has only recently been considered an option in humans. Now more commonly known as intestinal fecal transplantation (IFT), it has been shown to effectively treat diarrhea in over 90% of *C. diff* infections. The idea is that a healthy donor—usually a close family household member such as a spouse or significant partner—donates their feces. The feces are mixed with physiological saline, filtered, and then introduced into the recipient's gastrointestinal (GI) tract by one of two ways: the upper GI tract route or the lower GI tract route. The upper GI tract route uses either a gastroscope or nasogastric tube to transfer the material to

the recipient's intestine. Of the two, this one is easier and costs less. However, there is the possibility the donor microbiota may not reach the end of the colon or that the patient may vomit the fecal material. The lower GI tract route uses a colonoscope or enema and is sometimes the preferred approach, but does run the risk of perforating the colon. Thus, as yet, there is no standardized method for transferring the donor feces. But, research is showing that more and more patients may overcome their initial reluctance when presented with a predictable success rate and greater reliability than other protocols. In addition, the recent "RePOOPulating" study shows promise that doctors may soon be able to treat *C. diff* infections simply by prescribing a pill that contains normal microbiota.

Predict 7

Predict the mechanism by which ingestion of a capsule filled with dried normal microbiota could treat a *C. diff* infection. Would the pill be able to be swallowed, or would it have to be administered directly into the intestine? Explain.

The muscular layer of the colon differs from the small intestine. The circular muscle layer of the colon is complete, but the longitudinal muscle layer is incomplete. Rather than completely enveloping the intestinal wall, the longitudinal layer forms three bands, called the **teniae coli** (tē'nē-ē kō'li). The teniae coli run the length of the colon (figure 24.26a; see figure 24.25). Contractions of the teniae coli cause pouches called **haustra** (haw'strä; to draw up) to form along the length of the colon, giving it a puckered appearance. Small, lipid-filled connective tissue pouches called **omental appendages** are attached to the outer surface of the colon along its length.

The mucosal lining of the large intestine consists of simple columnar epithelium. This epithelium is not formed into folds or villi like that of the small intestine but has numerous, straight, tubular glands called **crypts** (figure 24.26b–d). The crypts, which are somewhat similar to the intestinal glands of the small intestine, are composed of three cell types—absorptive, goblet, and granular cells. The major difference is that, in the large intestine, goblet cells predominate, and the other two cell types are greatly reduced in number.

Rectum

The **rectum** is a straight, muscular tube that begins at the distal end of the sigmoid colon and ends at the anal canal (see figure 24.25).

The mucosal lining of the rectum is simple columnar epithelium, and the muscular tunic is relatively thick, compared with the rest of the digestive tract.

Anal Canal

The last 2–3 cm of the digestive tract is the **anal canal** (see figure 24.25). It begins at the inferior end of the rectum and ends at the **anus** (external digestive tract opening). The smooth muscle layer of the anal canal is even thicker than that of the rectum and forms the **internal anal sphincter** at its superior end. Skeletal muscle forms the **external anal sphincter** at the inferior end of the canal. The epithelium of the superior part of the anal canal is simple columnar, and that of the inferior part is stratified squamous. Rectal veins that supply the anal canal can become enlarged or inflamed, a condition known as **hemorrhoids**. Hemorrhoids cause pain, itching, and bleeding around the anus. They can usually be treated by changes in diet or medications.

Secretions of the Large Intestine

The mucosa of the colon has numerous goblet cells scattered along its length and numerous crypts lined almost entirely with goblet cells. Little enzymatic activity is associated with secretions of the

FIGURE 24.26 Histology of the Large Intestine

(a) Section of the transverse colon cut open to show the inner surface. (b) Enlargement of the inner surface, showing openings of the crypts. (c) Higher magnification of a single crypt. (d) Photomicrograph showing the histology of the large intestine wall.

colon because the major secretory product is mucus (see tables 24.1 and 24.2). Mucus lubricates the wall of the colon and helps the fecal matter stick together. Tactile stimuli and irritation of the colon wall trigger local enteric reflexes that increase mucous secretion. Parasympathetic stimulation also increases the secretory rate of the goblet cells.

The feces that leave the digestive tract consist of water, solid substances (e.g., undigested food), microorganisms, and sloughed-off epithelial cells. An abnormally frequent discharge of watery feces is called **diarrhea** (see Systems Pathology, later in this chapter).

Numerous microorganisms inhabit the colon. They reproduce rapidly and ultimately constitute about 30% of the dry weight of the feces. An important function of colonic bacteria is to synthesize vitamin K, which is passively absorbed in the colon. Acids are secreted by colonic bacteria as metabolic by-products. A molecular pump exchanges HCO_3^- for Cl^- in epithelial cells of the colon in response to acid produced by colic bacteria. Another pump exchanges Na^+ for H^+ . Water leaves the lumen of the colon through osmosis as Na^+ and Cl^- move into the epithelial cells. Colonic bacteria also break down a small amount of cellulose to glucose. However, the glucose cannot be absorbed in the large intestine. Bacterial actions in the colon produce gases called **flatus** (flā'tūs; blowing). The amount of flatus depends partly on the bacterial population in the colon and partly on the type of food consumed. For example, beans, which contain certain complex carbohydrates, are well known for their flatus-producing effect.

Movement in the Large Intestine

Segmental mixing movements occur in the colon much less often than in the small intestine. Peristaltic waves are largely responsible for moving chyme along the ascending colon. At widely spaced intervals (normally three or four times each day), large parts of the transverse and descending colon undergo several strong contractions, called **mass movements**. Each mass movement contraction extends over a much longer part of the digestive tract (≥ 20 cm) than does a peristaltic contraction and propels the colon contents a considerable distance toward the anus (figure 24.27). Mass movements are very common after meals because they are initiated by the presence of food in the stomach or duodenum. Mass movements are most common about 15 minutes after breakfast. They usually persist for 10–30 minutes and then stop for perhaps half a day.

Mass movements are coordinated by local reflexes in the ENS. **Gastrocolic reflexes** are initiated by distension in the stomach, and **duodenocolic reflexes** are initiated by distension in the duodenum. The gastrocolic and duodenocolic reflexes promote peristalsis of the small and large intestines, including mass movements. These reflexes are mediated by parasympathetic reflexes, local reflexes, and hormones, such as cholecystokinin and gastrin. The thought or smell of food, distension of the stomach, and the movement of chyme into the duodenum can stimulate them.

During defecation, the contractions that move feces toward the anus must be coordinated with the relaxation of the internal

and external anal sphincters. The movement of feces from the colon into the rectum distends the rectal wall, which stimulates the defecation reflex. The **defecation reflex** consists of local and parasympathetic reflexes (figure 24.27). Local reflexes cause weak contractions of the distal colon and rectum and relaxation of the internal anal sphincter. Parasympathetic reflexes are responsible for most of the defecation reflex. Action potentials produced in response to distension of the rectal wall travel along afferent nerve fibers to the defecation reflex center (S2–S4) in the conus medullaris of the spinal cord. Then efferent action potentials are initiated that return through nerves to the colon and rectum, reinforcing peristaltic contractions and relaxation of the internal anal sphincter.

There is also conscious control of the defecation reflex. Action potentials from the sacral spinal cord ascend to the brain, where parts of the brainstem and hypothalamus inhibit or facilitate reflex activity in the spinal cord. In addition, action potentials ascend to the cerebrum, where awareness of the need to defecate is realized. The external anal sphincter is composed of skeletal muscle and is under conscious cerebral control. If this sphincter is relaxed voluntarily, feces are expelled. On the other hand, increased contraction of the external anal sphincter prevents defecation. The defecation reflex persists for only a few minutes and quickly declines. Generally, the reflex is reinitiated after a period that may be as long as several hours. Mass movements in the colon are usually the reason for reinitiation of the defecation reflex.

The internal and external **anal sphincters** prevent defecation. Resting sphincter pressure results from tonic muscle contractions, mostly of the internal anal sphincter. In response to increased abdominal pressure, reflexes mediated through the spinal cord cause contractions of the external anal sphincter. Thus, the untimely expulsion of feces during coughing or exertion is avoided.

Defecation can be initiated by voluntary actions that stimulate a defecation reflex. This “straining” includes a large inspiration of air, followed by closure of the larynx and forceful contraction of the abdominal muscles. As a consequence, the pressure in the abdominal cavity increases and forces feces into the rectum. Stretch of the rectum initiates a defecation reflex, and input from the brain overrides the reflexive contraction of the external anal sphincter stimulated by increased abdominal pressure. The increased abdominal pressure also helps push feces through the rectum.

ASSESS YOUR PROGRESS

53. Describe the parts of the large intestine. What are *teniae coli*, *haustra*, and *crypts*?
54. Explain the difference in structure between the internal anal sphincter and the external anal sphincter.
55. Name the substances secreted and absorbed in the large intestine.
56. What is the role of microorganisms in the colon?
57. What kinds of movements occur in the colon? Describe the defecation reflex.

- Distension of the stomach and chyme in the duodenum can stimulate the gastrocolic and duodenocolic reflexes (green arrows).
- Mass movements occur in the colon, which propel the contents toward the rectum (orange arrow).
- Distension of the rectum by feces stimulates local defecation reflexes that cause contractions of the colon and rectum (brown arrow), which move feces toward the anus.
- Local reflexes cause relaxation of the internal anal sphincter (brown arrow).
- Distension of the rectum by feces stimulates parasympathetic reflexes. Action potentials are propagated to the defecation reflex center located in the spinal cord (yellow arrow).
- Action potentials stimulate contraction of the colon and rectum and relaxation of the internal anal sphincter (purple arrows).
- Action potentials are propagated through ascending nerve tracts to the brain (blue arrow).
- Descending nerve tracts from the brain regulate the defecation reflex center (pink arrow).
- Action potentials from the brain control the external anal sphincter (purple arrow).

PROCESS FIGURE 24.27 Control of Defecation

24.14 Digestion and Absorption

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the chemical digestion and absorption of carbohydrates, lipids, and proteins.
- Explain the transport of water and ions through the intestinal wall.

Digestion is the breakdown of food to molecules small enough to be absorbed into the blood. **Mechanical digestion** breaks large food particles into smaller ones. **Chemical digestion** is the breaking of covalent chemical bonds in organic molecules by digestive enzymes. Carbohydrates break down into monosaccharides, lipids break down into fatty acids and monoglycerides, and proteins break down into amino acids. However, some molecules (e.g., vitamins, minerals, and water) are not broken down. A relatively small amount of digestion begins in the oral cavity and some occurs in the stomach, but the vast majority of digestion occurs in

the proximal end of the small intestine, especially in the duodenum.

Absorption is the means by which molecules are moved out of the digestive tract into the blood for distribution throughout the body. Nearly all absorption of nutrients occurs in the duodenum and jejunum of the small intestine. Some absorption also occurs in the ileum. A few chemicals, such as nitroglycerin, can be absorbed through the thin mucosa of the oral cavity below the tongue. Some small molecules (e.g., alcohol and aspirin) can diffuse through the stomach epithelium into the blood.

Some molecules can be absorbed by diffusion, whereas others must be transported across the intestinal wall. Transport requires transport proteins, which work by facilitated diffusion, active-transport, or secondary-transport mechanisms, such as symport and antiport. The epithelial cells that form the intestinal wall have two distinct sides with different transport proteins on each side. The side that faces the digestive tract lumen is called the **apical membrane**, and the side that faces the blood vessels is called the **basolateral membrane**. The transport proteins in these membranes are responsible for the one-way movement of molecules from the digestive tract to the rest of the body.

Once the digestive products have been absorbed, they are transported to other parts of the body by two routes. Water, ions, and water-soluble digestion products, such as glucose and amino acids, enter the hepatic portal system and travel to the liver. The products of lipid metabolism are coated with proteins and transported into lymphatic capillaries called lacteals (see figure 24.16c,d). The lacteals are connected by lymphatic vessels to the thoracic duct (see chapter 22), which empties into the left subclavian vein. The protein-coated lipid products then travel in the blood to adipose tissue or to the liver.

Carbohydrates

Ingested **carbohydrates** consist primarily of polysaccharides, such as starches; disaccharides, such as sucrose (table sugar) and lactose (milk sugar); and monosaccharides, such as glucose and fructose (the sugar found in many fruits).

During digestion, polysaccharides break down first into smaller chains and some disaccharides and monosaccharides. Disaccharides then break down into monosaccharides. A minor amount of carbohydrate digestion begins in the oral cavity with the partial digestion of starches by **salivary amylase** (am'il-ās). Digestion continues in the stomach until the food is well mixed with acid, which inactivates salivary amylase. Carbohydrate

digestion is resumed in the small intestine by **pancreatic amylase** (figure 24.28). Finally, a series of **disaccharidases** that are bound to the microvilli of the intestinal epithelium digest disaccharides into monosaccharides. The major monosaccharide is glucose.

The monosaccharides glucose and galactose are taken up into intestinal epithelial cells by symport, powered by a Na^+ gradient (figure 24.29). The Na^+ gradient is generated by the **sodium-potassium pump** located on the basolateral membrane. Diffusion of Na^+ down its concentration gradient provides the energy to transport glucose or galactose across the plasma membrane. In contrast to glucose and galactose, the monosaccharide fructose is taken up by facilitated diffusion. Once inside the intestinal epithelial cell, monosaccharides are transported by facilitated diffusion to the capillaries of the intestinal villi and carried by the hepatic portal system to the liver, where the nonglucose sugars are converted to glucose. Glucose enters the cells through facilitated diffusion. The rate of glucose transport into most types of cells is greatly influenced by **insulin** and may increase 10-fold in its presence (see chapter 18).

Lipids

Lipids are molecules that are insoluble or only slightly soluble in water. They include triglycerides, phospholipids, cholesterol, steroids, and fat-soluble vitamins. **Triglycerides** (trī-glis'er-īdz) are the most common type of lipid and are often referred to as fats. They consist of three fatty acids bound to glycerol.

Lipase (lip'ās) digests lipid molecules (see figure 24.28). The vast majority of lipase is secreted by the pancreas and is referred to as **pancreatic lipase**. A minor amount of **lingual lipase**, which is secreted in the oral cavity and swallowed with food, digests a small amount (<10%) of lipid in the stomach. The stomach also produces very small amounts of **gastric lipase**. The primary products of lipase digestion are free fatty acids and monoglycerides.

However, the lipases alone cannot efficiently digest lipids. A key step in lipid digestion is **emulsification** (ē-mūl'si-fi-kā'shūn), by which bile salts transform large lipid droplets into much smaller droplets. Bile salts mix with lipids and act as detergents to disrupt lipid droplets. By decreasing the droplet size, emulsification increases the surface area of the lipid exposed to lipases and other digestive enzymes. This is necessary because the lipases are water-soluble and can digest lipids only at the surface of the droplets. The bile salts are secreted by the liver and stored in the gallbladder until needed in the duodenum.

Once lipids are digested in the intestine, bile salts aggregate around the small droplets. Lipid droplets surrounded by bile salts are called **micelles** (mī-selz'; small morsels; figure 24.30). The hydrophobic ends of the bile salts are directed toward the free fatty acids, cholesterol, and monoglycerides at the center of the micelle; the hydrophilic ends are directed outward toward the water environment. When a micelle comes in contact with the epithelial cells of the small intestine, the lipid contents of the micelle pass by simple diffusion through the plasma membrane of the epithelial cells. The bile salts are not absorbed until they reach the epithelium of the distal ileum.

Case STUDY

Spinal Cord Injury and Defecation

Dan, a 17-year-old male, was driving home late at night after a ski trip when he missed a sharp curve and crashed. He suffered traumatic injury at the T11 level of the spinal cord, with complete paralysis of both lower limbs. As a result, Dan became incontinent and unable to control his bowel movements.

Approximately 10,000 new spinal cord injuries occur per year in the United States. About 80% of those injuries involve men, usually in their late teens or twenties. The most common cause is motor vehicle accidents, followed by violence, falls, and sports.

Loss of the ability to control defecation affects the quality of life of most spinal cord injury patients, at least temporarily. The spinal cord is required for a normal defecation reflex and for voluntary control of the external anal sphincter (figure 24.27). In terms of their effect on defecation, spinal cord injuries can be divided into two groups: injuries that occur above the conus medullaris and those that damage the conus medullaris where the defecation reflex center is located. Immediately following a spinal cord injury, loss of reflexes below the level of the injury, called **spinal shock**, occurs. However, the reflexes usually become functional again, and the defecation reflex may be depressed for a few weeks but eventually returns.

➤ Predict 8

Explain how an enema involving the injection of fluid into the rectum can stimulate defecation.

Clinical IMPACT

Lactose Intolerance

Lactose intolerance is the inability to digest the lactose in milk and other dairy products. Adults in most of the world are lactose intolerant, although infants are not. Why can infants digest milk, whereas their parents cannot? The reason is that many adults lack the enzyme lactase. Lactase, present on the surface of absorptive cells in the intestinal mucosa, digests the disaccharide lactose down to two monosaccharides. Lactase is made at birth but is no longer synthesized after about age 6 in 5–15% of Europeans and 80–90% of Africans and Asians. Therefore, these people can no longer digest lactose. The major exceptions are

people of northern European ancestry and some pastoral nomadic tribes in Africa and the Middle East. In these populations, a mutation in the promoter (see chapter 3) of the lactase gene permits the continued expression of lactase into adulthood. Normally, lactase production stops because the promoter is “turned off” as the infant ages, but the mutation allows the promoter to ignore this developmental switch.

Researchers believe that the dietary reliance on milk and milk products in some societies provided a selective advantage for lactase persistence. In the United States, most people are lactose tolerant, but intolerance is still one

of the most common digestive tract disorders seen by primary care physicians. The main symptom of lactose intolerance is diarrhea due to fluid loss as water follows lactose through the digestive tract. In addition, a considerable amount of gas is generated from lactose metabolism by bacteria in the large intestine. Even though these colonic bacteria metabolize lactose to monosaccharides, it is too late for the monosaccharides to be absorbed. Gene therapy has proven successful in animal models of lactose intolerance, although at present the best treatment is simply to avoid foods containing lactose.

Lipid Transport

Within the smooth endoplasmic reticulum of the intestinal epithelial cells, free fatty acids are combined with monoglyceride molecules to form triglycerides. Proteins synthesized in the epithelial cells attach to droplets of triglycerides, phospholipids, and cholesterol. These aggregates are called **chylomicrons** (kī-lō-mi'kronz). Chylomicrons contain about 90% triglyceride, 5% cholesterol, 4% phospholipid, and 1% protein (figure 24.31).

The chylomicrons leave the epithelial cells and enter the lacteals of the lymphatic system within the villi. Chylomicrons enter the lymphatic capillaries rather than the blood capillaries because the lymphatic capillaries lack a basement membrane and are more permeable to large particles, such as chylomicrons, which are about 0.3 mm in diameter. They travel through the lymphatic system via the thoracic duct to the bloodstream and then by the blood to adipose tissue. Before entering the adipose cells, triglycerides break back down into fatty acids and glycerol, which enter the adipocytes and are once more converted to triglycerides. Triglycerides are stored in adipose tissue until an energy source is needed elsewhere in the body. In the liver, the chylomicron lipids are stored, converted into other molecules, or used as energy. The chylomicron remnant, minus the triglyceride, is conveyed through the blood to the liver, where it breaks up.

Because lipids are either insoluble or only slightly soluble in water, they are transported through the blood in combination with proteins, which are water-soluble. Lipids combined with proteins are called **lipoproteins** and are categorized as high- or low-density (figure 24.31). *Density* describes the compactness of a substance and is the ratio of mass to volume. Lipids are less dense than water and tend to float in water. Proteins, which are denser than water, tend to sink in water. A lipoprotein with a high lipid content has a very low density, whereas a lipoprotein with a high protein content has a relatively high density. Chylomicrons, which are made up of

99% lipid and only 1% protein, are lipoproteins with an extremely low density. The other major transport lipoproteins are **very low-density lipoprotein (VLDL)**, which is 92% lipid and 8% protein; **low-density lipoprotein (LDL)**, which is 75% lipid and 25% protein; and **high-density lipoprotein (HDL)**, which is 55% lipid and 45% protein (figure 24.31).

Clinical IMPACT

Rehydration

What do an endurance sport athlete and a person with severe diarrhea have in common? Both share the risk for dehydration from excessive water loss. An effective rehydration strategy for both situations is to drink water containing sodium and glucose. As sodium and glucose are absorbed by symport across the intestinal epithelium, water follows by osmosis. As an added value, this strategy also replaces ions and provides an immediate energy source.

Most sports drinks contain sodium and glucose, which efficiently rehydrate the athlete. The same principle is used in oral rehydration therapy for severe diarrhea. The World Health Organization estimates that millions of people in third world countries die every year from severe diarrhea caused by intestinal infections. Drinking a sodium and glucose solution is often sufficient to prevent dehydration until the infection clears. Since oral rehydration therapy was adopted as a main strategy for treating diarrhea, the annual number of deaths of children under 5 dropped worldwide from over 4 million in 1980 to about 1.5 million in 2000. Unfortunately, this simple, cheap treatment and the clean water it requires are unavailable in many areas of exploding populations and poor sanitary conditions.

FIGURE 24.28 Digestion of the Three Major Food Types

The enzymes involved in digesting carbohydrates, lipids, and proteins are depicted in relation to the region of the digestive tract where each functions. **APR**

About 15% of the cholesterol in the body is ingested in the food we eat. Eating foods containing saturated fatty acids can raise plasma cholesterol levels by stimulating LDL production and inhibiting LDL receptor production. Conversely, ingesting unsaturated fatty acids lowers plasma cholesterol. Replacing fats with carbohydrates in the diet can also reduce blood cholesterol. The remaining 85% is manufactured in body cells, mostly in the liver and intestinal mucosa. Most of the cholesterol and other lipids taken into or manufactured in the liver leave the liver in the form of VLDL. Most of the triglycerides are removed from the VLDL to be stored in adipose tissue; as a result, VLDL becomes LDL.

The cholesterol in LDL is critical for the production of steroid hormones and bile salts in the liver. It is also an important component of plasma membranes. Abnormally low cholesterol levels may lead to weakened blood vessel walls and an increased risk for cerebral hemorrhage.

LDL is delivered to cells of various tissues through the blood. Cells have **LDL receptors** in “pits” on their surfaces, which bind the LDL. Once LDL is bound to the receptors, the pits on the cell surface become endocytotic vesicles, and the cell takes in LDL by receptor-mediated endocytosis (figure 24.32). For example, each fibroblast has 20,000–50,000 LDL receptors on the surface. However, those receptors are confined to cell surface pits, which

Monosaccharide (glucose) transport

- 1 Glucose is absorbed by symport with Na^+ into intestinal epithelial cells.
- 2 Symport is driven by a sodium gradient established by a Na^+-K^+ pump.
- 3 Glucose moves out of the intestinal epithelial cells by facilitated diffusion.
- 4 Glucose enters the capillaries of the intestinal villi and is carried through the hepatic portal vein to the liver.

PROCESS FIGURE 24.29 Transport of Glucose Across the Intestinal Epithelium

occupy only 2% of the cell surface. Once inside the cell, the endocytotic vesicle combines with a lysosome, and the LDL components are separated for use in the cell.

Cells not only take in cholesterol and other lipids from LDLs but also make their own cholesterol. When the combined intake and manufacture of cholesterol exceeds a cell's needs, a negative-feedback system reduces the amount of LDL receptors and

cholesterol manufactured by the cell. Excess lipids are also packaged into HDLs by the cells. These are transported back to the liver for recycling or excretion in bile.

LDL is commonly considered “bad” because, when in excess, it deposits cholesterol in arterial walls. On the other hand, HDL is considered “good” because it transports cholesterol from the tissues via blood to the liver for removal from the body in the bile.

Lipid transport

- 1 Bile salts surround fatty acids and monoglycerides to form micelles.
- 2 Micelles attach to the plasma membranes of intestinal epithelial cells, and the fatty acids and monoglycerides pass by simple diffusion into the intestinal epithelial cells.
- 3 Within the intestinal epithelial cell, the fatty acids and monoglycerides are converted to triglycerides; proteins coat the triglycerides to form chylomicrons, which move out of the intestinal epithelial cells by exocytosis.
- 4 The chylomicrons enter the lacteals of the intestinal villi and are carried through the lymphatic system to the general circulation.

Clinical IMPACT

Cystic Fibrosis

Cystic fibrosis is a hereditary disorder that occurs in 1 of every 2000 births and affects 33,000 people in the United States; it is the most common lethal genetic disorder among Caucasians. The most critical effects of the disease, accounting for 90% of the deaths, are on the respiratory system. Several other problems occur, however, in affected people. Because the disease is a disorder in a Cl^- transport channel protein—which affects chloride transport and, as a result, the movement of water—all exocrine glands are affected. The buildup of thick mucus in the pancreatic and hepatic ducts causes blockage of the ducts, so that bile salts and pancreatic digestive enzymes are prevented from reaching the duodenum. As a result, digestion is reduced, and fat-soluble vitamins are poorly absorbed due to the lack of bile to form micelles. The person suffers from vitamin A, D, E, and K deficiencies, which result in conditions such as night blindness, skin disorders, rickets, and excessive bleeding. Therapy includes administering the missing vitamins to the person and reducing dietary fat intake.

A high HDL/LDL ratio in the blood is related to a lower risk for heart disease. Low HDL levels are linked to obesity, and weight reduction increases HDL levels. Aerobic exercise can decrease LDL levels and increase HDL levels.

Proteins

Proteins are taken into the body from a number of dietary sources. Digestion of proteins begins in the stomach. **Pepsin** secreted by the stomach catalyzes the cleavage of covalent bonds in proteins to produce smaller polypeptide chains. Pepsin digests as much as 10–20% of the total ingested protein. Once the proteins and polypeptide chains leave the stomach, **pancreatic proteases**, including trypsin, chymotrypsin, and carboxypeptidase, continue the digestive process to produce small peptide chains (see figure 24.28). These are finally broken down into tripeptides, dipeptides, and amino

Clinical GENETICS

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is a common genetic disorder in Europe and North America that affects 1 out of 500 people. The clinical sign of the disease is increased blood levels of LDL cholesterol. The elevated cholesterol levels accelerate the development of atherosclerosis, which often leads to coronary artery disease and heart attacks among people in their forties and fifties. Another common feature of FH is the presence of **xanthomas** (zan-thō'mās), which are nodules of cholesterol and other lipids just under the skin, especially at joints.

FH is caused by mutations in the LDL receptor gene that result in defective LDL receptors. The LDL receptor normally removes cholesterol from the blood by transporting LDL cholesterol into cells. Once inside the

cell, LDL cholesterol is metabolized, and cholesterol synthesis is inhibited by a negative-feedback mechanism. When less LDL cholesterol is transported into cells, blood LDL cholesterol rises for two reasons: (1) The normal removal of LDL cholesterol does not occur, and (2) there is less inhibition of cholesterol synthesis. The usual treatment for FH is statin drugs, which lower blood LDL levels by inhibiting the synthesis of cholesterol.

FH is an example of an incomplete dominance disorder, in which the dominant allele does not completely mask the effects of the recessive allele in the heterozygote (see chapter 29). The severity of FH depends on whether a person is homozygous dominant, heterozygous, or homozygous recessive. Homozygous dominant individuals have two mutant alleles and

completely lack LDL receptors. These patients have the most severe form of FH. Their blood LDL cholesterol levels are very high, and they often have heart attacks in their teens. Most FH patients are heterozygous, with one normal and one mutant allele. These patients have half the number of normal LDL receptors and are at increased risk for heart attacks at midlife. Homozygous recessive individuals have two normal LDL receptor alleles and a normal number of receptors. Although genetic testing is not yet standard, automated assays are available for the more common mutations in the LDL receptor, and they can allow early diagnosis and treatment before life-threatening symptoms develop. In the future, FH will be an excellent candidate for gene therapy because it is a severe but well-studied single-gene defect.

acids by **peptidases** bound to the microvilli of the small intestine. Each peptidase is specific for a certain peptide chain length or for a certain amino acid sequence.

Basic, acidic, and neutral amino acids are transported into the epithelial cells by separate carrier molecules. Acidic and most neutral amino acids enter by symport with a Na^+ gradient (figure 24.33), similar to the mechanism used for glucose transport. Basic amino acids enter the epithelial cells by facilitated diffusion. Dipeptides and tripeptides enter intestinal epithelial cells by a H^+ symport mechanism analogous to Na^+ symport. The total amount of each amino acid that enters the intestinal epithelial cells as dipeptides or tripeptides is considerably more than the amount that enters as single amino acids. Once inside the cells, dipeptidases and tripeptidases split the dipeptides and tripeptides into their component amino acids. Individual amino acids then leave the epithelial cells and enter the hepatic portal system, which transports them to the liver (figure 24.33). The amino acids may be modified in the liver or released into the bloodstream and distributed throughout the body.

Amino acids are actively transported into the various cells of the body. This transport is stimulated by growth hormone and insulin. Most amino acids serve as building blocks to form new proteins (see chapter 2), but some amino acids may be used for energy.

Water

About 9 L of **water** enter the digestive tract each day as a combination of ingested and secreted fluids. Of this 9 L, about 92% is absorbed in the small intestine, and another 6–7% is absorbed in the large intestine (figure 24.34). Water moves in either direction across the wall of the small intestine by osmosis. Osmotic gradients across the epithelium determine the direction of this diffusion. When the chyme is dilute, water is absorbed by osmosis across the intestinal wall into the blood. When the chyme is very concentrated and

contains very little water, water moves by osmosis into the lumen of the small intestine. As nutrients are absorbed in the small intestine, its osmotic pressure decreases; as a consequence, water moves from the small intestine into the surrounding extracellular fluid. Water in the extracellular fluid can then enter the blood. Because of the osmotic gradient produced as nutrients are absorbed in the small intestine, nearly all the water that enters the small intestine by way of the oral cavity, stomach, or intestinal secretions is reabsorbed.

Ions

Ions are predominantly absorbed by active transport in the small intestine. Active transport mechanisms drive the absorption of **sodium, potassium, calcium, magnesium, and phosphate**. **Chloride** ions move passively through the intestinal wall of the duodenum and the jejunum following the positively charged sodium ions, but chloride ions are actively transported from the ileum. Although calcium ions are actively transported along the entire length of the small intestine, vitamin D is required for that transport process. The absorption of calcium is under hormonal control, as are its excretion and storage. Parathyroid hormones, calcitonin, and vitamin D all play a role in regulating blood levels of calcium (see chapters 6, 18, and 27).

ASSESS YOUR PROGRESS

58. Describe the mechanism of absorption and the route of transport for water-soluble and lipid-soluble molecules.
59. Describe the enzymatic digestion of carbohydrates, lipids, and proteins. List where each step of digestion occurs and the breakdown products of each step.
60. Explain how lipids are emulsified. Describe the role of micelles, chylomicrons, VLDLs, LDLs, and HDLs in the absorption and transport of lipids in the body.

Amino acid transport

- 1 Acidic and most neutral amino acids are absorbed by symport into intestinal epithelial cells.
- 2 Symport is driven by a sodium gradient established by a $\text{Na}^+ - \text{K}^+$ pump.
- 3 Amino acids move out of intestinal epithelial cells.
- 4 Amino acids enter the capillaries of the intestinal villi and are carried through the hepatic portal vein to the liver.

62. Describe the movement of water through the intestinal wall.
63. When and where are various ions absorbed?

24.15 Effects of Aging on the Digestive System

LEARNING OUTCOME

After reading this section, you should be able to

- A. Discuss the effects of aging on the digestive system.**

As a person ages, gradual changes occur throughout the digestive tract. The connective tissue layers of the digestive tract—the submucosa and serosa—tend to thin. The blood supply to the digestive tract decreases. The number of smooth muscle cells in the muscularis also decreases, resulting in reduced motility in the digestive tract. In addition, goblet cells within the mucosa secrete less mucus. Glands along the digestive tract, such as the gastric glands, the liver, and the pancreas, also tend to secrete less with age. However, these changes by themselves do not appreciably decrease the function of the digestive system.

Through the years, the digestive tract, like the skin and lungs, is directly exposed to materials from the outside environment. Some of those substances can cause mechanical damage to the digestive tract, and others are toxic to the tissues. Because the connective tissue of the digestive tract becomes thin with age and because the protective mucous covering is reduced, an elderly person's digestive tract becomes less and less protected from these outside influences. In addition, the mucosa of elderly people tends to heal more slowly following injury. Declines also occur in the liver's ability to detoxify certain chemicals, the hepatic phagocytic cells' ability to remove

Systems PATHOLOGY

Diarrhea

Background Information

Diarrhea is one of the most common complaints in clinical medicine. Diarrhea affects more than half the tourists in developing countries (figure 24A), where it may result from eating food to which the digestive tract is not accustomed or from ingesting food or water contaminated with microorganisms.

Diarrhea is any change in bowel habits involving increased stool frequency or fluidity. It is not a disease in itself, but it can be a symptom of a wide variety of disorders. Diarrhea that lasts less than 2–3 weeks is acute diarrhea; diarrhea lasting longer is considered chronic. Acute diarrhea is usually self-limiting, but some forms of diarrhea can be fatal if not treated. Diarrhea results from either a decrease in fluid absorption in the intestine or an increase in fluid secretion. It can also be caused by increased bowel motor activity that moves chyme rapidly through the small intestine, so that more water enters the colon. Normally, about 600 mL of fluid enter the colon each day, and all but 150 mL are reabsorbed. The loss of more than 200 mL of fluid per day in the stool is considered abnormal.

Mucus secretion by the colon increases dramatically in response to diarrhea. This mucus contains large quantities of bicarbonate ions, which come from dissociation of carbonic acid into bicarbonate ions and hydrogen ions within the blood supply to the colon. The bicarbonate ions enter the mucus secreted by the colon, whereas the hydrogen ions remain in the circulation; as a result, the blood pH decreases. Thus, a condition called metabolic acidosis can develop (see chapter 27).

Diarrhea is usually caused by bacteria, viruses, amoebic parasites, or chemical toxins. Symptoms can begin from as little as 1–2 hours after bacterial toxins are ingested to as long as 24 hours or more for some strains of bacteria. Nearly any bacterial species is capable of causing diarrhea. Some types of bacterial diarrhea are associated with severe vomiting, whereas others

are not. Some bacterial toxins also induce fever. Identifying the causal organism usually requires laboratory analysis of the food or stool but, in cases of acute diarrhea, the infectious agent is seldom identified.

Treatment of diarrhea involves replacing lost fluids and ions. The diet should be limited to clear fluids during at least the first day or so.

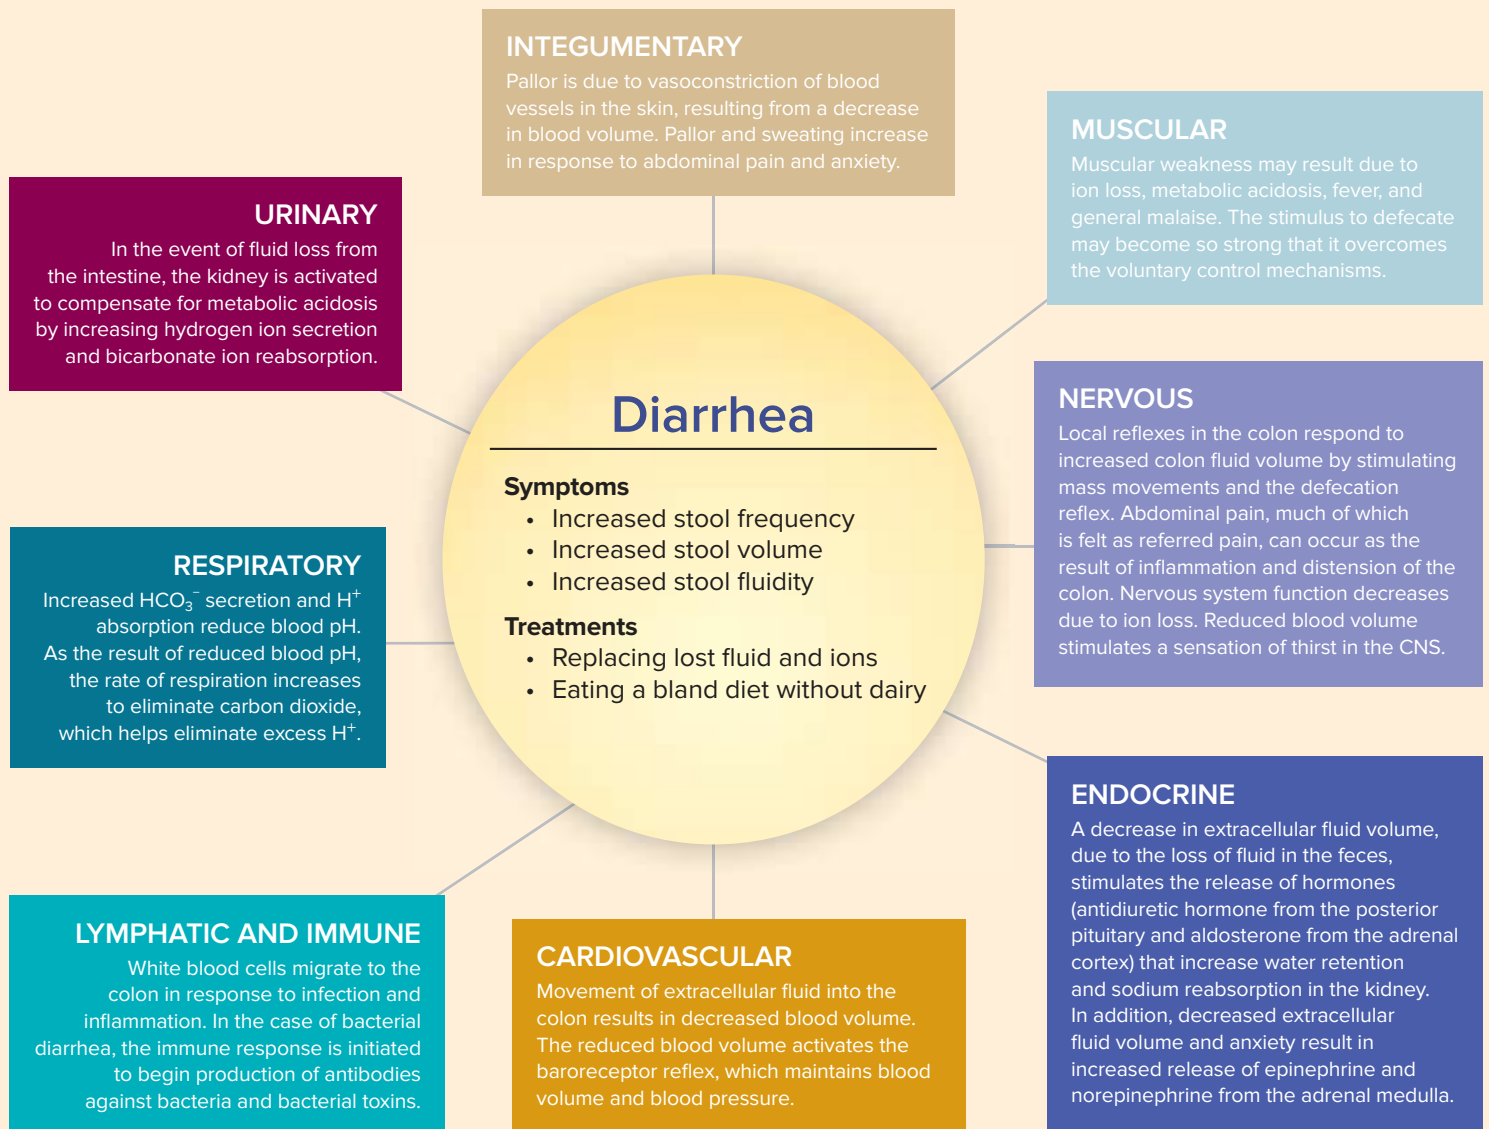

Figure 24A

particulate contaminants, and the liver's ability to store glycogen. These problems worsen in people who smoke.

The overall decline in the defenses of the digestive tract leaves elderly people more susceptible to infections and toxic agents. Elderly people are therefore more likely to develop ulcerations and cancers of the digestive tract. Colorectal cancers, for example, are the second leading cause of cancer deaths in the United States, with an estimated 135,000 new cases and 57,000 deaths each year.

Gastroesophageal reflux disorder increases with advancing age. It is probably the main reason that elderly people take antacids, H_2 antagonists, and proton pump inhibitors. Disorders that are not necessarily age-induced, such as hiatal hernia and irregular or inadequate esophageal motility, can be worsened by the effects of aging because of general decreased motility in the digestive tract.

The enamel on the surface of elderly people's teeth becomes thinner with age and may expose the underlying dentin. In addition,

Medicines that may help combat diarrhea include bismuth subsalicylate (süb-sä-lis'i-lät), which increases mucus and HCO_3^- secretion and decreases pepsin activity, and loperamide (lō-per'ä-mīd), which slows intestinal motility. Patients should avoid milk and milk products. Breads, rice, and baked fish or chicken can be added to the diet as the person's condition improves. A normal diet can be resumed after 2–3 days.

➤ Predict 9

Predict the effects of prolonged diarrhea.

the gingiva covering the tooth root recedes, exposing additional dentin. Exposed dentin may become painful and change the person's eating habits. Many elderly people also lose teeth, which can have a marked effect on eating habits unless they are fitted with artificial teeth. The muscles of mastication tend to become weaker; as a result, older people tend to chew their food less before swallowing.

Another age-related complication in the digestive system involves the way medications and other chemicals are absorbed

from the digestive tract. The decreased mucous covering and the thinned connective tissue layers allow chemicals to pass more readily from the digestive tract into the blood. However, a decline in the blood supply to the digestive tract hinders the absorption of such chemicals. Drugs administered to treat cancer, which occurs in many elderly people, may irritate the mucosa of the digestive tract, resulting in nausea and loss of appetite.

Diseases and Disorders

TABLE 24.4 Digestive System

Condition	Description
Stomach	
Vomiting	Contraction of the diaphragm and abdominal muscles and relaxation of the esophageal sphincters to forcefully expel gastric contents; vomiting reflex is initiated by irritation of the stomach or small intestine
Peptic ulcer	Lesions in the lining of the stomach or duodenum, usually due to infection by the bacterium <i>Helicobacter pylori</i> ; stress, diet, smoking, or alcohol may be a predisposing factor; antibiotic therapy is the accepted treatment
Liver	
Cirrhosis (sir-ō'sis)	Characterized by damage and death of hepatic cells and replacement by connective tissue; results in loss of normal liver function and interference with blood flow through the liver; a common consequence of alcoholism
Hepatitis (hep-ă-ti'tis)	Inflammation of the liver that causes liver cell death and replacement by scar tissue; if not corrected, results in loss of liver function and eventually death; symptoms include nausea, abdominal pain, fever, chills, malaise, and jaundice; caused by any of seven distinct viruses
Hepatitis A	Infectious hepatitis; usually transmitted by poor sanitation practices or from mollusks living in contaminated waters
Hepatitis B	Serum hepatitis; usually transmitted through blood or other body fluids through either sexual contact or contaminated hypodermic needles
Hepatitis C	Often a chronic disease leading to cirrhosis and possibly cancer of the liver
Gallstones	Most often due to excess cholesterol in the bile; gallstones can enter the cystic duct, where they block the release of bile and/or pancreatic enzymes, which interferes with digestion
Intestine	
Inflammatory bowel disease (IBD)	Localized inflammatory degeneration that may occur anywhere along the digestive tract but most commonly involves the distal ileum and proximal colon; the intestinal wall often becomes thickened, constricting the lumen, with ulcers and fissures in the damaged areas; symptoms include diarrhea, abdominal pain, fever, fatigue, and weight loss; cause is unknown; treatments involve anti-inflammatory drugs, avoidance of foods that produce symptoms, and surgery in some cases; also called Crohn disease or ulcerative colitis
Irritable bowel syndrome (IBS)	Disorder of unknown cause marked by alternating bouts of constipation and diarrhea; may be linked to stress or depression; high familial incidence
Gluten enteropathy (celiac disease)	Malabsorption in the small intestine due to the effects of gluten, a protein in certain grains, especially wheat; the reaction can destroy newly formed epithelial cells, causing the intestinal villi to become blunted and decreasing the intestinal surface, which reduces absorption of nutrients
Constipation (kon-sti-pā'shūn)	Slow movement of feces through the large intestine, causing the feces to become dry and hard because of increased fluid absorption while being retained; often results from inhibiting normal defecation reflexes; spasms of the sigmoid colon resulting from irritation can also result in slow feces movement and constipation; high-fiber diet can be preventive
Infections of the Digestive Tract	
Food poisoning	Caused by ingesting bacteria or toxins, such as <i>Staphylococcus aureus</i> , <i>Salmonella</i> , or <i>Escherichia coli</i> ; symptoms include nausea, abdominal pain, vomiting, and diarrhea; in severe cases, death can occur
Typhoid (ti'foid) fever	Caused by a virulent strain of the bacterium <i>Salmonella typhi</i> , which can cross the intestinal wall and invade other tissues; symptoms include severe fever, headaches, and diarrhea; usually transmitted through poor sanitation practices; leading cause of death in many developing countries
Cholera (kol'er-a)	Caused by a bacterium, <i>Vibrio cholerae</i> , in contaminated water; bacteria produce a toxin that stimulates the secretion of chloride, bicarbonate, and water into the large intestine, resulting in severe diarrhea; the loss of as much as 12–20 L of fluid per day causes shock and even death; still a major health problem in parts of Asia
Giardiasis (jē-ar-dī'a-sis)	Caused by a protozoan, <i>Giardia lamblia</i> , invading the large intestine; symptoms include nausea, abdominal cramps, weakness, weight loss, and malaise; the protozoans are transmitted in the feces of humans and other animals, often by drinking from contaminated wilderness streams
Intestinal parasites	Common under conditions of poor sanitation; parasites include tapeworms, pinworms, hookworms, and roundworms
Diarrhea (dī-ă-rē'ă)	Intestinal mucosa secretes large amounts of water and ions due to irritation, inflammation, or infection; diarrhea moves feces out of the large intestine more rapidly and speeds recovery
Dysentery (dis'en-tār-ē)	Severe form of diarrhea with blood or mucus in the feces; can be caused by bacteria, protozoa, or amoebae

ASSESS YOUR PROGRESS

64. List the effects of aging on the digestive system.
65. What are the effects of the overall decline in the defenses of the digestive tract with advancing age?

66. Explain why absorption of medication is a problem with aging.

Learn to Predict From page 869

In this chapter we learned that the gallbladder stores bile, a secretion of the liver that neutralizes stomach acids and emulsifies lipids. We also learned that gallstones may form when there is an abundance of cholesterol in the bile, such as from a high-cholesterol diet. Gallstones can block the cystic duct, blocking the flow of bile from the gallbladder to the duodenum. Eating food high in fat causes gallbladder contractions. Specifically, gallbladder contraction is stimulated hormonally by cholecystokinin from the duodenum and parasympathetic stimulation. If Rebecca's cystic duct were blocked by gallstones, the increased pressure in the contracting gallbladder would result in pain and inflammation.

But why did Rebecca's skin turn yellow? Recall that bile contains bilirubin, a yellow pigment produced from the breakdown of hemoglobin that when further processed in the intestine turns

brown and contributes to the normal color of feces. The gallstones blocked Rebecca's common bile duct, preventing bile from passing from the liver to the duodenum and reducing the amount of bilirubin removed from the blood. Rebecca's skin turned yellow due to the accumulation of bile pigments in the blood. Also, the reduced volume of bile entering the duodenum resulted in poor emulsification of lipids. The lipids remained in the small intestine, causing distension of the intestine, and the undigested lipids passing through the small and large intestine were responsible for the diarrhea. The lack of bilirubin resulted in the clay-colored feces.

Answers to the rest of this chapter's Predict questions are in appendix G.

Answer

24.1 Anatomy of the Digestive System (p. 870)

1. The digestive system consists of a digestive tube and its associated accessory organs.
2. The digestive system includes the oral cavity, pharynx, esophagus, stomach, small intestine, large intestine, and anus.
3. Accessory organs, such as the salivary glands, liver, gallbladder, and pancreas, are located along the digestive tract.

24.2 Functions of the Digestive System (p. 870)

The functions of the digestive system are ingestion, mastication, propulsion, mixing, secretion, digestion, absorption, and elimination.

24.3 Histology of the Digestive Tract (p. 872)

The digestive tract is composed of four tunics: mucosa, submucosa, muscularis, and serosa or adventitia.

Mucosa

1. The mucosa consists of a mucous epithelium, a lamina propria, and a muscularis mucosae.
2. The epithelium extends into the lamina propria to form intestinal glands.

Submucosa

The submucosa is a connective tissue layer containing the submucosal plexus, blood vessels, and small glands.

Muscularis

1. The muscularis consists of an inner layer of circular smooth muscle and an outer layer of longitudinal smooth muscle.
2. The myenteric plexus is between the two muscle layers.
3. Interstitial pacemaker cells are located throughout the myenteric plexus.

Serosa or Adventitia

The serosa or adventitia forms the outermost layer of the digestive tract.

24.4 Regulation of the Digestive System (p. 874)

Nervous, hormonal, and local chemical mechanisms regulate digestion.

Nervous Regulation of the Digestive System

Nervous regulation involves the ENS and CNS reflexes.

Chemical Regulation of the Digestive System

1. Over 30 neurotransmitters are associated with the ENS.
2. The digestive tract produces hormones that regulate digestion.
3. Other chemicals produced by the digestive tract exercise local control of digestion.

24.5 Peritoneum (p. 875)

1. The peritoneum is a serous membrane that lines the abdominal cavity and organs.

Summary

2. Mesenteries are peritoneum that extends from the body wall to many of the abdominal organs.
3. Retroperitoneal organs are located behind the peritoneum.

24.6 Oral Cavity (p. 877)

The oral cavity includes the vestibule and the oral cavity proper.

Lips, Cheeks, and Palate

1. The lips and cheeks are involved in facial expression, mastication, and speech.
2. The roof of the oral cavity is divided into the hard and soft palates.
3. The palatine tonsils are located in the lateral wall of the fauces.

Tongue

1. The tongue is involved in speech, taste, mastication, and swallowing.
2. The intrinsic tongue muscles change the shape of the tongue, and the extrinsic tongue muscles move the tongue.
3. The anterior two-thirds of the tongue is covered with papillae; the posterior one-third is devoid of papillae.

Teeth

1. Twenty deciduous teeth are replaced by 32 permanent teeth.
2. The types of teeth are incisors, canines, premolars, and molars.
3. A tooth consists of a crown, a neck, and a root.
4. The root is composed of dentin. Within the dentin of the root is the pulp cavity, which is filled with pulp, blood vessels, and nerves. The crown is dentin covered by enamel.
5. Periodontal ligaments hold the teeth in the alveoli.

Mastication

The muscles of mastication are the temporalis, masseter, medial pterygoid, and lateral pterygoid.

Salivary Glands

1. Salivary glands produce serous and mucous secretions.
2. The three pairs of large salivary glands are the parotid, submandibular, and sublingual.

24.7 Swallowing (p. 881)

Swallowing involves the pharynx and esophagus. It is divided into three phases.

Pharynx

The pharynx consists of the nasopharynx, oropharynx, and laryngopharynx.

Esophagus

1. The esophagus connects the pharynx to the stomach. The upper and lower esophageal sphincters regulate movement.
2. The esophagus consists of an outer adventitia, a muscular layer (longitudinal and circular), a submucosal layer (with mucous glands), and a stratified squamous epithelium.

Swallowing Phases

1. During the voluntary phase of swallowing, a bolus of food is moved by the tongue from the oral cavity to the pharynx.
2. The pharyngeal phase is a reflex caused by the stimulation of stretch receptors in the pharynx.
 - The soft palate closes the nasopharynx, and the epiglottis and vestibular folds close the opening into the larynx.
 - Pharyngeal muscles move the bolus to the esophagus.

3. The esophageal phase is a reflex initiated by the stimulation of stretch receptors in the esophagus. A wave of contraction (peristalsis) moves the food to the stomach.

24.8 Stomach (p. 884)

Anatomy of the Stomach

The openings of the stomach are the gastroesophageal (to the esophagus) and the pyloric (to the duodenum).

Histology of the Stomach

1. The wall of the stomach consists of an external serosa, a muscle layer (longitudinal, circular, and oblique), a submucosa, and simple columnar epithelium (surface mucous cells).
2. Rugae are the folds in the stomach when it is empty.
3. Gastric pits are the openings to the gastric glands, which contain mucous neck cells, parietal cells, chief cells, and endocrine cells.

Secretions of the Stomach

1. Mucus protects the stomach lining.
2. Pepsinogen is converted to pepsin, which digests proteins.
3. Hydrochloric acid promotes pepsin activity and kills microorganisms.
4. Intrinsic factor is necessary for vitamin B₁₂ absorption in the small intestine.
5. The sight, smell, taste, or thought of food initiates the cephalic phase. Nerve impulses from the medulla stimulate hydrochloric acid, pepsinogen, gastrin, and histamine secretion.
6. Distension of the stomach, which stimulates gastrin secretion and activates CNS and local reflexes that promote secretion, initiates the gastric phase.
7. Acidic chyme, which enters the duodenum and stimulates neuronal reflexes and the secretion of hormones that inhibit gastric secretions, initiates the intestinal phase.

Movements of the Stomach

1. The stomach stretches and relaxes to increase volume.
2. Mixing waves mix the stomach contents with stomach secretions to form chyme.
3. Peristaltic waves move the chyme into the duodenum.
4. Gastrin and stretching of the stomach stimulate stomach emptying.
5. Chyme entering the duodenum inhibits movement through neuronal reflexes and the release of hormones.

24.9 Small Intestine (p. 892)

The small intestine is divided into the duodenum, jejunum, and ileum.

Anatomy and Histology of the Small Intestine

1. Circular folds, villi, and microvilli greatly increase the surface area of the intestinal lining.
2. Absorptive, goblet, and endocrine cells are in intestinal glands. Duodenal glands produce mucus.

Secretions of the Small Intestine

1. Mucus protects against digestive enzymes and stomach acids.
2. Digestive enzymes (disaccharidases and peptidases) are bound to the intestinal wall.
3. The vagus nerve, secretin, and chemical or tactile irritation stimulate intestinal secretion.

Movement in the Small Intestine

1. Segmental contractions mix intestinal contents. Peristaltic contractions move materials distally.
2. Stretch of smooth muscles, local reflexes, and the parasympathetic nervous system stimulate contractions. Distension of the cecum initiates a reflex that inhibits peristalsis.

24.10 Liver (p. 895)

Anatomy of the Liver

1. The liver has four lobes: right, left, caudate, and quadrate.
2. The liver is divided into lobules.
 - The hepatic cords are composed of columns of hepatocytes separated by the bile canaliculi.
 - The sinusoids are enlarged spaces filled with blood and lined with endothelium and hepatic phagocytic cells.

Histology of the Liver

1. The portal triads supply the lobules.
 - The hepatic arteries and the hepatic portal veins take blood to the lobules and empty into the sinusoids.
 - The sinusoids empty into central veins, which join to form the hepatic veins, which leave the liver.
 - Bile canaliculi converge to form hepatic ducts, which leave the liver.
2. Bile leaves the liver through the hepatic duct system.
 - The hepatic ducts receive bile from the lobules.
 - The cystic duct from the gallbladder joins the hepatic duct to form the common bile duct.
 - The common bile duct joins the pancreatic duct at the point at which it empties into the duodenum.

Functions of the Liver

1. The liver produces bile, which contains bile salts that emulsify lipids.
2. The liver stores and processes nutrients, detoxifies harmful chemicals, and synthesizes new molecules.
3. Hepatic phagocytic cells phagocytize red blood cells, bacteria, and other debris.
4. The liver produces blood proteins.

24.11 Gallbladder (p. 900)

1. The gallbladder is a small sac on the inferior surface of the liver.
2. The gallbladder stores and concentrates bile.
3. Cholecystokinin stimulates gallbladder contraction.

24.12 Pancreas (p. 901)

Anatomy of the Pancreas

1. The pancreas is both an endocrine and an exocrine gland. Its exocrine function is the production of digestive enzymes.
2. The pancreas is divided into lobules that contain acini. The acini connect to a duct system that eventually forms the pancreatic duct, which empties into the duodenum.

Pancreatic Secretions

1. Digestive enzymes, including inactive proteolytic enzymes that are activated in the small intestine
2. A watery bicarbonate solution that neutralizes acidic chyme

Regulation of Pancreatic Secretion

Cholecystokinin and the vagus nerve stimulate the release of digestive enzymes. Secretin stimulates release of bicarbonate ions and water.

24.13 Large Intestine (p. 902)

Anatomy of the Large Intestine

1. The cecum forms a blind sac at the junction of the small and large intestines. The vermiform appendix is a blind tube off the cecum.
2. The ascending colon extends from the cecum superiorly to the right colic flexure. The transverse colon extends from the right to the left colic flexure. The descending colon extends inferiorly to join the sigmoid colon.
3. The sigmoid colon is an S-shaped tube that ends at the rectum.
4. Longitudinal smooth muscles of the large intestine wall are arranged into bands, called teniae coli, that contract to produce pouches called haustra.
5. The mucosal lining of the large intestine is simple columnar epithelium with mucus-producing crypts.
6. The rectum is a straight tube that ends at the anus.
7. An internal anal sphincter (smooth muscle) and an external anal sphincter (skeletal muscle) surround the anal canal.

Secretions of the Large Intestine

1. Mucus protects the intestinal lining.
2. Epithelial cells secrete HCO_3^- . Sodium is absorbed by active transport, and water is absorbed by osmosis.
3. Microorganisms are responsible for vitamin K production, gas production, and much of the bulk of feces.

Movement in the Large Intestine

1. Segmental movements mix the colon's contents.
2. Mass movements are strong peristaltic contractions that occur three or four times a day.
3. Defecation is the elimination of feces. Reflex activity moves feces through the internal anal sphincter. Voluntary activity regulates movement through the external anal sphincter.

24.14 Digestion and Absorption (p. 908)

1. Digestion is the breakdown of organic molecules into their components.
2. Absorption is the means by which molecules are moved out of the digestive tract and distributed throughout the body.
3. Transport from the intestinal epithelium occurs by two routes.
 - Water, ions, and water-soluble products of digestion are transported to the liver through the hepatic portal system.
 - The products of lipid digestion are transported through the lymphatic system to the circulatory system.

Carbohydrates

1. Carbohydrates consist of starches, glycogen, sucrose, lactose, glucose, and fructose.
2. Polysaccharides are broken down into monosaccharides by a number of different enzymes.
3. Monosaccharides are taken up by intestinal epithelial cells by symport that is powered by a Na^+ gradient or by facilitated diffusion.
4. The monosaccharides are carried to the liver, where the nonglucose sugars are converted to glucose.
5. Glucose is transported to the cells that require energy.
6. Glucose enters the cells through facilitated diffusion.
7. Insulin influences the rate of glucose transport.

Lipids

1. Lipids include triglycerides, phospholipids, steroids, and fat-soluble vitamins.

- Lipase digests lipid molecules to form free fatty acids and monoglycerides.
- Emulsification, the transformation of large lipid droplets into smaller droplets, is accomplished by bile salts.
- Micelles form around lipid digestion products and move to epithelial cells of the small intestine, where the products pass into the cells by simple diffusion.
- Within the epithelial cells, free fatty acids are combined with a monoglyceride to form triglycerides.
- Proteins coat triglycerides, phospholipids, and cholesterol to form chylomicrons.
- Chylomicrons enter lacteals within intestinal villi and are carried through the lymphatic system to the bloodstream.
- Triglycerides are stored in adipose tissue, converted into other molecules, or used as energy.
- Lipoproteins include chylomicrons, VLDL, LDL, and HDL.
- LDL transports cholesterol to cells, and HDL transports it from cells to the liver.
- LDLs are taken into cells by receptor-mediated endocytosis, which is controlled by a negative-feedback mechanism.

Proteins

- Pepsin in the stomach breaks proteins into polypeptide chains.
- Trypsin and other proteolytic enzymes from the pancreas produce smaller peptides.
- Peptidases, bound to the microvilli of the small intestine, break down peptides.

- Amino acids, dipeptides, and tripeptides are absorbed by symport that is powered by Na^+ or H^+ gradients or by facilitated diffusion.
- Amino acids are transported to the liver, where the amino acids can be modified or released into the bloodstream.
- Amino acids are actively transported into cells under the stimulation of growth hormone and insulin.
- Amino acids are used as building blocks or for energy.

Water

Water moves in either direction across the wall of the small intestine, depending on the osmotic gradients across the epithelium.

Ions

- Sodium, potassium, calcium, magnesium, and phosphate are actively transported.
- Chloride ions move passively through the wall of the duodenum and jejunum but are actively transported from the ileum.
- Calcium ions are actively transported, but vitamin D is required for transport, and the transport is under hormonal control.

24.15 Effects of Aging on the Digestive System (p. 915)

The mucous layer, the connective tissue, the muscles, and the secretions of the digestive tract all tend to decrease as a person ages. These changes make an older person more open to infections and toxic agents.

REVIEW AND COMPREHENSION

- Which layer of the digestive tract is in direct contact with the food that is consumed?
 - mucosa
 - muscularis
 - serosa
 - submucosa
- The ENS is found in
 - the submucosa layer.
 - the muscularis layer.
 - the serosa layer.
 - Both a and b are correct.
 - All of these are correct.
- Dentin
 - forms the surface of the crown of the teeth.
 - holds the teeth to the periodontal ligaments.
 - is found in the pulp cavity.
 - makes up most of the structure of the teeth.
 - is harder than enamel.
- The number of premolar deciduous teeth is
 - 0.
 - 2.
 - 4.
 - 8.
 - 12.
- Which of these glands does *not* secrete saliva into the oral cavity?
 - submandibular gland
 - pancreas
 - sublingual gland
 - parotid gland
- The portion of the digestive tract in which digestion begins is the
 - oral cavity.
 - esophagus.
 - stomach.
 - duodenum.
 - jejunum.
- During swallowing,
 - the movement of food results primarily from gravity.
 - the swallowing center in the medulla oblongata is activated.
 - food is pushed into the oropharynx during the pharyngeal phase.
 - the soft palate closes off the opening into the larynx.
- The stomach
 - has large folds in the submucosa and mucosa called rugae.
 - has two layers of smooth muscle in the muscularis tunic.
 - opening from the esophagus is the pyloric opening.
 - has an area closest to the duodenum called the fundus.
 - All of these are correct.
- Which of these stomach cell types is *not* correctly matched with its function?
 - surface mucous cells—produce mucus
 - parietal cells—produce hydrochloric acid
 - chief cells—produce intrinsic factor
 - endocrine cells—produce regulatory hormones
- Why doesn't the stomach digest itself?
 - The stomach wall is not composed of protein, so it is not affected by proteolytic enzymes.
 - The digestive enzymes of the stomach are not strong enough to digest the stomach wall.
 - The lining of the stomach wall has a protective layer of epithelial cells.
 - The stomach wall is protected by large amounts of mucus.
- Which of these hormones stimulates stomach secretions?
 - cholecystokinin
 - insulin
 - gastrin
 - secretin
- Which of these structures increase the mucosal surface of the small intestine?
 - circular folds
 - villi
 - microvilli
 - length of the small intestine
 - All of these are correct.

13. Which cells in the small intestine have digestive enzymes attached to their surfaces?
 - a. mucous cells
 - b. goblet cells
 - c. endocrine cells
 - d. absorptive cells
14. The hepatic sinusoids
 - a. receive blood from the hepatic artery.
 - b. receive blood from the hepatic portal vein.
 - c. empty into the central veins.
 - d. All of these are correct.
15. Which of the following might occur if a person suffers from a severe case of hepatitis that impairs liver function?
 - a. Lipid digestion is difficult.
 - b. By-products of hemoglobin breakdown accumulate in the blood.
 - c. Plasma proteins decrease in concentration.
 - d. Toxins in the blood increase.
 - e. All of these occur.
16. The gallbladder
 - a. produces bile.
 - b. stores bile.
 - c. contracts and releases bile in response to secretin.
 - d. contracts and releases bile in response to sympathetic stimulation.
 - e. Both b and c are correct.
17. The aqueous pancreatic juice
 - a. is secreted by the pancreatic islets.
 - b. contains HCO_3^- .
 - c. is released primarily in response to cholecystokinin.
 - d. passes directly into the blood.
 - e. All of these are correct.
18. Which of these is *not* a function of the large intestine?
 - a. absorption of glucose
 - b. absorption of certain vitamins
 - c. absorption of water and salts
 - d. production of mucus
19. Defecation
 - a. can be initiated by stretch of the rectum.
 - b. can occur as a result of mass movements.
 - c. involves local reflexes.
 - d. involves parasympathetic reflexes mediated by the spinal cord.
 - e. All of these characteristics are true of defecation.
20. Which of these structures produces enzymes that digest carbohydrates?
 - a. salivary glands
 - b. pancreas
 - c. lining of the small intestine
 - d. Both a and b are correct.
 - e. All of these are correct.
21. Bile
 - a. is an important enzyme for the digestion of lipids.
 - b. is made by the gallbladder.
 - c. contains breakdown products from hemoglobin.
 - d. emulsifies lipids.
 - e. Both c and d are correct.
22. Micelles are
 - a. lipids surrounded by bile salts.
 - b. produced by the pancreas.
 - c. released into lacteals.
 - d. stored in the gallbladder.
 - e. reabsorbed in the colon.
23. If the thoracic duct were tied off, which of these classes of nutrients would *not* enter the blood at their normal rate?
 - a. amino acids
 - b. glucose
 - c. lipids
 - d. fructose
 - e. nucleotides
24. Which of these lipoprotein molecules transports excess lipids from cells back to the liver?
 - a. high-density lipoprotein (HDL)
 - b. low-density lipoprotein (LDL)
 - c. very low-density lipoprotein (VLDL)

Answers in appendix E

CRITICAL THINKING

1. While anesthetized, patients sometimes vomit. Given that the anesthetic eliminates the swallowing reflex, explain why it is dangerous for an anesthetized patient to vomit.
2. Achlorhydria is a condition in which the stomach stops producing hydrochloric acid and other secretions. What effect would achlorhydria have on the digestive process? On red blood cell count?
3. Victor Worrystudent experienced the pain of a duodenal ulcer during final examination week. Explain what habits caused the ulcer, and recommend possible remedies.
4. Gallstones sometimes obstruct the common bile duct. What are the consequences of such a blockage?
5. A patient has a spinal cord injury at level L2. How does this injury affect the patient's ability to defecate? What components of the defecation response are still present, and which are lost?
6. The bacterium *Vibrio cholerae* produces cholera toxin, which activates a chloride channel in the intestinal epithelium. In contrast, mutations that inactivate the same channel cause cystic fibrosis. Explain how increased chloride channel activity causes severe diarrhea, whereas decreased activity causes the intestinal symptoms of cystic fibrosis.
7. Discuss why the most effective oral rehydration therapy is water containing sodium and glucose instead of water alone or water with fructose.
8. Would a patient with familial hypercholesterolemia (FH) benefit from dietary changes?

Learn to Predict

Sadie and David loved it when their mothers planned a picnic at the park. They enjoyed running and playing on the jungle gym. Today, Sadie begged her mom to pack a snack of chocolate chip cookies and grape soda. This snack was packed with calories that would give the children lots of energy, but otherwise, it had very little nutritional value. Sadie's mom explained that a snack of fruits, whole-wheat crackers, and water would be much better for everyone. **After reading this chapter and recalling what you learned about nutrient digestion and absorption in chapter 24, predict the outcome if Sadie's mom allowed them to bring Sadie's suggested snack, rather than the snack her mother suggested they take to the park.**

Nutrition, Metabolism, and Temperature Regulation

You are what you eat” is a common phrase we all hear. Health claims about foods and food supplements bombard us every day. Meanwhile, obesity rates in U.S. children and adults have soared. Nutrition and weight maintenance are subjects of constant discussion on television, in newspapers, and around the water cooler. When choosing food, many of us are more concerned about its taste than its nutritional value. What happens if we do not obtain enough vitamins, or if we eat too much sugar and fat? Which new diets or diet supplements are ridiculous, and which ones have merit? A basic understanding of nutrition can answer these and other questions, so that we can develop a healthful diet. It also allows us to know which nutrition questions currently do not have good answers.

25.1 Nutrition

LEARNING OUTCOMES

After reading this section, you should be able to

- Define **nutrition**, **nutrients**, **essential nutrients**, and **kilocalorie**.
- Describe **MyPlate** and its use.
- For **carbohydrates**, **lipids**, and **proteins**, describe their **dietary sources**, their **uses in the body**, and the **daily recommended amounts of each in the diet**.
- List the **important vitamins and minerals for body health**. Give the **function and symptoms of deficiency for each**.
- Discuss the **Reference Daily Intake and the Daily Reference Value of food**.

Most of us think *nutrition* refers to the evaluation of food and drink requirements for normal body functions. Though this is an important area of focus when deciding on what to eat and drink, **nutrition** is the process by which the body obtains and uses certain components of food. In this definition of *nutrition*, the process includes digestion, absorption, transportation, and cell metabolism.

Nutrients

Nutrients are the substances taken into the body that are used by the cells of the body to produce energy, to provide building blocks for new molecules, and to function in other chemical reactions. Some substances in food, such as nondigestible plant fibers, are not nutrients per se because the cells of the body do not use them; however, these substances can still serve important functions for the body as a whole. For example, fiber is considered an important component of our diet even though we cannot digest it. Instead, fiber adds to the bulk of feces, which stimulates normal motility of the large intestine.

Nutrients are divided into six major classes: (1) carbohydrates, (2) lipids, (3) proteins, (4) vitamins, (5) minerals, and (6) water. Carbohydrates, lipids, and proteins are the major organic nutrients. They must be broken down by enzymes into their components during digestion before they can be absorbed by the small intestine. Many of these subunits are broken down further by the body's cells to supply energy, whereas others are used by the cells as building blocks for new carbohydrates, lipids, and proteins. Carbohydrates, lipids, proteins, and water are required in fairly substantial quantities. Vitamins and minerals, on the other hand, are required in only small amounts. Vitamins, minerals, and water are absorbed by the digestive tract without being digested.

Our body has the ability to produce many of the substances necessary for normal cellular activity from the nutrients we ingest. Interestingly, when some nutrient levels are low, our cells have the ability to convert other substances to the nutrient that is lacking. For example, if glucose levels are low, the body can convert some lipids to glucose through a specific metabolic pathway. **Essential nutrients** are substances that must be ingested because the body cannot manufacture them at all or cannot manufacture adequate amounts of them.

The essential nutrients include certain amino acids and fatty acids, most vitamins, minerals, water, and a few carbohydrates. However, the term *essential* does not mean that the body requires only the essential nutrients. Other nutrients are necessary; if they are not part of the diet, they can be synthesized from the essential nutrients. Most of this synthesis takes place in the liver, which has a remarkable ability to transform and manufacture molecules.

Kilocalories

The body uses the energy stored within the chemical bonds of certain nutrients. A **calorie** (kal'ō-rē; **cal**) is the amount of energy (heat) necessary to raise the temperature of 1 g of water 1°C. A **kilocalorie** (kil'ō-kal-ō-rē; **kcal**) is 1000 calories and is used to express the larger amounts of energy supplied by foods and released through metabolism.

A kilocalorie is often called a *Calorie* (with a capital *C*). Unfortunately, this usage has been confused with the term *calorie* (with a lowercase *c*). Food labels and nutrition books commonly use *calorie* when *Calorie* (*kilocalorie*) is the proper term.

Most of the kilocalories supplied by food come from carbohydrates, proteins, or lipids (fats). The number of kilocalories per gram of each of these nutrients is well established. For each gram of carbohydrate or protein the body metabolizes, about 4 kcal of energy are released. Fats contain more energy per unit of weight than carbohydrates and proteins and yield about 9 kcal/g. Table 25.1 lists the kilocalories supplied by some common foods. A typical diet in the United States consists of 50–60% carbohydrates, 35–45% fats, and 10–15% proteins. Table 25.1 also lists the carbohydrate, fat, and protein composition of some foods.

MyPlate

Every 5 years, the U.S. Department of Health and Human Services (HHS) and the Department of Agriculture (USDA) jointly recommend the types and amounts of food Americans should eat to be healthy. These recommendations, *Dietary Guidelines for Americans 2010*, were published in January 2011. In light of the increasing problem of obesity in the United States, the latest recommendations focus on two concepts: (1) balancing calorie intake to obtain and maintain a healthy weight and (2) increasing consumption of healthful, nutrient-rich foods. In June 2011, the USDA also introduced MyPlate, a new food icon to replace the former food guide icon, called MyPyramid. MyPlate (figure 25.1) is a simple visual reminder of how to build a healthful meal. The MyPlate icon shows a plate and glass with portions representing foods from the fruits, vegetables, grains, proteins, and dairy food groups. To emphasize the importance of making healthful food choices, half the plate is fruits and vegetables. In addition to the MyPlate icons, the USDA also launched ChooseMyPlate.gov, a website that includes information on how to make healthful dietary choices.

ASSESS YOUR PROGRESS

- What is **nutrition**, and what processes does it include?
- Distinguish between a **nutrient** and an **essential nutrient**.
- List the six major classes of **nutrients**.

TABLE 25.1 Nutrient Content of Some Typical Foods

Food	Quantity	Food Energy (kcal)	Carbohydrate (g)	Fat (g)	Protein (g)
Dairy Products					
Whole milk (3.3% fat)	1 cup	150	11	8	8
Low-fat milk (2% fat)	1 cup	120	12	5	8
Butter	1 tablespoon	100	—	12	—
Grains					
Bread, white enriched	1 slice	75	24	1	2
Bread, whole-wheat	1 slice	65	14	1	3
Fruits

FIGURE 25.1 MyPlate

The MyPlate icon provides a visual reminder for making choices at mealtime, by selecting healthful foods from five food groups. Half the meal should be fruits and vegetables. Source: U.S. Department of Agriculture.

4. Define kilocalorie. State the number of kilocalories supplied by a gram of carbohydrate, a gram of lipid, and a gram of protein.
5. List the five food groups shown in MyPlate. How is the importance of eating fruits and vegetables indicated in MyPlate?

Carbohydrates

Sources in the Diet

Carbohydrates include monosaccharides, disaccharides, and polysaccharides (see chapter 2). Most of the carbohydrates humans ingest come from plants. An exception is lactose, which is found in milk and other dairy products.

Glucose and fructose are the most common monosaccharides in the diet. Plants capture the energy in sunlight and use it to produce glucose, which can be found in vegetables. Fructose (fruit sugar) and galactose are isomers of glucose (see figure 2.14). Fructose is in fruits, berries, honey, and high-fructose corn syrup, which is used to sweeten soft drinks and desserts. Galactose is found in milk.

When most of us think of sugar, we are probably thinking of the sugar you can buy in big bags in the grocery store. This is commonly referred to as table sugar. Table sugar is actually the disaccharide sucrose. As a disaccharide, each molecule of sucrose is composed of two monosaccharides, a glucose molecule and a fructose molecule joined together. The principal sources of sucrose are sugarcane, sugar beets, maple sugar, and honey. Two other common dietary disaccharides are maltose and lactose. Maltose (malt sugar), derived from germinating cereals, is composed of two

glucose molecules, and lactose (milk sugar) consists of a glucose and a galactose molecule (see figure 2.14).

Complex carbohydrates are polysaccharides, which consist of many glucose molecules bound together to form long chains. Examples of common dietary polysaccharides include starch, glycogen, and cellulose. Starch is an energy-storage molecule found primarily in plants (vegetables, fruits, and grains). Glycogen is an energy-storage molecule in animals and is located primarily in muscle and in the liver. By the time meats have been processed, they contain little, if any, glycogen because it is used up by the dying muscle cells (see “Anaerobic Glycolysis” in section 25.3). Cellulose forms plant cell walls.

Uses of Carbohydrates in the Body

During digestion, polysaccharides and disaccharides are split into monosaccharides, which are absorbed into the blood (see chapter 24). Humans can digest starch and glycogen because our bodies produce enzymes that break the bonds between the glucose molecules of starch and glycogen. Digestion of certain polysaccharides requires specific enzymes that can break the bonds linking the monosaccharides in the molecule. Humans are unable to digest cellulose because our bodies do not produce the enzymes that break the bonds between its glucose molecules. As a consequence, the digestive tract is unable to absorb cellulose. Instead, cellulose provides fiber, or “roughage,” thereby increasing the bulk of feces and making it easier to defecate.

The liver converts fructose, galactose, and other monosaccharides absorbed by the small intestine into glucose. Glucose, whether absorbed from the digestive tract or synthesized in the liver, provides energy to produce **adenosine triphosphate (ATP)** molecules (see section 25.3). Because the brain relies almost entirely on glucose for its energy, the body carefully regulates blood glucose levels (see chapter 18).

Muscle and liver cells convert excess glucose into glycogen for storage. Cells can store only a limited amount of glycogen; therefore, any additional glucose is converted into lipids and stored in adipose tissue. Glycogen can be rapidly converted back to glucose when energy is needed. For example, during exercise, muscles convert glycogen to glucose, and between meals the liver helps maintain blood sugar levels by converting glycogen to glucose, which is released into the blood.

In addition to serving as a source of energy, sugars have other functions. They form part of deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and ATP molecules (see chapter 2). They also combine with proteins to form glycoproteins, such as the glycoprotein receptor molecules on the outer surface of the plasma membrane (see chapter 3).

Recommended Consumption of Carbohydrates

According to the Dietary Guidelines Advisory Committee, the **Acceptable Macronutrient Distribution Range (AMDR)** for carbohydrates is 45–65% of total kilocalories. Although a minimum level of carbohydrates has not been established, researchers believe that amounts of 100 g or less per day result in overuse of the body’s proteins and lipids for energy. Because muscles are primarily protein, the use of proteins for energy can result in the

breakdown of muscle tissue. The extensive use of lipids for energy can lead to acidosis (see chapter 18).

Complex carbohydrates are recommended in the diet because many starchy foods contain other valuable nutrients, such as vitamins and minerals. Complex carbohydrates are also recommended over simple sugars because the slower rate of digestion and absorption of complex carbohydrates does not cause large increases and decreases in blood glucose levels, as the consumption of large amounts of simple sugars does. Foods primarily composed of simple sugars, such as soft drinks and candy, are rich in carbohydrates but have few other nutrients. For example, a typical soft drink is mostly sucrose, containing 9 teaspoons of sugar per 12 oz can. Consuming these kinds of foods in excess usually results in obesity and tooth decay.

ASSESS YOUR PROGRESS

6. What are the most common monosaccharides in the diet? What are the sources of the three common disaccharides: sucrose, maltose, and lactose?
7. Give three examples of complex carbohydrates. How does the body use them?
8. How does the body use glucose and other monosaccharides?
9. What is the recommended daily consumption of carbohydrates?

Lipids

Sources in the Diet

About 95% of the lipids in the human diet are **triglycerides** (trī-glis'er-īdz). Triglycerides, which are sometimes called *triacylglycerols* (trī-as'il-glis'er-olz), consist of three fatty acids attached to a glycerol molecule (see chapter 2). Triglycerides are often referred to as fats, which are solid at room temperature, or oils, which are liquid at room temperature. Fats and oils can be categorized as saturated or unsaturated depending on the types of bonds in the fatty acid. **Saturated fats and oils** have only single covalent bonds between the carbon atoms of their fatty acids (see figure 2.17). These types of fats are found in the fats of meat (e.g., beef, pork), dairy products (e.g., whole milk, cheese, butter), eggs, coconut oil, and palm oil. **Unsaturated fats and oils** have one or more double covalent bonds between the carbon atoms of their fatty acids (see figure 2.17). **Monounsaturated fats** have one double bond, and **polyunsaturated fats** have two or more double bonds. Monounsaturated fats include olive and peanut oils; polyunsaturated fats are in fish, safflower, sunflower, and corn oils.

Unsaturated fatty acids can also be classified according to the location of the first double bond in the carbon chain. The “starting” point for determining the location of the double bonds is the omega (methyl) end of the fatty acid. The first double bond of an omega-3 fatty acid starts three carbon atoms after the omega end; an omega-6 fatty acid starts after six carbons; and an omega-9 fatty acid starts after nine carbons (see figure 2.17).

The remaining 5% of lipids include cholesterol and phospholipids, such as **lecithin** (les'i-thin). Cholesterol is a steroid (see chapter 2) found in high concentrations in liver and egg yolks, but it is also present in whole milk, cheese, butter, and meats. Cholesterol is not in plants. Phospholipids, major components of plasma membranes, are found in a variety of foods, including egg yolks.

Uses of Lipids in the Body

Triglycerides are important sources of energy that can be used to produce ATP. A gram of triglyceride delivers more than twice as many kilocalories as a gram of carbohydrate. Some cells, such as skeletal muscle cells, derive most of their energy from triglycerides.

After a meal, excess triglycerides that are not immediately used are stored in adipose tissue or the liver. Later, when energy is required, the triglycerides are broken down, and their fatty acids are released into the blood to be taken up and used by various tissues. In addition to storing energy, adipose tissue surrounds and pads organs. Adipose tissue located under the skin is an insulator, which prevents heat loss.

Cholesterol is an important molecule that has many functions in the body. It can be either obtained in food or manufactured by the

Clinical IMPACT

What Are “Trans” Fats?

Solid fats, mainly shortening and margarine, work better than liquid oils for preparing some foods, such as pastries. Polyunsaturated vegetable oils can be changed from a liquid to a solid by making them more saturated—that is, by decreasing the number of double covalent bonds in their polyunsaturated fatty acids. To saturate an unsaturated oil, the oil can be *hydrogenated*, which means that hydrogen gas is bubbled through the oil to produce a change in molecular shape that solidifies the oil. The more saturated the product, the harder it becomes at room temperature. These processed fats are usually referred to as **trans fats**.

Unprocessed polyunsaturated fats are found mostly in the **cis form**, which means the hydrogen atoms are on the same side of the carbon-carbon double bond in their fatty acids (see figure 2.17). During hydrogenation, some of the hydrogen atoms are transferred to the opposite side of the double bond to make the **trans form**, characterized by one hydrogen atom on one side of the double bond and another on the opposite side. Processed foods and oils account for most of the **trans** fats in the American diet, although some **trans** fats occur naturally in food from animal sources. **Trans** fatty acids raise the concentration of low-density lipoproteins and lower the concentration of high-density lipoproteins in the blood (see chapter 24). These changes are associated with a greater risk for cardiovascular disease. Beginning in 2006, the Food and Drug Administration (FDA) required that food labels include a detailed list of the amounts of saturated and **trans** fats, allowing the consumer to make better dietary choices.

liver and most other tissues. Cholesterol is a component of the plasma membrane, and it can be modified to form other useful molecules, such as bile salts and steroid hormones. Bile salts are necessary for lipid digestion and absorption. Steroid hormones include the reproductive hormones estrogen, progesterone, and testosterone.

The eicosanoids (ī'kō-sā-noydz), which include prostaglandins and leukotrienes, are derived from fatty acids. The molecules are involved in activities such as inflammation, blood clotting, tissue repair, and smooth muscle contraction. Phospholipids, such as lecithin, are part of the plasma membrane and are used to construct the myelin sheath around the axons of neurons. Lecithin is also found in bile and helps emulsify lipids.

Recommended Consumption of Lipids

The AMDR for lipids is 20–35% for adults, 25–35% for children and adolescents 4 to 18 years of age, and 30–35% for children 2 to 3 years of age. Saturated fats should amount to no more than 10% of total kilocalories or be as low as possible. Most dietary fat should come from sources of polyunsaturated and monounsaturated fats. Nutritionists recommend that people limit their cholesterol intake to 300 mg (the amount in one egg yolk) or less per day and keep their *trans* fat consumption as low as possible. These guidelines reflect the belief that excess fats, especially saturated fats, *trans* fats, and cholesterol, contribute to cardiovascular disease. The typical American diet derives 35–45% of its kilocalories from lipids, indicating that most Americans need to reduce their dietary fat consumption.

Clinical IMPACT

Fatty Acids and Blood Clotting

Essential fatty acids are used to synthesize prostaglandins that affect blood clotting. Linoleic acid can be converted to **arachidonic** (ă-rak-i-don'ik) **acid**, an omega-6 fatty acid used to produce thromboxanes, which increase blood clotting. Alpha-linolenic acid can be converted to **eicosapentaenoic** (ī'kō-sā-pen-tā-nō'ik) **acid (EPA)** and **docosahexaenoic** (dō'kō-sā-heks-ă-nō'ik) **acid (DHA)**, omega-3 fatty acids that can be used to synthesize prostaglandins, which decrease blood clotting. People who eat foods rich in EPA and DHA, such as herring, salmon, tuna, and sardines, increase the synthesis of prostaglandins from EPA and DHA. Those who eat these fish two or more times per week have a lower risk for heart attack than those who do not, possibly because of reduced blood clotting. EPA and DHA are also known to reduce blood triglyceride levels. People who do not like to eat fish can take fish oil supplements as a source of EPA and DHA. Flaxseed is a source of alpha-linolenic acid, from which EPA and DHA can be synthesized. Whether or not flaxseed can provide the same benefits as EPA and DHA is under investigation. People who have bleeding disorders, take anticoagulants, or anticipate surgery should follow their physicians' advice regarding the use of these supplements because they can increase the risk for bleeding and hemorrhagic stroke.

Most of the lecithin consumed in the diet is broken down in the digestive tract. The liver can manufacture all the lecithin necessary to meet the body's needs, so taking lecithin supplements is not necessary.

The **essential fatty acids** in the human diet include **alpha-linolenic** (lin-ō-len'ik) **acid**, an omega-3 fatty acid, and **linoleic** (lin-ō-lē'ik) **acid**, an omega-6 fatty acid. These fatty acids must be ingested because humans lack the enzymes necessary to synthesize them. Seeds, nuts, and legumes are good sources of alpha-linolenic and linoleic acids. Alpha-linolenic acid is in the green leaves of plants, and linoleic acid is in grains. Other fatty acids, such as omega-9 fatty acids, can be synthesized from essential fatty acids.

ASSESS YOUR PROGRESS

10. What is the major source of lipids in the diet? What are some other sources?
11. Distinguish between saturated and unsaturated fats. What are *trans* fats?
12. How does the body use triglycerides, cholesterol, prostaglandins, and lecithin?
13. Describe the recommended dietary intake of lipids. List the essential fatty acids, and state food sources that contain them.

Proteins

Sources in the Diet

Proteins are chains of amino acids (see chapter 2). Proteins in the body are constructed of 20 kinds of amino acids, which are divided into two groups: essential and nonessential. The body cannot synthesize **essential amino acids**, so they must be obtained in the diet. The nine essential amino acids are histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. **Nonessential amino acids**, which are necessary to construct our proteins, do not necessarily need to be ingested because they can be synthesized from essential amino acids.

A **complete protein** is a food that contains adequate amounts of all nine essential amino acids, whereas an **incomplete protein** does not. Examples of complete protein foods are meat, fish, poultry, milk, cheese, and eggs; incomplete proteins include leafy green vegetables, grains, and legumes (peas and beans). If two incomplete proteins, such as rice and beans, are ingested together, the amino acid composition of each complements the other, and a complete protein is created. Thus, a vegetarian diet, if balanced correctly, provides all the essential amino acids.

Uses of Proteins in the Body

The body uses essential and nonessential amino acids to synthesize proteins. Proteins perform numerous functions in the body. For example, collagen provides structural strength in connective tissue, as does keratin in the skin. The interactions of actin and myosin make muscle contraction possible. Enzymes regulate the rate of chemical reactions, and protein hormones regulate many physiological processes (see chapter 18). Proteins in the blood

prevent changes in pH (buffers), promote blood clotting (coagulation factors), and transport oxygen and carbon dioxide (hemoglobin). Transport proteins (see chapter 3) move materials across plasma membranes, and other proteins in the plasma membrane function as receptor molecules. Antibodies, lymphokines, and complement are part of the immune system response that protects against microorganisms and other foreign substances.

The body also uses proteins for energy. As an energy source, proteins yield the same amount of kilocalories as carbohydrates. If excess proteins are ingested, the energy in the proteins can be stored by converting their amino acids into glycogen or lipids.

Recommended Consumption of Proteins

The AMDR for protein is 10–35% of total kilocalories. When protein intake is adequate, the synthesis and breakdown of proteins in a healthy adult occur at the same rate.

The amino acids of proteins contain nitrogen, so saying that a person is in **nitrogen balance** means that the nitrogen content of ingested protein is equal to the nitrogen excreted in urine and feces. A starving person is in negative nitrogen balance because the nitrogen gained in the diet is less than that lost by excretion. In other words, when proteins are broken down for energy, more nitrogen is lost than is replaced in the diet. On the other hand, a growing child or a healthy pregnant woman is in positive nitrogen balance because more nitrogen is going into the body to produce new tissues than is lost by excretion.

ASSESS YOUR PROGRESS

14. Distinguish between essential and nonessential amino acids, and between complete and incomplete protein foods.
15. Describe the functions of proteins in the body.
16. What is the AMDR of proteins? What is nitrogen balance? What would place a person in negative nitrogen balance?

Vitamins

Vitamins (vīt'ă-minz; life-giving chemicals) are organic molecules that exist in very small quantities in food. These molecules are essential to normal metabolism (table 25.2). **Essential vitamins** cannot be produced by the body and must be obtained through the diet. Because no single food or nutrient provides all the essential vitamins, people should maintain a balanced diet by eating a variety of foods. The absence of an essential vitamin in the diet can result in a deficiency disease.

A few vitamins, such as vitamin K, are produced by intestinal bacteria, and a few others can be formed by the body from substances called provitamins. A **provitamin** is a part of a vitamin that the body can convert into a functional vitamin. For example, beta carotene is a provitamin that the body can form into vitamin A. The other provitamins are **7-dehydrocholesterol** (dē-hī'dro-kō-les'ter-ol), which can be converted to vitamin D, and **tryptophan** (trip'tō-fan), which can be converted to niacin.

Rather than breaking down vitamins by catabolism, the body uses them in their original or slightly modified forms. If the chemical structure of a vitamin is destroyed, its function is usually

lost. For example, the chemical structure of many vitamins is destroyed by heat, as when food is overcooked.

Many vitamins function as **coenzymes**, which combine with enzymes to make the enzymes functional (see chapter 2). Without enzymes and their coenzymes, many chemical reactions would occur too slowly to support good health and life. For example, vitamins B₂ and B₃, biotin (bī'ō-tin), and pantothenic (pan-tō-then'ik) acid are critical for some of the chemical reactions involved in producing ATP. Folate (fō'lāt) and vitamin B₁₂ are required for nucleic acid synthesis. Vitamins A, B₁, B₆, B₁₂, C, and D are necessary for growth. Vitamin K is necessary for the synthesis of proteins involved in blood clotting (table 25.2).

Vitamins are classified as either fat-soluble or water-soluble. **Fat-soluble vitamins**, such as vitamins A, D, E, and K, dissolve in lipids and are absorbed from the intestine along with lipids. Some of them can be stored in the body for a long time. Because they can be stored, these vitamins can accumulate in the body to the point of toxicity. **Water-soluble vitamins**, such as the B vitamins and vitamin C, dissolve in water. They are absorbed from the water in the intestinal tract and typically remain in the body only a short time before being excreted in the urine.

Vitamins were discovered at the beginning of the twentieth century. They were found to be associated with certain foods known to protect people from diseases such as rickets and beriberi. In 1941, the first Food and Nutrition Board established the **Recommended Dietary Allowances (RDAs)**, which are the nutrient intakes sufficient to meet the needs of nearly all people in certain age and gender groups. RDAs were established for different-aged males and females, starting with infants and

Clinical IMPACT

Free Radicals and Antioxidants

Free radicals are molecules, produced as part of normal metabolism, that are missing an electron. The loss of an electron from a molecule is called oxidation. Free radicals can replace the missing electron by taking an electron from cell molecules, such as lipids, proteins, or DNA, resulting in damage to the cell. Damage from free radicals may contribute to aging and certain diseases, such as atherosclerosis and cancer. However, substances called **antioxidants** may counteract these effects by donating an electron to free radicals and thus preventing the oxidation of cell components. Examples of antioxidants are beta carotene (provitamin A), vitamin C, and vitamin E.

Many studies have attempted to determine whether taking large doses of antioxidants is beneficial. The best evidence presently available does not support the claim that large doses of antioxidants can prevent chronic disease or otherwise improve health. On the other hand, the amount of antioxidants normally found in a balanced diet (including fruits and vegetables rich in antioxidants), combined with the complex mix of other chemicals found in food, can be beneficial.

TABLE 25.2 Principal Vitamins

Vitamin	Fat-Soluble (F) or Water-Soluble (W)	Source	Function	Symptoms of Deficiency	Reference Daily Intake (RDI)*
A (retinol)	F	From provitamin beta carotene found in yellow and green vegetables: preformed in liver, egg yolk, butter, and milk	Necessary for rhodopsin synthesis, normal health of epithelial cells, and bone and tooth growth	Rhodopsin deficiency, night blindness, delayed growth, skin disorders, and increased infection risk	5000 IU
B ₁ (thiamine)	W	Yeast, grains, and milk	Involved in carbohydrate and amino acid metabolism, necessary for growth	Beriberi—muscle weakness (including cardiac muscle), neuritis, and paralysis	1.5 mg
B ₂ (riboflavin)	W	Green vegetables, liver, wheat germ, milk, and eggs	Component of flavin adenine dinucleotide, involved in citric acid cycle	Eye disorders and skin cracking, especially at corners of the mouth	1.7 mg
B ₃ (niacin)	W	Fish, liver, red meat, yeast, grains, peas, beans, and nuts	Component of nicotinamide adenine dinucleotide, involved in glycolysis and citric acid cycle	Pellagra—diarrhea, dermatitis, and nervous system disorders	20 mg
Pantothenic acid	W	Liver, yeast, green vegetables, grains, and intestinal bacteria	Constituent of coenzyme-A, glucose production from lipids and amino acids, and steroid hormone synthesis	Neuromuscular dysfunction and fatigue	10 mg
Biotin	W	Liver, yeast, eggs, and intestinal bacteria	Fatty acid and nucleic acid synthesis, movement of pyruvic acid into citric acid cycle	Mental and muscle dysfunction, fatigue, and nausea	30 µg
B ₆ (pyridoxine)	W	Fish, liver, yeast, tomatoes, and intestinal bacteria	Involved in amino acid metabolism	Dermatitis, delayed growth, and nausea	2.0 mg
Folate	W	Liver, leafy green vegetables, and intestinal bacteria	Nucleic acid synthesis, hemopoiesis, and prevention of birth defects	Macrocytic anemia (enlarged red blood cells) and neural tube defects	0.4 mg
B ₁₂ (cobalamins)	W	Liver, red meat, milk, and eggs	Necessary for red blood cell production, some nucleic acid and amino acid metabolism	Pernicious anemia and nervous system disorders	6.0 µg
C (ascorbic acid)	W	Citrus fruit, tomatoes, and green vegetables	Collagen synthesis, general protein metabolism	Scurvy—defective bone formation and poor wound healing	60 mg
D (cholecalciferol, ergosterol)	F	Fish liver oil, enriched milk, and eggs; provitamin D converted by sunlight to cholecalciferol in the skin	Promotes calcium and phosphorus use, normal growth and bone and tooth formation	Rickets—poorly developed, weak bones; osteomalacia; and bone reabsorption	400 IU
E (tocopherol, tocotrienols)	F	Wheat germ; cottonseed, palm, and rice oils; grain; liver; and lettuce	Prevents oxidation of plasma membranes and DNA	Hemolysis of red blood cells	30 IU
K (phylloquinone)	F	Alfalfa, liver, spinach, vegetable oils, cabbage, and intestinal bacteria	Required for synthesis of a number of clotting factors	Excessive bleeding due to slow blood clotting	80 µg

*Reference Daily Intakes for people over 4 years of age; IU = international units.

continuing on to adults. RDAs were also set for pregnant and lactating women. The RDAs have been reevaluated every 4–5 years and updated when necessary on the basis of new information.

The RDAs establish a minimum intake of vitamins and minerals that should protect almost everyone (97%) in a given group from diseases caused by vitamin or mineral deficiencies. Although personal requirements can vary, the RDAs are a good benchmark. The further below the RDAs an individual's dietary intake is, the more likely that person is to develop a nutritional deficiency. On the other hand, consuming too much of some vitamins and minerals can be harmful. For example, the long-term ingestion of 3–10 times the RDA for vitamin A can cause bone and muscle pain, skin disorders, hair loss, and an enlarged liver. Consuming 5–10 times the RDA of vitamin D over the long term can result in calcium deposits in the kidneys, heart, and blood vessels, and consuming more than 2 g of vitamin C daily can cause stomach inflammation and diarrhea.

➤ Predict 2

What would happen if vitamins were broken down during digestion rather than being absorbed intact into the circulation?

ASSESS YOUR PROGRESS

17. What are vitamins, essential vitamins, and provitamins?
18. Name the fat-soluble vitamins and the water-soluble vitamins.
19. List some of the functions of vitamins in the body.
20. What are Recommended Dietary Allowances (RDAs)? Why are they useful?
21. What are some symptoms of specific vitamin deficiencies?

Minerals

Minerals (min'er-älz) are inorganic nutrients that are necessary for normal metabolic functions. The minerals are divided into two groups, major minerals and trace minerals, based on the amount required in the diet for good health. The daily requirement for **major minerals** is 100 mg or more daily. The daily requirement for **trace minerals** is less than 100 mg daily. The trace minerals are needed in such low amounts that the required amount for some is unknown. Minerals constitute about 4–5% of total body weight. Some minerals are components of other important molecules in the body, such as coenzymes, a few vitamins, and hemoglobin. Minerals are involved in a number of important functions, including establishing resting membrane potentials and generating action potentials, adding mechanical strength to bones and teeth, combining with organic molecules, and acting as coenzymes, buffers, and regulators of osmotic pressure. Table 25.3 lists important minerals and their functions.

People ingest minerals alone or in combination with organic molecules, as well as obtain them from both animal and plant sources. However, mineral absorption from plants can be limited because the minerals tend to bind to plant fibers. Refined breads and cereals contain hardly any minerals or vitamins because the seeds used to make them are crushed, and the outer parts of the

seeds housing most of the minerals and vitamins, are discarded. Minerals and vitamins are often added to refined breads and cereals to compensate for their loss during the refinement process.

A balanced diet can provide all the vitamins and minerals required for good health for most people. Some nutritionists, however, recommend taking a once-a-day multiple vitamin and mineral supplement as insurance because many people's diets are not balanced.

ASSESS YOUR PROGRESS

22. What are minerals? What is the daily requirement for major minerals?
23. List several minerals the body needs and a function of each.

Daily Values for Nutrients

Daily Values are dietary values that appear on food labels to help consumers plan a healthful diet. Daily Values are based on two other sets of reference values: Reference Daily Intakes and Daily Reference Values.

- **Reference Daily Intakes (RDIs)** are based on the 1968 RDAs for certain vitamins and minerals. RDIs have been set for four categories of people: infants, toddlers, people over 4 years of age, and pregnant or lactating women. Generally, the RDIs are set to the highest 1968 RDA value of an age category. For example, the highest RDA for iron in males over 4 years of age is 10 mg/day and, for females over 4 years of age, 18 mg/day. Thus, the RDI for iron is set at 18 mg/day.
- **Daily Reference Values (DRVs)** are set for total fat, saturated fat, cholesterol, total carbohydrate, dietary fiber, sodium, potassium, and protein.

Having two standards on food labels, RDIs for vitamins and minerals and DRVs for other nutrients, was thought to be more confusing for consumers than having one standard. Therefore, the RDIs and DRVs were combined to form the Daily Values.

The Daily Values appearing on food labels are based on a 2000 kcal reference diet, which approximates the weight maintenance requirements of postmenopausal women, women who exercise moderately, teenage girls, and sedentary men (figure 25.2). On large food labels, additional information is listed based on a daily intake of 2500 kcal, which is adequate for young men. However, government standards do not require that all possible Daily Values be listed on food labels.

The Daily Values for energy-producing nutrients are determined as a percentage of daily kilocalorie intake: 60% for carbohydrates, 30% for total fats, 10% for saturated fats, and 10% for proteins. The Daily Value for fiber is 14 g for each 1000 kcal of intake. The Daily Values for a nutrient in a 2000 kcal/day diet can be calculated on the basis of the recommended daily percentage of the nutrient and the kilocalories in a gram of the nutrient. For example, carbohydrates should compose 60% of a 2000 kcal/day diet, or 1200 kcal/day (0.60×2000). Since there are 4 kcal in a gram of carbohydrate, the Daily Value for carbohydrate is 300 g/day ($1200/4$).

TABLE 25.3 Important Minerals

Mineral	Function	Symptoms of Deficiency	Reference Daily Intake (RDI)*
Calcium	Bone and teeth formation, blood clotting, muscle activity, nerve function	Spontaneous action potential generation in neurons, tetany	1000 mg
Chlorine	Blood acid-base balance; hydrochloric acid production in stomach	Acid-base imbalance	2.3 g [†]
Chromium	Associated with enzymes in glucose metabolism	Unknown	35 µg
Cobalt	Component of vitamin B ₁₂ , red blood cell production	Anemia	Unknown
Copper	Hemoglobin and melanin production, electron-transport system	Anemia and loss of energy	0.9 mg
Fluorine	Provides extra strength in teeth, prevents dental caries	No real pathology	4 mg
Iodine	Thyroid hormone production; maintenance of normal metabolic rate	Goiter and decrease in normal metabolism	150 µg
Iron	Component of hemoglobin; ATP production in electron-transport system	Anemia, decreased O ₂ transport, energy loss	18 mg
Magnesium	Coenzyme constituent, bone formation, muscle and nerve function	Increased nervous system irritability, vasodilation, arrhythmias	420 mg
Manganese	Hemoglobin synthesis, growth, activation of several enzymes	Tremors, convulsions	2.3 mg
Molybdenum	Enzyme component	Unknown	45 µg
Phosphorus	Bone and teeth formation; energy transfer (ATP); component of nucleic acids	Loss of energy and cellular function	1250 mg
Potassium	Muscle and nerve function	Muscle weakness, abnormal electrocardiogram, alkaline urine	3.5 g
Selenium	Component of many enzymes	Unknown	55 µg
Sodium	Osmotic pressure regulation; nerve and muscle function	Nausea, vomiting, exhaustion, dizziness	1.5 g [†]
Sulfur	Component of hormones, several vitamins, proteins	Unknown	Unknown
Zinc	Component of several enzymes; CO ₂ transport and metabolism; protein metabolism	Deficient CO ₂ transport, deficient protein metabolism	11 mg

*Reference Daily Intakes for people over 4 years of age, except for sodium.

[†]3.8 g sodium chloride (table salt).

The Daily Values for some nutrients are limited due to their link to certain diseases. Thus, the Daily Values for total fats are less than 65 g; for saturated fats, less than 20 g; and for cholesterol, less than 300 mg because these nutrients are associated with increased risk for heart disease. The Daily Value for sodium is less than 2400 mg because of its association with high blood pressure in some people.

For a particular food, the Daily Value is used to calculate the **Percent Daily Value (% Daily Value)** for some of the nutrients in one serving of the food (figure 25.2). For example, if a serving of food has 3 g of fat and the Daily Value for total fat is 65 g, the % Daily Value is 5% ($3/65 = 0.05$, or 5%). The Food and Drug Administration (FDA) requires % Daily Values to be on food labels, so that the public has useful and accurate dietary information.

➤ Predict 3

One serving of a food contains 30 g of carbohydrate. What % Daily Value for carbohydrate would appear on the food label?

The % Daily Values for nutrients related to energy consumption are based on a 2000 kcal/day diet. For people who maintain their weight on a 2000 kcal/day diet, the total of the % Daily Values for each of these nutrients should be no more than 100%. However, for individuals consuming more or fewer than 2000 kcal/day, the total % Daily Values can be more or fewer than 100%. For example, for a person consuming 2200 kcal/day, the total of the % Daily Values for each of these nutrients should be no more than 110% because $2200/2000 = 1.10$, or 110%.

When using the % Daily Values of a food to determine how the amounts of its nutrients fit into the overall diet, the number of servings in a container or package needs to be considered. For example, suppose a small (2.25-ounce) bag of corn chips has a % Daily Value of 16% for total fat. A person might suppose that eating the bag of chips accounts for 16% of total fat for the day. The bag, however, contains 2.5 servings. Therefore, if all the chips in the bag are consumed, they account for 40% ($16\% \times 2.5$) of the maximum recommended total fat.

**FIGURE 25.2 Food Labels**

ASSESS YOUR PROGRESS

- What are the Reference Daily Intakes and the Daily Reference Values? When combined, what reference set of values is established?
- Define % Daily Values. The % Daily Values appearing on food labels is based on how many kilocalories per day?

25.2 Metabolism**LEARNING OUTCOMES**

After reading this section, you should be able to

- Define **metabolism**, **anabolism**, and **catabolism**.
- Relate **hydrogen atoms** to **energy**.

Metabolism (mě-tab'ō-lizm; change) is the total of all the chemical reactions that occur in the body. It consists of catabolism and anabolism. **Catabolism** (kă-tab'ō-lizm) includes the energy-releasing process by which large molecules are broken down into smaller molecules. **Anabolism** (ă-nab'ō-lizm) includes the energy-requiring process by which small molecules are joined to form larger molecules.

Catabolism of nutrients begins during digestion when large molecules, such as polysaccharides and fats, are broken down for absorption by the small intestine. The process of catabolism continues in the cells when the absorbed nutrients are further broken down for ATP production. The energy derived from catabolism is used to drive anabolic reactions and processes such as active transport and muscle contraction. Anabolism occurs in all the body cells as they divide to form new cells, maintain their own

intracellular structure, and produce molecules, such as hormones, neurotransmitters, and extracellular matrix molecules, for export.

Large nutrient molecules, such as carbohydrates, lipids, and proteins, are broken down by digestion into smaller molecules, such as glucose, amino acids, and fatty acids, which are absorbed from the digestive tract into the blood (see chapter 24). These smaller molecules are taken into cells, where they are catabolized, and the energy from them is used to combine adenosine diphosphate (ADP) and an inorganic phosphate group (P_i) to form ATP (figure 25.3):

The energy in small nutrient molecules is used to produce many ATP molecules, each of which stores a small amount of energy. These smaller amounts of energy are more readily available for use in cells than is the larger amount of energy stored in nutrient molecules. ATP is often called the energy currency of the cell because, when it is spent, or broken down to ADP, energy becomes available for use by the cell. As a comparison, if a quarter represents an ATP molecule, then a \$20 bill is analogous to a small nutrient molecule. The quarter (ATP) can be used in various vending machines (chemical reactions), but the \$20 bill (nutrient molecule) cannot.

The chemical reactions responsible for transferring energy from the chemical bonds of nutrient molecules to ATP molecules involve oxidation-reduction reactions (see chapter 2). A molecule is reduced when it gains electrons. A molecule is oxidized when it loses electrons. A nutrient molecule has many hydrogen atoms covalently bonded to the carbon atoms that form the “backbone” of the molecule. Because a hydrogen atom is composed of a H^+ (proton) and an electron, the nutrient molecule has many electrons and is, therefore, highly reduced. When a H^+ and an associated electron are lost from the nutrient molecule, the molecule loses energy and becomes oxidized. The energy in the electron is used to synthesize ATP. The major events of ATP synthesis are summarized in figure 25.4.

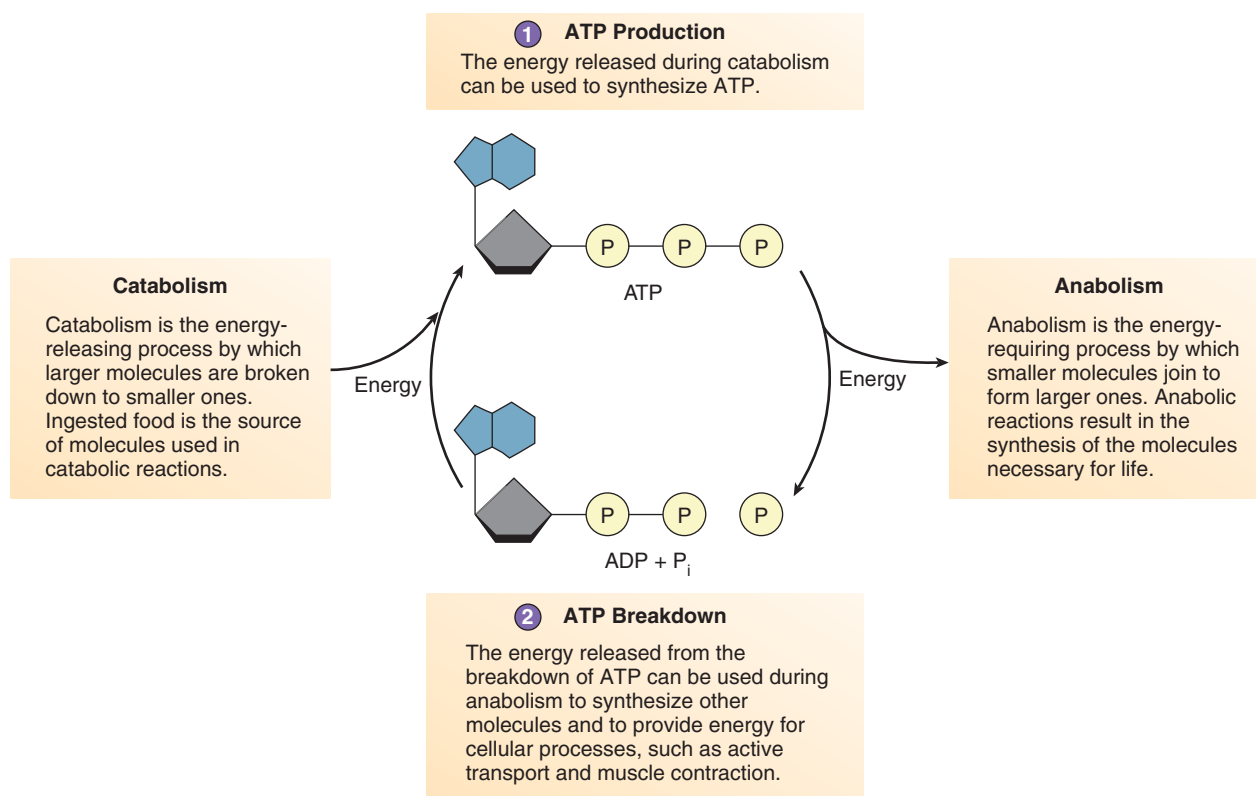

ASSESS YOUR PROGRESS

- How are **metabolism**, **anabolism**, and **catabolism** related? How is the energy derived from catabolism used to drive anabolic reactions?
- How does the removal of hydrogen atoms from nutrient molecules result in a loss of energy from the nutrient molecule?

25.3 Carbohydrate Metabolism**LEARNING OUTCOMES**

After reading this section, you should be able to

- Describe **glycolysis** and name its products.
- Describe the **citric acid cycle** and name its products.
- Explain the **electron-transport chain** and how **ATP** is produced in the process.
- Explain the difference between the number of **ATP** molecules produced by **aerobic respiration** and the number produced by **anaerobic glycolysis**.

PROCESS FIGURE 25.3 ATP Derived from Catabolic Reactions Drives Anabolic Reactions

Energy released by catabolism is required to form ATP from ADP and phosphate (P_i). Energy and a phosphate are given off when ATP is converted back to ADP during anabolism.

Monosaccharides are the breakdown products of carbohydrate digestion. Glucose is the most important monosaccharide in terms of cellular metabolism for humans. Glucose is transported in the blood to all the tissues of the body, where it serves as a source of energy. Any excess glucose in the blood following a meal can be used to form glycogen, or glucose can be partially broken down and the components used to form lipids. Glycogen is a short-term energy-storage molecule that the body can store in limited amounts, whereas lipids are long-term energy-storage molecules that the body can store in large amounts. Most of the body's glycogen is in skeletal muscle and in the liver.

Glycolysis

Carbohydrate metabolism begins with **glycolysis** (glī-kol'i-sis), a series of chemical reactions in the cytosol that results in the breakdown of glucose into two **pyruvic** (pī-roo'vik) **acid** molecules (figure 25.5).

Glycolysis is divided into four phases:

1. *Input of ATP.* The first steps in glycolysis require the input of energy in the form of two ATP molecules (figure 25.5, *step 1*). The energy is necessary to make the glucose molecule, a relatively stable molecule, more reactive. An ATP molecule is used in the process called **phosphorylation** (fos'fōr-i-lā'shūn), where a phosphate group is transferred

from ATP to glucose. This first step forms glucose-6-phosphate. The glucose-6-phosphate atoms are rearranged to form fructose-6-phosphate. A second ATP molecule is then used to phosphorylate fructose-6-phosphate, producing fructose-1,6-bisphosphate.

2. *Sugar cleavage.* Fructose-1,6-bisphosphate is cleaved, or broken, into two 3-carbon molecules, glyceraldehyde (glis'er-al'dē-hīd)-3-phosphate and dihydroxyacetone (dī'hī-drok-sē-as'e-tōn) phosphate. Dihydroxyacetone phosphate is rearranged to form a second glyceraldehyde-3-phosphate; consequently, two molecules of glyceraldehyde-3-phosphate result (figure 25.5, *step 2*).
3. *NADH production.* Each glyceraldehyde-3-phosphate molecule is oxidized (loses two electrons) to form 1,3-bisphosphoglyceric (biz'phos-fo-gli'sēr'ik) acid, and **nicotinamide adenine** (nik-ō-tin'ā-mīd ad'ē-nēn) **dinucleotide** (NAD⁺) is reduced (gains two electrons) to **NADH** (figure 25.5, *step 3*). Glyceraldehyde-3-phosphate also loses two H⁺, one of which binds to NAD⁺:

NADH is referred to as an electron carrier molecule. The two high-energy electrons (e⁻) gained by NADH can be used to produce ATP molecules through the electron-transport chain (see “Electron-Transport Chain,” later in this section).

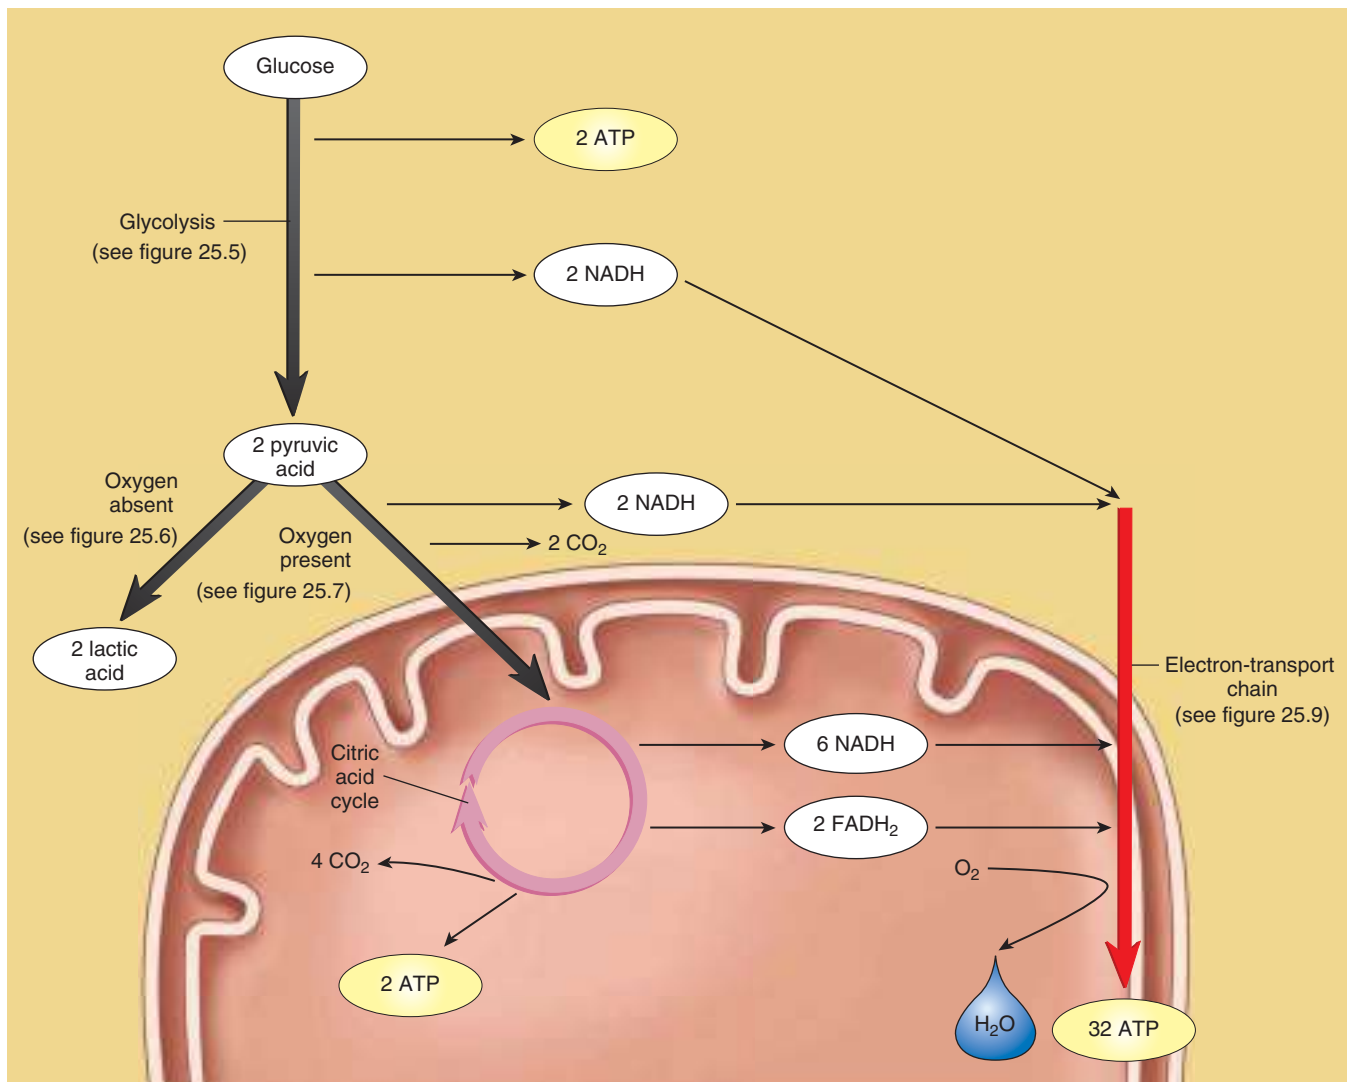

FIGURE 25.4 ATP Synthesis

The major events of ATP synthesis are glycolysis, the citric acid cycle, and the electron-transport chain.

4. *ATP and pyruvic acid production.* The last four steps of glycolysis produce two ATP molecules and one pyruvic acid molecule from each 1,3-bisphosphoglyceric acid molecule. Since the previous step produced two 1,3-bisphosphoglyceric acid molecules, this last step produces four ATP molecules and two pyruvic acid molecules (figure 25.5, *step 4*).

The products of glycolysis are summarized in table 25.4. Each glucose molecule that enters glycolysis forms two glyceraldehyde-3-phosphate molecules at the sugar cleavage phase. Each glyceraldehyde-3-phosphate molecule produces two ATP molecules, one NADH molecule, and one pyruvic acid molecule. The breakdown of each glucose molecule, therefore, produces four ATP, two NADH, and two pyruvic acid molecules. However, because the start of glycolysis requires the input of two ATP molecules, the final yield of each glucose molecule is two ATP, two NADH, and two pyruvic acid molecules (see figure 25.4).

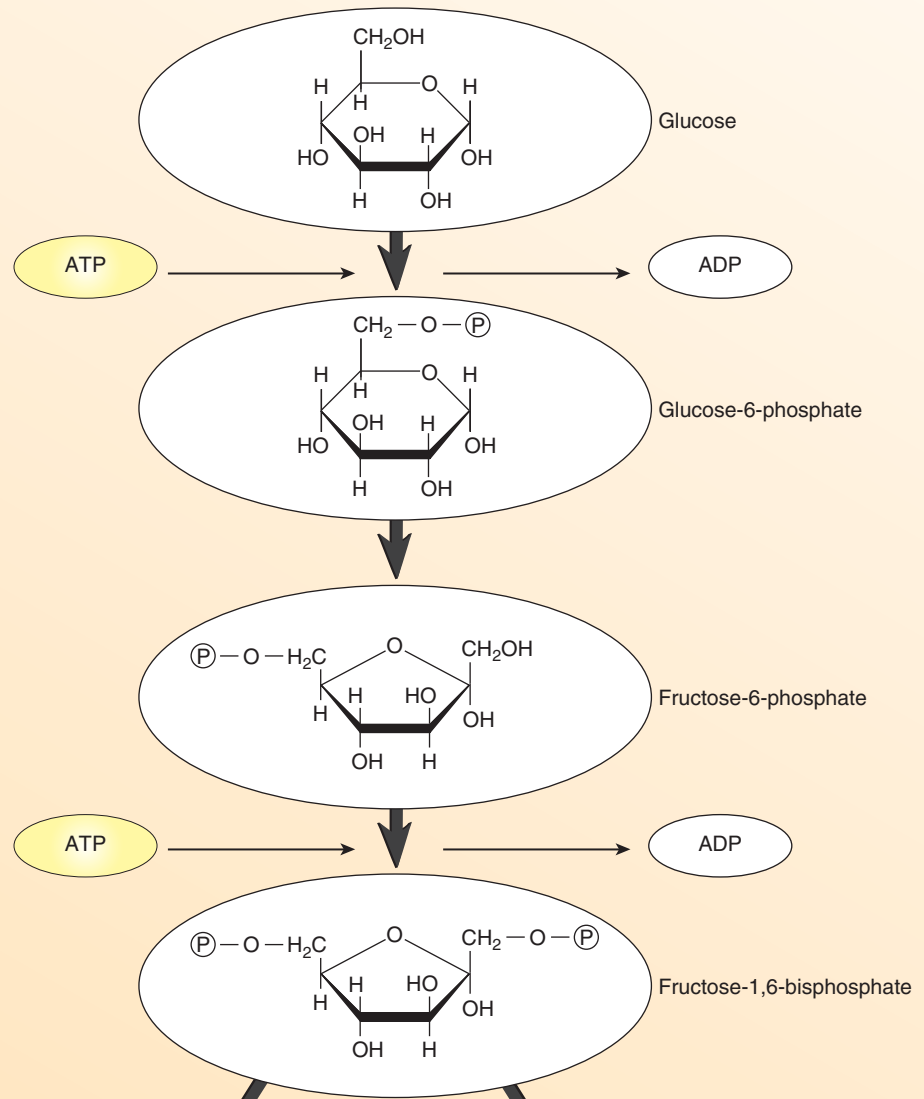

If the cell has adequate amounts of oxygen, the NADH and pyruvic acid molecules are used in aerobic respiration to produce ATP. In the absence of sufficient oxygen, they are used in anaerobic glycolysis.

Anaerobic Glycolysis

Anaerobic (an-ār-ō'bik) **glycolysis** is the breakdown of glucose in the absence of oxygen. In human cells, the breakdown of a glucose molecule in the absence of oxygen produces two molecules of **lactate** and two molecules of ATP (figure 25.6). The ATP thus produced is a source of energy during activities such as intense exercise, when insufficient oxygen is delivered to tissues. Anaerobic glycolysis can be divided into two phases:

1. *Glycolysis.* Glucose undergoes several reactions to produce two pyruvic acid molecules and two NADH. There is also a net gain of two ATP molecules.

1 Input of ATP
 Two ATP molecules are required to start glycolysis; fructose-1,6-bisphosphate is formed.

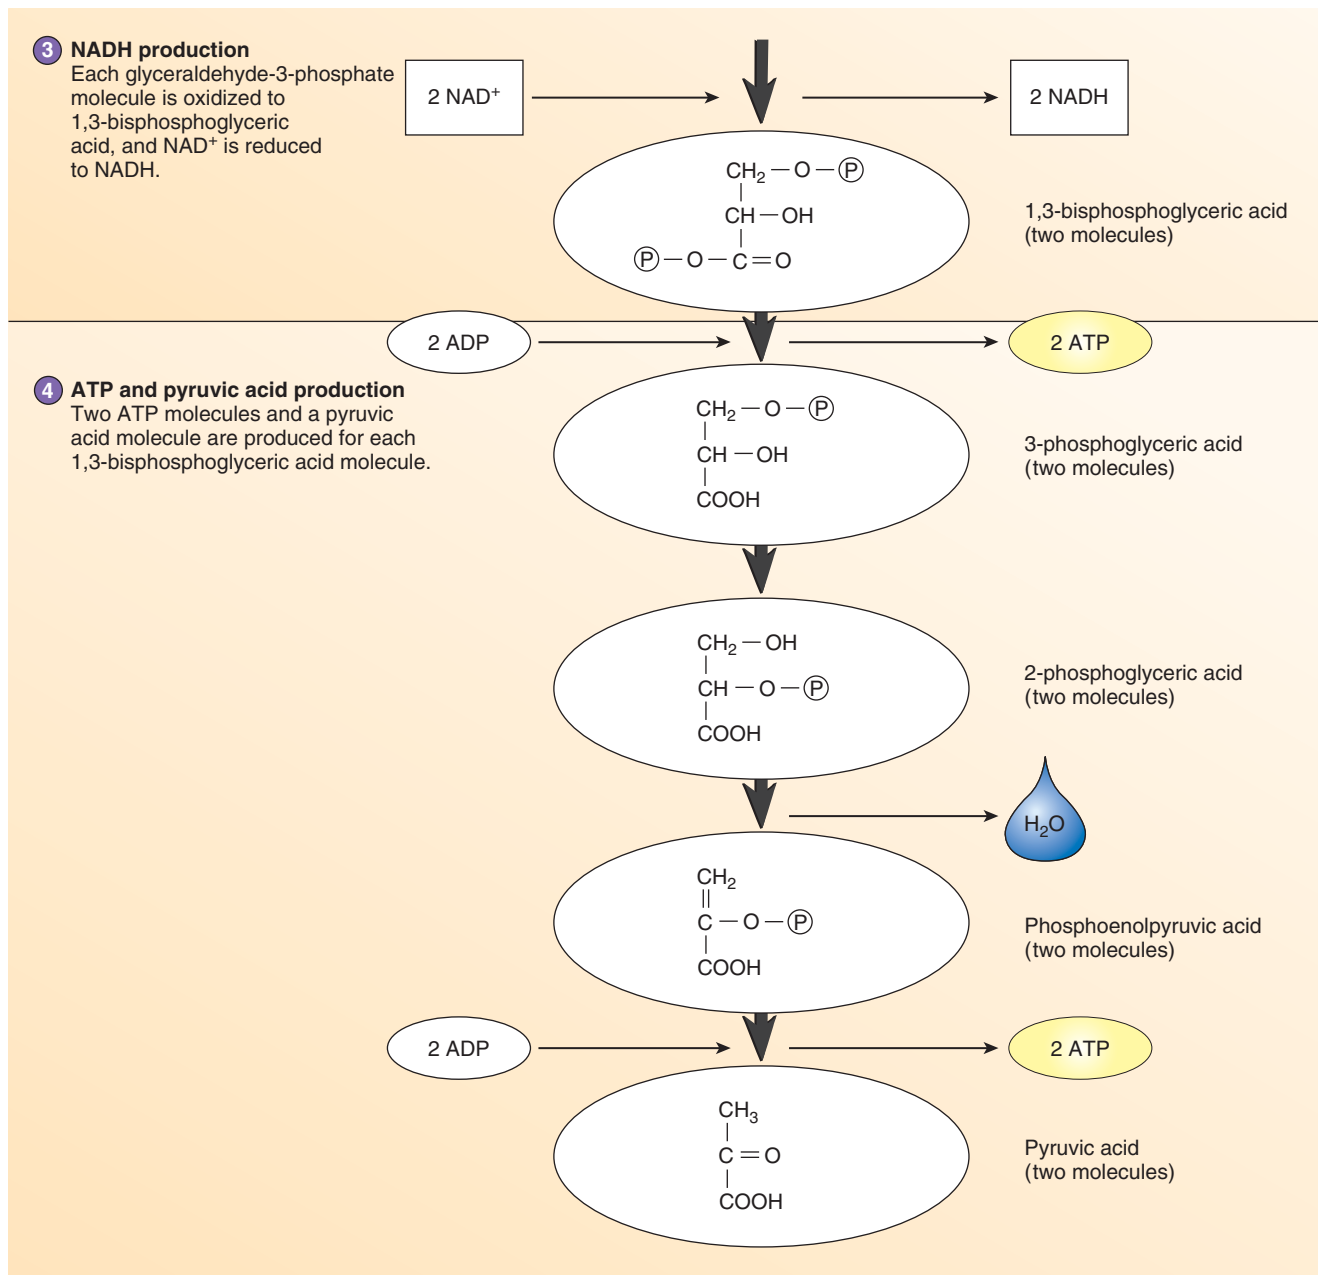

2 Sugar cleavage
 Fructose-1,6-bisphosphate is split to form two 3-carbon glyceraldehyde-3-phosphate molecules.

PROCESS FIGURE 25.5 Glycolysis

The chemical reactions of glycolysis take place in the cytosol.

**PROCESS FIGURE 25.5 (continued)**

2. **Lactate formation.** Pyruvic acid is first converted to **lactic acid**, a reaction that requires the input of energy from the NADH produced in step 3 of glycolysis. In cells, lactic acid usually releases a H^+ and is converted to lactate, the ionized form of lactic acid. Lactate is released from the cells that produce it, and blood transports it to the liver.

When oxygen becomes available, the lactate in the liver can be converted through a series of chemical reactions into glucose. The glucose then can be released from the liver and transported in the blood to cells that use glucose for energy. This process of converting lactate to glucose is called the **Cori cycle**. Some of the reactions involved in this process require energy derived from ATP that is produced by aerobic respiration. The

oxygen necessary for synthesizing the ATP is part of the **oxygen deficit** (see chapter 9).

ASSESS YOUR PROGRESS

- Describe the four phases of glycolysis. What are the products of glycolysis?
- What determines whether the pyruvic acid produced in glycolysis is used in aerobic respiration or anaerobic glycolysis?
- Describe the two phases of anaerobic glycolysis. How many ATP molecules result from anaerobic glycolysis?
- What happens to the lactate produced in anaerobic glycolysis once oxygen becomes available?

TABLE 25.4 ATP Production from One Glucose Molecule

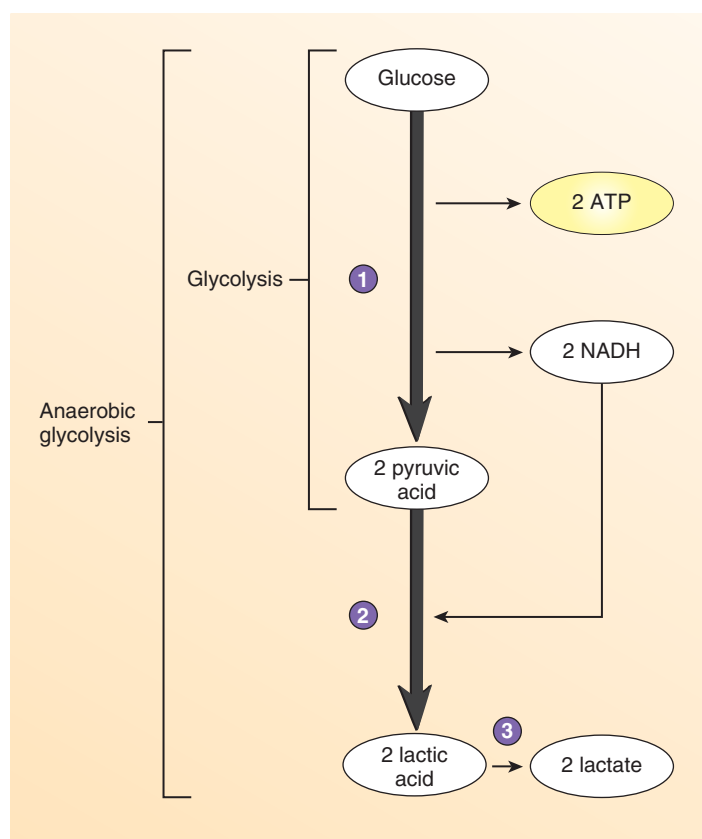

Process	Product	Total ATP Produced*
Glycolysis	4 ATP	2 ATP (4 ATP produced minus 2 ATP to start)
	2 NADH	4 ATP
Acetyl-CoA production	2 NADH	6 ATP
Citric acid cycle	2 ATP	2 ATP
	6 NADH	18 ATP
	2 FADH ₂	4 ATP
Total		36 ATP

*NADH and FADH₂ are used in the production of ATP in the electron-transport chain.
 Abbreviations: ATP = adenosine triphosphate; NADH = reduced nicotinamide adenine dinucleotide; FADH₂ = reduced flavin adenine diphosphate; acetyl-CoA = acetyl coenzyme A.

Aerobic Respiration

Aerobic (ār-ō'vik) **respiration** is the breakdown of glucose in the presence of oxygen to produce carbon dioxide, water, and 36 ATP molecules. Most of the ATP molecules required to sustain life are produced through aerobic respiration. This process is quite complex. For simplicity, aerobic respiration can be considered in four phases: (1) glycolysis (which is also the first phase of anaerobic glycolysis), (2) acetyl-CoA formation, (3) the citric acid cycle, and (4) the electron-transport chain (figure 25.7).

- 1 Glycolysis converts glucose to two pyruvic acid molecules. There is a net gain of two ATP and two NADH from glycolysis.
- 2 The two pyruvic acid molecules produced by glycolysis are first converted to two lactic acid molecules. This conversion requires energy, which is derived from the NADH generated in glycolysis.
- 3 Lactic acid molecules release H⁺, forming lactate.

PROCESS FIGURE 25.6
 Anaerobic Glycolysis

Acetyl-CoA Formation

Recall that glycolysis, the first phase, produces pyruvic acid. In the second phase of aerobic respiration, pyruvic acid is converted to acetyl-CoA, releasing carbon dioxide in the process. The pyruvic acid moves from the cytosol into a mitochondrion. A mitochondrion is separated into the intermembrane space and the matrix by the inner mitochondrial membrane (see figure 3.29). Within the matrix, enzymes remove a carbon and two oxygen atoms from the 3-carbon pyruvic acid molecule to form carbon dioxide and a 2-carbon acetyl (as'e-til) group (figure 25.8, *step 2*). During this reaction, H⁺ and electrons are also released and used to reduce NAD⁺ to NADH. The acetyl group combines with coenzyme A (CoA) to form acetyl-CoA. For each two pyruvic acid molecules from glycolysis, two acetyl-CoA molecules, two carbon dioxide molecules, and two NADH are formed (see figure 25.4).

Citric Acid Cycle

The third phase of aerobic respiration is the **citric acid cycle**, which is named after the 6-carbon citric acid molecule formed in the first step of the cycle (figure 25.8, *step 3*). It is also called the *Krebs cycle* after its discoverer, British biochemist Sir Hans Krebs. The citric acid cycle begins with the production of citric acid. This occurs when the 2-carbon acetyl-CoA, produced in the second phase, combines with a 4-carbon molecule called **oxaloacetic acid** (ok'sā-lō-ă-sē'tik) **acid**. A series of reactions occurs in which the citric acid molecule is modified, producing ATP, electron carriers (NADH and FADH₂), and carbon dioxide. As the cycle proceeds, another oxaloacetic acid molecule is produced. This new oxaloacetic acid can start the cycle again by combining with another acetyl-CoA. During the reactions of the citric acid cycle, three important events occur:

1. **ATP production.** For each citric acid molecule, one ATP is formed.
2. **NADH and FADH₂ production.** For each citric acid molecule, three NAD⁺ molecules are converted to NADH molecules, and one flavin (flā'vin) adenine dinucleotide (FAD) molecule is converted to FADH₂. The NADH and FADH₂ molecules are electron carriers that enter the electron-transport chain and are used to produce ATP.
3. **Carbon dioxide production.** Each 6-carbon citric acid molecule at the start of the cycle becomes a 4-carbon oxaloacetic acid molecule at the end of the cycle. Two carbon and four oxygen atoms from the citric acid

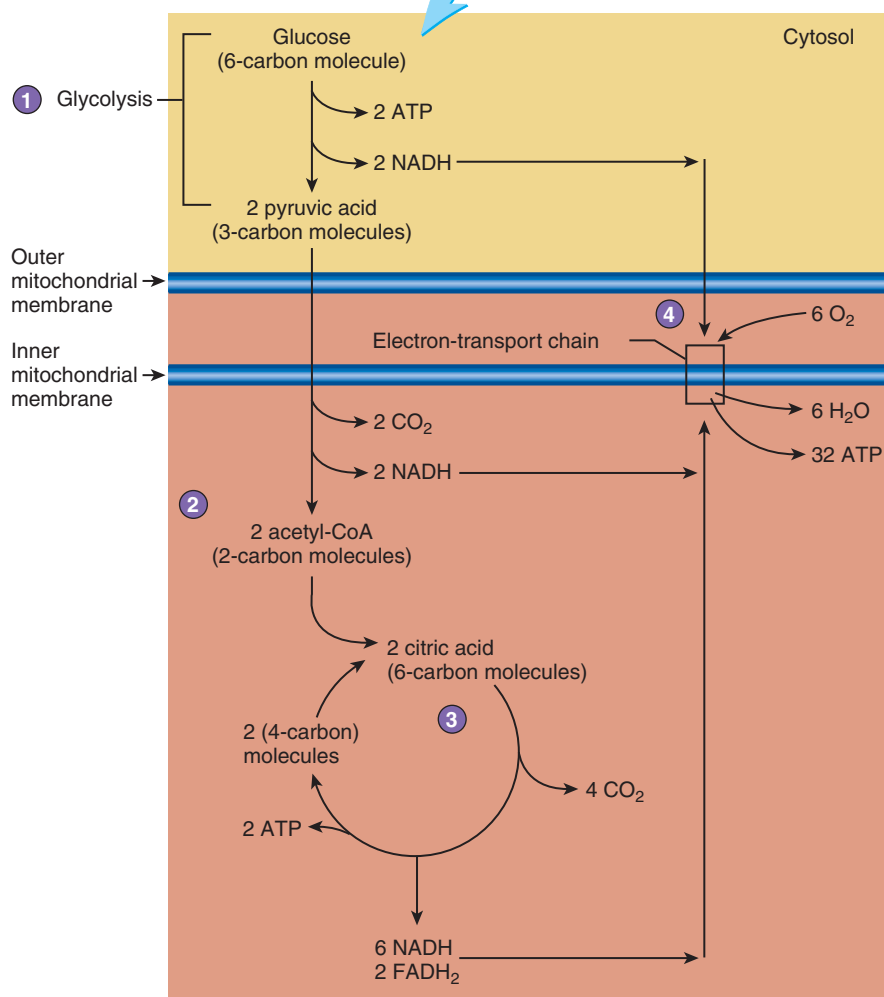

1 Glycolysis in the cytosol converts glucose to two pyruvic acid molecules and produces two ATP and two NADH. The NADH can go to the electron-transport chain in the inner mitochondrial membrane.

2 The two pyruvic acid molecules produced in glycolysis are converted to two acetyl-CoA molecules, producing two CO₂ and two NADH. The NADH can go to the electron-transport chain.

3 The two acetyl-CoA molecules enter the citric acid cycle, which produces four CO₂, six NADH, two FADH₂, and two ATP. The NADH and FADH₂ can go to the electron-transport chain.

4 The electron-transport chain uses NADH and FADH₂ to produce 32 ATP. This process requires O₂, which combines with H⁺ to form H₂O.

PROCESS FIGURE 25.7 Aerobic Respiration

Aerobic respiration involves four phases: (1) glycolysis, (2) acetyl-CoA formation, (3) the citric acid cycle, and (4) the electron-transport chain. The number of carbon atoms in a molecule is indicated after the molecule’s name. As glucose is broken down, the carbon atoms from glucose are incorporated into carbon dioxide.

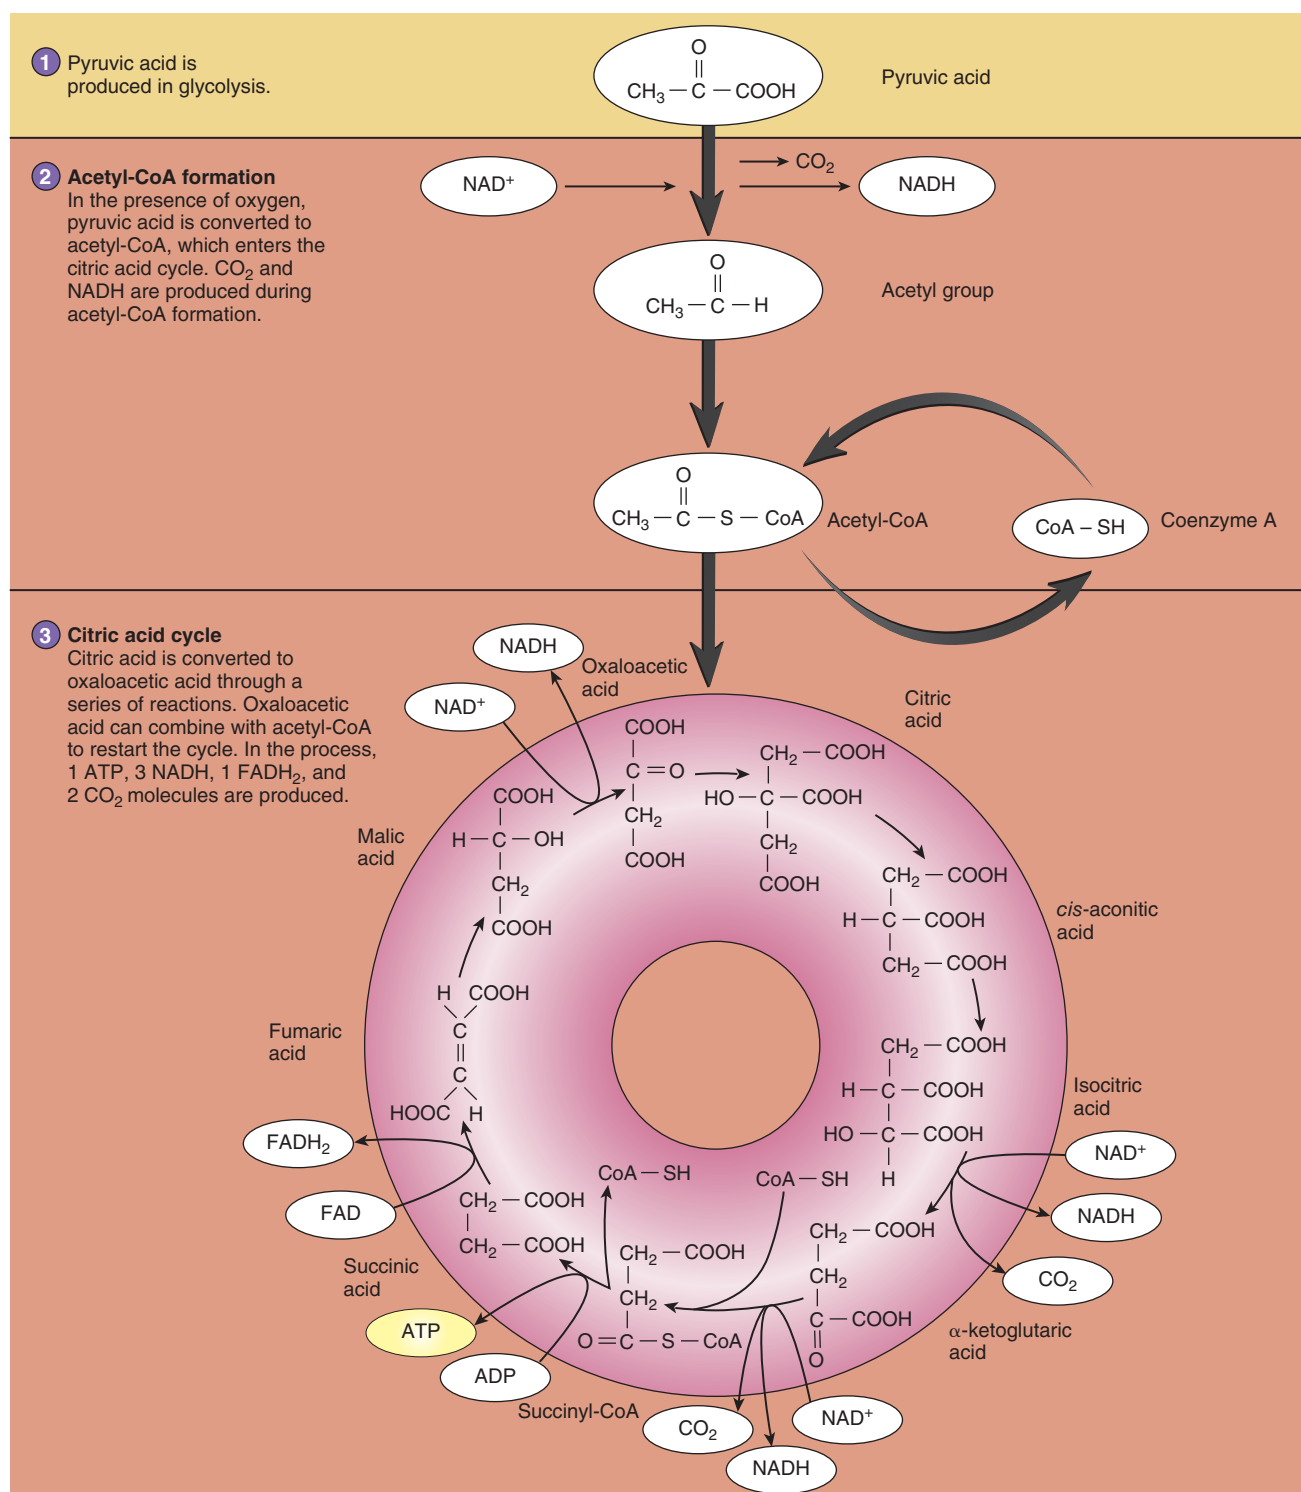

molecule are used to form two carbon dioxide molecules. Thus, some of the carbon and oxygen atoms that make up food molecules, such as glucose, are eventually eliminated from the body as carbon dioxide. Humans literally breathe out part of the food they eat.

Before moving to the last phase, let’s summarize the reactions in the first three phases. For each glucose molecule that begins aerobic respiration, two pyruvic acid molecules are produced in glycolysis, and they are converted into two acetyl-CoA molecules, each of which then enters the citric acid cycle. To determine the number of molecules produced from glucose by the citric acid cycle, two “turns” of the cycle must be counted; the results are two ATP, six NADH, two FADH₂, and four carbon dioxide molecules (see figure 25.4).

Electron-Transport Chain

The fourth phase of aerobic respiration involves the **electron-transport chain** (figure 25.9), which is a series of electron carriers in the inner mitochondrial membrane. At the beginning of this phase, electrons are transferred from NADH and FADH₂ to the electron-transport carriers. Electrons and H⁺ are released from NADH and FADH₂ (figure 25.9, *step 1*). After the loss of the electrons and the H⁺, the oxidized NAD⁺ and FAD are reused to transport additional electrons from the citric acid cycle to the electron-transport chain.

The electrons released from NADH and FADH₂ pass from one electron carrier to the next through a series of oxidation-reduction reactions. Three of the electron carriers also function as proton pumps, which move the H⁺ from the mitochondrial matrix into the intermembrane space (figure 25.9, *step 2*). Each proton pump

PROCESS FIGURE 25.8 Acetyl-CoA and the Citric Acid Cycle

Pyruvic acid from the cytosol is converted to acetyl-CoA in mitochondria. The acetyl-CoA enters the citric acid cycle.

accepts an electron, uses some of the electron's energy to export a H⁺, and passes the electron to the next electron carrier. The last electron carrier in the series collects the electrons and combines them with oxygen and H⁺ to form water (figure 25.9, *step 3*):

Oxygen is the final acceptor of electrons in this process. Without oxygen to accept the electrons, the reactions of the electron-transport chain cease, effectively stopping aerobic respiration.

The H⁺ released from NADH and FADH₂ is moved from the intermembrane space to the matrix by active transport. As a result, the concentration of H⁺ in the intermembrane space exceeds that

FUNDAMENTAL Figure

- 1 NADH or $FADH_2$ transfers its electrons to the electron-transport chain.
- 2 As the electrons move through the electron-transport chain, some of their energy is used to pump H^+ into the intermembrane space, resulting in a higher concentration of H^+ in the intermembrane space than in the matrix.
- 3 The H^+ diffuses back into the matrix through special channels (ATP synthase) that couple the H^+ movement with the production of ATP. The electrons, H^+ , and O_2 combine to form H_2O .
- 4 ATP is transported out of the matrix by a carrier protein that exchanges ATP for ADP. A different carrier protein moves phosphate into the matrix.

PROCESS FIGURE 25.9 Electron-Transport Chain

The electron-transport chain in the mitochondrial inner membrane consists of four protein complexes (purple; numbered I to IV) with carrier proteins.

of the matrix and a H^+ concentration gradient is established. The H^+ cannot simply diffuse down the concentration gradient but must pass through certain channels formed by an enzyme called **ATP synthase**. As the H^+ diffuses down the concentration gradient, energy is released that is used to produce ATP (figure 25.9, step 3). This process is called **chemiosmosis** (kem-ē-os-mō'sis) because the chemical formation of ATP is coupled to a diffusion force similar to osmosis.

Predict 4

Many poisons function by blocking certain steps in metabolic pathways. For example, cyanide blocks the last step in the electron-transport chain. Explain why this blockage causes death.

Summary of ATP Production

As stated earlier, the process of aerobic respiration is complex. The major product of this process is ATP, so it is helpful to now summarize the combined yield of ATP from all phases. For each glucose molecule, aerobic respiration produces a net gain of 36 ATP

molecules: 2 from glycolysis, 2 from the citric acid cycle, and 32 from the NADH molecules and $FADH_2$ molecules that pass through the electron-transport chain (table 25.4). For each NADH molecule formed, 2 or 3 ATP molecules are produced by the electron-transport chain; for each $FADH_2$ molecule, 2 ATP molecules are produced.

The number of ATP molecules produced from each glucose molecule is a theoretical number. The calculations that predict 36 ATP molecules per glucose molecule assume that 2 H^+ are necessary for the formation of each ATP. If more than 2 are required, the efficiency of aerobic respiration decreases. In addition, the 2 NADH molecules produced by glycolysis in the cytosol cannot cross the inner mitochondrial membrane; thus, their electrons are donated to a shuttle molecule, which carries the electrons to the electron-transport chain. Depending on the shuttle molecule, each glycolytic NADH molecule can produce 2 or 3 ATP molecules. In skeletal muscle and the brain, 2 ATP molecules are produced for each NADH molecule, resulting in a total number of 36 ATP molecules; however, in the liver, kidneys, and heart, 3 ATP molecules may be produced for each NADH molecule, and the total number of ATP molecules formed may be higher. Also, it costs energy to get

ADP and phosphates into the mitochondria and to get ATP out. Considering all these factors, each glucose molecule yields about 25 ATP molecules instead of 36.

In addition to ATP, aerobic respiration also produces carbon dioxide and water. Specifically, aerobic respiration produces 6 carbon dioxide molecules. Water molecules are reactants in some of the chemical reactions of aerobic respiration and products in others. Six water molecules are used, but 12 are formed, for a net gain of 6 water molecules. Thus, aerobic respiration can be summarized as follows:

ASSESS YOUR PROGRESS

32. Define aerobic respiration, and list its products. Describe the four phases of aerobic respiration.
33. Why is the citric acid cycle a cycle? What molecules are produced as a result of the citric acid cycle?
34. What is the function of the electron-transport chain? Describe the process of chemiosmosis that occurs during ATP production.
35. In aerobic respiration, how many ATP molecules are produced from one molecule of glucose through glycolysis, the citric acid cycle, and the electron-transport chain?
36. Why is the total number of ATP produced in aerobic respiration listed as 36? Why could that number be different?
37. Write the summary equation for the aerobic breakdown of one glucose molecule.

25.4 Lipid Metabolism

LEARNING OUTCOME

After reading this section, you should be able to

A. Describe the basic steps involved in using lipids as an energy source.

Lipids are the body's main energy-storage molecules. In a healthy person, lipids are responsible for about 99% of the body's energy storage, and glycogen accounts for about 1%. Although proteins serve as an energy source, they are not considered storage molecules because their breakdown normally involves the loss of molecules that perform other functions.

Triglycerides are the main lipid stored in adipose tissue. Synthesis and breakdown of triglycerides occur constantly; thus, the lipids present in adipose tissue today are not the same lipids that were there a few weeks ago. Between meals, when triglycerides are broken down in adipose tissue, some of the fatty acids produced are released into the blood, where they are called **free fatty acids**. Other tissues, especially skeletal muscle and the liver, use the free fatty acids as a source of energy.

The metabolism of fatty acids occurs by **beta-oxidation**, a series of reactions in which two carbon atoms are removed

from the end of a fatty acid chain to form acetyl-CoA. The process of beta-oxidation continues to remove two carbon atoms at a time until the entire fatty acid chain is converted into acetyl-CoA molecules. Acetyl-CoA can enter the citric acid cycle and be used to generate ATP (figure 25.10).

Acetyl-CoA is also used in **ketogenesis** (kē-tō-jen'ě-sis), the formation of ketone bodies. In the liver, when large amounts of acetyl-CoA are produced, not all of the acetyl-CoA enters the citric acid cycle. Instead, two acetyl-CoA molecules combine to form a molecule of acetoacetic (as'e-tō-a-sē'tik) acid, which is converted mainly into β-hydroxybutyric (hī-drōk'sē-bu-tir'ik) acid and a smaller amount of acetone (as'e-tōn). Acetoacetic acid, β-hydroxybutyric

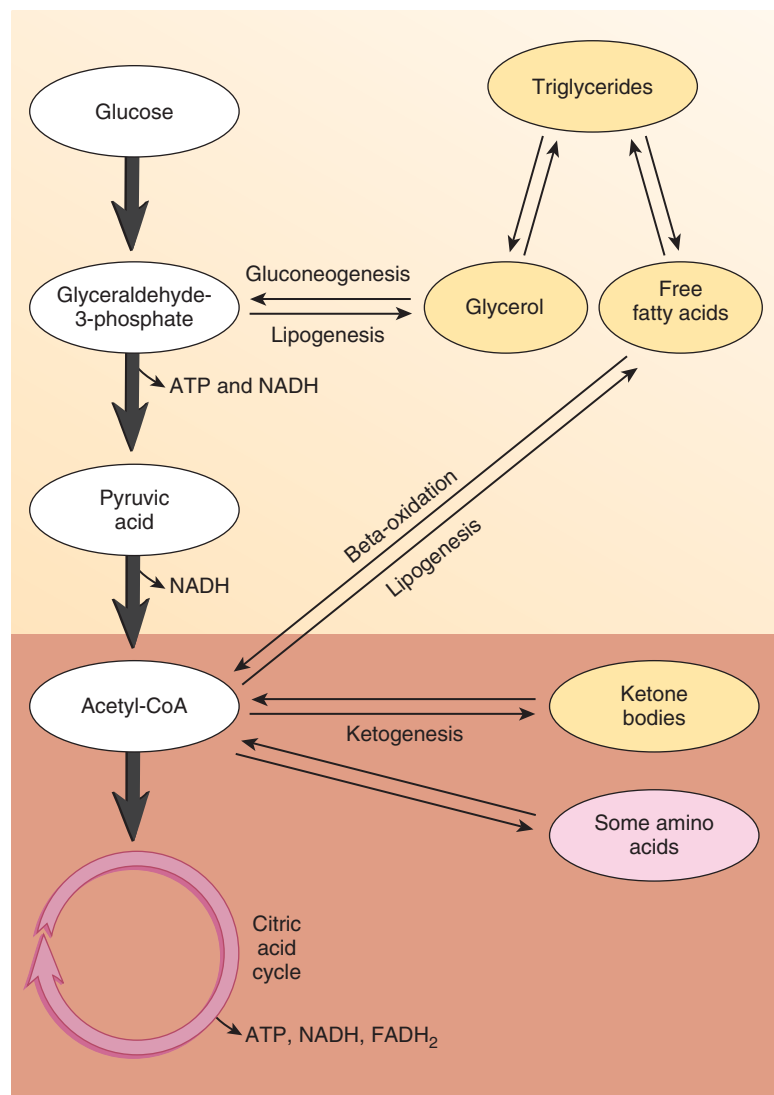

FIGURE 25.10 Lipid Metabolism

Triglycerides are broken down into glycerol and fatty acids. Glycerol enters glycolysis to produce ATP. The fatty acids are broken down by beta-oxidation into acetyl-CoA, which enters the citric acid cycle to produce ATP and electron carriers. Acetyl-CoA can also be used to produce ketone bodies (ketogenesis). Lipogenesis is the production of lipids. Glucose is converted to glycerol, and amino acids are converted to acetyl-CoA molecules. Acetyl-CoA molecules can combine to form fatty acids. Glycerol and fatty acids join to form triglycerides.

acid, and acetone are called **ketone** (kē'tōn) **bodies**; they are released into the blood, where they travel to other tissues, especially skeletal muscle. In these tissues, the ketone bodies are converted back into acetyl-CoA, which enters the citric acid cycle to produce ATP.

The presence of small amounts of ketone bodies in the blood is normal and beneficial, but excessive production of ketone bodies is called **ketosis** (kē-tō'sis). Because ketone bodies are acidic, if the increased number of ketone bodies exceeds the capacity of the body's buffering systems, acidosis, a decrease in blood pH, can occur (see chapter 27). Because ketone bodies are derived from the breakdown of fatty acids, conditions that increase lipid metabolism can speed the rate of ketone body formation, thus increasing the possibility of ketosis. Examples of conditions that increase lipid metabolism are starvation (see Clinical Impact, "Starvation"), diets consisting mainly of proteins and lipids with few carbohydrates, and untreated diabetes mellitus. Ketone bodies are excreted by the kidneys and diffuse into the alveoli of the lungs. Because ketone bodies are excreted by the kidneys and lungs, the characteristics of untreated diabetes mellitus include ketone bodies in the urine and "acetone breath."

38. What is beta-oxidation? Explain how it results in ATP production.
39. What are ketone bodies, how are they produced, and for what are they used? What occurs when there is an excess?

25.5 Protein Metabolism

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe the basic steps involved in using proteins as an energy source.

Recall that proteins are polymers of amino acids. During digestion and absorption in the small intestine, proteins are broken down to individual amino acids. Once absorbed into the body, amino acids are quickly taken up by cells, especially in the liver. Amino acids are used primarily to synthesize needed proteins (see chapter 3), and only secondarily as a source of energy (figure 25.11). Unlike glycogen and triglycerides, amino acids are not stored in the body.

As stated earlier in the chapter, the body can manufacture some amino acids. The synthesis of nonessential amino acids usually begins with keto acids. A keto acid can be converted into an amino acid by replacing its oxygen atom with an amine group (figure 25.12). Usually, this conversion is accomplished by transferring an amine group from an amino acid to the keto acid, a reaction called **transamination** (trans-am'i-nā'shūn). For example, α -ketoglutaric acid (a keto acid) reacts with an amino acid to form glutamic acid (an amino acid; figure 25.13a). Most amino acids can undergo transamination to produce glutamic acid. The

Clinical IMPACT

Starvation

Starvation is the inadequate intake of nutrients or the inability to metabolize or absorb nutrients. It has a number of causes, including prolonged fasting, anorexia, deprivation, and disease. But no matter what the cause, starvation follows the same course and consists of three phases. The first two phases take place even during relatively short periods of fasting or dieting, but the third phase occurs only in prolonged starvation and can end in death.

During the first phase of starvation, blood glucose levels are maintained through the production of glucose from glycogen, lipids, and proteins. At first, glycogen is broken down into glucose; however, only enough glycogen is stored in the liver to last a few hours. Thereafter, blood glucose levels are maintained by the breakdown of lipids and proteins. Triglycerides are decomposed into fatty acids and glycerol. Fatty acids can provide energy, especially for skeletal muscle, thus decreasing the use of glucose by tissues other than the brain. The

brain cannot use fatty acids as an energy source, so the conservation of glucose is critical to normal brain function. Glycerol can be used to make a small amount of glucose, but most of the glucose is formed from the amino acids of proteins. In addition, some amino acids can be used directly for energy.

In the second phase, which can last for several weeks, lipids are the primary energy source. The liver metabolizes fatty acids into ketone bodies, which serve as a source of energy. After about a week of fasting, the brain begins to use ketone bodies, as well as glucose, for energy. This usage decreases the demand for glucose, and the rate of protein breakdown diminishes but does not stop. In addition, the use of proteins is selective; that is, proteins not essential for survival are used first.

The third phase of starvation begins when the lipid reserves are depleted and the body switches to proteins as the major energy source. Muscles, the largest source of protein in the body, are rapidly depleted. At the end of this

phase, proteins essential for cell functions are broken down, and cell function degenerates.

In addition to weight loss, the symptoms of starvation include apathy, listlessness, withdrawal, and increased susceptibility to infection. Few people die directly from starvation because they usually die of an infectious disease first. Other signs of starvation include changes in hair color, flaky skin, and massive edema in the abdomen and lower limbs, causing the abdomen to appear bloated.

During starvation, the body's ability to consume normal volumes of food also decreases. Foods high in bulk but low in protein often cannot reverse the process of starvation. Intervention involves feeding the starving person low-bulk food that provides ample proteins and kilocalories and is fortified with vitamins and minerals. Starvation also results in dehydration; thus, rehydration is an important part of intervention. Even with intervention, a person may be so affected by disease or weakness that he or she cannot recover.

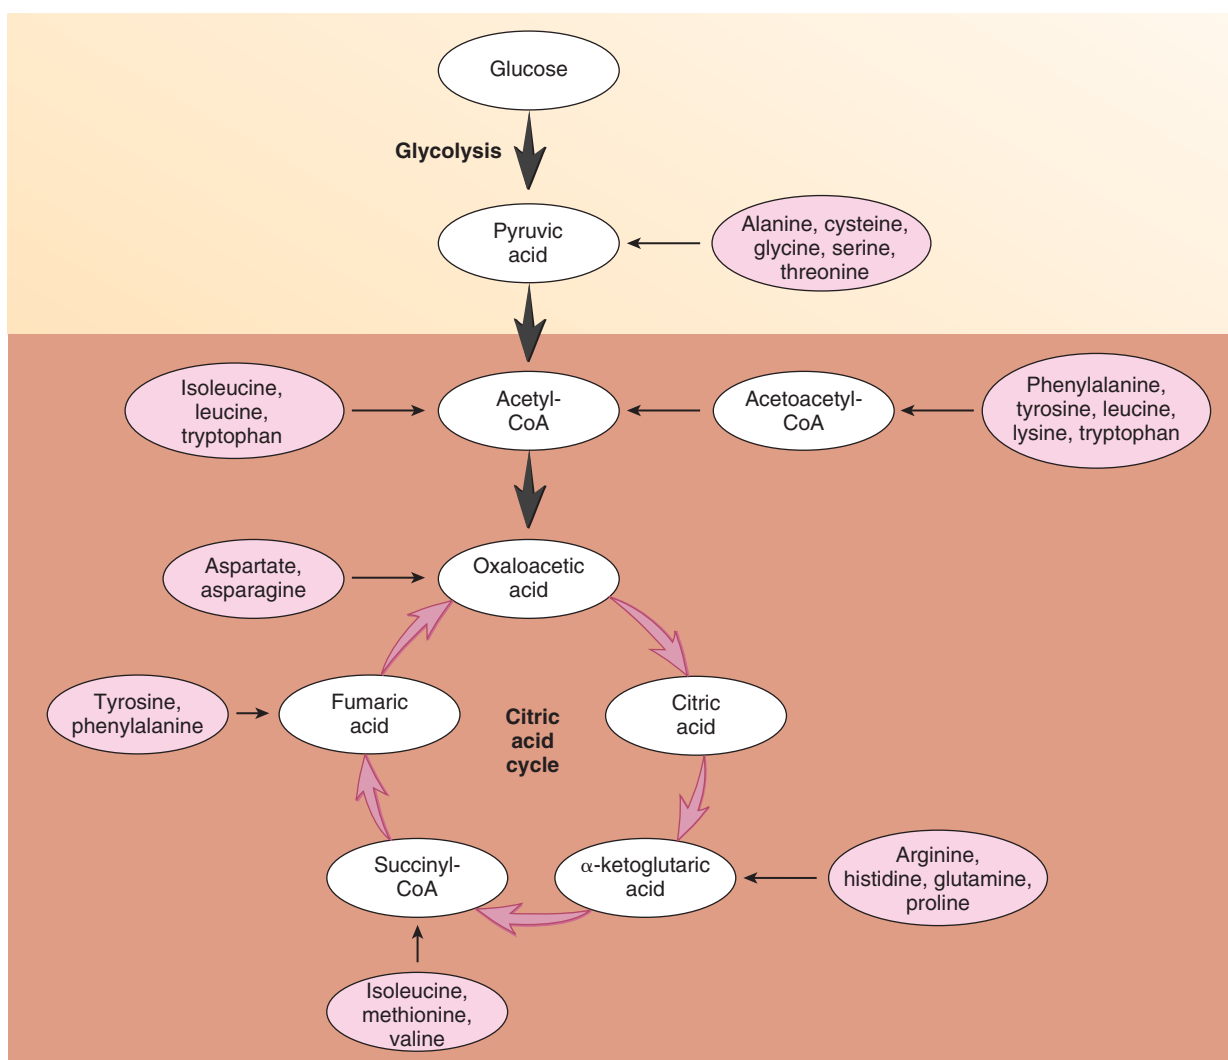

FIGURE 25.11 Amino Acid Metabolism

Amino acids (pink ovals) can enter carbohydrate metabolism at various points.

glutamic acid provides an amine group that is used to synthesize most of the nonessential amino acids. A few nonessential amino acids are formed from the essential amino acids by other chemical reactions.

FIGURE 25.12 General Formulas of an Amino Acid and a Keto Acid

(a) Amino acid with a carboxyl group ($-\text{COOH}$), an amine group (NH_2), a hydrogen atom (H), and a group called “R,” which represents the rest of the molecule. (b) Keto acid with a double-bonded oxygen replacing the amine group and the hydrogen atom of the amino acid.

If serving as a source of energy, amino acids can be used in two ways:

- In **oxidative deamination** (dē-am-i-nā’shŭn), or *deamination* (dē-am’i-nizā’shŭn), an amine group is removed from an amino acid (usually glutamic acid), leaving ammonia and a keto acid (figure 25.13b). In the process, NAD^+ is reduced to NADH , which can enter the electron-transport chain to produce ATP. Although ammonia is toxic to cells, it does not accumulate to toxic levels because the liver converts it to urea, which the blood carries to the kidneys for elimination (figure 25.13c; see chapter 26).
- Amino acids can also be converted into the intermediate molecules of carbohydrate metabolism (see figure 25.11). These molecules are then metabolized to yield ATP. The conversion of an amino acid often begins with a transamination or oxidative deamination reaction, in which the amino acid is converted into a keto acid (see figure 25.12). The keto acid enters the citric acid cycle or is converted into pyruvic acid or acetyl-CoA.

(a) **Transamination**

(b) **Oxidative deamination**

(c) **Conversion of ammonia to urea**

FIGURE 25.13 Amino Acid Reactions

(a) Transamination reaction in which an amine group is transferred from an amino acid to a keto acid to form a different amino acid. (b) Oxidative deamination reaction in which an amino acid loses an amine group to become a keto acid and to form ammonia. In the process, NADH, which can be used to generate ATP, is formed. (c) Ammonia is converted to urea in the liver. (The actual conversion of ammonia to urea is more complex, involving a number of intermediate reactions that constitute the urea cycle.)

- What is accomplished by transamination and oxidative deamination?
- How are proteins (amino acids) used to produce energy?

25.6 Interconversion of Nutrient Molecules

LEARNING OUTCOME

After reading this section, you should be able to

- A. Define glycogenesis, lipogenesis, glycogenolysis, and gluconeogenesis.**

The body relies on homeostatic levels of nutrients in the blood. In maintaining these levels, the cells of the body can store nutrients or convert one type of nutrient molecule to another. This interconversion of nutrient molecules includes several processes, including glycogenesis, lipogenesis, glycogenolysis, and gluconeogenesis.

Blood glucose enters most cells by facilitated diffusion and is immediately converted to glucose-6-phosphate, which cannot recross the plasma membrane (figure 25.14a). Glucose-6-phosphate then continues through glycolysis to produce ATP. However, if excess glucose is present (e.g., after a meal), it is used to form glycogen through a process called **glycogenesis** (glī-kō-jen'ě-sis). Most of the body's glycogen is contained in skeletal muscle and the liver.

Once glycogen stores, which are quite limited, are filled, glucose and amino acids are used to synthesize lipids, a process called **lipogenesis** (lip-ō-jen'ě-sis; see figure 25.10). This process requires the production of glycerol and fatty acid chains, the components of triglycerides. Glucose and amino acids can be converted to intermediates necessary for glycerol and fatty acid production. Glucose molecules can be used to form glyceraldehyde-3-phosphate and acetyl-CoA. Amino acids can also be converted to acetyl-CoA. Glyceraldehyde-3-phosphate is converted to glycerol, and the 2-carbon acetyl-CoA molecules join together to form fatty acid chains. Glycerol and three fatty acids then combine to form triglycerides.

When glucose is needed, glycogen can be broken down into glucose-6-phosphate through a set of reactions called **glycogenolysis** (glī'kō-jě-nol'i-sis; figure 25.14b). In skeletal muscle, glucose-6-phosphate continues through glycolysis to produce ATP. The liver can use glucose-6-phosphate for energy or can convert it to glucose, which diffuses into the blood. Although the liver can release glucose into the blood, skeletal muscle cannot because it lacks the necessary enzymes to convert glucose-6-phosphate into glucose.

The release of glucose from the liver is necessary to maintain blood glucose levels between meals. Maintaining these levels is especially important to the brain, which normally uses only glucose for an energy source and consumes about two-thirds of the total glucose used each day. When liver glycogen levels are inadequate to supply glucose, it is synthesized from molecules other than carbohydrates, such as amino acids from proteins and glycerol from triglycerides. The process of synthesizing glucose from noncarbohydrate sources is called **gluconeogenesis** (gloo'kō-nē-ō-jen'ě-sis). Most amino acids can be converted into citric acid cycle molecules, acetyl-CoA, or pyruvic acid (see figure 25.11). Through a series of

(a) When blood glucose levels are high, glucose enters the cell and is phosphorylated to form glucose-6-phosphate, which can enter glycolysis or glycogenesis.

(b) When blood glucose levels drop, glucose-6-phosphate can be produced through glycogenolysis or gluconeogenesis. Glucose-6-phosphate can enter glycolysis, or in the liver, the phosphate group can be removed and glucose released into the blood.

FIGURE 25.14 Interconversion of Nutrient Molecules

chemical reactions, these molecules are converted into glucose. Glycerol can be converted to glyceraldehyde-3-phosphate, which in turn can be converted to glucose.

ASSESS YOUR PROGRESS

42. Distinguish among the processes of glycogenesis, lipogenesis, glycogenolysis, and gluconeogenesis.

Clinical IMPACT

Alcoholism and Cirrhosis of the Liver

Enzymes in the liver convert ethanol (beverage alcohol) into acetyl-CoA; in the process, two NADH molecules are produced. The NADH molecules enter the electron-transport chain and are used to produce ATP molecules. Each gram of ethanol provides 7 kcal of energy. A high level of NADH in the cell results from the metabolism of ethanol, thereby inhibiting the production of NADH by glycolysis and the citric acid cycle. Consequently, carbohydrates and amino acids do not break down but are converted into lipids, which accumulate in the liver. Therefore, chronic alcohol abuse can result in **cirrhosis** (sir-rō'sis) **of the liver**, which involves lipid deposition, cell death, inflammation, and scar tissue formation. Because the liver is unable to carry out its normal functions, death can result.

25.7 Metabolic States

LEARNING OUTCOME

After reading this section, you should be able to

- A. Differentiate between the absorptive and postabsorptive metabolic states.**

Metabolism refers to the collection of chemical reactions that take place in the cells of the body. These reactions vary depending on levels of activity and availability of nutrients. The body experiences two major metabolic states: the absorptive state and the postabsorptive state. The regulation of these states is discussed in chapter 18 (see section 18.7). The **absorptive state** is the period immediately after a meal, when nutrients are being absorbed through the intestinal wall into the circulatory and lymphatic systems (figure 25.15). The absorptive state usually lasts about 4 hours after each meal, though the rate of absorption declines after 1–2 hours. During this time the cells use most of the glucose that enters the blood for the energy they require. The remainder of the glucose is converted into glycogen or lipids. Most of the absorbed lipids are deposited in adipose tissue. Many of the absorbed amino acids are used by cells in protein synthesis, some are used for energy, and still others enter the liver and are converted into lipids or carbohydrates.

The **postabsorptive state** occurs late in the morning, late in the afternoon, or during the night after each absorptive state is concluded (figure 25.16). The maintenance of normal blood glucose levels is vital to the body's homeostasis, especially for normal functioning of the brain. Therefore, during the postabsorptive state, blood glucose levels are maintained by the conversion of other molecules to glucose. The first source of blood glucose during the

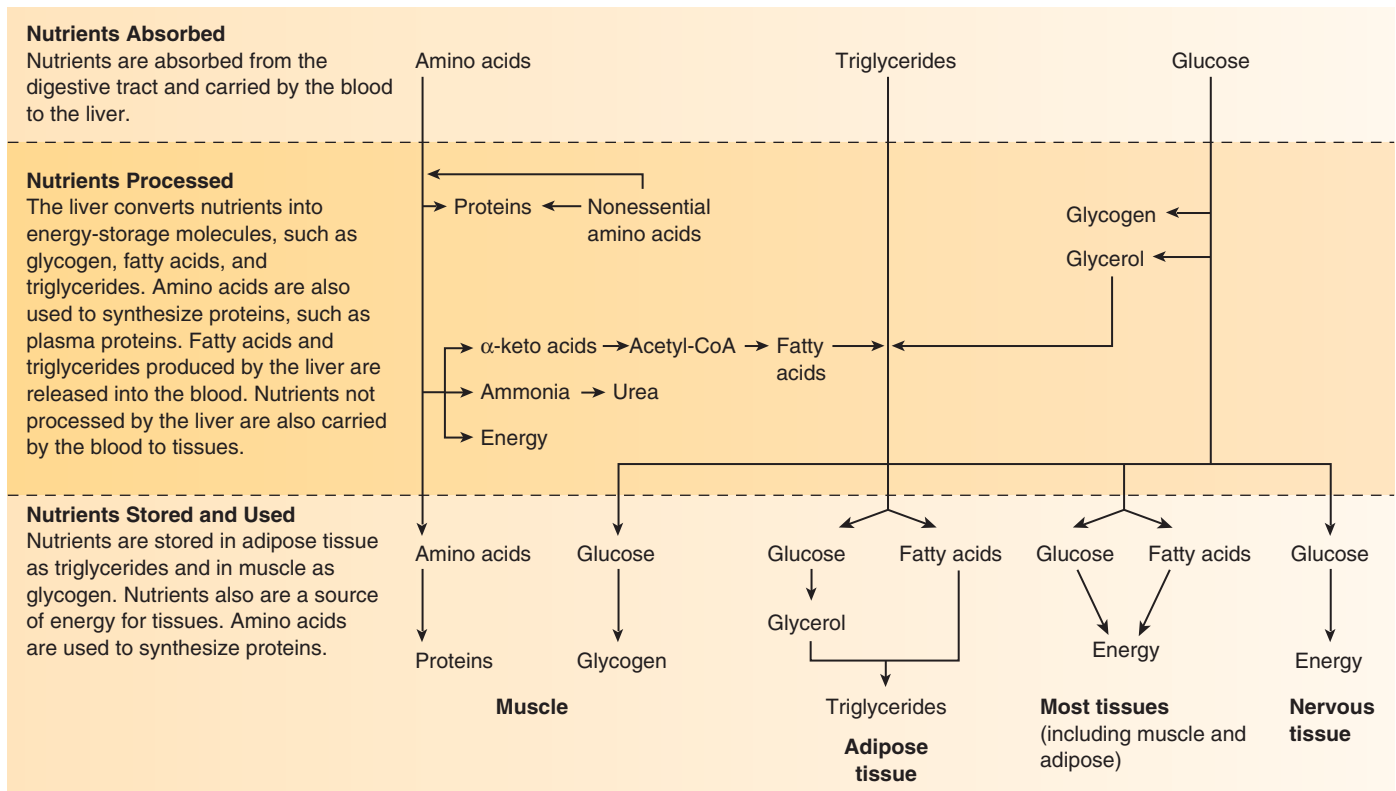

FIGURE 25.15 Events of the Absorptive State

Absorbed molecules, especially glucose, are used as sources of energy. Molecules not immediately needed for energy are stored: Glucose is converted to glycogen or triglycerides, triglycerides are deposited in adipose tissue, and amino acids are converted to triglycerides or carbohydrates.

FIGURE 25.16 Events of the Postabsorptive State

Stored energy molecules are used as sources of energy: Glycogen is converted to glucose; triglycerides are broken down to fatty acids, some of which are converted to ketones; and proteins are converted to glucose.

postabsorptive state is the glycogen stored in the liver, but this glycogen supply can provide glucose for only about 4 hours. The glycogen stored in skeletal muscles can also be used during times of vigorous exercise. As glycogen stores are depleted, the body uses lipids as an energy source. The glycerol from triglycerides can be converted to glucose. The fatty acids from lipids can be converted to acetyl-CoA, moved into the citric acid cycle, and used as energy to produce ATP. In the liver, acetyl-CoA is used to produce ketone bodies, which other tissues use for energy. The use of fatty acids as an energy source partly eliminates the need to use glucose for energy, so less glucose is removed from the blood and homeostasis is maintained. Amino acids can again be converted to glucose or used to produce energy, conserving blood glucose.

ASSESS YOUR PROGRESS

43. When does the absorptive state occur?
44. What happens to glucose, lipids, and amino acids during the absorptive state?
45. When does the postabsorptive state occur?
46. Why is it important to maintain blood glucose levels during the postabsorptive state? Name three sources of this glucose.

25.8 Metabolic Rate

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Define **metabolic rate** and describe the three major uses of metabolic energy in the body.
- B. Explain how to maintain body weight.

Metabolic rate is the total amount of energy produced and used by the body per unit of time. A molecule of ATP exists for less than 1 minute before it is degraded back to ADP and inorganic phosphate. For this reason, ATP is produced in cells at about the same rate as it is used. Thus, in examining metabolic rate, ATP production and use can be roughly equated. Because most ATP production involves the use of oxygen, metabolic rate is usually estimated by measuring the amount of oxygen used per minute. One liter of oxygen consumed by the body is estimated to produce 4.825 kcal of energy.

To maintain weight, the daily input of energy should equal the metabolic expenditure of energy; otherwise, a person will gain or lose weight. For a typical 23-year-old, 70 kg (154-pound) male to maintain his weight, the daily input should be 2700 kcal/day; for a typical 58 kg (128-pound) female of the same age, 2000 kcal/day is sufficient. A pound of body fat (adipose tissue) provides about 3500 kcal. Reducing kilocaloric intake by 500 kcal/day can result in the loss of 1 pound of body fat per week. Clearly, adjusting kilocaloric input is an important way to control body weight.

When considering the types of nutrients to eat to maintain a healthy weight, we need to consider the number of kilocalories but also the types of nutrients. The energy expense of metabolizing nutrients is not always the same. To convert dietary fat into body fat, 3% of the energy in the dietary fat is used, leaving 97% for

storage as body fat deposits. On the other hand, converting dietary carbohydrate to lipids requires 23% of the energy in the carbohydrate, leaving just 77% as body fat. If two people have the same kilocaloric intake, the one consuming the higher proportion of dietary fat is more likely to gain weight because fewer kilocalories are used to convert the dietary fat into body fat.

Metabolic energy is used in three ways: (1) for basal metabolism, (2) for the thermic effect of food, and (3) for muscular activity.

Basal Metabolic Rate

The **basal metabolic rate (BMR)** is the energy needed to keep the resting body functional. It is expressed in expended kilocalories per square meter of body surface area per hour (kcal/m²/hr). BMR is determined by measuring the oxygen consumption of a person who is awake but restful and has not eaten for 12 hours. The liters of oxygen consumed are then multiplied by 4.825 because each liter of oxygen used results in 4.825 kcal of energy. A typical BMR for a 70 kg (154-pound) male is 38 kcal/m²/h.

In the average person, basal metabolism accounts for about 60% of energy expenditure. Basal metabolism supports active-transport mechanisms, muscle tone, maintenance of body temperature, beating of the heart, and other activities. A number of factors can affect the BMR. Muscle tissue is metabolically more active than adipose tissue, even at rest, so people with well-developed muscles have a higher BMR than other people. Younger people have a higher BMR than older people because of increased cell activity, especially during growth. Fever can increase BMR 7% for each degree Fahrenheit elevation in body temperature. During dieting or fasting, greatly reduced kilocaloric input can depress BMR, which apparently is a protective mechanism to prevent weight loss. Thyroid hormones can increase BMR on a long-term basis, and epinephrine can increase BMR on a short-term basis (see chapter 18). Males have a greater BMR than females because men have proportionately more muscle tissue and less adipose tissue than women do. During pregnancy, a woman's BMR can increase 20% because of the metabolic activity of the fetus.

Thermic Effect of Food

The second component of metabolic energy is used for activities involved in digestion and absorption of food. When food is ingested, the accessory digestive organs and the intestinal lining produce secretions, the motility of the digestive tract increases, active transport increases, and the liver is involved in synthesizing new molecules. The energy cost of these events, called the **thermic effect of food**, accounts for about 10% of the body's energy expenditure.

Muscular Activity

Muscular activity consumes about 30% of the body's energy. Therefore, physical activity resulting from skeletal muscle movement requires the expenditure of energy. In addition, energy is needed for the increased contraction of the heart and muscles of respiration. The number of kilocalories expended in an activity depends almost entirely on the amount and duration of muscular work performed. Despite the fact that studying can make a person feel tired, intense mental concentration produces little change in BMR.

Energy loss through muscular activity is the only component of energy expenditure that a person can reasonably control. Comparing the number of kilocalories gained from food with the number of

Clinical GENETICS

Newborn Screening of Metabolic Disorders

Metabolic disorders, sometimes called inborn errors of metabolism, are a large class of genetic disorders that result in biochemical defects. Metabolic disorders affect the body's ability to break down or use nutrients needed for energy, growth, and repair. Too little synthesis of certain substances or a buildup of toxic compounds can cause significant health problems. Although the frequency

of any given individual disorder is rare, the overall incidence of metabolic disorders is estimated to be up to 1 in 1000 births.

Early detection through newborn screening is vital. Metabolic disorders can hinder early mental and physical development. Depending on the disorder, specific treatment can prevent or limit harm if it is started early. In the United States, most states require the screening of

newborns. However, there is no national standard for newborn screening, so the specific disorders for which tests are performed vary from state to state. Although over several hundred genetic disorders are known, most are so rare that it is not cost-effective to test for them.

Table 25A lists the most common blood tests performed for metabolic disorders. All of the disorders listed are autosomal recessive.

TABLE 25A

Metabolic Disorders

Disorder	Description	Effect	Treatment
Phenylketonuria (PKU)	Inability to metabolize the amino acid phenylalanine (see chapter 29)	Intellectual disability	Restrict dietary phenylalanine.
Galactosemia	Inability to convert the sugar galactose to glucose, resulting in a buildup of galactose	Intellectual disability, growth deficiency, cataracts, severe infections, death	Eliminate milk and other dairy products from the diet. Galactose is one of two sugars in lactose (milk sugar).
Biotinidase deficiency	Inability to separate the vitamin biotin from other chemicals, resulting in a biotin deficiency	Seizures, hearing loss, optic atrophy, intellectual disability, poor muscle control	Take oral biotin supplements.
Maple syrup urine disease	Deficiency in an enzyme complex, resulting in an inability to metabolize the amino acids leucine, isoleucine, and valine	Intellectual disability in those surviving past 3 months of age	Restrict dietary intake of the affected amino acids.
Homocystinuria	Defect in methionine metabolism, leading to an accumulation of homocysteine	Dislocated lenses of the eyes, intellectual disability, skeletal abnormalities, abnormal blood clotting	Take high doses of vitamin B ₆ ; eat methionine-restricted diet supplemented with cysteine.
Tyrosinemia	Deficiency in a series of enzymes that break down the amino acid tyrosine	Mild intellectual disability, language skill difficulties, liver and kidney failure	Restrict dietary tyrosine and phenylalanine.

kilocalories lost in exercise reveals why losing weight can be difficult. For example, if brisk walking uses 225 kcal/h, it takes 20 minutes of brisk walking to burn off the 75 kcal in one slice of bread ($75/225 = 0.33$ h). Research suggests that a combination of appropriate physical activity and appropriate kilocaloric intake is the best way to maintain a healthy body composition and weight.

► Predict 5

If watching TV uses 95 kcal/h, how long does it take to burn off the kilocalories in one cola or beer (see table 25.1)? If jogging at a pace of 6 mph uses 580 kcal/h, how long does it take to use the kilocalories in one cola or beer?

51. How are kilocaloric input and output adjusted to maintain body weight?

25.9 Body Temperature Regulation

LEARNING OUTCOME

After reading this section, you should be able to

A. Describe heat production and regulation in the body.

Humans can maintain a relatively constant internal body temperature despite changes in the temperature of the surrounding environment. This is the result of heat production during normal metabolic activity. A constant body temperature is very important for homeostasis. For example, environmental temperatures are too low for normal enzyme function, so the heat produced by metabolism helps maintain body temperature at a steady level that is high enough for normal enzyme function. Excessively high body temperatures, on the other hand, can alter enzyme structure, resulting in loss of the enzyme's function.

Free energy is the total amount of energy liberated by the complete catabolism of food. It is usually expressed in terms of kilocalories (kcal) per mole of food consumed. For example, the complete catabolism of 1 mole of glucose (168 g; see chapter 2) releases 686 kcal of free energy. About 43% of the total energy released by catabolism is used to produce ATP and to accomplish biological work, such as anabolism, muscular contraction, and other cellular activities. The remaining energy is lost as **heat**.

Predict 6

Why do we become warm during exercise? Why is shivering useful when it is cold?

The average normal body temperature is considered to be 37°C (98.6°F) when measured orally and 37.6°C (99.7°F) when measured rectally. Rectal temperature comes closer to the true core body temperature, but an oral temperature is more easily obtained in older children and adults and therefore is the preferred measure.

Our bodies exchange heat with the environment in a number of ways (figure 25.17), including radiation, conduction, convection, and evaporation. **Radiation** is the gain or loss of heat between two objects that are not in physical contact. For example, the body can gain heat by radiation from the sun, a hot coal, or the hot sand of a beach. On the other hand, the body can lose heat by radiation to cool vegetation or snow on the ground. **Conduction** is the exchange of heat between objects in direct contact with each other, such as the bottoms of the feet and the floor. **Convection** is a transfer of heat between the body and the air or water, as the air or water moves across the surface of the skin. A cool breeze causes air to move over the body, allowing body heat to be lost. **Evaporation** is the conversion of water from a liquid to a gas, a process that requires heat. The evaporation of 1 g of water from the body surface results in the loss of 580 cal of heat.

Body temperature is maintained by balancing heat gain with heat loss. If heat gain exceeds heat loss, body temperature increases; if heat loss exceeds heat gain, body temperature

decreases. The body generates heat through normal metabolism as well as through the muscle contractions of shivering. The body also exchanges heat with the environment by radiation, conduction, or convection, depending on skin temperature and the environmental temperature. In addition, the body can lose heat to the environment through evaporation of perspiration from the skin.

The difference in temperature between the body and the environment determines the amount of heat exchanged between the two. The greater the temperature difference, the greater the rate of heat exchange. Control of the temperature difference is used to regulate body temperature. For example, if the environmental temperature is very cold, as on a cold winter day, a large temperature difference exists between the body and the environment, and therefore a large loss of heat occurs. Behaviorally, we can reduce the heat loss by seeking a warmer environment—for example, by going inside a heated house or putting on extra clothes.

Physiologically, the body controls temperature difference through the dilation and constriction of blood vessels in the skin and the activity of sweat glands. When the environmental temperature is greater than body temperature, vasodilation brings warm blood to the skin, causing an increase in skin temperature.

FIGURE 25.17 Heat Exchange

Heat exchange between a person and the environment occurs by radiation, conduction, convection, and evaporation. Arrows show the direction of net heat gain or loss in this environment.

Clinical IMPACT

Obesity

Consuming more food than is necessary for the body's energy needs can cause a person to be overweight or even **obese**. These conditions can be defined on the basis of three parameters: body weight, body mass index, and percent body fat.

"Desirable body weight" is listed in the Metropolitan Life Insurance Table (1999) and indicates, for any height, the weight associated with a maximum life span. By these standards, being overweight is defined as weighing 10–20% more than the "desirable weight," and being obese is defined as weighing 20% or more than the "desirable weight."

Another standard for assessing body weight is body mass index (BMI), which can be calculated by dividing a person's weight (Wt) in kilograms by the square of his or her height (Ht) in meters:

$$\text{BMI} = \text{Wt}/\text{Ht}^2$$

A person whose BMI is greater than 25–27 is overweight, and one whose BMI value is greater than 30 is considered obese. About 26% of people in the United States have a BMI of 30 or greater.

In terms of the percent of total body weight contributed by body fat, 15% body fat or less in men and 25% body fat or less in women is associated with reduced health risks. Obesity is defined as more than 25% body fat in men and 30–35% in women.

Obesity can be further classified according to the number and size of adipocytes. The greater the amount of lipids stored in the adipocytes, the larger their size. In **hyperplastic obesity**, adipocytes are both more numerous and larger than normal. This type of obesity, which is associated with massive obesity, begins at an early age. In nonobese children, the number of adipocytes triples or quadruples between birth and 2 years of age and then remains relatively stable until puberty, when the number increases further. However, in obese children between 2 years of age and puberty, the number of adipocytes continues to increase.

Hypertrophic obesity results from a normal number of adipocytes that have increased in size. This more common type of obesity is associated with moderate obesity and typically develops in adults. People who were thin or of average weight and quite active when they were young become less active as they grow older. Although they no longer use as many kilocalories, they still take in the same amount of food as when they were younger, and they begin to gain weight. The unused kilocalories are turned into lipids, causing adipocytes to increase in size. At one time, scientists believed that the number of adipocytes did not increase after adulthood, but now we know that the number of adipocytes can increase in adults. Apparently, if all the existing adipocytes are filled to capacity with lipids, new adipocytes form to store the excess lipids. Once adipocytes form, however, dieting and weight loss do not decrease their number; rather, the adipocytes become smaller in size as their lipid content decreases.

The distribution of adipose tissue in obese individuals varies. Adipose tissue can be found mainly in the upper body, such as in the abdominal region, or it can be associated with the hips and buttocks. These distribution differences are clinically significant because upper body obesity is associated with an increased likelihood of diabetes mellitus, cardiovascular disease, stroke, and death.

People commonly believe that the main cause of obesity is overeating and, certainly, for obesity to occur, energy intake must exceed energy expenditure. However, comparing the kilocaloric intakes of obese and lean individuals at their usual weights reveals that, on a per-kilogram basis, obese people consume fewer kilocalories than lean people. Obesity occurs for many other reasons. In some cases, a specific physiological mechanism can be identified. For example, a tumor in the hypothalamus can stimulate overeating. In most cases, however, no specific cause is apparent. In fact, obesity can have more than one cause in the same person. Obesity seems to have a genetic component; if

one or both parents are obese, their children are more likely to be obese also. In addition, environmental factors, such as eating habits, can play an important role, as in the case of adopted children who exhibit the obesity of their adoptive parents. Furthermore, psychological factors, such as overeating as a means for dealing with stress, can contribute to obesity.

Regulating body weight is actually a matter of regulating adipose tissue because most changes in body weight reflect changes in the amount of adipose tissue. According to the "set point" theory of weight control, the body maintains a certain amount of adipose tissue. If the amount varies below or above this level, mechanisms are activated to return the amount of body fat to its normal value.

When people lose a large amount of weight, their eating behavior changes. They become hyperresponsive to external food cues, think of food often, and cannot get enough to eat without gaining weight. This behavior is typical of both lean and obese individuals who are below their relative set point for weight. Other changes, such as a decrease in basal metabolic rate (BMR), take place in a person who has lost a large amount of weight. Most of this decline in BMR probably results from a decrease in muscle mass associated with weight loss. In addition, some evidence indicates that the amount of energy lost through exercise and the thermic effect of food are also reduced.

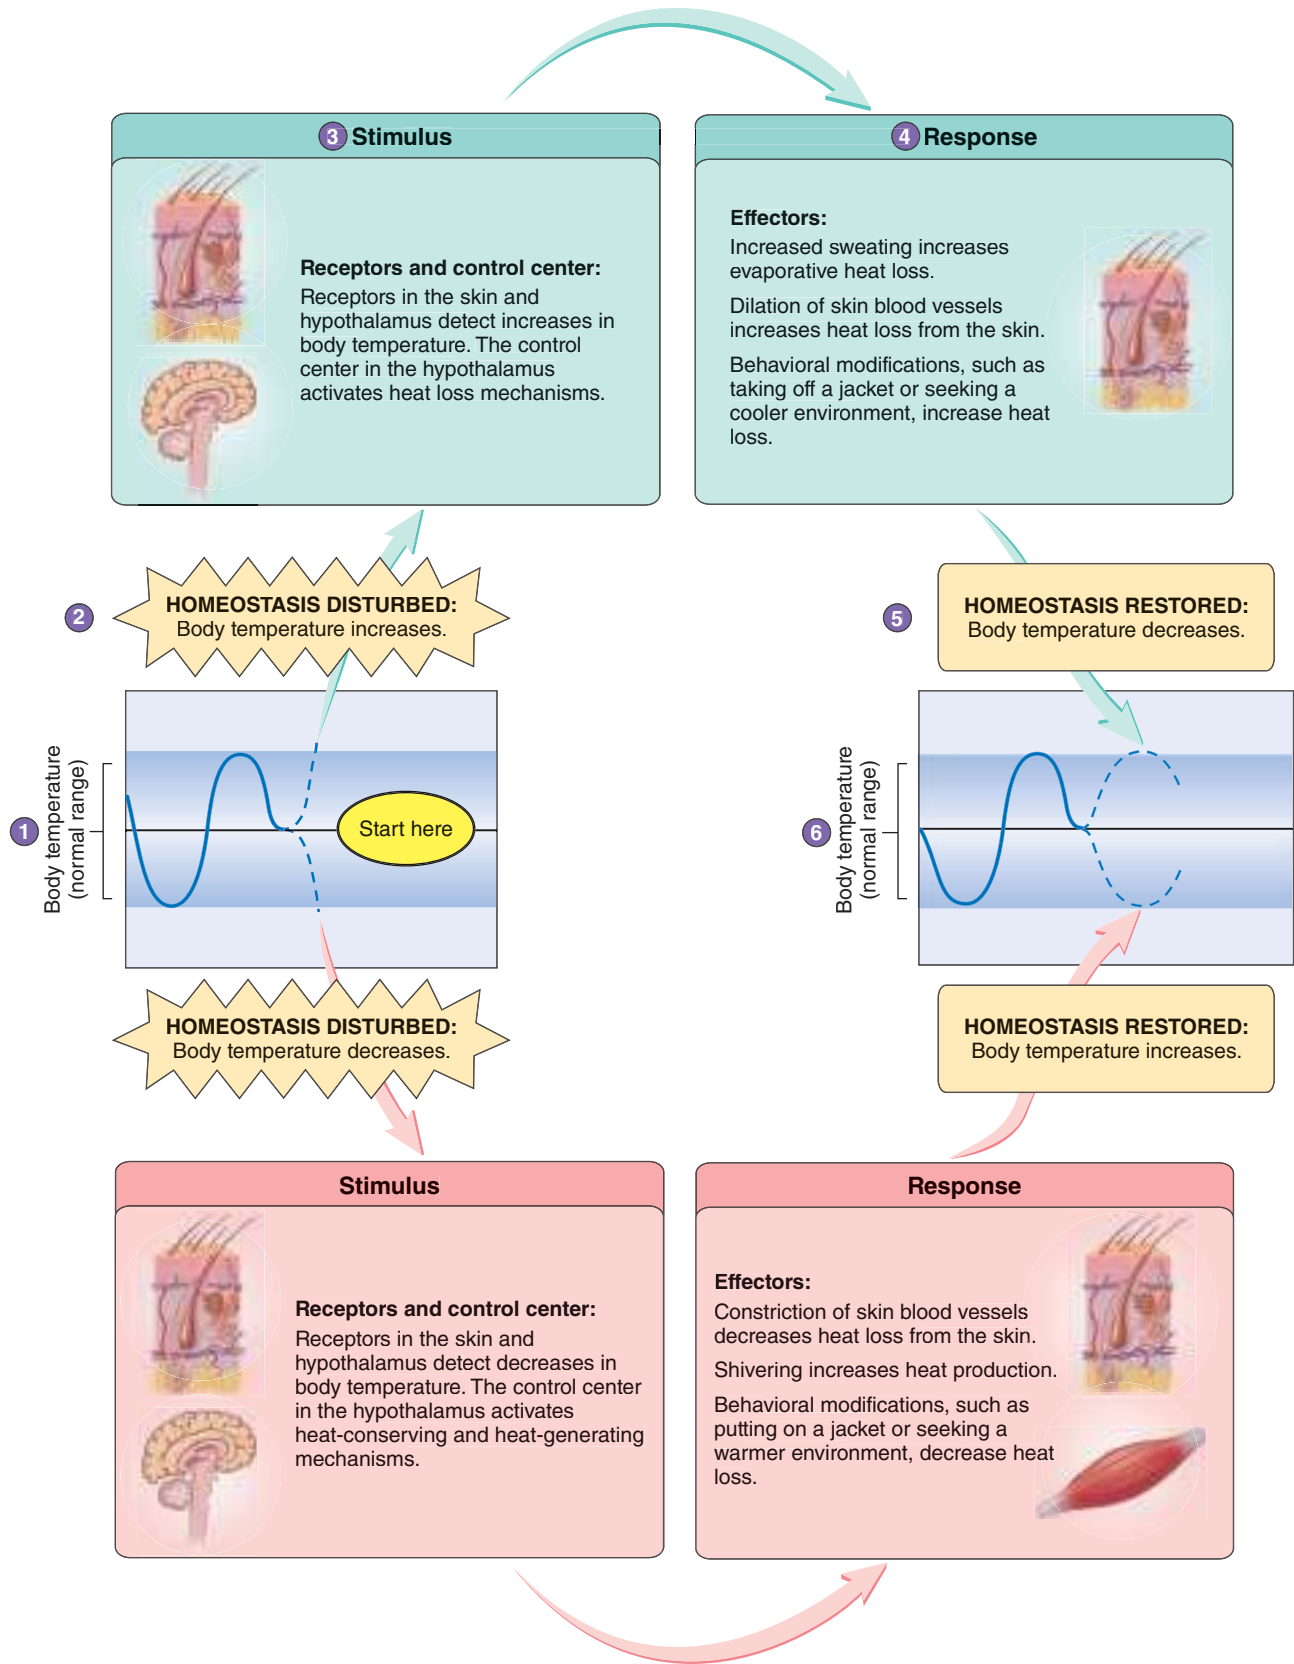

Because a person who has lost a large amount of weight has an increased appetite and a decreased ability to expend energy, it is no surprise that only a small percentage of obese people maintain weight loss over the long term. Instead, repeated cycles of weight loss followed by rapid regain are typical.

Current research indicates that body weight is determined by complicated genetic and metabolic factors that can go awry in many ways. Obesity is now regarded as a chronic condition that may respond to medication in much the same way that diabetes does. However, even though drugs can help, eating less and exercising more are still necessary for optimal health.

This reduces the heat gradient between the environment and skin and therefore decreases heat gain from the environment. At the same time, sweat glands increase secretion and evaporation carries away excess heat to prevent heat gain and overheating. Conversely, when the environmental temperature is less than body temperature, vasoconstriction reduces blood flow to the skin and skin

temperature decreases. This reduces the amount of heat that is lost to the environment.

Body temperature regulation is an example of a negative-feedback system controlled by a set point. A small area in the anterior part of the hypothalamus detects slight increases in body temperature through changes in blood temperature (figure 25.18). As a result,

HOMEOSTASIS FIGURE 25.18 Summary of Temperature Regulation

- (1) Body temperature is within normal range.
- (2) Body temperature increases outside the normal range, which causes homeostasis to be disturbed.
- (3) Receptors in the skin and hypothalamus detect the increase in body temperature, and the control center in the hypothalamus responds to the change in body temperature.
- (4) The effectors are activated. Blood vessels in the skin dilate, and sweating increases to promote heat loss and evaporative cooling.
- (5) Body temperature decreases.
- (6) Body temperature returns to its normal range, and homeostasis is restored.

Clinical IMPACT

Hyperthermia and Hypothermia

Hyperthermia

Hyperthermia, elevated body temperature, develops when heat gain exceeds the body's ability to lose heat. Hyperthermia can result from exercise, exposure to hot environments, fever, or anesthesia.

Exercise increases body temperature because heat is a by-product of muscle activity (see chapter 9). Normally, while a person is exercising, vasodilation and increased sweating prevent harmful body temperature increases. However, in a hot, humid environment, the evaporation of sweat decreases, and exercise must be curtailed to prevent overheating.

Exposure to a hot environment normally activates heat-loss mechanisms, so that body temperature is maintained within the normal range, a negative-feedback mechanism. However, with prolonged exposure to a hot environment, the normal negative-feedback mechanisms are unable to keep body temperature from increasing above normal, resulting in **heat exhaustion**. Heavy sweating causes dehydration, decreased blood volume, decreased blood pressure, and increased heart rate. Heat exhaustion is characterized by wet, cool skin due to heavy sweating. In addition, the person usually feels weak, dizzy, and nauseated. Treatment includes moving to a cooler environment to allow heat loss, ceasing activity to reduce the heat produced by muscle metabolism, and restoring blood volume by drinking fluids.

Heat stroke is more severe than heat exhaustion because it results from a breakdown in the normal negative-feedback mechanisms of temperature regulation. If the temperature of the hypothalamus becomes too high, it no

longer functions appropriately. Sweating stops, and the skin becomes dry and flushed. The person becomes confused, irritable, or even comatose. Treatment is the same as for heat exhaustion, except that efforts to promote heat loss from the skin should be increased—for example, by applying wet cloths to the skin or by immersing the person in a cool bath.

Fever is the development of a higher than normal body temperature due to invasion of the body by microorganisms or other foreign substances. Lymphocytes, neutrophils, and macrophages release chemicals called **pyrogens** (pī'rō-jenz), such as certain interleukins, interferons, and tissue necrosis factor. Pyrogens increase the synthesis of prostaglandins, which stimulate a rise in the temperature set point of the hypothalamus. Consequently, body temperature and metabolic rate increase. Physiologists believe fever is beneficial because it speeds the chemical reactions of the immune system (see chapter 22) and inhibits the growth of some microorganisms. However, body temperatures greater than 41°C (106°F) can be harmful. To lower body temperature, physicians prescribe aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and acetaminophen, which act by inhibiting the synthesis of prostaglandins.

In people who have the inherited muscle disorder **malignant hyperthermia**, certain general anesthetics cause sustained, uncoordinated muscle contractions. Consequently, body temperature increases.

Therapeutic hyperthermia is an induced elevation in local or general body temperature sometimes used to treat tumors and infections.

Hypothermia

If heat loss exceeds the body's ability to produce heat, body temperature falls below normal. **Hypothermia** is a decrease in body temperature to 35°C (95°F) or below. Hypothermia usually results from prolonged exposure to a cold environment. At first, body temperature is maintained by normal negative-feedback mechanisms—that is, heat loss is decreased by constricting blood vessels in the skin, and heat production is increased by shivering. However, if body temperature decreases despite these mechanisms, hypothermia develops. The individual's thinking becomes sluggish, and movements are uncoordinated. Heart, respiratory, and metabolic rates decline, and death results unless body temperature is restored to normal. Treatment for hypothermia calls for rewarming the body a few degrees per hour.

Frostbite is damage to the skin and deeper tissues resulting from prolonged exposure to the cold. Specifically, damage results from direct cold injury to cells, injury from ice crystal formation, and reduced blood flow to affected tissues. The fingers, toes, ears, nose, and cheeks are most commonly affected. The consequences of frostbite can range from redness and discomfort to loss of the affected part due to death of the tissue. The best treatment is immersion in a warm-water bath. Patients should avoid rubbing the affected area or applying local dry heat.

Therapeutic hypothermia is sometimes used to slow the metabolic rate during surgical procedures, such as heart surgery. Due to the decreased metabolic rate, the tissues do not require as much oxygen as normal and are less likely to be damaged.

mechanisms that cause heat loss, such as vasodilation and sweating, are activated, and body temperature decreases. Alternatively, a small area in the posterior hypothalamus can detect slight decreases in body temperature and can initiate heat gain by increasing muscular activity (shivering) and vasoconstriction.

Under some conditions, the set point of the hypothalamus changes. For example, during a fever, the set point is raised, heat-conserving and heat-producing mechanisms are stimulated, and body temperature increases. To recover from a fever, the set point is lowered to normal, heat-loss mechanisms are initiated, and body temperature decreases.

ASSESS YOUR PROGRESS

52. What is free energy? How much free energy is lost as heat from the body?
53. What are four ways that heat is exchanged between the body and the environment?
54. How is body temperature maintained behaviorally in a cold environment? How is body temperature maintained physiologically in a hot environment?
55. How does the hypothalamus regulate body temperature?

Answer

Learn to Predict ◀ From page 924

Although Sadie's suggested snack did contain a lot of calories, which she and David needed for their day at the park, the food choices were not ideal. Most of the calories in the cookies and grape soda were actually from simple sugars. Eating large amounts of simple sugars, such as Sadie's suggested snack, could result in large fluctuations in blood glucose levels. Though the children may initially have an increase in energy, they will most likely experience a drastic decrease in energy as well. Foods that include complex carbohydrates, such as those in the snack

Sadie's mom suggested, have other nutrients, such as vitamins, many of which are necessary for normal metabolism. In addition, complex carbohydrates are digested and absorbed at a slower rate and do not contribute to drastic changes in blood glucose levels. Essentially, Sadie's mom selected food that would provide the children with energy and additional beneficial nutrients.

Answers to the rest of this chapter's Predict questions are in appendix G.

Summary

25.1 Nutrition (p. 925)

Nutrition is the ingestion and use of food, as well as the evaluation of food and drink requirements.

Nutrients

1. Nutrients are the chemicals used by the body: carbohydrates, lipids, proteins, vitamins, minerals, and water.
2. Essential nutrients must be ingested because the body either cannot manufacture them at all or cannot manufacture them in adequate amounts.

Kilocalories

1. A calorie (cal) is the heat (energy) necessary to raise the temperature of 1 g of water 1°C. A kilocalorie (kcal), or Calorie (Cal), is 1000 calories.
2. A gram of carbohydrate or protein yields 4 kcal, and a gram of lipids yields 9 kcal.

MyPlate

The MyPlate icon provides a visual reminder for making choices at mealtime, by selecting healthful foods from five food groups. Half the meal should be fruits and vegetables.

Carbohydrates

1. Carbohydrates are ingested as monosaccharides (glucose, fructose), disaccharides (sucrose, maltose, lactose), and polysaccharides (starch, glycogen, cellulose).
2. Polysaccharides and disaccharides are converted to glucose, which can be used for energy or stored as glycogen or lipids.
3. The Acceptable Macronutrient Distribution Range (AMDR) for carbohydrates is 45–65% of total kilocalories.

Lipids

1. Lipids are ingested as triglycerides (95%) or cholesterol and phospholipids (5%).
2. Monounsaturated fats and oils have one double bond, and polyunsaturated fats and oils have two or more double bonds.
3. Most unprocessed polyunsaturated oils occur in the *cis* form, whereas hydrogenated polyunsaturated oils are in the *trans* form.
4. Triglycerides are used for energy or stored in adipose tissue. Cholesterol

forms other molecules, such as steroid hormones. Cholesterol and phospholipids are part of the plasma membrane.

5. The AMDR for lipids is 20–35%.

Proteins

1. Proteins are ingested and broken down into amino acids.
2. Proteins function in protection (antibodies), regulation (enzymes, hormones), structure (collagen), muscle contraction (actin and myosin), and transportation (hemoglobin, transport proteins); they also act as receptor molecules.
3. The AMDR for protein is 10–35% of total kilocalories.

Vitamins

1. Many vitamins function as coenzymes or as parts of coenzymes.
2. Most vitamins are not produced by the body and must be obtained in the diet. Some vitamins can be formed from provitamins.
3. Vitamins are classified as either fat-soluble or water-soluble.
4. Recommended Dietary Allowances (RDAs) are a guide for estimating the nutritional needs of groups of people based on their age, gender, and other factors.

Minerals

1. Minerals contribute to normal metabolism, add mechanical strength to bones and teeth, function as buffers, and are involved in osmotic balance.
2. The daily requirement for major minerals is 100 mg or more daily; for trace minerals, less than 100 mg daily is sufficient.

Daily Values for Nutrients

1. Daily Values are dietary references that can be used to plan a healthful diet.
2. Daily Values for vitamins and minerals are based on Reference Daily Intakes, which are generally the highest 1968 RDA values of age categories.
3. Daily Values are based on Daily Reference Values.
 - The Daily Reference Values for energy-producing nutrients (carbohydrates, total fat, saturated fat, and proteins) and dietary fiber are recommended percentages of the total kilocalories ingested daily for each nutrient.

- The Daily Reference Values for total fats, saturated fats, cholesterol, and sodium are the uppermost limits considered desirable because of their link to diseases.
4. The % Daily Value is the percent of the recommended Daily Value of a nutrient found in one serving of a particular food.

25.2 Metabolism (p. 934)

1. Metabolism consists of catabolism and anabolism. Catabolism breaks down molecules and gives off energy. Anabolism builds up molecules and requires energy.
2. The energy in carbohydrates, lipids, and proteins is used to produce ATP through oxidation-reduction reactions.

25.3 Carbohydrate Metabolism (p. 934)

Glycolysis

Glycolysis is the breakdown of glucose into two pyruvic acid molecules. Also produced are two NADH molecules and two ATP molecules.

Anaerobic Glycolysis

1. Anaerobic glycolysis is the breakdown of glucose in the absence of oxygen into two lactate molecules. Two ATP molecules are also produced.
2. Lactate can be converted to glucose (Cori cycle) using aerobically produced ATP (oxygen deficit).

Aerobic Respiration

1. Aerobic respiration is the breakdown of glucose in the presence of oxygen to produce carbon dioxide, water, and 36 ATP molecules.
2. The first phase is glycolysis, which produces two ATP, two NADH, and two pyruvic acid molecules.
3. The second phase is the conversion of the two pyruvic acid molecules into two molecules of acetyl-CoA. These reactions also produce two NADH and two carbon dioxide molecules.
4. The third phase is the citric acid cycle, which produces two ATP, six NADH, two FADH₂, and four carbon dioxide molecules.
5. The fourth phase is the electron-transport chain. The high-energy electrons in NADH and FADH₂ enter the electron-transport chain and are used in the synthesis of ATP and water.

25.4 Lipid Metabolism (p. 943)

1. Triglycerides are broken down and released as free fatty acids.
2. Free fatty acids are taken up by cells and broken down by beta-oxidation into acetyl-CoA.
 - Acetyl-CoA can enter the citric acid cycle.
 - Acetyl-CoA can be converted into ketone bodies.

25.5 Protein Metabolism (p. 944)

1. New amino acids are formed by transamination, the transfer of an amine group to a keto acid.
2. Amino acids are used to synthesize proteins. If used for energy, ammonia is produced as a by-product of oxidative deamination. Ammonia is converted to urea and excreted.

25.6 Interconversion of Nutrient Molecules (p. 946)

1. Glycogenesis is the formation of glycogen from glucose.
2. Lipogenesis is the formation of lipids from glucose and amino acids.
3. Glycogenolysis is the breakdown of glycogen to glucose.
4. Gluconeogenesis is the formation of glucose from amino acids and glycerol.

25.7 Metabolic States (p. 947)

1. In the absorptive state, nutrients are used as energy or stored.
2. In the postabsorptive state, stored nutrients are used for energy.

25.8 Metabolic Rate (p. 949)

Metabolic rate is the total energy expenditure per unit of time, and it has three components.

Basal Metabolic Rate

Basal metabolic rate, the energy used at rest, is 60% of the metabolic rate.

Thermic Effect of Food

The energy used to digest and absorb food, called the thermic effect of food, is 10% of the metabolic rate.

Muscular Activity

Muscular energy, that used for muscle contraction, is 30% of the metabolic rate.

25.9 Body Temperature Regulation (p. 951)

1. Body temperature is maintained by balancing heat gain and heat loss.
 - Heat is produced through metabolism.
 - Heat is exchanged with the environment through radiation, conduction, convection, and evaporation.
2. The greater the temperature difference between the body and the environment, the greater the rate of heat exchange.
3. Body temperature is regulated by a set point in the hypothalamus.

REVIEW AND COMPREHENSION

1. Which of these statements concerning kilocalories is true?
 - a. A kilocalorie is the amount of energy required to raise the temperature of 1 g of water 1°C.
 - b. There are 9 kcal in a gram of protein.
 - c. There are 4 kcal in a gram of lipids.
 - d. A pound of body fat contains 3500 kcal.
2. What type of nutrient is recommended as the primary energy source in the diet?
 - a. carbohydrates
 - b. lipids
 - c. proteins
 - d. cellulose
3. A source of monounsaturated fats is
 - a. fat associated with meat.
 - b. egg yolks.
 - c. whole milk.
 - d. fish oil.
 - e. olive oil.
4. A complete protein food
 - a. provides the daily amount (grams) of protein recommended for a healthful diet.
 - b. can be used to synthesize the nonessential amino acids.
 - c. contains all 20 amino acids.
 - d. includes beans, peas, and leafy green vegetables.

5. Concerning vitamins,
 - a. most can be synthesized by the body.
 - b. they are normally broken down before they can be used by the body.
 - c. A, D, E, and K are water-soluble vitamins.
 - d. many function as coenzymes.
6. Minerals
 - a. are inorganic nutrients.
 - b. compose about 4–5% of total body weight.
 - c. act as buffers and osmotic regulators.
 - d. are components of enzymes.
 - e. All of these are correct.
7. Glycolysis
 - a. is the breakdown of glucose to two pyruvic acid molecules.
 - b. requires the input of two ATP molecules.
 - c. produces two NADH molecules.
 - d. does not require oxygen.
 - e. All of these are correct.
8. Anaerobic glycolysis _____ oxygen and produces _____ energy (ATP) for the cell than aerobic respiration.
 - a. does not require, more
 - b. does not require, less
 - c. requires, more
 - d. requires, less
9. The molecule that moves electrons from the citric acid cycle to the electron-transport chain is
 - a. tRNA.
 - b. mRNA.
 - c. ADP.
 - d. NADH.
 - e. pyruvic acid.
10. The carbon dioxide you breathe out comes from
 - a. glycolysis.
 - b. the electron-transport chain.
 - c. anaerobic glycolysis.
 - d. the food you eat.
11. Lipids are
 - a. stored primarily as triglycerides.
 - b. synthesized by beta-oxidation.
 - c. broken down by oxidative deamination.
 - d. All of these are correct.
12. Amino acids
 - a. are classified as essential or nonessential.
 - b. can be synthesized in a transamination reaction.
 - c. can be used as a source of energy.
 - d. can be converted to keto acids.
 - e. All of these are correct.
13. Ammonia is
 - a. a by-product of lipid metabolism.
 - b. formed during ketogenesis.
 - c. converted into urea in the liver.
 - d. produced during lipogenesis.
 - e. converted to keto acids.
14. The conversion of amino acids and glycerol into glucose is called
 - a. gluconeogenesis.
 - b. glycogenesis.
 - c. glycogenolysis.
 - d. ketogenesis.
15. Which of these events takes place during the absorptive state?
 - a. Glycogen is converted into glucose.
 - b. Glucose is converted into lipids.
 - c. Ketones are produced.
 - d. Proteins are converted into glucose.
16. Loss of heat resulting from loss of water from the body's surface is
 - a. radiation.
 - b. conduction.
 - c. evaporation.
 - d. convection.

Answers in appendix E

CRITICAL THINKING

1. One serving of a food contains 2 g of saturated fat. What % Daily Value for saturated fat would appear on the food label for this food?
2. An active teenage boy has a daily intake of 3000 kcal. What is the maximum amount (weight) of total fats he should consume, according to the Daily Values?
3. If the teenager in question 2 eats a serving of food that has a total fat content of 10 g/serving, what is his % Daily Value for total fat?
4. Why does a vegetarian usually have to be more careful about his or her diet than a person who eats meat?
5. Explain why a person suffering from copper deficiency feels tired all the time.
6. Why can some people lose weight on a 1200 kcal/day diet, whereas others cannot?
7. After learning that sweat evaporation results in loss of calories, an anatomy and physiology student enters a sauna to try to lose weight. He reasons that a liter (about a quart) of water weighs 1000 g, which is equivalent to 580,000 cal, or 580 kcal, of heat when lost as sweat. Therefore, instead of reducing his diet by 580 kcal/day, he believes that losing a liter of sweat every day in the sauna will cause him to lose about a pound of fat a week. Will this approach work? Explain.
8. Thyroid hormone increases the activity of the sodium-potassium pump. If a person produced excess amounts of thyroid hormone, how would basal metabolic rate, body weight, and body temperature be affected? How would the body attempt to compensate for the changes in body weight and temperature?
9. In some diseases, an infection causes a high fever, resulting in a crisis state. Once body temperature begins to return to normal, the person is on the way to recovery. If you were looking for symptoms in a person who had just passed through the crisis state, would you look for dry, pale skin or flushed, wet skin? Explain.

Answers in appendix F

26

Learn to Predict

Fifty-seven-year-old Sadie is living proof that a person can live with type 2 diabetes. Since being diagnosed with the condition 15 years ago, she has taken good care of herself, watching her diet and regularly monitoring her blood glucose and blood pressure at home. Therefore, she was immediately aware when her blood pressure began to rise. She also felt tired much of the time, and her face appeared puffy. Her physician confirmed the hypertension and detected generalized edema. After ordering several laboratory tests, he concluded that Sadie was suffering from chronic renal failure. **With some information from chapters 19 and 20 and after reading chapter 26, explain the cause of chronic renal failure and predict the results of Sadie's blood test and urinalysis that led to this diagnosis. What is the probable prognosis for Sadie in the future?**

Urinary System

It must have been fate. Sam met Dave when they played on the same softball team, and the two became great friends. A few years later, Dave was diagnosed with a fatal, progressive kidney disease. Like Sadie in this chapter's "Learn to Predict," Dave began feeling tired and suffering from generalized edema. Without a kidney transplant, Dave could expect to live only a few more years. Immediately, Sam volunteered to be tested as a possible kidney donor and, amazingly, he was a nearly perfect match. After months of testing and planning, one of Sam's kidneys was removed and placed into Dave's body. Within a week, Dave's new kidney was functioning at almost normal capacity. Meanwhile, Sam recovered quickly, and his spirits were high because his donation had saved his friend's life. Doctors assured him that his remaining kidney, containing more than a million nephrons, would be sufficient for his future needs. The kidneys are remarkable organs that perform life-sustaining functions as part of the urinary system.

Photo: Removal of a healthy kidney, as shown in this photo, is performed when the patient donates his or her kidney to a recipient who may otherwise die. The donor can expect to live a normal life with just one kidney.

26.1 Functions of the Urinary System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the organs of the urinary system.**
- B. Describe the main functions of the kidneys.**

The **urinary system** is the major excretory system of the body. Organs of other systems eliminate some waste products; however, if the kidneys fail to function, these other excretory organs cannot adequately compensate. The urinary system consists of two kidneys, the primary excretory organs. Each kidney's excretory products are carried by a ureter to a single urinary bladder. The bladder is emptied of the waste liquid by the urethra (figure 26.1).

Although we categorize the kidneys as excretory organs, they are also important for many metabolic activities. The kidney functions include:

1. **Excretion.** Nearly 21% of the blood pumped out of the heart each minute is routed to the kidneys. There, some of the plasma is filtered and separated from the blood cells. Large molecules, such as proteins, remain in the blood, whereas smaller molecules and ions enter the filtered fluid. As the fluid flows through the kidneys, it is slowly modified until it is converted

into urine. This conversion requires the reabsorption of most of the fluid volume back into the blood, along with useful molecules and ions. The resulting fluid contains metabolic wastes, toxic molecules, and excess ions. Additional waste products are secreted into the fluid, eventually forming urine.

2. **Regulation of blood volume and pressure.** The kidneys play a major role in controlling the extracellular fluid volume in the body by producing either a large volume of dilute urine or a small volume of concentrated urine, depending on the hydration level of the body. Consequently, the kidneys regulate blood volume and hence blood pressure.
3. **Regulation of blood solute concentrations.** The kidneys help regulate the concentration of primarily the major ions— Na^+ , Cl^- , K^+ , Ca^{2+} , HCO_3^- , and HPO_4^{2-} ; they also regulate other solute concentration, such as urea.
4. **Regulation of extracellular fluid pH.** The kidneys secrete variable amounts of H^+ to help regulate the extracellular fluid acidity.
5. **Stimulation of red blood cell synthesis.** The kidneys secrete the hormone erythropoietin, which stimulates the synthesis of red blood cells in red bone marrow (see chapter 19).
6. **Activation of vitamin D.** The kidneys play an important role in controlling blood levels of Ca^{2+} by activating vitamin D (see chapter 6).

FIGURE 26.1 Urinary System

The urinary system consists of two kidneys, two ureters, the urinary bladder, and the urethra. **APR**

ASSESS YOUR PROGRESS

1. Name the organs that make up the urinary system.
2. List the functions performed by the kidneys, and briefly describe each.

26.2 Kidney Anatomy and Histology

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the location and external anatomy of the kidneys.**
- B. Describe the inner regions of the kidney.**
- C. Give the details of the nephron's structure and histology.**
- D. Explain the blood supply of the kidney.**

Location and External Anatomy of the Kidneys

The **kidneys** are retroperitoneal (see chapter 1) and are located on each side of the vertebral column near the psoas major muscles (figure 26.2). They extend from the lower portion of the rib cage at the level of the last thoracic (T12) vertebra to the third lumbar (L3) vertebra (see figure 7.20). The liver is superior to the right kidney, causing the right kidney to be slightly lower than the left. The kidneys are bean-shaped, and each measures about 11 cm long, 5 cm wide, and 3 cm thick, which is about the size of a clenched fist. They each weigh about 130 g. This is approximately the weight of 1 cup of flour. Each kidney is surrounded by an outer layer of connective tissue, called the **renal capsule**. Surrounding the outside of the

capsule is a thick layer of adipose tissue, which cushions and protects the kidneys. A thin layer of connective tissue, the **renal fascia**, surrounds the adipose tissue and helps anchor the kidneys to the abdominal wall. More adipose tissue surrounds the renal fascia.

The **hilum** (hī'lūm) is a small area on the concave, medial side of the kidney that is continuous with an adipose and connective tissue-filled cavity of the kidney, called the **renal sinus**. The hilum is where structures enter and exit the kidney, then pass through the renal sinus. These structures help the kidney perform its functions. The hilum structures are the renal artery and nerves, which enter the kidney and the renal vein and ureter, which exit the kidney (figure 26.3).

FIGURE 26.2 Anatomy of the Urinary System

(a) The kidneys are located in the abdominal cavity, with the right kidney just below the liver and the left kidney below the spleen. A ureter extends from each kidney to the urinary bladder within the pelvic cavity. An adrenal gland is located at the superior pole of each kidney. (b) The kidneys are located behind the parietal peritoneum, surrounded by adipose tissue. A connective tissue layer, the renal fascia, anchors the kidney to the abdominal wall. The renal arteries extend from the abdominal aorta to each kidney, and the renal veins extend from the kidneys to the inferior vena cava. **APR**

ASSESS YOUR PROGRESS

3. Describe the location, size, and shape of the kidneys.
4. Describe the renal capsule and the structures that surround the kidney.
5. List the structures found at the hilum and in the renal sinus of a kidney.

Internal Anatomy and Histology of the Kidneys

To fully appreciate the function of the kidneys, we must first understand their ultrastructure. The kidneys are organized into two major regions: an outer **cortex** and an inner **medulla** that surrounds the renal sinus (figure 26.3).

The medulla is composed of many cone-shaped structures called **renal pyramids**, whose bases project into the cortex. These projections are called **medullary rays**. Between the renal pyramids and their medullary rays, there are extensions of cortical tissue toward the medulla, called **renal columns**. The renal pyramids are a collection of tubes and ducts that transport fluid throughout the kidney and modify it into urine. Once urine is formed, ducts in the renal pyramids transport it toward the renal sinus. The tips of the pyramids, the **renal papillae**, point toward the renal sinus. In the renal sinus, another set of tubes collects the urine for movement to the bladder. When urine leaves a renal papilla, it empties into a small, funnel-shaped chamber surrounding the tip of the papilla called a **minor calyx** (kal'ix; pl. calyces). Urine from several minor calyces are emptied into a larger, funnel-shaped chamber called a **major**

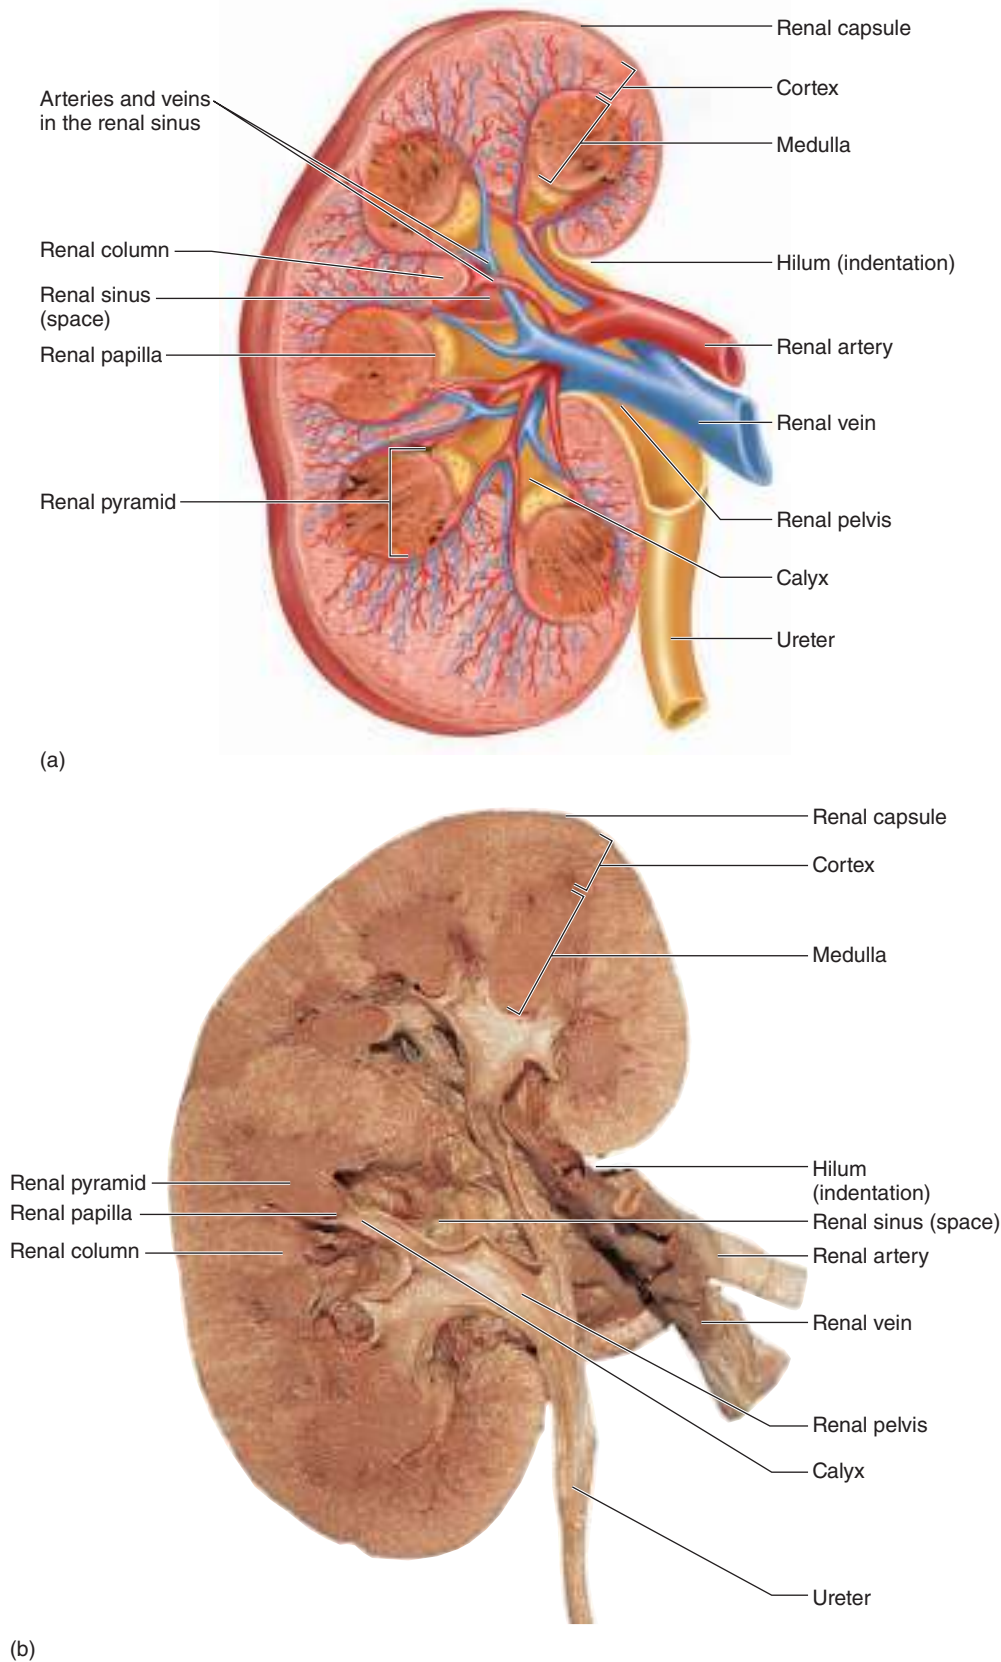

FIGURE 26.3 Frontal Section of the Kidney and Ureter

(a) A frontal kidney section shows that the cortex forms the outer part of the kidney, and the medulla forms the inner part. A central cavity called the renal sinus contains the renal pelvis. The renal columns of the kidney project from the cortex into the medulla and separate the pyramids. (b) Photograph of a longitudinal section of a human kidney and ureter. **AP R**

calyx. In each kidney, there are between 8 and 20 minor calyces converging to form about 2 or 3 major calyces. From the major calyces, urine empties into a single, enlarged, funnel-shaped chamber called the **renal pelvis**. The renal pelvis is embedded in and surrounded by the renal sinus. At the hilum, it narrows significantly, forming the small-diameter tube called the **ureter**. Urine moves from the renal pelvis into the ureter for transport to the bladder.

Structure of a Nephron

The **nephron** (nef'ron) is the histological and functional unit of the kidney (figure 26.4). There are approximately 1.3 million nephrons in each kidney. Nephrons usually measure about 50–55 mm in length. There are four separate segments of a nephron distributed throughout the cortex and medulla. They are the following: (1) a **renal corpuscle** in the cortex, (2) a proximal convoluted tubule in the cortex, (3) a loop of Henle with sections in both the cortex and the medulla, and (4) a distal convoluted tubule in the cortex. Each portion of a nephron plays a different role in urine production. Generally speaking, the renal corpuscle filters the blood, the proximal convoluted tubule returns filtered substances to the blood, the loop of Henle helps conserve water and solutes, and the distal convoluted tubule rids the blood of additional wastes. The fluid in the distal convoluted tubule then empties into a collecting duct, which carries the newly formed urine from the cortex of the kidney toward the renal papilla deep in the medulla. Near the tip of the renal papilla, several collecting ducts merge into a larger-diameter tubule called a **papillary duct**, which empties into a minor calyx.

Types of Nephrons

There are two types of nephrons in the kidney: juxtamedullary and cortical. **Juxtamedullary** (juks'ta-med'ŭ-lār-ē; next to medulla) **nephrons** have renal corpuscles that are found near the medulla. They have long loops of Henle, which extend deep into the medulla. Longer loops of Henle are well adapted for water conservation (see section 26.3). Only about 15% of the nephrons are juxtamedullary nephrons. **Cortical**

FIGURE 26.4 Functional Unit of the Kidney—the Nephron

A nephron consists of a renal corpuscle, proximal convoluted tubule, loop of Henle, and distal convoluted tubule. The distal convoluted tubule empties into a collecting duct. Juxtamedullary nephrons (those near the medulla of the kidney) have loops of Henle that extend deep into the medulla, whereas other nephrons do not. Collecting ducts undergo a transition to larger-diameter papillary ducts near the tip of the renal papilla. The papillary ducts empty into a minor calyx. **AP R**

nephrons have renal corpuscles that are distributed throughout the cortex. Their loops of Henle are shorter than those of juxtamedullary nephrons and are closer to the outer edge of the cortex (figure 26.4).

The Renal Corpuscle

The filtration portion of the nephron is housed in the renal corpuscle. In the renal corpuscle, there is a network of capillaries twisted around each other like a ball of yarn called the **glomerulus** (glō-mār'ū-lūs; ball of yarn; figure 26.5*a,b*). Fluid filtered from the glomerular capillaries is called the filtrate. Surrounding the glomerulus is an indented, double-walled chamber, called the **Bowman capsule**. Together, the glomerulus and Bowman capsule form the renal corpuscle. From the Bowman capsule, the filtered fluid flows into the proximal convoluted tubule.

A Bowman capsule has an outer layer, called the **parietal layer**, and an inner layer, called the **visceral layer** (figure 26.5*b*). The parietal layer is constructed of simple squamous epithelial cells. The epithelial cells become cube-shaped at the beginning of the proximal convoluted tubule. The visceral layer is constructed of specialized cells called **podocytes**, which wrap around the glomerular capillaries.

Because the kidneys' main function is to filter the blood, the glomerulus has several unique characteristics that make these capillaries especially permeable. The glomerular capillaries have **fenestrae** (fe-nes'trē; windows). Recall from chapter 21 that capillaries have different levels of permeability, depending on the size of their pores. In the case of fenestrae, neither large proteins nor blood cells can fit through them. Gaps, called **filtration slits**, are between the cell processes of the podocytes of the visceral layer (figure 26.5*c*). A basement membrane lies sandwiched between the endothelial cells of the glomerular capillaries and the podocytes of the Bowman capsule. All together, these structures make up the **filtration membrane**. The filtration membrane consists of capillary endothelium, the basement membrane, and the podocytes of the Bowman capsule (figure 26.5*d*). The filtration membrane performs the first major step in urine production. Urine production begins when the filtration membrane filters the blood. The filtered fluid then enters the lumen, or space, inside the Bowman capsule.

An **afferent** (af'er-ent) **arteriole** supplies blood to the glomerulus for filtration. An **efferent** (ef'er-ent) **arteriole** transports the filtered blood away from the glomerulus (figure 26.5*a*). An important regulatory structure, called the **juxtaglomerular apparatus**, is located next to the glomerulus (figure 26.5*b*). The juxtaglomerular apparatus consists of a unique set of afferent arteriole cells and specialized cells in the distal convoluted cells that are in close contact with each other. These specialized cells include the following:

1. At the point where the afferent arteriole enters the renal corpuscle, it has a cuff of specialized smooth muscle cells around it. These cells are called **juxtaglomerular cells**.
2. A part of the distal convoluted tubule of the nephron lies between the afferent and efferent arterioles next to the renal corpuscle. In this section of the distal convoluted tubule, there is a group of specialized cells called the **macula** (mak'ū-lā) **densa**.

Secretion of the enzyme renin by the juxtaglomerular apparatus plays an important role in the regulation of filtrate formation and blood pressure.

The Renal Tubule

Once the blood is filtered, the resulting fluid is modified to form urine as it passes through each section of the renal tubule. The first section is the **proximal convoluted tubule**. It is approximately 14 mm long and 60 μm in diameter. The wall of the proximal convoluted tubule is composed of simple cuboidal epithelium. The proximal convoluted tubule cells rest on a basement membrane, which forms the outer surface of the tubule. These cells have many microvilli projecting from the luminal (next to the filtrate) surface of the cells (figure 26.6*a,b*).

As the proximal convoluted tubule continues descending toward the medulla, the cell type begins to change. At this point the renal tubule is called the **loop of Henle**. Every loop of Henle has two limbs: the **descending limb** and the **ascending limb**. The first part of the descending limb is similar in structure to the proximal convoluted tubule. The portion of the loop of Henle that extends into the medulla becomes very thin near the bend of the loop (figure 26.6*a,c*). The lumen in the thin part narrows, and an abrupt

Clinical GENETICS

Polycystic Kidney Disease

Polycystic kidney disease is the third leading cause of renal failure (after diabetes mellitus and high blood pressure). Approximately 90% of patients inherit the condition as an autosomal dominant trait. Consequently, if one parent carries an allele for this disorder, each child has a 50% chance of also having the disorder (see chapter 29). The gene for this condition codes

for a protein that may regulate cell-to-cell interactions.

In people affected by polycystic kidney disease, the kidneys are enlarged and often contain large, fluid-filled cysts varying in size from a few millimeters to centimeters. The cysts increase in number and enlarge as the person ages. Development of the cysts results from abnormal cell-to-cell interactions and causes

excess proliferation of the epithelial cells that make up the kidney nephrons and collecting ducts.

Polycystic kidney disease is often detected using ultrasound techniques. The condition is usually diagnosed when patients are between 30 and 50 years of age. Approximately 50% of patients require hemodialysis (see Systems Pathology) by 70 years of age.

FIGURE 26.7 Blood Flow Through the Kidney

Numbers 1–14 show the sequence of blood flow through the kidney. (a) Blood flow through the larger arteries and veins of the kidney. (b) Blood flow through the arteries, capillaries, and veins that provide circulation to the nephrons. **APR**

transition occurs from simple cuboidal epithelium to simple squamous epithelium. Like the descending limb, the first part of the ascending limb is thin and made of simple squamous epithelium. Soon, however, it becomes thicker, and simple cuboidal epithelium replaces the simple squamous epithelium. The thick part of the ascending limb returns toward the renal corpuscle and ends by transitioning to the distal convoluted tubule near the macula densa.

The **distal convoluted tubule** is not as long as the proximal convoluted tubules. The epithelium is simple cuboidal, but the cells are smaller than the epithelial cells in the proximal convoluted tubules and do not possess a large number of microvilli (figure 26.6d). Several distal convoluted tubules connect to a single **collecting duct**, which is composed of simple cuboidal epithelium (figure 26.6c). The collecting duct, which is larger in diameter than other segments of the nephron, form much of the medullary rays and extend through the medulla toward the tips of the renal pyramids.

Arteries and Veins of the Kidneys

A system of blood vessels allows the exchange of materials that occurs in the kidneys. A **renal artery** branches off the abdominal aorta and enters the renal sinus of each kidney (figure 26.7a). **Segmental arteries** diverge from the renal artery to form **interlobar arteries**, which ascend within the renal columns toward the renal

cortex. Branches from the interlobar arteries diverge near the base of each pyramid and arch over the bases of the pyramids to form the **arcuate** (ar'kū-āt) **arteries**. **Interlobular arteries** project from the arcuate arteries into the cortex, and afferent arterioles are derived from the interlobular arteries or their branches. The afferent arterioles supply blood to the glomerular capillaries of the renal corpuscles. Efferent arterioles arise from the glomerular capillaries and carry blood away from the glomeruli. After each efferent arteriole exits the glomerulus, it gives rise to a plexus of capillaries, called the **peritubular capillaries**, around the proximal and distal convoluted tubules. Associated with the juxtamedullary nephrons are specialized sets of peritubular capillaries called the **vasa recta** (vā'sā rek'tā; figure 26.7b). From the peritubular capillaries, blood drains into the **interlobular veins**, which in turn drain into the **arcuate veins**. The arcuate veins empty into the **interlobar veins**, which drain into the **renal vein**. The renal vein exits the kidney and connects to the inferior vena cava, which returns blood to the heart.

ASSESS YOUR PROGRESS

6. What is the functional unit of the kidney? Name its parts.
7. Distinguish between cortical and juxtamedullary nephrons.
8. List the components of a renal corpuscle.

FUNDAMENTAL Figure

Urine production results from the following three processes:

- 1 Filtration** Filtration (*blue arrow*) is the movement of materials across the filtration membrane into the Bowman capsule to form filtrate.
- 2 Tubular reabsorption** Solutes are reabsorbed (*purple arrow*) across the wall of the renal tubule into the interstitial fluid by transport processes, such as active transport and cotransport.
Water is reabsorbed (*orange arrow*) across the wall of the renal tubule by osmosis. Water and solutes pass from the interstitial fluid into the peritubular capillaries.
- 3 Tubular secretion** Solutes are secreted (*green arrow*) across the wall of the renal tubule into the filtrate.

10. Describe the structure of the afferent and efferent arterioles and the juxtaglomerular apparatus. What is the function of the juxtaglomerular apparatus?
11. Describe the structure and location of the proximal convoluted tubule, loop of Henle, distal convoluted tubule, collecting duct, and papillary duct.
12. Explain the blood supply for the kidney.

26.3 Urine Production

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Briefly describe the three processes necessary for urine production.**
- B. Identify the principal factors that influence filtration and explain how they affect the rate of filtrate formation.**
- C. Explain how filtration is regulated.**
- D. Describe the role of the various regions of the kidney tubule in the process of reabsorption.**
- E. Explain how substances are able to move across the wall of the tubule.**
- F. Relate the types of substances that are moved during tubular secretion and explain how those substances are moved.**
- G. Describe the three mechanisms that explain the kidney's ability to concentrate urine.**

The primary function of the kidney is regulation of body fluid composition. The kidney is the organ that sorts the substances from the blood for either removal in the urine or return to the blood.

Substances that are waste products, toxins, and excess materials are permanently removed from the body, whereas other substances need to be preserved to maintain homeostasis. The structural components that perform this sorting are the nephrons, the functional units of the kidney. If you have ever decided to organize your “junk” drawer in your desk or kitchen, you may realize just how difficult it is to quickly sort through all its contents. In fact, you may have found yourself simply emptying the drawer onto a table and then sorting the contents one by one as you place objects into a “save group” or a “throw away group.” In a sense, the kidney uses the same approach when regulating blood composition. The “throw away” items end up in the urine, and the “save” items go back into the blood.

There are three major steps in urine production: filtration, tubular reabsorption, and tubular secretion (figure 26.8).

- 1. Filtration.** Blood pressure in the glomerular capillaries forces fluid and small molecules out of the blood. The filtered fluid is now called filtrate. Filtration is nonselective and separates based only on size or charge of molecules. Filtration is comparable to emptying your “junk” drawer of everything except perhaps some drawer dividers or other similar items. An important point to remember is that filtration of the blood does not remove everything in the blood, only those substances that fit through the filtration membrane.
- 2. Tubular reabsorption.** Cells throughout the nephron contain many transport proteins. These transport proteins move water and some filtered molecules from the filtrate back into the blood in the peritubular capillaries. This prevents them from being lost from the body as components of urine (these are the “saved” items from your junk drawer). Most of the filtered water and useful solutes have been returned to the blood by the time the filtrate has been modified to urine, whereas the remaining waste or excess substances, and a small amount of water form urine. For certain solutes, there is a higher concentration in the urine

TABLE 26.1 Concentrations of Major Solutes in Urine

Substance	Plasma	Filtrate	Net Movement of Solute*	Urine	Urine Concentration/Plasma Concentration‡
Water (L)	180	180	178.6	1.4	—
Organic molecules (mg/100 mL)					
Protein	3900–5000	6–11	–100.0	0†	0
Glucose	100	100	–100.0	0	0
Urea	26	26	–11.4	1820	70
Uric acid	3	3	–2.7	42	14
Creatinine	1.1	1.1	0.5	196	180
Ions (mEq/L)					
Na ⁺	142	142	–141.0	128	0.9
K ⁺	5	5	–4.5	60	12.0
Cl [–]	103	103	–101.9	134	1.3
HCO ₃ [–]	28	28	–27.9	14	0.5

*In many cases, solute moves into and out of the nephron. Numbers indicate net movement. Negative numbers are net movement out of the filtrate, and positive numbers are net movement into the filtrate.

†Trace amounts of protein can be found in the urine. A value of zero is assumed here.

‡Represents solute added to urine via secretion from the interstitial fluid.

compared with the plasma. This is a result of secretion and is explained in more detail later in this chapter (table 26.1).

3. **Tubular secretion.** Certain tubule cells transport additional solutes from the blood into the filtrate. Some of these solutes may not have been filtered by the filtration membrane (these are some “throw away” items that had been stuck in your junk drawer).

Therefore, urine consists of substances filtered directly from the blood and secreted directly from the blood into the renal tubule, minus any reabsorbed substances. The next few sections describe the overall process of urine production. Later, the section “Urine Concentration Mechanism” explores the topic of solute movement in more detail.

Filtration

Filtration is a nonspecific process whereby materials are separated based on size or charge. A simple example of size filtration is demonstrated by a coffee maker. In this case, the driving force of filtration is gravity. The kidneys also demonstrate size filtration by filtering the blood, but in this case, the driving force of filtration is blood pressure. The first step in urine production is filtration. All blood components except blood cells and most proteins can leave the glomerular capillaries and enter the Bowman capsule as filtrate. It is the filtrate that will be modified into urine.

The importance of filtration is indicated by the large percentage of total cardiac output, or blood, that is sent through the kidneys, given the proportionally small size of the kidneys compared with other body organs. This portion of the total cardiac output that flows through the kidneys is called the **renal fraction**. It varies from 12% to 30% of the cardiac output in healthy, resting adults, but it averages 21% (table 26.2).

Health professionals often use standard measures of blood flow through the kidney to determine whether the kidneys are functioning properly. One standard measure is the **renal blood flow rate**. Two pieces of information are used to calculate this number:

- Renal fraction, which averages 21%
- Cardiac output, which averages 5600 mL/min (see chapter 20)

Renal blood flow rate is calculated using the following formula:

$$\text{Cardiac output} \times \text{Renal fraction} = \text{Renal blood flow rate} \\ (5600 \times 0.21 = 1176 \text{ mL/min})$$

Health professionals also use the **renal plasma flow rate**, which is equal to the renal blood flow rate multiplied by 55% (percentage of whole blood that is plasma; see chapter 19).

$$1176 \text{ mL/min} \times 0.55 = 646.8 \text{ mL plasma/min, or approximately} \\ 650 \text{ mL/min (0.650 L)}$$

When the blood is filtered by the glomerulus, approximately 19% of the plasma is removed from the blood. This is called the **filtration fraction**, which is equal to 650 mL plasma/min \times 0.19 = 123.5 mL plasma/min. Thus, approximately 125 milliliters (0.125 liters) of filtrate are produced each minute and is called the **glomerular filtration rate (GFR)**. Approximately 180,000 milliliters (180 liters) of **filtrate** are produced daily. This enormous volume is equal to about 90 2-liter soft drink bottles per day. Because a healthy person produces only 1000–2000 milliliters (1–2 liters) of *urine* each day, the equivalent of one 2-liter soft drink bottle, it is readily apparent that not all of the filtrate becomes urine. In fact, about 99% of the filtrate volume is reabsorbed into the blood as it travels through the renal tubule, and less than 1% becomes urine. Although it may seem pointless to remove so much material from the blood only to return it right away, it is important that filtration remains

TABLE 26.2 Calculation of Renal Flow Rates

	Amount per Minute (mL)	Calculation
Renal Blood Flow	1176	Amount of blood flowing through the kidneys per minute; equals cardiac output (5600 mL blood/min) times the percentage (21%; renal fraction) of cardiac output that enters the kidneys $5600 \text{ mL blood/min} \times 0.21 = 1176 \text{ mL blood/min}$
Renal Plasma Flow	650	Amount of plasma flowing through the kidneys per minute; equals renal blood flow times percentage of the blood that is plasma. Because the hematocrit is the percentage of the blood that consists of formed elements, the percentage of the blood that is plasma is 100 minus the hematocrit. Assuming a hematocrit of 45, the percentage of the blood that is plasma is 55% (100 – 45). Renal plasma flow is therefore 55% of renal blood flow. $1176 \text{ mL blood/min} \times 0.55 \approx 650 \text{ mL plasma/min}$
Glomerular Filtration Rate (GFR)	125	Amount of plasma (filtrate) that enters the Bowman capsule per minute; equals renal plasma flow times the percentage (19%; filtration fraction) of the plasma that enters the renal capsule $650 \text{ mL plasma/min} \times 0.19 \approx 125 \text{ mL filtrate/min}$
Urine	1	Nonreabsorbed filtrate that leaves the kidneys per minute; equals glomerular filtration rate times the percentage (0.8%) of the filtrate that is not reabsorbed into the blood $125 \text{ mL filtrate/min} \times 0.008 = 1 \text{ mL urine/min}$ Milliliters of urine per minute can be converted to liters of urine per day by multiplying by 1.44. $1 \text{ mL urine/min} \times 1.44 = 1.4 \text{ L/day}$

continuous, so that waste products can be removed from the blood as quickly as possible.

Filtration Membrane

The **filtration membrane** is a specialized structure that filters blood in the kidneys. It is located within the renal corpuscle in the renal cortex. The filtration membrane allows water and small molecules to leave the blood while preventing blood cells and most proteins from leaving the blood. The basis for separation is both size and charge of the blood components. Several structures make up the filtration membrane. The principal component of the filtration membrane is the glomerulus. The glomerular capillaries are many times more permeable than a typical capillary. Part of this is due to the presence of fenestrae in the glomerular capillaries. The following is a list of all filtration membrane structures:

1. The fenestrated glomerular capillaries
2. The basement membrane between the capillary wall and the visceral layer of the Bowman capsule
3. Podocytes of the visceral layer of the Bowman capsule (see figure 26.5d)

Together, these components prevent molecules larger than 7 nm in diameter or those having a molecular mass equal to or greater than 40,000 daltons from passing through. For comparison, an antibody molecule is 12 nm, glucose is 0.9 nm, and the amino acid methionine is 0.7 nm in diameter. The exclusion of molecules larger than 7 nm is partially due to the fact that the fenestrae are about 7 nm in size. Most plasma proteins are slightly larger than 7 nm in diameter and are retained in the glomerular capillaries. However, albumin, which has a diameter just slightly less than 7 nm, enters the filtrate only in small amounts. Therefore, the filtrate is not protein-free but, rather, contains about 0.03% protein. In addition, some protein hormones, such as thyrotropin-releasing hormone, oxytocin, and antidiuretic hormone, are small enough to pass through the filtration membrane.

Any protein that is filtered is actively reabsorbed by endocytosis and metabolized by the cells in the proximal convoluted tubule. The basement membrane and the podocytes further contribute to filtration through charge exclusions. They contain negatively charged glycoproteins, which repel negatively charged plasma proteins and prevent them from exiting the blood. In summary, the combined effect of the filtration membrane components prevents most proteins from exiting the blood on the basis of size and charge, and only a small amount of protein is found in the urine of healthy people.

Predict 2

A hemoglobin molecule has a smaller diameter than an albumin molecule, but very little hemoglobin passes from the blood into the filtrate. Explain why. Under what circumstances do large amounts of hemoglobin enter the filtrate?

Filtration Pressure

No matter the type of size-based filter, there is one commonality: They all require a force to enhance movement through it. For example, for a coffee maker, as noted earlier, the force is gravity. For the filtration membrane, three forces, or pressures, determine the amount of filtrate formed. The combination of these three pressures is called **filtration pressure** (figure 26.9). The three pressures contributing to filtration pressure are:

1. The **glomerular capillary pressure (GCP)** is an *outward pressure* from blood pressing on the capillary walls. This is simply blood pressure. The GCP forces fluid and solutes out of the blood into the Bowman capsule. This GCP is higher than that in other capillaries of the body. The higher GCP is due to the smaller diameter of the efferent arteriole compared to that of the afferent arteriole and glomerular capillaries. As you learned in chapter 21, when the diameter of a vessel

- 1 Glomerular capillary pressure (GCP), the blood pressure (50 mm Hg) within the glomerulus, moves fluid from the blood into the Bowman capsule.
- 2 Capsular hydrostatic pressure (CHP), the fluid pressure inside the Bowman capsule (10 mm Hg), moves fluid from the Bowman capsule into the blood.
- 3 Blood colloid osmotic pressure (BCOP), produced by the concentration of blood proteins in the glomerular capillaries (30 mm Hg), moves fluid from the Bowman capsule into the blood by osmosis.
- 4 Filtration pressure is equal to the glomerular capillary pressure minus the capsular hydrostatic and blood colloid osmotic pressures.

PROCESS FIGURE 26.9 Filtration Pressure

Filtration pressure across the filtration membrane is equal to the glomerular capillary pressure (GCP) minus the blood colloid osmotic pressure (BCOP) in the glomerular capillary minus the capsular hydrostatic pressure (CHP) in the Bowman capsule.

decreases, the resistance to blood flow through the vessel is greater. The efferent arteriole has a smaller diameter than the afferent arteriole and glomerular capillary. Thus, as the blood flows from the larger-diameter afferent arteriole through the glomerular capillaries to the smaller-diameter efferent arteriole, the blood pressure increases in the glomerular capillaries. Consequently, filtrate is forced across the filtration membrane into the lumen of the Bowman capsule. The GCP is approximately 50 mm Hg compared with approximately 30 mm Hg at the arterial end of other capillary beds.

2. The **capsular hydrostatic pressure (CHP)** is an *inward pressure* that opposes filtration. This pressure is due to the force of filtrate volume on the wall of the Bowman capsule. CHP is comparable to blood pressure in that they are both due to fluid volume in a tube or chamber. The CHP usually measures about 10 mm Hg.
3. The **blood colloid osmotic pressure (BCOP)** is also an *inward pressure* that opposes filtration. It is due to the osmotic pressure of plasma proteins in the glomerular capillaries. The presence of these proteins draws fluid back into the glomerular capillary from the Bowman capsule. The BCOP is greater at the end of the glomerular capillary than at its beginning because there is a higher protein concentration at the end of the glomerulus. The average BCOP is approximately 30 mm Hg.

To calculate filtration pressure, all three filtration pressures are summed, and we see that in a normal kidney GCP is greater than CHP and BCOP combined. The filtration pressure is a net *outward* pressure of approximately 10 mm Hg:

		Capsular	
Filtration	Glomerular	hydrostatic	Blood colloid
pressure	capillary pressure	pressure	osmotic pressure
(10 mm Hg) =	(50 mm Hg)	– (10 mm Hg) –	(30 mm Hg)

Normally, the filtrate does not exert an osmotic force on the plasma because its solute concentration is very low. This is because few proteins cross the filtration membrane. However, in a disease such as **glomerular nephritis**, the filtration membrane becomes more permeable, allowing more protein than normal to enter the filtrate. The elevated protein in the filtrate increases the colloid osmotic pressure of the filtrate. This results in elevated filtration pressure, thereby increasing the filtrate volume.

Regulation of Glomerular Filtration Rate

The glomerular filtration rate (GFR) is very stable. GFR does not significantly change even if systemic blood pressure drops as low as 90 mm Hg or rises as high as 180 mm Hg. The maintenance of the GFR is due to the process called **autoregulation**. However, under severe conditions such as hemorrhage or dehydration, the mean arterial pressure can drop below 90 mm Hg, and the sympathetic nervous system causes a dramatic decrease in renal blood flow and GFR in an effort to maintain homeostatic blood pressure.

Mechanisms of Autoregulation

Autoregulation is achieved through two processes: the myogenic mechanism and tubuloglomerular feedback. As the name suggests, the myogenic mechanism is associated with the intrinsic properties of smooth muscle cells in the afferent and efferent arterioles. These smooth muscle cells act as stretch receptors, which detect changes in blood pressure. When blood pressure goes up, the smooth muscle in the wall of the afferent arteriole stretches. In direct response to stretch, the smooth muscle contracts, which constricts the afferent arteriole. On the other hand, when blood pressure decreases, the smooth muscle in the wall of the afferent arteriole relaxes and the vessels dilate. In this way, blood supply to the glomerulus, and thus GFR, fluctuates very little, even when the mean arterial pressure changes.

The tubuloglomerular feedback mechanism correlates filtrate flow past the macula densa of the juxtaglomerular apparatus to GFR. When the macula densa cells detect an increased flow rate, these cells send a signal to the juxtaglomerular cells of the afferent arteriole to constrict. Thus, glomerular filtration rate decreases due to a decreased glomerular capillary pressure.

Sympathetic Stimulation

Autoregulation maintains renal blood flow and filtrate formation at a relatively constant rate unless sympathetic stimulation is intense. Because norepinephrine-secreting sympathetic neurons innervate the blood vessels of the kidneys, sympathetic stimulation constricts the small arteries and afferent arterioles, thereby decreasing renal blood flow and filtrate formation. Intense sympathetic stimulation, as may occur during shock or intense exercise, decreases the rate of filtrate formation to only a few milliliters per minute; however, small changes in sympathetic stimulation have a minimal effect on renal blood flow and filtrate formation.

In response to severe stress or circulatory shock, the afferent arterioles greatly constrict. This lowers renal blood flow so severely that the blood supply to the kidney is inadequate to maintain normal kidney metabolism. As a consequence, kidney tissues can be damaged and thus unable to perform their normal functions if blood flow is not reestablished. Therefore, shock should be treated quickly. On the other hand, reduced blood flow to the kidneys during stress or shock is consistent with homeostasis. Intense vasoconstriction maintains blood pressure at levels adequate to sustain blood flow to organs such as the heart and brain. A reduction in blood flow to organs such as the kidneys is only harmful if the lack of blood flow is prolonged.

ASSESS YOUR PROGRESS

13. Name the three general processes involved in producing urine.
14. Contrast the rates of renal blood flow, renal plasma flow, and glomerular filtration. How do they affect urine production?
15. Describe the filtration membrane. What substances do not pass through it?
16. What is filtration pressure? How does glomerular capillary pressure affect filtration pressure and the amount of urine produced?
17. How do systemic blood pressure and afferent arteriole diameter affect glomerular capillary pressure?
18. Describe autoregulation.
19. Explain the effect of sympathetic stimulation on the kidney and the GFR during rest, exercise, and shock.

Tubular Reabsorption

Tubular reabsorption is the return of water and solutes in the filtrate to the blood. Nearly all (99%) of the water and solutes are rapidly returned to the blood via the renal tubules, and because of this, toxins are quickly removed from the blood. However, the body

would become overly dehydrated and deficient in important materials without proper tubular reabsorption. The filtrate leaves the lumen of the Bowman capsule and flows through the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule and then into the collecting ducts. As it passes through these structures, many of the substances in the filtrate are removed by one or more of several processes. These processes, such as simple and facilitated diffusion, active transport, symport, and osmosis, all result in tubular reabsorption. Inorganic salts, organic molecules, and about 99% of the filtrate volume leave the renal tubule and enter the interstitial fluid. Because the pressure is low in the peritubular capillaries, these substances enter the peritubular capillaries and flow through the renal veins to enter the general circulation (see figure 26.8).

Solutes reabsorbed from the lumen of the renal tubule to the interstitial fluid include amino acids, glucose, and fructose, as well as Na^+ , K^+ , Ca^{2+} , HCO_3^- , and Cl^- . A more complete list is provided in table 26.3 for each part of the nephron.

As the solutes in the renal tubule are reabsorbed, water follows the solutes by the process of osmosis (see chapter 3). The small volume of the filtrate (approximately 1%) that forms urine contains urea, uric acid, creatinine, K^+ , and other substances. The regulation of solute reabsorption and the permeability characteristics of portions of the nephron allow for the production of a small volume of very concentrated urine or a large volume of very dilute urine. The following section describes the mechanisms responsible for reabsorption by the renal tubules of the nephron. The mechanisms that regulate urine concentration are then described in the section “Urine Concentration Mechanism.”

Reabsorption in the Proximal Convoluted Tubule

The majority of reabsorption occurs in the proximal convoluted tubule. The mechanisms underlying reabsorption can be better understood by considering the cells found there. These cells have an apical surface, which makes up the inside surface of the tubule wall; a basal surface, which forms the outer wall of the tubule; and lateral surfaces, which are bound to the surfaces of other cells of the tubule. Reabsorption of most solutes from the proximal convoluted tubule is linked to a steep Na^+ concentration gradient between the filtrate and the cytoplasm of the tubule cells. Active transport of Na^+ across the **basal membrane** of the tubule epithelial cells from the cytoplasm into the interstitial fluid creates a low concentration of Na^+ inside the cells (figure 26.10). At the basal membrane, the sodium-potassium pump moves Na^+ out of the cell and K^+ into the cell. Because the concentration of Na^+ in the lumen of the proximal convoluted tubule is high, a large concentration gradient is present from the lumen of the tubule to the cytoplasm of the tubule cells. This concentration gradient for Na^+ is responsible for the secondary active transport of many other solutes from the lumen of the tubule into the tubule cells (see chapter 3).

Carrier proteins that transport amino acids, glucose, and other solutes are located within the **apical membrane**, which separates the lumen of the proximal convoluted tubule from the cytoplasm of epithelial cells. Each of these carrier proteins binds specifically to one of those substances to be transported and to Na^+ . The concentration gradient for Na^+ provides the energy that moves both the Na^+ and the other molecules or ions from the

lumen into the tubule cell. Once the symported molecules are inside the cell, they cross the basal membrane of the cell by facilitated diffusion or symport. The number of carrier proteins limits the rate at which a substance can be transported. For example, the high blood glucose in someone with untreated diabetes mellitus can lead to such high glucose levels in the filtrate that not all of it can be removed by the glucose transport proteins. The excess glucose remains in the filtrate and becomes part of the urine (see section 26.5).

Some solutes also diffuse from the lumen of the proximal convoluted tubule into the interstitial fluid by moving *between* the cells. As other solutes are transported out of the lumen, through the proximal convoluted tubule cells, and into the interstitial fluid, water follows by osmosis. The reabsorption of water causes the concentration of solutes that remain in the lumen to increase. When the concentration of these solutes in the lumen becomes higher than in the interstitial fluid, these solutes will diffuse between the tubule cells into the interstitial fluid. Examples of solutes that diffuse between tubule cells of the proximal convoluted tubule include K⁺, Ca²⁺, and Mg²⁺. These solutes are reabsorbed by diffusion, even though the same ions are also sometimes reabsorbed by symport processes.

Reabsorption of solutes and water in the proximal convoluted tubule is extensive. As solute molecules are transported from the tubule to the interstitial fluid, water moves by osmosis in the same direction. By the time the filtrate has reached the end of the proximal convoluted tubule, its volume has been reduced by approximately 65%. Because the proximal convoluted tubule is permeable to water, the concentration of the filtrate there remains about the same as that of the interstitial fluid (300 mOsm/kg).

Reabsorption in the Loop of Henle

As the filtrate from the proximal convoluted tubule moves toward the loop of Henle, the wall of the tubule undergoes a histological change. As the loop of Henle descends into the medulla of the kidney, where the concentration of solutes in the interstitial fluid is very high, the wall transforms from simple cuboidal epithelial tissue to simple squamous epithelial tissue in the thin segment. Thus, the thin segment of the descending limb of the loop of Henle (figure 26.11a) is highly permeable to water. In addition, it is moderately permeable to urea, Na⁺, and many other ions. Because the thin segment of the descending limb is so permeable to water and somewhat permeable to solutes, water leaves this portion of the tubule by osmosis and some solutes move into this portion of the loop of Henle. By the time the filtrate has reached the end of the thin segment of the descending limb, the volume of the filtrate has been reduced by another 15%, and the concentration of the filtrate is equal to the high concentration of the interstitial fluid (1200 mOsm/L).

The thin segment of the ascending limb of the loop of Henle is permeable to solutes but impermeable to water (figure 26.11b). Therefore, although the gradient encourages water to leave the lumen of the thin segment of the ascending limb, no additional water exits. The ascending limb of the loop of Henle is surrounded by interstitial fluid, which becomes less concentrated toward the cortex. As the filtrate flows through the thin segment of the limb, solutes diffuse into the interstitial fluid, making the filtrate less concentrated.

Because the thick segment of the ascending limb is not freely permeable to water or solutes, solutes such as Na⁺, K⁺, and Cl⁻ must be actively transported from the thick segment of the ascending limb of the loop of Henle into the interstitial fluid. Symport is responsible for moving K⁺ and Cl⁻ with Na⁺ across the apical membrane of the ascending limb of the loop of Henle (figure 26.12). Once inside the cells of the ascending limb, Cl⁻ and K⁺ exit the cells of the ascending limb via facilitated diffusion. The concentration of Na⁺ in the lumen of the ascending limb is high, and the concentration inside the cells of the ascending limb is low. This concentration gradient is created

FIGURE 26.10 Reabsorption of Solutes in the Proximal Convoluted Tubule

The symport of molecules and ions across the epithelial lining of the proximal convoluted tubule depends on the active transport of Na^+ , in exchange for K^+ , across the basal membrane. Symport is the process by which carrier proteins move molecules or ions with Na^+ across the apical membrane. The Na^+ concentration gradient provides the energy for symport. Amino acids, glucose, K^+ , Cl^- , and most other solutes are transported into the tubule cells with Na^+ . Water enters and leaves the cell by osmosis. Glucose, amino acids, Na^+ , Cl^- , and many other solutes leave the cells across the basal membrane by facilitated diffusion.

(a) The wall of the thin segment of the descending limb of the loop of Henle is permeable to water and, to a lesser extent, to solutes. The interstitial fluid in the medulla of the kidney and the blood in the vasa recta have a high solute concentration (high osmolality). Water therefore moves by osmosis from the tubule into the interstitial fluid and into the vasa recta. An additional 15% of the filtrate volume is reabsorbed. To a lesser extent, solutes diffuse from the vasa recta and interstitial fluid into the tubule.

(b) The thin segment of the ascending limb of the loop of Henle is not permeable to water but is permeable to solutes. The solutes diffuse out of the tubule and into the more dilute interstitial fluid as the ascending limb projects toward the cortex. Then the solutes diffuse into the descending vasa recta.

FIGURE 26.11 Reabsorption in the Loop of Henle: The Descending Limb and the Thin Segment of the Ascending Limb

by the active transport of the Na^+ out of the cell in exchange for K^+ across the basal membrane (figure 26.12).

As we follow the filtrate through the loop of Henle, we see that it becomes very concentrated toward the bend of the loop of Henle, but the concentration of the filtrate is reduced to about

100 mOsm/kg by the time the fluid reaches the distal convoluted tubule. In contrast, the concentration of the interstitial fluid in the cortex is about 300 mOsm/kg. Thus, the filtrate entering the distal convoluted tubule is much more dilute (hypotonic) than the interstitial fluid surrounding it.

Reabsorption in the Distal Convolved Tubule and Collecting Duct

Some solutes (Na^+ , Cl^- , H^+) are not reabsorbed until further along the renal tubule in the distal convolved tubule or collecting duct. The reabsorption of these solutes is generally under hormonal control and depends on the current conditions of the body. The distal convolved tubule and the collecting duct are not always permeable to water. Hormone regulation can change the permeability of the distal convolved tubule and the collecting duct (see section 26.4). Reabsorption of water is via osmosis across the wall of the distal convolved tubule and the collecting duct when the hormone ADH is present (see chapter 18). The interstitial fluid surrounding the

distal convolved tubule and collecting duct is more concentrated than the filtrate, so the water moves toward the high solute concentration area. In these conditions, a small volume of concentrated urine is produced. ADH causes the tubule wall to become more permeable to water, a mechanism discussed in more detail later in this chapter. When ADH is absent, the distal convolved tubule and collecting duct are not permeable to water and water stays in the filtrate. In this case, a large volume of dilute urine is produced.

The distal convolved tubule also plays a major role in secretion, which is discussed later in this section.

Changes in the Concentration of Urea and Other Solutes in the Nephron

One of the nephron's major functions is to remove wastes from the body. For example, **urea** (ū-rē'ă), a protein breakdown product, enters the glomerular filtrate at the same concentration as in the plasma. Because renal tubules are not as permeable to urea as they are to water, urea tends to stay inside the tubules. Thus, as the volume of filtrate decreases in the renal tubule, the concentration of urea increases. Only 40–60% of the urea is

The wall of the ascending limb of the loop of Henle is not permeable to water. Sodium ions move across the wall of the basal membrane by active transport, establishing a concentration gradient for Na⁺. Potassium ions and Cl⁻ are symported with Na⁺ across the apical membrane, and ions pass by facilitated diffusion across the basal membrane of the tubule cells.

passively reabsorbed by the renal tubule, although about 99% of the water is reabsorbed. In addition to urea, urate ions, creatinine, sulfates, phosphates, and nitrates are reabsorbed, but not to the same extent as water. They therefore become more concentrated in the filtrate as the volume of the filtrate becomes smaller. These substances are toxic if they build up in the body, so their accumulation in the filtrate and elimination in urine help maintain homeostasis (see table 26.1).

Tubular Secretion

Tubular secretion is the movement of nonfiltered substances from the blood into the filtrate. These substances include toxic by-products of metabolism and drugs or molecules not normally produced by the body (table 26.4). As with tubular reabsorption, tubular secretion can be either active or passive. For example, ammonia is a toxic by-product of protein metabolism. It is produced when the epithelial cells of the renal tubule remove amino groups from amino acids, which diffuse into the lumen of the renal tubule. On the other hand, H⁺, K⁺, penicillin, and **para-aminohippuric acid** (par'ă-a-mī'nō-hi-pūr'ik; p-aminohippuric acid; **PAH**; a medical diagnostic chemical) are actively secreted by either active transport or antiport processes into the renal tubule. An example of an antiport process in the kidney is that which moves H⁺ from tubule cells into the renal tubule lumen. Hydrogen ions bind the carrier proteins on the inside of the plasma membrane, and Na⁺ binds to the carrier proteins on the outside of the plasma membrane. As Na⁺ moves into the cell, H⁺ moves out

of the cell (figure 26.13). The secreted H⁺ is produced when carbon dioxide and water react to form H⁺ and HCO₃⁻. The antiporters secrete H⁺ into the tubule lumen in exchange for Na⁺. Sodium ions and HCO₃⁻ are symported across the basal membrane of the cell and enter the peritubular capillaries. Hydrogen ions are secreted into the proximal and distal convoluted tubules. This secretion of H⁺ by the renal tubule plays a major role in regulating body fluid pH and is discussed in more detail in chapter 27.

ASSESS YOUR PROGRESS

20. What is the direction of movement of substances in tubular reabsorption?
21. Describe what happens to most of the filtrate that enters the renal tubule.
22. On what side of the renal tubule cell does active transport take place during reabsorption of materials?
23. Describe how symport works in the renal tubule.
24. Name the substances that are moved by active and passive transport. In what part of the renal tubule does this movement take place?
25. Explain the differences between the descending limb and the ascending limb of the loop of Henle.
26. Where does tubular secretion take place? What is the direction of movement?
27. What substances are secreted? List the mechanisms by which these substances are transported.

Urine Concentration Mechanism

As you have just read, the kidneys are remarkable at regulating blood composition. But how does the kidney move such a large volume of fluid from the blood into the filtrate and then back into the blood? The kidneys employ a unique mechanism, called the **countercurrent mechanism**. A countercurrent mechanism is one where fluid in separate structures flows in opposite directions relative to each other. As the fluids pass by each other, materials can be exchanged between the fluids.

When a person drinks a large amount of liquid, the body must eliminate that excess fluid without losing dangerous amounts of electrolytes or other substances essential for maintaining homeostasis. The kidneys respond by producing a large volume of dilute urine. On the other hand, if a person did not drink enough water, producing an excessive amount of dilute urine would lead to rapid dehydration. Therefore, when water intake is restricted, the kidneys produce a small volume of concentrated urine that conserves water and contains just enough waste products to keep them from accumulating in the blood. The kidneys are able to produce urine with concentrations ranging from a minimum of 65 to a maximum of 1200 mOsm/kg while maintaining the extracellular fluid concentration very close to 300 mOsm/kg. The kidneys' ability to control the volume and concentration of the urine depends on several factors: the maintenance of a high concentration of solutes in the medulla, the countercurrent functions of the loops of Henle, and the antidiuretic hormone mechanism that controls the permeability of the distal convoluted tubules and collecting ducts to water.

(a) Hydrogen ions are secreted into the filtrate by an antiport mechanism in the proximal convoluted tubule, in which H^+ are exchanged for Na^+ . The H^+ are derived from two sources. They diffuse from the peritubular capillaries into the interstitial fluid and then into epithelial cells of the tubule, or they are derived from the reaction between carbon dioxide and water in the cells of the tubule. Sodium ions and HCO_3^- are symported across the basal membrane into the interstitial fluid and then diffuse into the peritubular capillaries.

(b) Hydrogen ions and K^+ are secreted into the filtrate by antiport mechanisms in the distal convoluted tubule. Sodium ions and K^+ are moved by active transport across the basal membrane of the tubule cell. Sodium ions and HCO_3^- are symported across the basal membrane into the interstitial fluid and then diffuse into the peritubular capillaries.

FIGURE 26.13 Secretion of H^+ and K^+ into the Renal Tubule

Medullary Concentration Gradient

The kidney's ability to concentrate urine depends on maintaining a high concentration of solutes in the medullary region of the kidney. The interstitial fluid concentration is about 300 mOsm/kg in the cortical region. Moving from the cortex toward the medulla, the interstitial fluid becomes progressively more concentrated until it achieves a maximum concentration of 1200 mOsm/kg at the tip of the renal pyramid (see figure 26.16). Countercurrent mechanisms in the loops of Henle and the vasa recta maintain the high solute concentration in the kidney medulla (figure 26.14). In addition, the

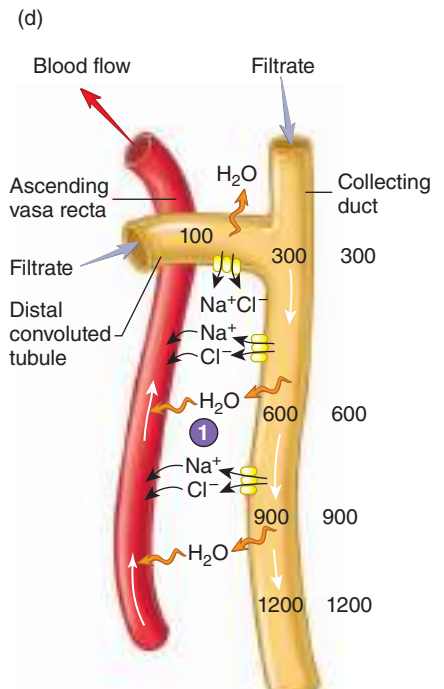

distribution of urea throughout the interstitial fluid is an integral aspect of the medullary concentration gradient. The following major mechanisms create and maintain the high solute concentration in the renal medulla:

1. *Transport of solutes and diffusion of water across the wall of the loop of Henle.* The long loops of Henle of the juxtamedullary nephrons are essential for maintaining a high medullary solute concentration. They constitute a countercurrent mechanism. The countercurrent mechanism of the kidney consists of the parallel tubes, the loop of Henle and the vasa recta, in

- (a)
- 1 Water diffuses out of the thin segment of the loop of Henle.
 - 2 The filtrate concentration is 1200 mOsm.
 - 3 Sodium and other solutes are actively transported out of the loop of Henle into the medulla.
- (b)
- 1 Water diffuses out and solutes diffuse into the descending portion of the vasa recta.
 - 2 The blood concentration is 1200 mOsm.
 - 3 Water diffuses into and solutes diffuse out of the ascending portion of the vasa recta.
 - 4 At the end of the vasa recta, the blood osmolality is only slightly greater than the osmolality of the blood at the beginning of the vasa recta.

- (c)
- 1 Water moves out of the descending limb of the loop of Henle and enters the ascending vasa recta.
 - 2 Solute diffuses out of the ascending thin segment of the loop of Henle and enter the vasa recta.
 - 3 Solute transported out of the thick segment of the ascending limb of the loop of Henle enter the descending vasa recta. The vasa recta do not dilute the high medullary concentration.
 - 4 The concentration of the filtrate is reduced to 100 mOsm/kg by the time it reaches the distal convoluted tubule.

- (d)
- 1 Water and solutes, such as Na⁺ and Cl⁻ leave the distal convoluted tubule and the collecting duct and enter the ascending vasa recta.

PROCESS FIGURE 26.14 Filtrate Concentration and the Medullary Concentration Gradient

The loop of Henle and the vasa recta function together to maintain a high concentration of solutes in the medulla of the kidney.

which fluid flows, but in opposite directions. Via this mechanism, substances such as water or solutes diffuse from the loop of Henle carrying filtrate in one direction to the vasa recta carrying blood in the opposite direction so that the fluid in both sets of tubes has nearly the same solute composition. The walls of the descending limbs of the loops of Henle are permeable to water. As filtrate flows into the kidney medulla through the descending limbs, water diffuses out of the renal tubules into the more concentrated interstitial fluid. The excess water that enters the interstitial fluid enters the vasa recta and is removed from the medulla (see mechanism 2). Some solutes diffuse into the descending limb, but in relatively small amounts. By the time the filtrate reaches the bend of the loop of Henle, it is very concentrated. The walls of the thick and thin segments of the ascending limbs of the loops of Henle are impermeable to water. Consequently, solutes diffuse out of the thin segment of the ascending limb as it passes through progressively less concentrated interstitial fluid on its way back to the kidney cortex. Also, Na^+ , K^+ , and Cl^- are symported out of the thick segment of the ascending limb into the interstitial fluid. Thus, water enters the interstitial fluid from the descending limbs, and solutes enter the interstitial fluid from the ascending limbs (figure 26.14a). The solutes that diffuse from the thin segments, and those that are symported from the thick segments, add solutes to the medulla. This maintains a high medullary fluid osmolality.

Only the juxtamedullary nephrons have loops of Henle that descend deep into the medulla, but enough of them exist to maintain the high concentration of solutes in the interstitial fluid of the medulla. Not all of the nephrons need to have loops of Henle that descend into the medulla to concentrate urine effectively. The cortical nephrons function as the juxtamedullary nephrons do, but their loops of Henle are not as efficient at concentrating urine. However, because the filtrate from the cortical nephrons passes through the collecting ducts, water can diffuse out of the collecting ducts into the interstitial fluid. Thus, the filtrate becomes concentrated. Animals that concentrate urine more effectively than humans have a greater percentage of nephrons descending into the kidney medulla. For example, in desert mammals, many nephrons descend into the medulla, and the renal pyramids are longer than those in humans and most other mammals.

2. *Diffusion of water and solutes across the walls of the vasa recta.* The vasa recta supply blood to the kidney medulla, and they act as countercurrent mechanisms that remove excess water and solutes from the medulla without changing the high concentration of solutes in the medullary interstitial fluid. The vasa recta are a countercurrent mechanism because blood flows through them to the kidney medulla, and after the vessels turn near the tip of the renal pyramid, the blood flows the opposite direction, back toward the cortex. The walls of the vasa recta are permeable to both water and solutes. As blood flows toward the medulla, water moves out of the vasa recta, and some solutes diffuse into them. As blood flows back toward the cortex, water moves into the vasa recta, and some solutes diffuse out of them (figure 26.14b). The directions of

diffusion are such that the vasa recta carry slightly more water and solute from the medulla than to it. Thus, the composition of the blood at both ends of the vasa recta is nearly the same, with the volume and osmolality slightly greater as the blood once again reaches the cortex. In addition, blood pressure in the vasa recta is very low and blood flow rate is extremely slow, even sluggish. This encourages ready diffusion of solutes into and back out of the vasa recta, ensuring the maintenance of the high medullary concentration gradient. Figure 26.14c,d further illustrate this mechanism by showing the close anatomical relationship of the loops of Henle, the collecting ducts, and the vasa recta.

3. *Urea cycling.* Urea is responsible for a substantial part of the high osmolality in the kidney medulla (figure 26.15). Due to their histology, the walls of the descending limbs of the loops of Henle are permeable to urea; thus, urea diffuses into the descending limbs from the interstitial fluid. However, due to their histology, the ascending limbs of the loops of Henle and the distal convoluted tubules are impermeable to urea, so the urea remains in the loop of Henle until it reaches the collecting ducts, which are permeable to urea. Some urea then diffuses out of the collecting ducts into the

FIGURE 26.15 Medullary Concentration Gradient and Urea Cycling

The concentration of urea in the medulla of the kidney is high and contributes to the overall high concentration of solutes there. The wall of the collecting duct is permeable to urea. Urea diffuses out of the collecting duct into the interstitial fluid of the medulla. The wall of the descending limb of the loop of Henle is also permeable to urea. Urea diffuses from the interstitial fluid into the descending limb. Thus, a cycle is produced: Urea flows into the descending limb, through the ascending limb, through the distal convoluted tubule, through the collecting duct, out of the collecting duct, and back into the descending limb.

interstitial fluid of the medulla. Therefore, urea is recycled from the interstitial fluid into the descending limbs of the loops of Henle, through the ascending limbs, through the distal convoluted tubules, and into the collecting ducts. Most urea then diffuses from the collecting ducts back into the interstitial fluid of the medulla. Consequently, a high urea concentration is maintained in the medulla of the kidney. To summarize, several key events occur in the renal tubule to establish and maintain a high medullary solute concentration:

- Sodium ions and other solutes are actively transported into the interstitial fluid of the medulla, maintaining a high medullary osmolarity.
- Because blood flows sluggishly and there is low blood pressure in the vasa recta, solutes are not washed away from the medulla.
- Much urea returns to the medulla from the collecting duct, rather than exiting with the urine.

Summary of Changes in Filtrate Volume and Concentration

Following are the steps in urine production from the proximal convoluted tubule to the collecting duct. In the average person, about 180 L of filtrate enter the proximal convoluted tubules daily. Glucose, amino acids, Na^+ , Ca^{2+} , K^+ , Cl^- , water, and other substances (see table 26.3) move from the lumens of the proximal convoluted tubules into the interstitial fluid. The excess solutes and water then enter the peritubular capillaries. Consequently, cells of the proximal convoluted tubule reabsorb approximately 65% of the filtrate, which moves solutes and water into the interstitial fluid. The osmolality of both the interstitial fluid and the filtrate is maintained at about 300 mOsm/kg.

As the filtrate continues to flow through the renal tubule, it enters the descending limbs of the loops of Henle. This portion of the loops of Henle is highly permeable to water and solutes. As the descending limbs penetrate deep into the kidney medulla, the surrounding interstitial fluid has a progressively greater osmolality. Water diffuses out of the loops of Henle as solutes slowly diffuse into them. By the time the filtrate reaches the deepest part of the loops of Henle, its volume has been reduced by an additional 15% of the original volume, at least 80% of the filtrate volume has been reabsorbed, and its osmolality has increased to about 1200 mOsm/kg (figure 26.16).

After passing through the descending limbs of the loops of Henle, the filtrate enters the ascending limbs. Both the thin and thick segments are impermeable to water, but solutes diffuse out of the thin segment, and Na^+ , Cl^- , and K^+ are symported from the filtrate into the interstitial fluid in the thick segments (figure 26.16). The movement of solutes, but not water, across the wall of the ascending limbs causes the osmolality of the filtrate to decrease from 1200 to about 100 mOsm/kg by the time the filtrate again reaches the kidney cortex. The volume of the filtrate does not change as it passes through the ascending limbs. As a result, the filtrate entering the distal convoluted tubules is dilute, compared with the concentration of the surrounding interstitial fluid, which has an osmolality of about 300 mOsm/kg.

The changes just described are *obligatory*; that is, they occur regardless of the concentration and volume of urine that the kidney finally produces. The mechanisms by which the kidney forms concentrated and dilute urine are described in section 26.4.

ASSESS YOUR PROGRESS

- List the major mechanisms that create and maintain the high solute concentration in the renal medulla.
- Describe the roles of the loop of Henle, the vasa recta, and urea cycling in maintaining a high interstitial solute concentration in the kidney medulla.
- Describe how the filtrate volume and concentration change as filtrate flows through the renal tubules and collecting ducts.

26.4 Regulation of Urine Concentration and Volume

LEARNING OUTCOME

After reading this section, you should be able to

- Explain how antidiuretic hormone, the renin-angiotensin-aldosterone hormone mechanism, and atrial natriuretic hormone influence the concentration and volume of urine.

Urine can be dilute or very concentrated, and it can be produced in large or small amounts. Mechanisms that maintain the kidneys' extracellular fluid and volume keep the urine concentration and volume within narrow limits.

Filtrate reabsorption in the proximal convoluted tubules and the descending limbs of the loops of Henle is obligatory and therefore remains relatively constant. However, filtrate reabsorption in the distal convoluted tubules and collecting ducts is tightly regulated and can change dramatically, depending on the conditions to which the body is exposed. If homeostasis requires the elimination of a large volume of dilute urine, the dilute filtrate can pass through the distal convoluted tubules and collecting ducts with little change in concentration. On the other hand, if water must be conserved to maintain homeostasis, water is reabsorbed from the filtrate as it passes through the distal convoluted tubules and collecting ducts. This results in a small volume of very concentrated urine. The regulation of urine concentration and volume involves hormonal mechanisms, described next, as well as autoregulation and the sympathetic nervous system, described earlier.

Hormonal Mechanisms

Two major hormonal mechanisms are involved in regulating urine concentration and volume: the renin-angiotensin-aldosterone hormone mechanism and the antidiuretic hormone (ADH) mechanism. Each mechanism is activated by different stimuli, but they work together to achieve homeostasis. The renin-angiotensin-aldosterone hormone mechanism is more sensitive to changes in blood pressure, and the ADH mechanism is more sensitive to changes in blood osmolality.

- 1 Approximately 180 L of filtrate enters the nephrons each day. The filtrate concentration is 300 mOsm/kg.
- 2 Approximately 65% of the water and NaCl in the original filtrate is reabsorbed in the proximal convoluted tubule. The filtrate concentration is 300 mOsm/kg.
- 3 Approximately 15% of the water is reabsorbed in the thin segment of the descending limb of the loop of Henle. At the tip of the renal pyramid, filtrate concentration is 1200 mOsm/kg, which is equal to the interstitial fluid concentration.
- 4 The thin segment of the ascending limb of the loop of Henle is not permeable to water. Sodium chloride diffuses out of the thin segment.
- 5 The thick segment of the ascending limb of the loop of Henle is not permeable to water. Sodium ions are actively transported into the interstitial fluid and Cl^- follow by diffusion.
- 6 The volume of the filtrate does not change as it passes through the ascending limb, but the concentration is greatly reduced. By the time the filtrate reaches the cortex, the concentration is 100 mOsm/kg, and an additional 25% of NaCl has been reabsorbed.
- 7 The distal convoluted tubules and collecting ducts reabsorb water and NaCl.
- 8 If ADH is present, water moves by osmosis from the less concentrated filtrate into the more concentrated interstitial fluid. By the time the filtrate reaches the tip of the renal pyramid, an additional 19% of water and 9–10% of NaCl has been reabsorbed.
- 9 One percent or less of the filtrate remains as urine when ADH is present (see “Hormonal Mechanisms” later in this chapter).

PROCESS FIGURE 26.16 Urine-Concentrating Mechanism

Renin-Angiotensin-Aldosterone Hormone Mechanism

Renin is an enzyme secreted by the juxtaglomerular cells of the juxtaglomerular apparatus. When the juxtaglomerular cells detect reduced stretch of the afferent arteriole, and thus a drop in afferent arteriole pressure, they secrete renin. In addition, the macula densa cells signal the juxtaglomerular cells to secrete renin when the

Na^+ concentration of the filtrate drops. Upon secretion, renin enters the blood and converts **angiotensinogen**, a plasma protein produced by the liver, to **angiotensin I**. **Angiotensin-converting enzyme (ACE)** is a proteolytic enzyme produced by capillaries of organs such as the lungs that converts angiotensin I to **angiotensin II** (figure 26.17). Angiotensin II is a potent vasoconstricting hormone that increases peripheral resistance, causing

- 1 Aldosterone secreted from the adrenal cortex enters cells of the distal convoluted tubule.
- 2 Aldosterone binds to nuclear receptors and increases the synthesis of transport proteins of the apical and basal membranes.
- 3 Newly synthesized transport proteins increase the rate at which Na⁺ is absorbed and K⁺ and H⁺ are secreted. Chloride ions move with the Na⁺ because they are attracted to the positive charge of Na⁺.

PROCESS FIGURE 26.17 Effect of Aldosterone on the Distal Convoluted Tubule

blood pressure to increase. However, angiotensin II is rapidly broken down, so its effect lasts for only a short time. Angiotensin II also increases the rate of aldosterone secretion, the sensation of thirst, salt appetite, and ADH secretion.

The rate of renin secretion decreases if blood pressure in the afferent arteriole increases, or if the Na⁺ concentration of the filtrate increases as it passes by the macula densa of the juxtaglomerular apparatuses.

A large decrease in the concentration of Na⁺ in the interstitial fluid acts directly on the aldosterone-secreting cells of the adrenal cortex to increase the rate of aldosterone secretion. However, angiotensin II is much more important than the blood level of Na⁺ for regulating aldosterone secretion.

Aldosterone, a steroid hormone secreted by the cortical cells of the adrenal glands (see chapter 18), passes through the blood from the adrenal glands to the cells in the distal convoluted tubules and the collecting ducts. Aldosterone molecules diffuse through the plasma membranes and bind to receptor molecules within the cells. The combination of aldosterone molecules with their receptor molecules increases synthesis of the transport proteins that increase the transport of Na⁺ across the basal and apical membranes of tubule cells. As a result, the rate of Na⁺ reabsorption increases (figure 26.17).

Reduced secretion of aldosterone decreases the rate of Na⁺ reabsorption. As a consequence, the concentration of Na⁺ in the distal convoluted tubules and the collecting ducts remains high.

Because the concentration of filtrate passing through the distal convoluted tubules and the collecting ducts has a greater-than-normal concentration of solutes, water's capacity to move by osmosis from the distal convoluted tubules and the collecting ducts is diminished, urine volume increases, and the urine has a greater concentration of Na^+ .

Increases in blood K^+ levels act directly on the adrenal cortex to stimulate aldosterone secretion, whereas decreases in blood K^+ levels decrease aldosterone secretion (see chapter 27).

Predict 3

Drugs that increase urine volume are called diuretics. Some diuretics inhibit the active transport of Na^+ in the renal tubule. Explain how these diuretic drugs cause increased urine volume.

ASSESS YOUR PROGRESS

31. What factors stimulate the release of renin? What will decrease the rate of renin secretion?
32. How is angiotensin II activated? What effects does it produce?
33. Where is aldosterone produced? What factors stimulate its secretion?
34. What are the effects of aldosterone on Na^+ and Cl^- transport? How does aldosterone affect urine concentration, urine volume, and blood pressure?

Antidiuretic Hormone Mechanism

The distal convoluted tubules and collecting ducts remain relatively impermeable to water in the absence of **antidiuretic hormone (ADH)**, also known as *vasopressin* (figure 26.18). ADH is secreted from the posterior pituitary. When little ADH is secreted, a large part of the 19% of the filtrate that is normally reabsorbed in the distal convoluted tubules and the collecting ducts becomes part of the urine. Insufficient ADH secretion results in a condition called **diabetes insipidus** (dī-ă-bē'tēz in-sip'i-dūs); the word *diabetes* refers to the production of a large volume of urine, and the word *insipidus* means the urine is clear, tasteless, and dilute. People who secrete insufficient ADH often produce 10–20 L of urine per day and develop major problems, such as dehydration and ion imbalances. In contrast to diabetes insipidus, **diabetes mellitus** (me-lī'tūs) refers to the production of a large volume of urine that contains a high concentration of glucose (*mellitus*, honeyed, sweet).

Neurons of the supraoptic nucleus of the hypothalamus produce ADH, which is stored in the posterior pituitary gland (see chapter 18). ADH is released into the blood from the posterior pituitary. Cells called **osmoreceptor cells** in the supraoptic nucleus are very sensitive to even slight changes in the osmolality of the interstitial fluid. If the osmolality of the blood and interstitial fluid increases, these cells stimulate the ADH-secreting neurons. Action potentials are then propagated along the axons of the

Clinical IMPACT

Diabetic Nephropathy and Renal Failure

D **diabetic nephropathy** (ne-frop'ă-thē) is a disease of the kidneys associated with diabetes mellitus, and it is the principal cause of chronic renal failure. This condition damages renal glomeruli and ultimately destroys functional nephrons through progressive scar tissue formation, mediated in part by an inflammatory response. The damaged glomeruli no longer filter the blood effectively, allowing proteins to pass through the filtration membrane and be excreted in the urine. The presence of protein in the urine of people who have type 2 diabetes strongly suggests significant diabetic nephropathy, which can lead to end-stage renal failure. About 1 in 14 Americans over age 30 have some degree of type 2 diabetes mellitus, and most hemodialysis patients have type 2 diabetes mellitus.

The development of diabetic nephropathy is complex. Although the mechanism is not completely understood, the level of angiotensin II is elevated in diabetes mellitus. This causes exaggerated efferent arteriole vasoconstriction and consequently increased glomeru-

lar capillary pressure. The increased glomerular capillary pressure damages the glomerular basement membrane, causing it to thicken and become more permeable. The glomerular basement membrane is also damaged by the production of glycoproteins called **advanced glycosylation end products (AGEs)**. AGEs are produced when glucose forms irreversible cross-links with kidney and plasma proteins. The AGEs stimulate the secretion of growth factors from glomerular cells, which promote glomerular basement membrane thickening.

Because the glomerular basement membrane in patients with diabetes mellitus is more permeable than normal, plasma proteins cross the filtration membrane and enter the urine. The initial amount of protein entering the urine is small, a condition called **microalbuminuria** (mī'krō-al-boo-min-ū'rē-ă). However, as the number of functional nephrons in the kidney decreases, microalbuminuria eventually progresses to overt proteinuria (prō-tē-noo'rē-ă), the secretion of more than 300 mg albumin/day. By the time overt proteinuria has developed, which

may take 10–15 years, the number of functional nephrons has decreased to less than 10% of normal, and the kidneys are no longer able to excrete adequate amounts of waste products. This condition is called **end-stage renal disease (ESRD)**. In ESRD, renal failure has worsened to the point that kidney function is less than 10% of normal. Unless ESRD is treated by hemodialysis or kidney transplantation, the patient dies.

The use of **angiotensin-converting enzyme (ACE) inhibitors** slows or, in some cases, even halts the progression of proteinuria and end-stage renal disease. ACE inhibitors prevent the formation of angiotensin II; consequently, arterial blood pressure and glomerular capillary pressure remain within their normal ranges. When ACE inhibitors are used in combination with drugs called **angiotensin receptor blockers (ARBs)**, which prevent angiotensin II molecules from binding to their receptors, proteinuria decreases up to 45%. People with type 2 diabetes who maintain their blood glucose within normal levels have a much lower incidence of diabetic nephropathy and ESRD.

- 1 ADH moves from the peritubular capillaries and binds to ADH receptors in the plasma membranes of the distal convoluted tubule cells and the collecting duct cells.
- 2 When ADH binds to its receptor, a G protein mechanism is activated, which in turn activates adenylate cyclase.
- 3 Adenylate cyclase increases the rate of cAMP synthesis. Cyclic AMP promotes the insertion of aquaporin-2 containing cytoplasmic vesicles into the apical membranes of the distal convoluted tubules and collecting ducts, thereby increasing their permeability to water. Water then moves by osmosis out of the distal convoluted tubules and collecting ducts into the tubule cells through the aquaporin-2 water channels.
- 4 Water exits the tubule cells and enters the interstitial fluid through aquaporin-3 and aquaporin-4 water channels in the basal membranes.

PROCESS FIGURE 26.18 Effect of Antidiuretic Hormone (ADH) on Renal Tubule Water Movement

ADH-secreting neurons to the posterior pituitary gland, where the axons release ADH from their ends. Reduced osmolality of the interstitial fluid within the supraoptic nucleus inhibits ADH secretion from the posterior pituitary gland (see figure 18.6).

Baroreceptors that monitor blood pressure in the atria of the heart, large veins, carotid sinuses, and aortic arch also influence ADH secretion when the blood pressure changes by more than 5–10%. Decreases in blood pressure are detected by baroreceptors when there is reduced stretch of the blood vessel wall. This reduced stretch of the baroreceptors causes them to send a lower frequency of action potentials to the hypothalamus along afferent pathways. These pathways terminate in the supraoptic nucleus of the hypothalamus (see chapter 13). As a result, the hypothalamus

secretes more ADH. ADH secretion is also stimulated by elevated blood osmolality.

ADH secretion promotes increased water reabsorption by the distal convoluted tubule when blood osmolality increases or when blood pressure declines significantly. Water reabsorption lowers blood osmolality. It also increases blood volume, which elevates blood pressure. Conversely, when blood osmolality decreases or when blood pressure goes up, ADH secretion declines. The reduced ADH levels cause the kidneys to reabsorb less water and to produce a larger volume of dilute urine. The greater loss of water in the urine raises blood osmolality and lowers blood pressure. ADH secretion occurs in response to small changes in osmolality, whereas a substantial change in blood pressure is required

to alter ADH secretion. Thus, ADH is more important in regulating blood osmolality than it is in regulating blood pressure.

► Predict 4

Ethyl alcohol inhibits ADH secretion. Given this information, describe the mechanism by which alcoholic beverages affect urine production.

Production of Concentrated Urine

Filtrate enters the distal convoluted tubules after passing through the loops of Henle. From the distal convoluted tubule, filtrate then passes through the collecting ducts. Near the ends of the distal convoluted tubules and in the collecting ducts, the walls of the tubules become very permeable to water, provided antidiuretic hormone (ADH) is present. Water then diffuses from the lumens of the distal convoluted tubule and collecting duct into the more concentrated interstitial fluid.

ADH increases the permeability of the apical membranes of the distal convoluted tubules and collecting ducts to water by binding to membrane-bound receptors. This activates a G protein mechanism that increases cAMP synthesis inside these cells. Cyclic AMP

promotes the insertion of aquaporins into the apical membrane (figure 26.18). **Aquaporins** are water channel proteins that increase the apical membrane's permeability to water. There are multiple forms of aquaporins. In cells of the distal convoluted tubules and collecting ducts, the basal membranes contain aquaporin molecules—aquaporin-3 and aquaporin-4—that are insensitive to ADH. These aquaporin molecules provide channels for water to exit from the collecting duct cells into the interstitial fluid. Aquaporin-2 molecules regulate water movement into the cells. In cells that have not been exposed to ADH, the aquaporin-2 molecules are found in the membranes of vesicles in the cytoplasm (see figure 3.3b). In response to ADH, the increased cAMP initiates the incorporation of the membranes of vesicles containing aquaporin-2 channels into the apical membrane. Thus, when ADH is present, water moves by osmosis out of the distal convoluted tubules and collecting ducts; conversely, when ADH is absent, water remains in the distal convoluted tubules and collecting ducts to become urine (figure 26.19). Abnormal aquaporin-2 genes can result in excessive urine production because these genes code for abnormal aquaporin-2 molecules that do not function normally. Thus, the number of functional aquaporins decreases, and water remains in the renal tubule.

Clinical IMPACT

Diuretics

Diuretics (dī-ū-ret'iks) are chemicals that increase the rate of urine production. Although the definition is simple, a number of physiological mechanisms are involved.

Diuretics are used to treat hypertension, as well as several types of edema caused by congestive heart failure, cirrhosis of the liver, and other anomalies. However, treatment with diuretics can lead to complications, including dehydration and electrolyte imbalances.

The varying degree of diuretic chemical types is outlined in the following descriptions, along with their physiological mechanisms. The action of **carbonic anhydrase** (kar-bon'ik an-hī'drās) **inhibitors** reduces the rate of H^+ secretion and the reabsorption of bicarbonate ion (HCO_3^-). As H^+ is secreted into the renal tubule, it combines with HCO_3^- to form carbonic acid. Carbonic acid dissociates into water and carbon dioxide, which can diffuse across the wall of the renal tubule. Reduced H^+ secretion causes HCO_3^- to remain in the renal tubule. The HCO_3^- increases tubular osmotic pressure, causing osmotic diuresis. The diuretic effect is useful in treating conditions such as glaucoma and altitude sickness. However, with long-term

use, carbonic anhydrase inhibitors tend to lose their diuretic effect.

Sodium ion reabsorption inhibitors include thiazide-type diuretics. They promote the loss of Na^+ , Cl^- , and water in the urine. These diuretics are sometimes given to people who have hypertension. The increased loss of water in the urine lowers blood volume and thus blood pressure. Other inhibitors of Na^+ reabsorption, such as bumetanide, furosemide, and ethacrynic acid, specifically inhibit transport in the ascending limb of the loop of Henle. These diuretics are frequently used to treat congestive heart failure, cirrhosis of the liver, and renal disease. A possible side effect of these drugs is increased excretion of K^+ in the urine.

Certain **potassium-sparing diuretics** act on the distal convoluted tubules and the collecting ducts to reduce the exchange between Na^+ and K^+ . Potassium-sparing diuretics are used to diminish the loss of K^+ in the urine, thereby preserving, or “sparing,” these ions. Some potassium-sparing diuretic drugs act by competitive inhibition of aldosterone, whereas others inhibit the symporters for Na^+ in apical membranes of cells in the distal convoluted tubules and collecting ducts. Both types result in Na^+ diuresis and K^+ retention. A side effect

of prolonged treatment with certain diuretics is K^+ depletion. These diuretics are inhibitors of Na^+-Cl^- symporters in the ascending limb of the loop of Henle. To prevent K^+ depletion, potassium-sparing diuretics are commonly used in combination with Na^+-Cl^- symport inhibitors.

Osmotic diuretics freely pass into the filtrate and undergo limited reabsorption by the renal tubule. These diuretics increase urine volume by elevating the osmotic concentration of the filtrate, thus reducing the amount of water moving by osmosis out of the renal tubule. Urea, mannitol, and glycerine have been used as osmotic diuretics and can be effective in treating patients who have cerebral edema and edema in acute renal failure (see the Diseases and Disorders table, later in this chapter).

Xanthines (zan'thēnz), including caffeine and related substances, act as diuretics partly because they increase renal blood flow and the rate of glomerular filtrate formation. They also influence the renal tubule by decreasing Na^+ and Cl^- reabsorption.

Alcohol acts as a diuretic, although it is not used clinically for that purpose. It inhibits ADH secretion from the posterior pituitary and results in increased urine volume.

Case STUDY

Diabetes Insipidus

Two infants were born to different families within the same week. Not long after the newborns arrived home from the hospital, their respective parents noticed that their diapers were excessively wet hour after hour throughout the day and night. In addition, both infants were irritable, had slight fevers, and had vomited, even though they had not eaten for several feedings. The parents took the babies to their pediatricians. Subsequently, blood tests indicated that both infants had high blood Na^+ levels. Following water deprivation tests, which monitor plasma levels of ADH, the physicians diagnosed nephrogenic diabetes insipidus. One infant was found to have an ADH receptor abnormality, whereas the other was diagnosed with an aquaporin-2 abnormality.

The term *diabetes* refers to a disease state characterized by polyuria, excess production of urine. There are two major causes of diabetes: (1) inadequate production of or response to insulin, called diabetes mellitus (see chapter 18), and (2) inadequate production of or response to ADH, called diabetes insipidus. Diabetes insipidus is a relatively rare disease that occurs in two varieties: **Central diabetes insipidus (CDI)** is caused by failure of ADH secretion, and **nephrogenic diabetes insipidus (NDI)** results when ADH secretion is normal but the ADH receptor, or the response to ADH, in the kidney is abnormal. Consequently, the G protein mechanism, which normally functions in the insertion of the aquaporin-2 water channel protein in the apical membranes, does not operate. In most cases, NDI results from an inherited condition that affects the function of the ADH receptor. NDI can also be acquired,

Clinical GENETICS

Nephrogenic Diabetes Insipidus

There are three types of inherited nephrogenic diabetes insipidus (NDI). X-linked NDI, the most common form, affects more males than females. X-linked NDI is caused by a mutation in the V_2 ADH receptor gene on the X chromosome. Mutations in this gene result in defective ADH receptors, which prevent a normal response to ADH in the kidneys.

Autosomal recessive NDI is more rare than the X-linked form, and it affects males and females equally. This form of NDI requires both parents to be carriers for an abnormal aquaporin-2 gene. For children to

have autosomal recessive NDI, they must inherit a recessive allele from each parent. In autosomal recessive NDI, there is a 25% chance that each child of heterozygous parents will have NDI.

Autosomal dominant NDI is the most rare form of NDI, and it affects males and females equally. With this form, only one parent must have a dominant allele for an abnormal aquaporin-2 gene, but that parent will also have symptoms of NDI. There is a 50% chance that each child will have NDI.

but that usually happens later in life and can be due to several factors, including the use of certain prescription drugs or the existence of an underlying systemic disease.

Treatment of NDI includes ensuring a plentiful supply of water, following a low-sodium and sometimes a low-protein diet, and using thiazide diuretics (Na^+ reabsorption inhibitors) in combination with a potassium-sparing diuretic.

➤ Predict 5

Use your knowledge of kidney physiology and figure 26.18 to answer the following questions.

a. Why did the two infants have high blood Na^+ levels and dilute urine?

- Predict how the infants' plasma levels of ADH changed during the water deprivation test, given the diagnosis of NDI. (*Hint:* See "Production of Concentrated Urine" earlier in this section.)
- Why does an abnormal aquaporin-2 gene result in excessive urine production?
- Predict plasma levels of ADH following a water deprivation test in an individual with central diabetes insipidus.
- Why is treatment with a thiazide diuretic helpful to patients with NDI? (*Hint:* See Clinical Impact, "Diuretics.")

The filtrate flows into the distal convoluted tubules and collecting ducts that pass through the kidney medulla with its high concentration of solutes. If ADH is present, water moves by osmosis from the distal convoluted tubules and the collecting ducts into the interstitial fluid. By the time the filtrate has reached the end of the collecting ducts, another 19% of the filtrate has been reabsorbed. Thus, 1% of the filtrate remains as urine, and 99% of the filtrate has been reabsorbed. The osmolality of the filtrate at the ends of the collecting ducts is approximately 1200 mOsm/kg (see figure 26.16).

In addition to the dramatic decrease in filtrate volume and the increase in filtrate osmolality, a marked alteration occurs in the filtrate composition. Waste products, such as creatinine and urea, and excess ions, such as K^+ , H^+ , phosphate, and sulfate, are at a much higher concentration in urine than in the original filtrate because water has

been removed from the filtrate. Overall, the processes of reabsorption and secretion are selective so that, in the end, beneficial substances are retained in the body and toxic substances are eliminated.

Production of Dilute Urine

If ADH is not present or its concentration is low, the distal convoluted tubules and collecting ducts are less permeable to water. This lowered permeability dampens water reabsorption. The concentration of the urine produced is less than 1200 mOsm/kg, and the volume is increased. The volume of this more dilute urine can be much larger than 1% of the filtrate formed each day. If no ADH is secreted, the osmolality of the urine may be close to the osmolality of the filtrate in the distal convoluted tubule, and the volume of urine may approach 20–30 L/day, which is the same volume as 10–15 2-liter soda bottles per day (figure 26.19).

FIGURE 26.19 Effect of ADH on Urine Concentration and Volume

In a healthy person, even when the kidneys produce dilute urine, the concentration of waste products in the urine is large enough to maintain homeostasis. Again, as with the production of concentrated urine, beneficial substances are retained, and both toxic substances and excess water are eliminated.

Predict 6

Amanda, an inexperienced runner, competed in her first marathon last spring in Phoenix, Arizona. During the run, the temperature reached 35°C (95°F) with 30% humidity. Amanda drank very little water during the race. When she finished 4½ hours later, she was dizzy and disoriented and had an increased heart rate. She was also very pale. Friends took her to a hospital, where the doctor diagnosed severe dehydration and prescribed IV fluids. Amanda did not urinate until nearly 12 hours later. Explain the physiological responses that resulted in her reduced urine production. (*Hint:* See the discussion of blood pressure regulation in chapter 21.)

Other Hormones

Right atrial cardiac muscle cells secrete the polypeptide **atrial natriuretic** (nā'trē-ū-ret'ik) **hormone (ANH)** when they are stretched more than normal. Increased stretch of the right atrium

occurs when blood volume is higher than usual (see chapter 21). Atrial natriuretic hormone decreases blood volume through inhibition of Na⁺ reabsorption in the kidney tubules. ANH also inhibits ADH secretion from the posterior pituitary gland. Consequently, increased ANH secretion increases the volume of urine produced, which lowers blood volume and thus blood pressure. Atrial natriuretic hormone also dilates arteries and veins, which reduces peripheral resistance and lowers blood pressure. Thus, venous return and blood volume decrease in the right atrium.

ASSESS YOUR PROGRESS

35. Where is ADH produced? What factors stimulate an increase in ADH secretion?
36. How does ADH affect urine volume and concentration?
37. Describe how the presence of ADH causes the production of a small volume of concentrated urine.
38. How does the absence of ADH cause the production of a large volume of dilute urine?
39. Where is atrial natriuretic hormone produced, and how does it affect urine production?

26.5 Plasma Clearance and Tubular Maximum

LEARNING OUTCOMES

After reading this section, you should be able to

- Define **plasma clearance** and show how it is calculated.
- Describe why **inulin** is used to estimate **GFR** through **plasma clearance**.
- Explain how **plasma clearance** is used to calculate **renal plasma flow**.
- Define **tubular load** and **tubular maximum**.

A clinician who is concerned that a patient's kidney function is declining will measure the GFR by determining plasma clearance. **Plasma clearance** is a calculated value representing the volume of plasma that is cleared of a specific substance each minute. For example, if the clearance value is 100 mL/min for a substance, the substance is completely removed from 100 mL of plasma each minute. The plasma clearance can be calculated for any substance that enters the blood according to the following formula:

$$\text{Plasma clearance (mL/min)} = \frac{\text{Quantity of urine (mL/min)} \times \frac{\text{Concentration of substance in urine}}{\text{Concentration of substance in plasma}}}{\text{Concentration of substance in plasma}}$$

Plasma clearance can be used to estimate GFR if the appropriate substance is monitored (see table 26.2). Such a substance must have the following characteristics: (1) It must pass through the filtration membrane of the renal corpuscle as freely as water or other small molecules, (2) it must not be reabsorbed, (3) it must not be secreted into the renal tubule, and (4) it must not be either metabolized or produced in the kidneys. **Inulin** (in'ū-lin; not to be confused with the hormone insulin) is a nonphysiological polysaccharide that has these characteristics. As filtrate forms, it has the same concentration of inulin as plasma; however, as the filtrate flows through the renal tubule, all the inulin remains in the tubule lumen to enter the urine. As a consequence, all the volume of plasma that becomes filtrate is cleared of inulin, and the plasma clearance for inulin is equal to the rate of glomerular filtrate formation.

GFR is reduced when a kidney fails. Therefore, measurement of the GFR can indicate the degree of kidney damage. The clearance value for urea and creatinine can also be used clinically. One advantage of using these substances is that they are naturally occurring metabolites, so foreign substances do not have to be injected. A high plasma concentration and a lower-than-normal clearance value for urea and creatinine indicate a reduced GFR and kidney failure. Creatinine clearance can also be used to monitor the progress of GFR changes in people experiencing kidney failure.

Plasma clearance can also be used to calculate renal plasma flow (see table 26.2). However, substances with the following characteristics must be used: (1) The substance must pass through the filtration membrane of the renal corpuscle, and (2) it must be secreted into the renal tubule at a sufficient rate that very little of

it remains in the blood as the blood leaves the kidney. Para-amino-hippuric acid (PAH) meets these requirements (see “Tubular Secretion” in section 26.3). As blood flows through the kidney, essentially all the PAH is either filtered or secreted into the renal tubule. The clearance calculation for PAH is therefore a good estimate of the volume of plasma flowing through the kidney each minute. Also, if the hematocrit is known, the total volume of blood flowing through the kidney each minute can be calculated easily.

In addition, the concept of plasma clearance can be used to help determine how drugs or other substances are excreted by the kidney. A plasma clearance value greater than the inulin clearance value suggests that the substance is secreted by the tubule into the filtrate.

The **tubular load** of a substance is the total amount that passes through the filtration membrane into the renal tubule each minute. Normally, glucose is almost completely reabsorbed from the tubule by active transport. However, the tubule's capacity to actively transport glucose across the epithelium of the tubule is limited. If the tubular load is greater than the tubule's capacity to reabsorb it, the excess glucose remains in the urine.

The **tubular maximum** is the maximum rate at which a substance can be actively reabsorbed (figure 26.20). Each substance that is reabsorbed has its own tubular maximum, determined by the number of active transport carrier proteins and the rate at which they are able to transport molecules of the substance. For example, in people who have diabetes mellitus, the tubular load for glucose can exceed the tubular maximum by a substantial amount, thus allowing glucose to appear in the urine. Urine volume is also greater than normal because the glucose molecules in the filtrate increase the osmolality of the filtrate in the tubule and reduce the effectiveness of water reabsorption by osmosis.

FIGURE 26.20 Tubular Maximum for Glucose

As the concentration of glucose increases in the filtrate, it reaches a point that exceeds the renal tubule's ability to actively reabsorb it. That concentration is called the tubular maximum. Beyond that concentration, the excess glucose enters the urine.

Predict 7

A person is suspected of having chronic renal failure. To assess kidney function, urea clearance is measured and found to be very low. Explain what a very low urea clearance indicates for this patient. Compare that with the effect of chronic renal failure on the tendency for the blood K^+ level to be higher than normal and the blood Na^+ level to be lower than normal.

ASSESS YOUR PROGRESS

40. What is plasma clearance, and how is it calculated?
41. Explain why plasma clearance of inulin can be used to estimate GFR.
42. Describe how PAH is used to determine renal plasma flow.
43. Explain the significance of tubular load and tubular maximum.

26.6 Urine Movement

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the anatomy and histology of the ureters, urinary bladder, and urethra.
- B. Explain the flow of urine from the nephron to the urinary bladder.
- C. Discuss the micturition reflex.

Anatomy and Histology of the Ureters and Urinary Bladder

The **ureters** are tubes through which urine flows from the kidneys to the urinary bladder. The ureters extend inferiorly and medially from the renal pelvis and exit the kidney at the renal hilum. The ureters descend through the abdominal cavity and enter the urinary bladder (figure 26.21; see figures 26.1 and 26.2). The **urinary bladder** is a hollow, muscular container that lies in the pelvic cavity just posterior to the symphysis pubis. The ureters enter on its posterolateral surface. In males, the urinary bladder is just anterior to the rectum; in females, it is just anterior to the vagina and inferior and anterior to the uterus. Its volume increases and decreases, depending on how much or how little urine is stored in it.

The **urethra**, which transports urine to the outside of the body, exits the urinary bladder inferiorly and anteriorly (figure 26.21, center). The triangular area of the bladder's posterior wall between the two ureters and the urethra on the bladder's anterior wall is called the **trigone** (trī'gōn). This region is histologically unique. The trigone does not expand with the urinary bladder wall as it fills. This causes the trigone to act as a funnel for emptying the bladder.

Transitional epithelium lines both the ureters and the urinary bladder. The rest of the walls of these structures consists of a lamina propria, a muscular coat, and a fibrous adventitia (figure 26.21b,c). The wall of the urinary bladder is much thicker than the wall of a ureter because it consists of layers of primarily

smooth muscle, sometimes called the **detrusor** (dī-troo'ser) **muscle**. Contraction of this smooth muscle forces urine out of the urinary bladder. The epithelium itself ranges from four or five cells thick when the urinary bladder is empty to two or three cells thick when it is distended. Transitional epithelium is specialized, so that the cells slide past one another, and the number of cell layers decreases as the volume of the urinary bladder increases. The urethra is lined with stratified or pseudostratified columnar epithelium.

Where the urethra exits the urinary bladder, elastic connective tissue and smooth muscle keep urine from flowing out of the urinary bladder until the pressure in the urinary bladder is great enough to force urine to flow from it. In males, the elastic tissue and smooth muscle form an **internal urinary sphincter**. Females do not have a functional internal urinary sphincter. In males, the internal urinary sphincter contracts to keep semen from entering the urinary bladder during sexual intercourse (see chapter 28). The **external urinary sphincter** is composed of skeletal muscle that surrounds the urethra as the urethra extends through the pelvic floor. This sphincter acts as a valve that controls the flow of urine through the urethra.

In males, the urethra extends to the end of the penis, where it opens to the outside (see chapter 28). The urethra is much shorter in females than in males, and it opens into the vestibule anterior to the vaginal opening.

Predict 8

Cystitis (sis-ti'tis) is inflammation of the urinary bladder. It typically results from infection by bacteria from outside the body. Are males or females more prone to cystitis? Explain.

Urine Flow Through the Nephron and Ureters

Pressure decreases in the renal tubule as filtrate moves along it during urine production. Hydrostatic pressure from filtrate averages 10 mm Hg in the Bowman capsule and drops to nearly 0 mm Hg in the renal pelvis. This pressure gradient forces the filtrate to flow from the Bowman capsule through the renal tubule into the renal pelvis. Because the hydrostatic pressure is 0 mm Hg in the renal pelvis, no pressure gradient exists to force urine to flow through the ureters to the urinary bladder. However, the circular smooth muscle in the walls of the ureters undergoes peristaltic waves of contractions (see chapter 24), which force urine through the ureters. The peristaltic waves progress from the region of the renal pelvis to the urinary bladder. They occur from once every few seconds to once every 2–3 minutes. Parasympathetic stimulation increases their frequency, and sympathetic stimulation decreases it.

The peristaltic contractions of each ureter proceed at a velocity of approximately 3 cm/s and can generate pressures in excess of 50 mm Hg. Where the ureters penetrate the urinary bladder, they run obliquely through the trigone. Pressure inside the urinary bladder compresses that part of the ureter to prevent urine from backing up into the ureters.

MICROBES In Your Body

Can Bacteria Actually Help Cure Urinary Bladder Cancer?

In the United States, there are more than 60,000 new cases of urinary bladder cancer diagnosed each year; it is the ninth leading type of cancer. The majority of urinary bladder cancer is transitional cell carcinoma, which is cancer of the endothelial cell lining of the urinary bladder. However, if the cancer is detected and treated before it penetrates the urinary bladder's muscular wall or spreads to other areas of the body, the 5-year survival rate is 77%. Reliable treatments can resolve these cases relatively quickly. Surprisingly, the most common treatment for early-stage bladder cancer tumors is the introduction of a fluid containing live tuberculosis-causing bacteria into the bladder. In this “Microbes in Your Body,” we will examine the causes of and screening tests for urinary bladder cancer and explore how a bacterium serves as an anticancer treatment for urinary bladder cancer.

At least 50% of urinary bladder cancer cases can be attributed to cigarette smoking, even 10 years or more after a person has quit smoking. About 30% of cases are due to exposure to environmental carcinogens, such as certain industrial dyes or hair dyes used by professional hairdressers. The remaining cases are often due to a combination of factors, none of which are well understood.

In about 80–90% of urinary bladder cancer cases, the first sign is blood in the urine, called macrohematuria. Sometimes, pain with urination or a change in urination frequency is also an indicator of possible cancer. However, confirmation is usually done with a procedure called **cystoscopy** (si-stos'kuh-pee), in which a catheter is inserted into the bladder to view the wall and collect cells, which are then examined under a microscope to look for abnormalities in appearance.

The treatments for urinary bladder cancer are dependent on how deeply the tumor has penetrated into the bladder wall. In earlier stages, treatment is more effective. If the tumor is quite small and shallow in the endothelium, a process called transurethral resection of the bladder tumor (TURBT) can be used to scrape the cancerous cells off the bladder wall. In other cases, in which the tumor is superficial but somewhat more advanced than the earliest stage, immunotherapy with intravesicular (inside the bladder) delivery of a medicine known as Bacillus Calmette-Guérin (BCG) is used. BCG was originally developed in 1906 as a vaccine against the bacterial disease tuberculosis. BCG is a live, attenuated (weakened) strain of *Mycobacterium bovis*, the bacterium that causes tuberculosis in cattle, but it can infect other organisms, including humans. BCG was used as an anticancer therapeutic after results from animal experiments demonstrated its effectiveness.

Tuberculosis and humans have a long history together. The disease was originally called “consumption” because one of its side effects in untreated patients is extreme weight loss. Human tuberculosis is caused by the bacterium *Mycobacterium tuberculosis*. Due to their cellular composition, members of the *Mycobacterium* genus are notoriously difficult to kill, including destruction by our body's immune system. Ironically, this characteristic is what makes tuberculosis bacteria effective at helping kill cancer cells. Urinary bladder cancer is the only cancer treated with BCG. Because the BCG fluid is isolated within the bladder, other organs in the body are not usually exposed to the bacteria.

Members of the *Mycobacterium* genus have cell walls with higher lipid content than

other bacteria. It is this lipid content that protects them once they are phagocytosed by macrophages or taken up by cancer cells. Once the infected cells have the bacteria inside, these cells then display the bacterial antigens. Display of the bacterial antigens induces destruction of the infected cells by the immune system (see chapter 22). Since the bacteria used in BCG are live, although attenuated, they can infect other body tissues if they enter the blood. If this happens, patients develop an illness called acute disseminated (widespread) tuberculosis and become contagious to others. Fortunately, development of tuberculosis is a rare occurrence for BCG recipients. Treatments are terminated once white blood cells are detectable in the patient's urine, indicating that an immunological reaction is occurring in the bladder. The average treatment time is about 6 weeks. The BCG urinary bladder cancer treatment is an elegant example of how knowledge of body systems can be applied in an unexpected way: purposefully infecting a patient with bacteria so cancer cells are destroyed by the patient's immune system.

► Predict 9

Based on your knowledge of the micturition reflex and using figure 26.22, predict how treatment with BCG and induction of an immunological response in the urinary bladder might affect action potential frequency in sensory neurons located in the wall of the bladder. Would there be a higher or lower frequency of action potentials? How would a patient interpret a change in action potential frequency in relation to the urge to urinate?

When no urine is present in the urinary bladder, internal pressure is about 0 mm Hg; even when the urine volume is 100 mL, pressure rises to only 10 mm Hg. Pressure continues to rise slowly as volume increases to approximately 300 mL, but above volumes of 400 mL the pressure rises rapidly.

Micturition Reflex

The flow of urine from the kidney to the urinary bladder through the ureter is relatively continuous. The urinary bladder acts as a reservoir for urine until it can be eliminated relatively quickly at an appropriate time and place. The urinary bladder can stretch to

hold a large urine volume. At its maximum volume, the urinary bladder can contain 1 L (about 1 quart) of urine, but discomfort becomes noticeable when urine volume exceeds approximately 500 mL. The urinary bladder's capacity to distend is due to three factors. First, the wall of the urinary bladder contains large folds, similar to those of the stomach, which unfold to enlarge the lumen. Second, the lining of the urinary bladder is transitional epithelium, which stretches. Third, the smooth muscle wall of the urinary bladder, with the exception of the trigone, also stretches to accommodate fluid. As urine enters, the urinary bladder lifts and expands superiorly to accommodate the fluid.

FIGURE 26.21 Ureters and Urinary Bladder

(a) Ureters extend from the pelvis of the kidney to the urinary bladder. (b) The walls of the ureters and the urinary bladder are lined with transitional epithelium, which is surrounded by a connective tissue layer (lamina propria), smooth muscle layers, and a fibrous adventitia. (c) Section through the wall of the urinary bladder.

Urination is called **micturition** (mik-choo-rish'un). The **micturition reflex** is activated when the urinary bladder wall is stretched as urine fills the urinary bladder. Integration of the micturition reflex occurs in the sacral region of the spinal cord and is modified by centers in the pons and cerebrum.

Urine filling the urinary bladder stimulates stretch receptors, which produce action potentials. The action potentials are carried by sensory neurons to the sacral segments of the spinal cord through the pelvic nerves. In response, action potentials travel to the urinary bladder through parasympathetic fibers in the pelvic nerves (figure 26.22). The parasympathetic action potentials cause the smooth muscle of the urinary bladder (the detrusor muscle) to contract. In addition, decreased somatic motor action potentials cause the external urinary sphincter, which consists of skeletal muscle, to relax. Urine flows from the urinary bladder when the pressure there is great enough to force the urine through the urethra while the external urinary sphincter is relaxed. The micturition reflex normally produces a series of contractions of the urinary bladder.

Action potentials carried by sensory neurons from stretch receptors in the urinary bladder wall also ascend the spinal cord to a micturition center in the pons and to the cerebrum. The micturition reflex integrated in the spinal cord is automatic, but it is either stimulated or inhibited by descending action potentials sent to the sacral region of the spinal cord. For example, higher brain centers prevent micturition by sending action potentials from the cerebrum and pons through spinal pathways to inhibit the spinal micturition reflex. Consequently, parasympathetic stimulation of the urinary bladder is inhibited, and somatic motor neurons that keep the external urinary sphincter contracted are stimulated. The micturition reflex, integrated in the spinal cord, predominates in infants. The ability to inhibit micturition voluntarily develops at the age of 2–3 years; subsequently, the influence of the pons and cerebrum on the spinal micturition reflex predominates.

The slow increase in internal pressure helps explain why there is little urge to urinate when the urinary bladder contains less than 300 mL. As stated previously, though, the pressure in

PROCESS FIGURE 26.22 Micturition Reflex APR

the urinary bladder increases rapidly once its volume exceeds approximately 400 mL. In addition, the frequency of action potentials conducted by the ascending spinal pathways to the pons and cerebrum also increases, resulting in a stronger urge to urinate.

Voluntary initiation of micturition requires an increase in action potentials sent from the cerebrum to facilitate the micturition reflex and to voluntarily relax the external urinary sphincter. In addition, voluntary contraction of the abdominal muscles increases abdominal pressure and thereby enhances the micturition reflex by increasing the pressure applied to the urinary bladder wall.

Normally, the urge to urinate results from stretch of the urinary bladder wall, but irritation of the urinary bladder or the urethra by a bacterial infection or some other condition can also initiate the urge to urinate, even if the urinary bladder is nearly empty.

45. What is the trigone?

Clinical IMPACT

Kidney Stones

Kidney stones are hard objects usually found in the pelvis of the kidney. They are typically 2–3 mm in diameter, with either a smooth or a jagged surface, but occasionally a large, branching kidney stone, called a **staghorn stone**, forms in the renal pelvis. About 1% of all autopsies reveal kidney stones, and many stones never cause symptoms. The symptoms associated with kidney stones occur when a stone passes into the ureter, resulting in referred pain down the back, side, and groin area. The ureter contracts around the stone, causing the stone to irritate the epithelium and produce bleeding, which appears as blood in the urine, a condition called **hematuria**. In addition to causing intense pain, kidney stones can block the ureter, cause ulceration in the ureter, and increase the probability of bacterial infection.

About 65% of all kidney stones are composed of calcium oxalate mixed with calcium phosphate, whereas another 15% are magnesium ammonium phosphate and 10% are uric acid or cystine; approximately 2.5% of each kidney stone is composed of mucoprotein.

The cause of kidney stones is usually obscure. Predisposing conditions include concentrated urine and an abnormally high calcium concentration in the urine, although the cause of the high calcium concentration is usually unknown. Magnesium ammonium phosphate stones are often found in people with recurrent kidney infections, and uric acid stones are common in people suffering from gout. Severe kidney stones must be surgically removed from the kidney. However, traditional surgical procedures have mainly been replaced by **lithotripsy** (lith'ō-trip-sē), in which kidney stones are pulverized using ultrasound or lasers.

46. What force moves urine through the nephron and ureters?
47. Explain the ability of the urinary bladder to distend.
48. Describe the micturition reflex. How is voluntary control of micturition accomplished?

26.7 Effects of Aging on the Kidneys

LEARNING OUTCOME

After reading this section, you will be able to

A. Describe the effects of aging on the kidneys.

Aging causes the kidneys to gradually decrease in size. This decrease can begin as early as age 20 but becomes obvious by age 50 and continues throughout the remainder of life. The decrease in kidney size appears to be related to changes in the blood vessels of the kidney. The amount of blood flowing through the kidneys gradually decreases. Starting at age 20, there appears to be an approximately 10% decrease every 10 years. Small arteries, including the afferent

and efferent arterioles, become irregular and twisted. Functional glomeruli are destroyed. By age 80, 40% of the glomeruli are not functioning. About 30% of the glomeruli that stop functioning no longer have a lumen through which blood flows. Other glomeruli thicken and assume a structure similar to that of arterioles. Some renal tubules and collecting ducts become thicker, shorter, and more irregular in structure. The capacity to secrete and absorb declines, and whole nephrons stop functioning. The kidney's ability to concentrate urine gradually declines. Eventually, changes in the kidney increase the risk for dehydration because of the kidney's reduced ability to produce a concentrated urine. The ability to eliminate uric acid, urea, creatine, and toxins from the blood also decreases.

An age-related loss of responsiveness to ADH and to aldosterone occurs. The kidney decreases renin secretion and has a reduced ability to participate in vitamin D synthesis, which contributes to Ca^{2+} deficiency, osteoporosis, and bone fractures.

Recall that one-third of one kidney is required to maintain homeostasis, and the additional kidney tissue beyond this constitutes a reserve capacity. Therefore, the age-related changes in the kidney reduce the kidney's reserve capacity. As the functional kidney mass is reduced substantially in older people, high blood pressure, atherosclerosis, and diabetes have greater adverse effects.

ASSESS YOUR PROGRESS

49. Discuss the effect of aging on the kidneys. Why do the kidneys gradually decrease in size?

Clinical IMPACT

Urinary Bladder Control

If the spinal cord is damaged above the sacral region, no micturition reflex exists for a time; however, if the urinary bladder is emptied frequently, the micturition reflex eventually regains the ability to cause the bladder to empty. Some time is generally required for the micturition reflex integrated within the spinal cord to begin to operate. Although a typical micturition reflex may exist, the person has no conscious control over its onset or duration. This condition is called **automatic bladder**.

Damage to the sacral region of the spinal cord or to the nerves that carry action potentials between the spinal cord and the urinary bladder can make the urinary bladder unable to contract even though the external urinary sphincter is relaxed. As a result, the micturition reflex cannot occur. The bladder fills to capacity, and urine is forced in a slow dribble through the external urinary sphincter.

In elderly people and in patients with damage to the brainstem or spinal cord, inhibitory action potentials to the sacral region of the spinal cord can be lost. Without inhibition, the sacral centers are hyperexcitable, and even a small amount of urine in the bladder can elicit an uncontrollable micturition reflex.

Background Information

For approximately 7 days, Roger required renal dialysis to maintain his blood volume and ion concentrations within normal ranges. After about 3 weeks, his kidney function slowly began to improve, although many months passed before it was back to normal. In Roger's case, the events after 24 hours are consistent with acute renal failure caused by prolonged low blood pressure and lack of blood flow to the kidneys. The reduced blood flow was severe enough to cause damage to the epithelial lining of the renal tubules. The period of reduced urine volume resulted from the tubule damage. Dead and damaged tubule cells sloughed off into the tubules and blocked them, so that filtrate could not flow through. In addition, the filtrate leaked from the blocked or partially blocked tubules back into the interstitial spaces and therefore back into the blood. As a result, the amount of filtrate that became urine was markedly reduced.

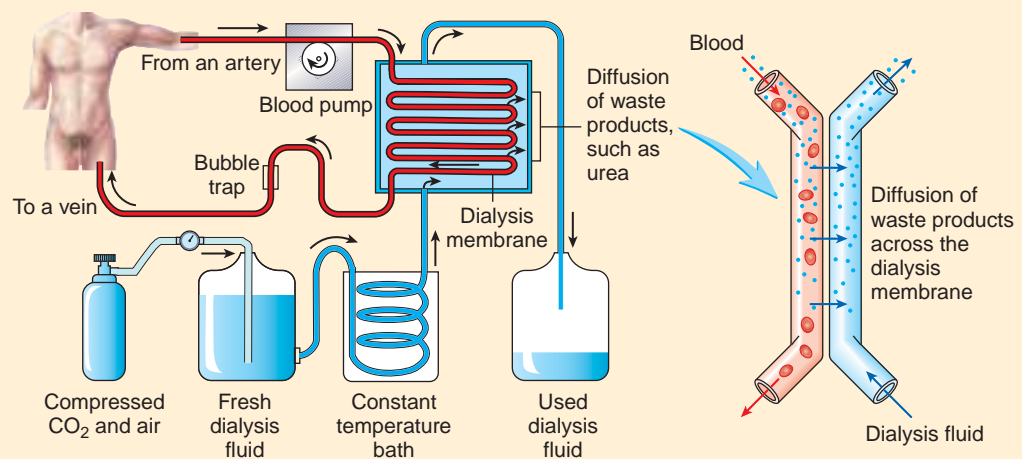

Blood levels of urea and creatine usually increase due to reduced filtrate formation and reduced function of the tubule epithelium. A small amount of urine is produced that has a high Na^+ concentration, although the osmolality is usually close to the concentration of the body fluids. The kidney is not able to reabsorb Na^+ , nor can it effectively concentrate urine.

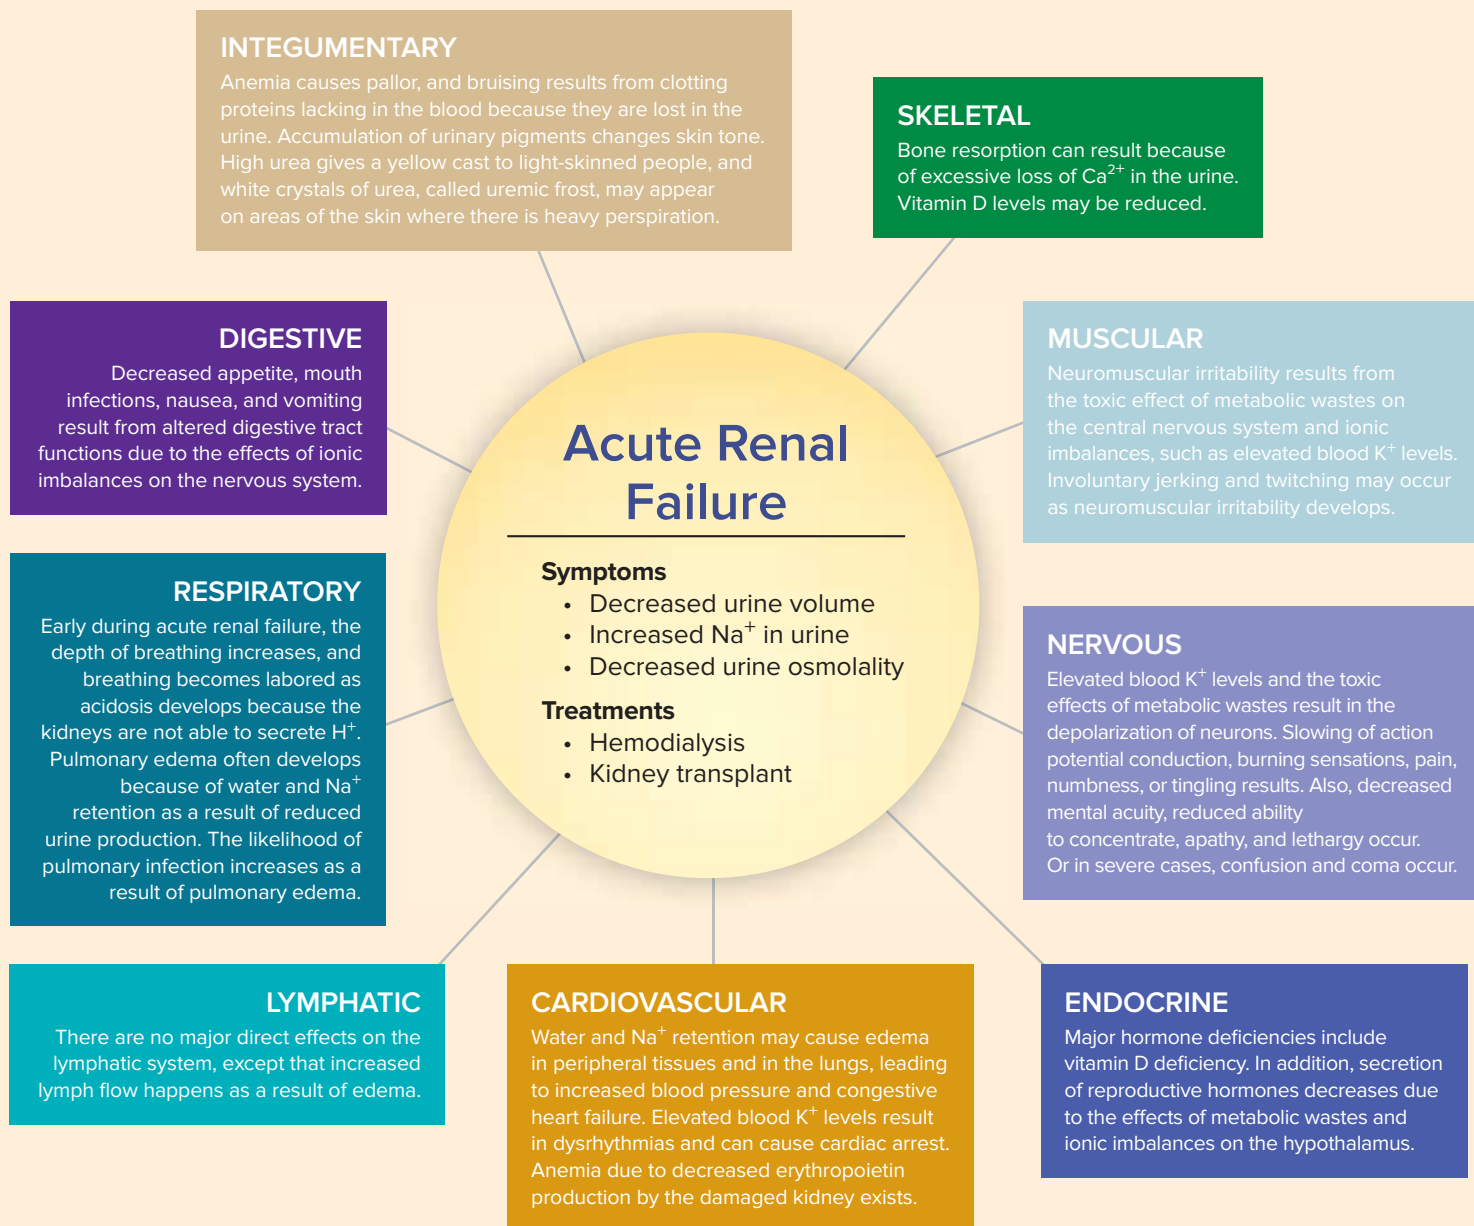

Treatments for Renal Failure

Hemodialysis (hē'mō-dī-al'i-sis) is used when a person is suffering from severe acute or chronic kidney failure. The procedure substitutes for the excretory functions of the kidney. Hemodialysis is based on blood flow through tubes composed of a selectively permeable membrane. Blood is usually taken from an artery, passed through tubes of the dialysis machine, and then returned to a vein (figure 26A). On the outside of the dialysis tubes is a fluid, called dialysis fluid, which contains the same concentration of solutes as normal plasma, except for the metabolic waste products. As a consequence, the metabolic wastes diffuse from the blood to the dialysis fluid. The dialysis membrane has pores that

Figure 26A Hemodialysis

During hemodialysis, blood flows through a system of tubes composed of a selectively permeable membrane. Dialysis fluid, which has a composition similar to that of normal blood (except that the concentration of waste products is very low), flows in the opposite direction on the outside of the dialysis tubes. Waste products, such as urea, diffuse from the blood into the dialysis fluid. Other substances, such as Na^+ , K^+ , and glucose, can diffuse from the blood into the dialysis fluid if they are present in higher-than-normal concentrations, because these substances are present in the dialysis fluid at the same concentrations found in normal blood.

are too small to allow plasma proteins to pass through them, and because the dialysis fluid contains the same beneficial solutes as the plasma, the net movement of these substances is zero. **Peritoneal** (per'i-tō-nē'āl) **dialysis** is sometimes used to treat kidney failure. The principles by which peritoneal dialysis works are the same as for hemodialysis, but the dialysis fluid flows through a tube inserted into the peritoneal cavity. The visceral and parietal peritonea act as the dialysis membrane. Waste products diffuse from the blood vessels beneath the peritoneum, across the peritoneum, and into the dialysis fluid.

Kidney transplants are sometimes performed on people who have severe renal failure. Often, the donor has suffered an accidental death and had granted permission to have his or her kidneys used for transplantation. The major cause of kidney transplant failure is rejection by the recipient's immune system. Physicians therefore attempt to match the immune

characteristics of the donor and recipient to reduce the tendency for rejection. Even with careful matching, recipients have to take medication for the rest of their lives to suppress their immune reactions. In most cases, the transplanted kidney functions well, and the tendency of the recipient's immune system to reject the transplanted kidney can be controlled.

➤ Predict 10

Nine days after the accident, Roger began to appear pale, became dizzy on standing, and was very weak and lethargic. His hematocrit was elevated and his heart was arrhythmic. Explain these manifestations.

Diseases and Disorders

Urinary System

Kidney Disorders	Description
Inflammation of the Kidneys	
Glomerulonephritis (glō-mā-r'ū-lō-ne-frī'tis)	Inflammation of the filtration membrane within the renal corpuscle, causing an increase in the filtration membrane's permeability; plasma proteins and blood cells enter the filtrate, which increases urine volume due to increased osmotic concentration of the filtrate
Acute glomerulonephritis	Often occurs 1–3 weeks after a severe bacterial infection, such as “strep throat”; normally subsides after several days
Chronic glomerulonephritis	Long-term, progressive process whereby the filtration membrane thickens and is eventually replaced by connective tissue; the kidneys become nonfunctional
Pyelonephritis (pī'ē-lō-ne-frī'tis)	Often begins as a bacterial, usually <i>E. coli</i> , infection of the renal pelvis, which spreads to the rest of the kidney; the infection can destroy nephrons, dramatically reducing the kidney's ability to concentrate urine
Renal Failure	
Acute renal failure	Occurs when damage to the kidney is rapid and extensive; leads to accumulation of wastes in the blood; if renal failure is complete, death can occur in 1–2 weeks
Chronic renal failure	Caused by permanent damage to so many nephrons that the remaining nephrons are inadequate for normal kidney function; can result from chronic glomerulonephritis, trauma to the kidneys, tumors, or kidney stones

Answer

Learn to Predict ◀ From page 958

We read in this chapter that chronic renal failure is caused by a decrease in the number of functional nephrons in the kidneys, which is common in type 2 diabetics, such as Sadie. Renal failure is most likely the result of damage to the glomerular basement membrane due to increased glomerular pressure and the production of advanced glycosylation end products, both of which are common side effects of type 2 diabetes.

Because Sadie's renal failure means her kidneys have a dramatically reduced filtration function, we would expect Sadie's blood tests to reveal high levels of glucose, K^+ , and creatinine and low levels of Na^+ . In addition, the creatinine clearance rate would be below normal, and there would be substantial protein in the urine. The increased blood glucose level results from a decrease in the tubular maximum for glucose reabsorption due to fewer functional nephrons. Similarly, the tubular maximum for Na^+ is decreased, and the kidneys' ability to secrete K^+ also decreases.

Consequently, blood Na^+ levels decrease and blood K^+ levels increase. The low creatinine clearance rate is consistent with a decreased number of functional nephrons, and protein in the urine reflects the increased permeability of the filtration membrane in the remaining nephrons. The puffiness of Sadie's face indicates that fluid is being retained, which is consistent with the increase in blood pressure.

The consequences for Sadie are severe. She needs to take precautions to make it easier for the remaining nephrons to maintain homeostasis—for example, by carefully regulating her blood glucose and controlling the hypertension. If her condition continues to worsen, she may have to resort to dialysis and consider a kidney transplant.

Answers to the rest of this chapter's Predict questions are in appendix G.

Summary

26.1 Functions of the Urinary System
(p. 959)

1. The urinary system consists of the kidneys, ureters, urinary bladder, and urethra.
2. The urinary system eliminates wastes; regulates blood volume, ion concentration, and pH; and is involved with red blood cell and vitamin D production.

26.2 Kidney Anatomy and Histology
(p. 959)

Location and External Anatomy of the Kidneys

1. A kidney lies behind the peritoneum on the posterior abdominal wall on each side of the vertebral column.

- The renal capsule surrounds each kidney, and adipose tissue and the renal fascia engulf each kidney and anchor it to the abdominal wall.
- Blood vessels and nerves enter and exit the kidney at the hilum, on the medial side of each kidney, which opens into the renal sinus, containing fat and connective tissue.

Internal Anatomy and Histology of the Kidneys

- The two major regions of the kidney are the cortex and the medulla.
 - The renal columns extend toward the medulla between the renal pyramids.
 - The renal pyramids of the medulla project to the minor calyces.
- The minor calyces open into the major calyces, which open into the renal pelvis. The renal pelvis leads to the ureter.
- The functional unit of the kidney is the nephron. The parts of a nephron are the renal corpuscle, the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule.
 - The renal corpuscle consists of the Bowman capsule and the glomerulus. Materials leave the blood in the glomerulus and enter the Bowman capsule through the filtration membrane.
 - The renal tubule empties through the distal convoluted tubule into a collecting duct.
- The juxtaglomerular apparatus consists of the macula densa (part of the distal convoluted tubule) and the juxtaglomerular cells of the afferent arteriole.

Arteries and Veins of the Kidneys

- Arteries branch as follows: renal artery to segmental artery to interlobar artery to arcuate artery to interlobular artery to afferent arteriole.
- Afferent arterioles supply the glomeruli.
- Efferent arteries from the glomeruli supply the peritubular capillaries and vasa recta.
- Veins form from the peritubular capillaries as follows: interlobular vein to arcuate vein to interlobar vein to renal vein.

26.3 Urine Production (p. 967)

Urine is produced by filtration, tubular reabsorption, and tubular secretion.

Filtration

- The renal filtrate is plasma minus blood cells and blood proteins. Most (99%) of the filtrate is reabsorbed.
- The filtration membrane is composed of a fenestrated endothelium, a basement membrane, and the slitlike pores formed by podocytes.
- Filtration pressure is responsible for filtrate formation.
 - Filtration pressure is glomerular capillary pressure minus capsular hydrostatic pressure minus blood colloid osmotic pressure.
 - Filtration pressure changes are primarily caused by changes in glomerular capillary pressure.

Regulation of Glomerular Filtration Rate

- Two important mechanisms regulating GFR are autoregulation and sympathetic stimulation.
- Autoregulation dampens systemic blood pressure changes by altering afferent arteriole diameter.
- Sympathetic stimulation decreases afferent arteriole diameter.

Tubular Reabsorption

- Filtrate is reabsorbed by passive transport, including simple diffusion and facilitated diffusion. Filtrate is also reabsorbed through active

transport and symport. Materials move from the renal tubule into the peritubular capillaries.

- Specialization of tubule segments
 - The thin segment of the loop of Henle is specialized for passive transport.
 - The rest of the renal tubules and collecting ducts perform active transport, symport, and passive transport.
- Substances transported
 - Active transport moves mainly Na^+ across the wall of the renal tubule. Other ions and molecules are moved primarily by symport.
 - Passive transport moves water, urea, and lipid-soluble, nonpolar compounds.

Tubular Secretion

- Substances enter the proximal or distal convoluted tubules and the collecting ducts.
- Hydrogen ions, K^+ , and some substances not produced in the body are secreted by antiport mechanisms.

Urine Concentration Mechanism

- The vasa recta, the loop of Henle, and the distribution of urea are responsible for the concentration gradient in the medulla. The concentration gradient is necessary for the production of concentrated urine.
- Production of urine
 - In the proximal convoluted tubule, Na^+ and other substances are removed by active transport. Water follows passively, filtrate volume is reduced 65%, and the filtrate concentration is 300 mOsm/L.
 - In the descending limb of the loop of Henle, water exits passively and solute enters. The filtrate volume is reduced 15%, and the osmolality of the filtrate concentration is 1200 mOsm/kg.
 - In the ascending limb of the loop of Henle, Na^+ , Cl^- , and K^+ are actively transported out of the filtrate, but water remains because this segment of the renal tubule is impermeable to water. The osmolality of the filtrate concentration is 100 mOsm/kg.

26.4 Regulation of Urine Concentration and Volume (p. 980)

Hormonal Mechanisms

- Aldosterone, produced in the adrenal cortex, affects Na^+ and Cl^- transport in the distal convoluted tubule and collecting ducts.
 - A decrease in aldosterone results in less Na^+ reabsorption and an increase in urine concentration and volume. An increase in aldosterone results in greater Na^+ reabsorption and a decrease in urine concentration and volume.
 - Aldosterone production is stimulated by angiotensin II, increased blood K^+ concentration, and decreased blood Na^+ concentration.
- Renin, produced by the kidneys, causes the production of angiotensin II.
 - Angiotensin II acts as a vasoconstrictor and stimulates aldosterone secretion, causing a decrease in urine production and an increase in blood volume.
 - Decreased blood pressure or decreased Na^+ concentration stimulates renin production.
- ADH, secreted by the posterior pituitary, increases water permeability in the distal convoluted tubules and collecting ducts.
 - ADH decreases urine volume, increases blood volume, and thus increases blood pressure.
 - ADH release is stimulated by increased blood osmolality or decreased blood pressure.

- Water movement out of the distal convoluted tubules and collecting ducts is regulated by ADH. If ADH is absent, water is not reabsorbed, and a dilute urine is produced. If ADH is present, water moves out, and a concentrated urine is produced.
4. Atrial natriuretic hormone, produced by the heart when blood pressure increases, inhibits ADH production and reduces the kidney's ability to concentrate urine.

26.5 Plasma Clearance and Tubular Maximum (p. 988)

1. Plasma clearance is the volume of plasma that is cleared of a specific substance each minute.
2. Tubular load is the total amount of a substance that enters the renal tubule each minute.
3. Tubular maximum is the fastest rate at which a substance is reabsorbed from the renal tubule.

26.6 Urine Movement (p. 989)

Anatomy and Histology of the Ureters and Urinary Bladder

1. Structure
 - The walls of the ureter and urinary bladder consist of the epithelium, the lamina propria, a muscular coat, and a fibrous adventitia.
 - The transitional epithelium permits changes in size.

2. Function
 - The ureters transport urine from the kidney to the urinary bladder.
 - The urinary bladder stores urine.

Urine Flow Through the Nephron and Ureters

1. Hydrostatic pressure forces urine through the nephron.
2. Peristalsis moves urine through the ureters.

Micturition Reflex

1. Stretch of the urinary bladder stimulates a reflex that causes the urinary bladder to contract and inhibits the urinary sphincters.
2. Higher brain centers can stimulate or inhibit the micturition reflex.

26.7 Effects of Aging on the Kidneys (p. 993)

1. The kidneys gradually decrease in size due to a decrease in renal blood flow.
2. The number of functional nephrons decreases.
3. Renin secretion and vitamin D synthesis decrease.
4. The renal tubule's ability to secrete and absorb declines.

REVIEW AND COMPREHENSION

1. Which of these is *not* a general function of the kidneys?
 - a. regulation of blood volume
 - b. regulation of solute concentration in the blood
 - c. regulation of the pH of the extracellular fluid
 - d. regulation of vitamin A synthesis
 - e. regulation of red blood cell synthesis
2. The cortex of the kidney contains the
 - a. hilum.
 - b. glomeruli.
 - c. adipose tissue.
 - d. renal pyramids.
 - e. renal pelvis.
3. Given these structures:
 - (1) major calyx (3) renal papilla
 - (2) minor calyx (4) renal pelvis

Choose the arrangement that lists the structures in order as urine leaves the collecting duct and travels to the ureter.

 - a. 1,4,2,3 b. 2,3,1,4 c. 3,2,1,4 d. 4,1,3,2 e. 4,3,2,1
4. Which of these structures contain(s) blood?
 - a. glomerulus
 - b. vasa recta
 - c. distal convoluted tubule
 - d. Bowman capsule
 - e. Both a and b are correct.
5. The juxtaglomerular cells of the _____ and the macula densa cells of the _____ form the juxtaglomerular apparatus.
 - a. afferent arteriole, proximal convoluted tubule
 - b. afferent arteriole, distal convoluted tubule
 - c. efferent arteriole, proximal convoluted tubule
 - d. efferent arteriole, distal convoluted tubule
6. Given these blood vessels:

(1) afferent arteriole	(3) glomerulus
(2) efferent arteriole	(4) peritubular capillaries

Choose the correct order as blood passes from an interlobular artery to an interlobular vein.

 - a. 1,2,3,4 b. 1,3,2,4 c. 2,1,4,3 d. 3,2,4,1 e. 4,3,1,2
7. Which of these processes is responsible for kidney function?
 - a. filtration
 - b. secretion
 - c. reabsorption
 - d. Both a and b are correct.
 - e. All of these are correct.
8. The amount of plasma that enters the Bowman capsule per minute is the
 - a. GFR.
 - b. renal plasma flow.
 - c. renal fraction.
 - d. renal blood flow.
9. If the glomerular capillary pressure is 40 mm Hg, the capsular hydrostatic pressure is 10 mm Hg, and the blood colloid osmotic pressure within the glomerulus is 30 mm Hg, the filtration pressure is
 - a. -20 mm Hg.
 - b. 0 mm Hg.
 - c. 20 mm Hg.
 - d. 60 mm Hg.
 - e. 80 mm Hg.
10. Which of these conditions reduces filtration pressure in the glomerulus?
 - a. elevated blood pressure
 - b. constriction of the afferent arterioles
 - c. decreased plasma protein in the glomerulus
 - d. dilation of the afferent arterioles
 - e. decreased capsular hydrostatic pressure
11. If blood pressure increases by 50 mm Hg,
 - a. the afferent arterioles constrict.
 - b. glomerular capillary pressure increases by 50 mm Hg.

- c. GFR increases dramatically.
 d. efferent arterioles constrict.
 e. All of these are correct.
12. Glucose is usually completely reabsorbed from the filtrate by the time the filtrate has reached the
 a. end of the proximal convoluted tubule.
 b. bend of the loop of Henle.
 c. end of the distal convoluted tubule.
 d. end of the collecting duct.
 e. Bowman capsule.
13. The greatest volume of water is reabsorbed from the renal tubule by the
 a. proximal convoluted tubule. c. distal convoluted tubule.
 b. loop of Henle. d. collecting duct.
14. Water leaves the renal tubule by
 a. active transport. d. facilitated diffusion.
 b. filtration into the capillary network. e. symport.
 c. osmosis.
15. Potassium ions enter the _____ by _____.
 a. proximal convoluted tubule, diffusion
 b. proximal convoluted tubule, active transport
 c. distal convoluted tubule, diffusion
 d. distal convoluted tubule, antiport
16. Reabsorption of most solute molecules from the proximal convoluted tubule is linked to the active transport of Na^+ across the
 a. apical membrane and out of the cell.
 b. apical membrane and into the cell.
 c. basal membrane and out of the cell.
 d. basal membrane and into the cell.
17. Which of these ions is used to symport amino acids, glucose, and other solutes through the apical membrane of tubule cells?
 a. K^+ b. Na^+ c. C^- d. Ca^{2+} e. Mg^{2+}
18. Which of the following contributes to the formation of a hyperosmotic environment in the medulla of the kidney?
 a. the effects of ADH on water permeability of the ascending limb of the loop of Henle
 b. the impermeability of the ascending limb of the loop of Henle to water
 c. the symport of Na^+ , K^+ , and Cl^- out of the ascending limb of the loop of Henle
 d. Both a and c are correct.
 e. Both b and c are correct.
19. At which of these sites is the osmolality of the filtrate at its lowest (lowest concentration)?
 a. glomerular capillary d. initial section of the distal convoluted tubule
 b. proximal convoluted tubule e. collecting duct
 c. bend of the loop of Henle
20. Increased aldosterone causes
 a. increased reabsorption of Na^+ .
 b. decreased blood volume.
 c. decreased reabsorption of Cl^- .
 d. increased permeability of the distal convoluted tubule to water.
 e. increased volume of urine.
21. Juxtaglomerular cells are involved in the secretion of
 a. ADH. c. aldosterone.
 b. angiotensin. d. renin.
22. Angiotensin II
 a. causes vasoconstriction. d. increases the sensation of thirst.
 b. stimulates aldosterone secretion. e. All of these are correct.
 c. stimulates ADH secretion.
23. ADH governs the
 a. Na^+ pump of the proximal convoluted tubules.
 b. water permeability of the loop of Henle.
 c. Na^+ pump of the vasa recta.
 d. water permeability of the distal convoluted tubules and collecting ducts.
 e. Na^+ reabsorption in the proximal convoluted tubule.
24. A decrease in blood osmolality results in
 a. increased ADH secretion.
 b. increased permeability of the collecting ducts to water.
 c. decreased urine osmolality.
 d. decreased urine output.
 e. All of these are correct.
25. The amount of a substance that passes through the filtration membrane into the renal tubule per minute is the
 a. renal plasma flow. c. plasma clearance.
 b. tubular load. d. tubular maximum.
26. The urinary bladder
 a. is composed of skeletal muscle.
 b. is lined by simple columnar epithelium.
 c. is connected to the outside of the body by the ureter.
 d. is located in the pelvic cavity.
 e. has two urethras and one ureter attached to it.

Answers in appendix E

CRITICAL THINKING

- To relax after an anatomy and physiology examination, Mucho Gusto goes to a local bistro and drinks 2 quarts of low-sodium beer. What effect does this beer have on urine concentration and volume? Explain the mechanisms involved.
- Harry is doing yard work one hot summer day and refuses to drink anything until he is finished. He then drinks glass after glass of plain water. Assuming that he drinks enough water to replace all the water he lost as sweat, how does this much water affect urine concentration and volume? Explain the mechanisms involved.
- A patient has the following symptoms: slight increase in extracellular fluid volume, large decrease in plasma sodium concentration, very concentrated urine, and cardiac fibrillation. An imbalance of what hormone is responsible for these symptoms? Are the symptoms caused by oversecretion or undersecretion of the hormone?
- Propose several ways to decrease the GFR.
- Design a kidney that can produce hyposmotic urine, which is less concentrated than plasma, or hyperosmotic urine, which is more concentrated than plasma, by the active transport of water instead of Na^+ .

Assume that the kidney's anatomical structure is the same as that in humans, but feel free to change anything else you choose.

6. If only a very small amount of urea, instead of its normal concentration, were present in the interstitial fluid of the kidney, how would the kidney's ability to concentrate urine be affected?
7. Some patients with hypertension are kept on a low-salt (low-sodium) diet. Propose an explanation for this therapy.
8. Research has shown that mammals with kidneys having relatively thicker medullas can produce more concentrated urine than humans. Explain why this is so.
9. Marvin Motormount was driving too fast on a remote mountain road at 3 a.m. when his car left the road and rolled down a steep hill. Marvin sustained numerous cuts and bruises. When medical help arrived 2 hours later, his systolic blood pressure was 70 mm Hg, and his pulse was weak (thready). Intravenous saline was administered immediately, and plasma and then whole blood were administered in the emergency room. After another hour, Marvin's blood pressure had returned to normal and he no longer appeared pale. While he was in the hospital, Marvin's urine volume decreased to less than 30 mL/h (<400 mL/day). A blood sample indicated elevated blood levels of urea, creatinine, and uric acid. He also exhibited hyperkalemia and some cardiac arrhythmia, and his arterial pH was <7.35 (below normal). Over the next few days, his red blood cell count decreased and he bruised easily. His jugular veins were distended, and there was some peripheral and pulmonary edema. From the following list, select the conditions that applied to Marvin at this time.
 - (1) hypoxic injury to the kidney
 - (2) increased reabsorption of wastes

- (3) decreased H^+ secretion
 - (4) decreased K^+ secretion
 - (5) increased HCO_3^- reabsorption
 - (6) decreased erythropoietin secretion
- a. 1,2,3,4,5,6 c. 1,2,3,4 e. 1,2,6
b. 2,3,4,5 d. 1,2,3,4,6

10. Which of the following will help compensate for the low pH of the patient in question 9?
 - a. increased respiration
 - b. increased HCO_3^- reabsorption
 - c. increased H^+ secretion
 - d. All of these are correct.
 - e. Both a and b are correct.
11. Renin-secreting tumors are usually found in the kidneys but rarely in other organs, such as the liver, lungs, pancreas, and ovaries. Predict the effects of renin-secreting tumors on blood K^+ levels, and explain the effects on action potential conduction in nerves and muscle tissues.
12. Even though mutations of aquaporin-3 and aquaporin-4 in the collecting duct have not been described in the literature, if mutations occurred that resulted in a reduced number of these aquaporins in the cells of the collecting ducts, how would urine volume and concentration be affected? Would ADH be an effective treatment?

Answers in appendix F

Water, Electrolyte, and Acid-Base Balance

Maintaining appropriate levels of water in the body is crucial to achieving homeostasis. We are highlighting two extremes of water balance in our bodies: too little or too much. Here, we describe what happens when the body receives too much water; the “Learn to Predict” question describes what happens when the body receives too little water.

In 2007, a mother of three died from drinking too much water during a radio contest. The rules required the contestants to drink one 8 oz bottle of water every 15 minutes for almost 2 hours without urinating. The successful contestant would win a video-gaming system. By the time the contest was over, the woman had drunk almost 2 gallons of water and was complaining of an extreme headache. One hour later, her mother found her dead. Water intoxication, also known as hyperhydration or water poisoning, results from overconsumption of water that causes the levels of electrolytes in the blood to become overly diluted. Water can move into cells via osmosis, causing malfunctions that lead to seizures, coma, and potentially death. In this chapter, you will learn how, under normal circumstances, the balance of electrolytes and body fluids is maintained within a very narrow range.

Learn to Predict

Satish and Kiran, two college students in search of adventure, embarked on an orienteering exercise—but it almost turned out to be their last adventure. Their compass malfunctioned, and they became lost in desert terrain during the hottest days of summer. One week later, they were discovered, near death, in a dry ravine. Rescuers estimated that the students had gone without water for 24 hours. **After reading this chapter and recalling your study of the kidneys in chapter 26, explain the students’ dehydration, the homeostatic mechanisms that would have tried to compensate for this condition, and the specific physiological cause of their illness.**

Photo: Water is not readily available in the desert. Hikers need to prepare for hot, dry conditions and pack plenty of drinking water.

27.1 Body Fluids

LEARNING OUTCOMES

After reading this section, you should be able to

- Identify the major fluid compartments of the body and their subdivisions.
- List the dominant cations and anions in the major fluid compartments.
- Describe the causes of edema.

The adult human body is at least 50% water by weight (table 27.1). In infants, water makes up as much as 75% of body weight; the content is significantly less in children and slowly declines further as they get older. Because the water content of adipose tissue is relatively low, people with more adipose tissue have a smaller proportion of water in their bodies. For example, the relatively lower water content of adult females compared with that of adult males reflects the greater development of subcutaneous adipose tissue characteristic of women.

The body has two major fluid compartments: the intracellular (in-tră-sel'ū-lă-r) fluid compartment and the extracellular (eks-tră-sel'ū-lă-r) fluid compartment. The **intracellular fluid compartment**

includes all the fluid in the trillions of cells of the body. The intracellular fluid from all cells has a similar composition, and it accounts for approximately 40% of total body weight.

The **extracellular fluid compartment** includes the fluid outside all of the cells of the body, constituting nearly 20% of total body weight. The extracellular fluid compartment can be divided into several subcompartments, including the interstitial fluid and the plasma of the blood. **Interstitial** (in-ter-stish'ăl) **fluid** is found in the extracellular spaces outside the blood vessels, while **plasma** (plaz'mă) is the extracellular fluid within blood vessels. The other subcompartments of the extracellular compartment include lymph, cerebrospinal fluid, and synovial fluid. These constitute relatively small volumes.

Although the specific fluid composition in each subcompartment differs from the others, their osmotic pressures are approximately equal. Because of this, there is continuous and extensive water and ion exchange between them. On the other hand, large molecules, such as proteins, do not move freely between compartments because they cannot cross the membranes that separate the fluid subcompartments (table 27.2). However, if the composition of one subcompartment changes significantly, fluid exchange may not be equal. For example, when water leaves the plasma and enters the interstitial fluid, edema occurs. Edema commonly results from an increase in the permeability of the capillary walls

TABLE 27.1 Approximate Volumes of Body Fluid Compartments*

	Total Body Water	Intracellular Fluid	Extracellular Fluid		Total
			Plasma	Interstitial Fluid

†Data are from skeletal muscle.

due to inflammation, allowing proteins to diffuse from the plasma into the interstitial fluid. Water moves in the same direction by osmosis. Edema can also result from a change in the hydrostatic pressure across capillary walls. Increased hydrostatic pressure in capillaries due to blocked veins or heart failure forces fluid from plasma into the interstitial spaces (see chapter 21).

ASSESS YOUR PROGRESS

1. What are the two major fluid compartments of the body? Name the subdivisions of the extracellular fluid compartment.
2. What cations and anions occur with the higher percentage in each major compartment?
3. Compare the osmotic concentration among most fluid compartments.
4. What factors contribute to edema?

27.2 Regulation of Body Fluid Concentration and Volume

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Explain how water content of the body is maintained.
- B. Discuss how body fluid osmolality is achieved and held in homeostatic balance.
- C. Explain the mechanisms that regulate extracellular fluid volume.

Regulation of Water Content

The body regulates its water content so that the total volume remains constant: The volume of water entering the body equals the volume exiting the body each day. Any changes in the total water volume would alter the solute concentration of body fluids, blood pressure, and interstitial fluid pressure.

The total volume of water that enters the body each day is 1500–3000 mL, most of which (90%) comes from beverages and food, while a smaller amount (10%) is produced during cellular respiration (table 27.3; see figure 24.34).

TABLE 27.3 Summary of Water Intake and Loss

Sources of Water	Routes by Which Water Is Lost
Ingestion (90%)	Urine (61%)
Cellular metabolism (10%)	Evaporation (35%)
	Perspiration
	Insensible
	Sensible
	Respiratory passages
	Feces (4%)

Water is absorbed across the wall of the digestive tract by osmosis. The volume of water entering the body depends on the amount of water consumed. The more water a person drinks, the faster it is absorbed. However, if a person drinks a small volume of concentrated liquid, absorption of water decreases.

Regulation of Thirst

Fluid consumption depends on three thirst regulation mechanisms: (1) hypothalamic osmoreceptors, (2) arterial baroreceptors, and (3) the juxtaglomerular apparatus in the kidney. The greatest influence on the sensation of thirst is due to increased solute concentration of the extracellular fluid and low blood pressure that is due to a reduction in plasma volume. When neurons of the supraoptic nucleus within the hypothalamus detect increased extracellular fluid concentration, their activity causes the thirst sensation (figure 27.1).

Baroreceptors can also influence the sensation of thirst. When they detect a substantial decrease in blood pressure, action potentials are conducted to the brain along sensory neurons to influence the sensation of thirst. Low blood pressure associated with hemorrhagic shock, for example, is correlated with an intense sensation of thirst.

The role of the juxtaglomerular apparatus in thirst regulation centers around its ability to detect blood pressure. Renin is released from the juxtaglomerular apparatus of the kidney in response to reduced blood pressure in the kidney. Renin increases the formation of angiotensin II in the circulatory system (see chapters 21 and 26). Angiotensin II opposes a decrease in blood pressure by stimulating thirst, increasing aldosterone secretion from the adrenal cortex, and causing vasoconstriction.

When people who are dehydrated drink water, they eventually consume a quantity sufficient to reduce the osmolality of the extracellular fluid to its normal value. They do not normally consume the water all at once. Instead, they drink intermittently until the proper osmolality of the extracellular fluid is established. The thirst sensation is temporarily reduced after a person drinks a small amount of liquid and the previously dry oral mucosa becomes wet. Sensory neurons conduct action potentials to the thirst center of the hypothalamus and temporarily decrease the sensation of thirst. Additionally, consumed fluid stretches the digestive tract, which initiates sensory action potentials in stretch receptors. The sensory neurons conduct action potentials to the thirst center of the hypothalamus, where they also temporarily suppress the sensation of thirst. Because the absorption of water from the digestive tract requires time, mechanisms that temporarily suppress thirst prevent a person from consuming extreme volumes of fluid that would exceed the amount required to reduce blood osmolality. Longer-term suppression of thirst results when extracellular fluid solute concentration and blood pressure have returned to their normal range.

Learned behavior can be very important in avoiding periodic dehydration. Feeling thirsty promotes water consumption, and thirst is relieved. Therefore, a healthy person usually drinks more than the minimum volume of fluid required to maintain homeostasis. In addition, beverage consumption is influenced by habit and social settings. Any excess body water is eliminated by the kidneys in urine.

- 1 The baroreceptors in the carotid sinuses and aortic arch detect reduced blood pressure, which signals the hypothalamic thirst center.
- 2 Simultaneously, the juxtaglomerular apparatus detects low blood pressure, which activates the renin-angiotensin system to produce angiotensin II. Angiotensin II stimulates the hypothalamic thirst center.
- 3 Osmoreceptors in the hypothalamus shrink when blood osmolality goes up, triggering action potentials that stimulate thirst.
- 4 The combination of these inputs activates thirst and promotes water consumption.

PROCESS FIGURE 27.1 Effect of Blood Osmolality and Blood Pressure on Thirst AP R

Regulation of Water Loss

Water loss from the body occurs through three routes (table 27.3). The greatest amount of water, approximately 61%, is excreted through the urine. Approximately 35% of water loss occurs through evaporation from respiratory passages and the skin, which includes perspiration. Approximately 4% is lost in the feces.

The kidneys are the primary organs that regulate the composition and volume of body fluids by controlling the volume and concentration of water excreted in the form of urine (see chapter 26). Temperature and humidity of the air, body temperature, and volume of air expired determine the volume of water lost through the respiratory passages. Water lost through the skin is called **insensible perspiration** (see chapter 25), and it regulates heat loss. For each degree that the body temperature rises above normal, an increased volume of 100–150 mL of water is lost each day in the form of insensible perspiration.

Sweat, or *sensible perspiration*, is secreted by the sweat glands (see chapters 5 and 25); in contrast to insensible perspiration, it contains solutes. Sweat resembles extracellular fluid in its composition, with sodium chloride as the major component, but it also contains some K^+ , ammonia, and urea (table 27.4). The volume of sweat produced is determined primarily by neural mechanisms that regulate body temperature, although some sweat is produced as a result of sympathetic stimulation in response to stress. During exercise,

elevated environmental temperature, or fever, the volume of sweat increases substantially and plays an important role in heat loss. In the heat of summer, outdoor workers lose a substantial amount of water as sweat. Sweat losses of as much as 8–10 L/day have been measured in these workers. The volume of fluid lost as sweat is negligible for a person at rest in a cool environment.

Adequate fluid replacement during extensive sweating is important. Sweat is hyposmotic to plasma. The loss of a large volume of hyposmotic sweat causes a decrease in body fluid volume and an increase in body fluid concentration. Fluid volume is lost primarily from the extracellular fluid, which leads to an increase in extracellular fluid solute concentration, a reduction in plasma volume, and an increase in hematocrit. During severe dehydration, the change can be great enough to cause blood viscosity to increase substantially, which increases the heart's workload enough that heart failure can result.

Relatively little water is lost by way of feces from the digestive tract. Although the total volume of fluid secreted into the digestive tract is large, nearly all the fluid is reabsorbed under normal conditions (see chapter 24). Exceptions are severe vomiting and diarrhea, which can result in a large volume of fluid loss.

The body can produce either a small volume of concentrated urine or a large volume of dilute urine, depending on the extracellular fluid osmolality and volume. These mechanisms operate to keep the total body water content within a narrow range of values.

Regulation of Extracellular Fluid Osmolality

Altering the water content of a solution changes its concentration, or osmolality. Consider a solution in a pan on a stove. Adding water to the solution decreases its concentration, or dilutes it. Boiling the solution in the pan removes water by evaporation, increasing its concentration. Body fluid osmolality changes just as the water in the pan does but is maintained between 285 and 300 mOsm/kg.

An increase in the osmolality of the extracellular fluid triggers thirst and antidiuretic hormone (ADH) secretion. Consumed

TABLE 27.4 Composition of Sweat	
Solute	Concentration (mM*)
Sodium	9.8–77.2
Potassium	3.9–9.2
Chloride	5.5–65.1
Ammonia	1.7–5.6
Urea	6.5–12.1

*1 mM is 1/1000 of a mole of solute in 1 liter of solution (see appendix C).

FIGURE 27.2 Effect of Blood Osmolality and Blood Pressure on Water Reabsorption in the Kidneys

Increased blood osmolality affects hypothalamic neurons, and decreased blood pressure (BP) affects baroreceptors in the aortic arch, carotid sinuses, and atrium. As a result of these stimuli, the rate of antidiuretic hormone (ADH) secretion from the posterior pituitary increases, which increases water reabsorption by the kidneys.

water is absorbed from the intestines and enters the extracellular fluid. ADH acts on the distal convoluted tubules and collecting ducts of the kidneys to increase the reabsorption of water from the filtrate. The increase in the amount of water entering the extracellular fluid decreases the osmolality (figures 27.2 and 27.3). The ADH and thirst mechanisms are sensitive to even small changes in extracellular fluid osmolality, and the response is fast (from minutes to a few hours). Larger increases in extracellular fluid osmolality, as occur during dehydration, cause an even greater increase in thirst and ADH secretion.

A decrease in extracellular fluid osmolality inhibits thirst and ADH secretion. Less water is consumed and reabsorbed from the filtrate in the kidneys. Consequently, more water is excreted as a large volume of dilute urine. The result is an increase in the osmolality of the extracellular fluid (figure 27.3). For example, drinking a large volume of water or some other dilute fluid results in reduced extracellular fluid osmolality. This leads to reduced ADH secretion, less reabsorption of water from the filtrate in the kidneys, and the production of a large volume of dilute urine. This response occurs quickly enough that the osmolality of the extracellular fluid is maintained within its normal range.

ASSESS YOUR PROGRESS

- List three factors that stimulate thirst. Name two factors that inhibit the sense of thirst.
- Describe three routes for the loss of water from the body. Contrast insensible and sensible perspiration.
- What are the primary organs that regulate the composition and volume of body fluids?
- What two mechanisms are triggered by an increase in the osmolality of the extracellular fluid?

Regulation of Extracellular Fluid Volume

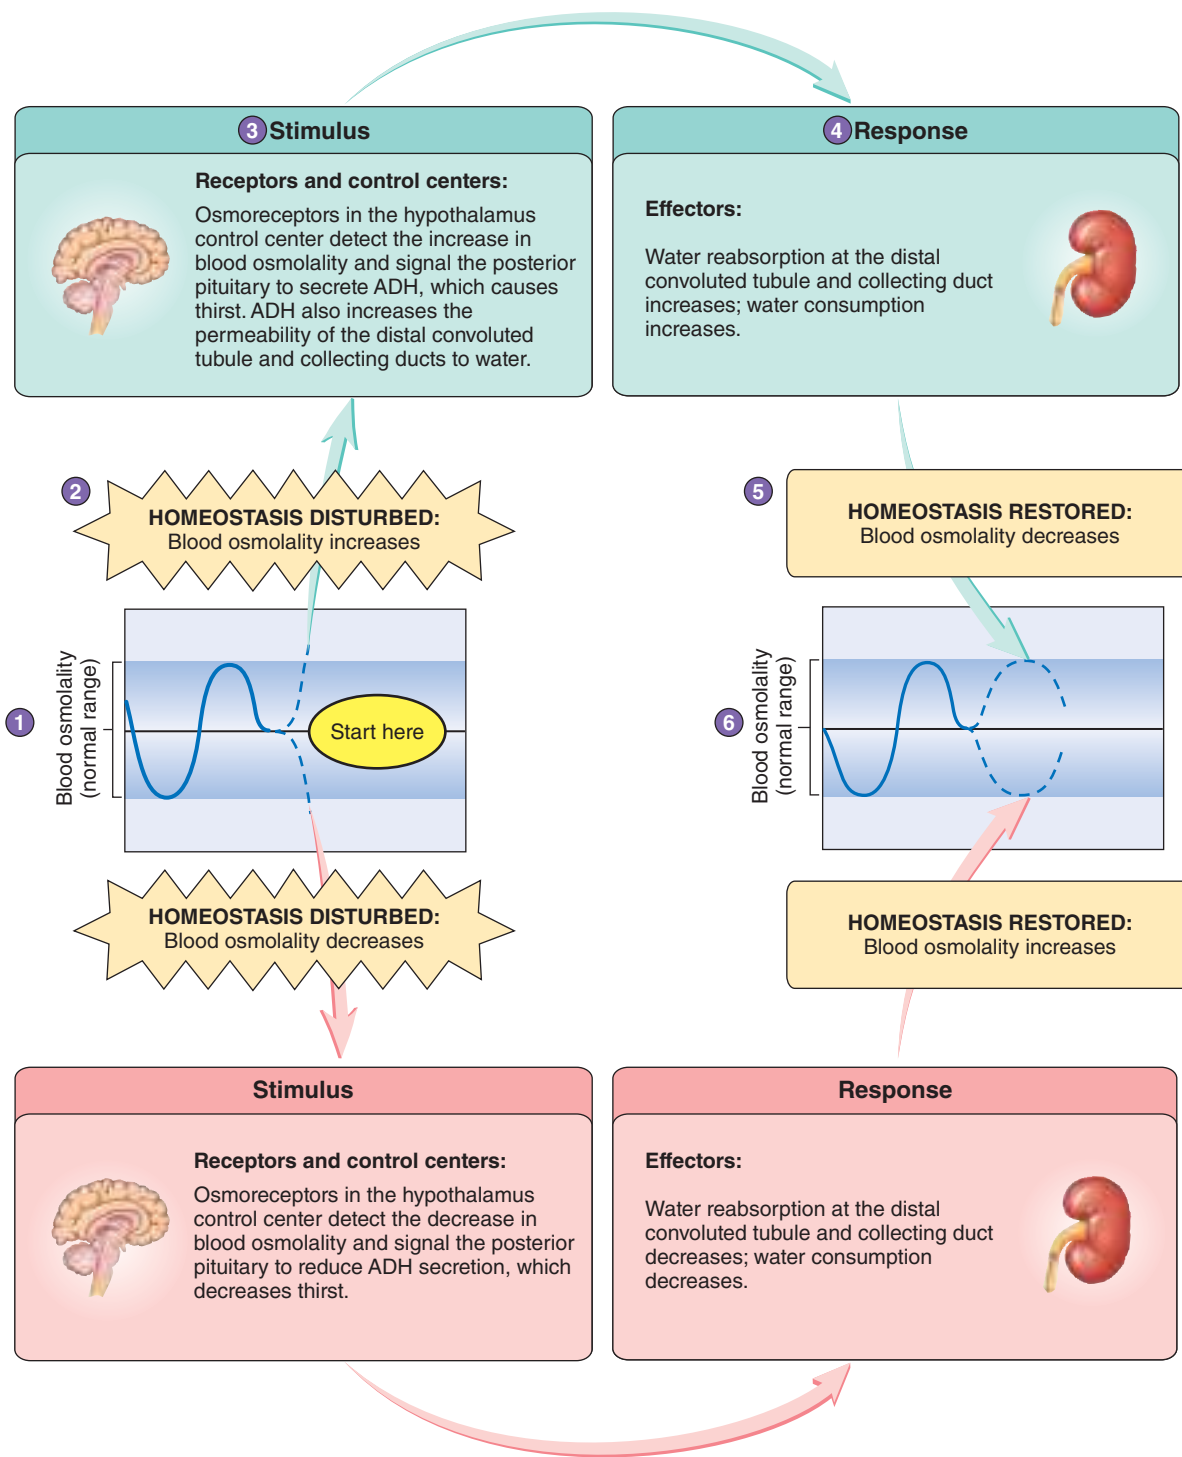

The volume of extracellular fluid can change even if its osmolality is maintained within a narrow range. Special sensory receptors detect changes in blood pressure by monitoring blood volume and are important in regulating extracellular fluid volume. Recall that blood volume is directly proportional to blood pressure. When blood volume increases, blood pressure goes up as well. The carotid sinus and aortic arch baroreceptors monitor blood pressure in the carotid arteries and the aorta; receptors in the juxtaglomerular apparatus monitor pressure changes in the afferent arterioles of the kidneys; and receptors in the walls of the atria of the heart and large veins monitor slight blood pressure changes there. These receptors activate neural mechanisms and three hormonal mechanisms that regulate extracellular fluid volume (figure 27.4):

- Neural mechanisms.** The frequency of action potentials conducted along sympathetic neurons to the afferent arterioles of the kidneys changes in response to alterations in blood pressure. When baroreceptors detect an increase in arterial and venous blood pressure, the frequency of sympathetic fiber action potentials to the afferent arterioles decreases. Consequently, the afferent arterioles dilate. This vasodilation increases glomerular capillary pressure, resulting in an increase in the glomerular filtration rate (GFR), which increases filtrate volume, thereby increasing urine volume.

When baroreceptors detect a decrease in arterial and venous blood pressure, the frequency of action potentials carried by sympathetic neurons to the afferent arterioles increases. Consequently, the afferent arterioles constrict. This decreases GFR, filtrate volume, and urine volume.

- Renin-angiotensin-aldosterone hormone mechanism.** The renin-angiotensin-aldosterone hormone mechanism responds to small changes in blood volume (see chapter 26). Increased blood volume causes increased blood pressure. Juxtaglomerular cells detect a rise in blood pressure in the afferent arterioles and reduce renin secretion. Decreased renin secretion leads to a lower conversion rate of angiotensinogen to angiotensin I, which slows the conversion of angiotensin I to angiotensin II. With less angiotensin II, there is a decline in aldosterone secretion from the adrenal cortex. Lower aldosterone levels reduce the rate of Na^+ reabsorption from the distal convoluted tubules and collecting ducts. Consequently, more Na^+ remains in the filtrate, and less Na^+ is reabsorbed. The effect is to increase the osmolality of the filtrate, which lessens water reabsorption in the kidneys. The water remains, with the excess Na^+ , in the filtrate. Thus, because the volume of urine produced by the kidneys goes up, the extracellular fluid volume is reduced, and blood pressure returns to the normal range (figure 27.4).

Whereas increased blood volume results in more urine, a decreased blood volume causes less urine to be produced. Once blood volume goes down, blood pressure decreases. Juxtaglomerular cells secrete renin when blood pressure drops. Renin stimulates production of angiotensin II. Angiotensin II stimulates aldosterone secretion from the

HOMEOSTASIS FIGURE 27.3 Blood Osmolality Regulation

(1) Blood osmolality is in the normal range. (2) Blood osmolality increases outside the normal range, which causes homeostasis to be disturbed. (3) The control center responds to the change in blood osmolality. (4) The control center causes ADH to be secreted, which increases water reabsorption at the distal convoluted tubule and the collecting duct. (5) These changes cause blood osmolality to decrease. (6) Blood osmolality returns to the normal range and homeostasis is restored. Observe the responses to a decrease in blood osmolality outside the normal range by following the red arrows.

adrenal cortex. Increased aldosterone increases the rate of Na^+ reabsorption in the kidney, primarily from the distal convoluted tubules and collecting ducts. Consequently, less Na^+ remains in the filtrate, and more Na^+ is reabsorbed. The effect is to decrease the osmolality of the filtrate. This increases the kidneys' ability to reabsorb water and to increase extracellular fluid volume. Thus, the volume of

urine produced by the kidneys decreases, and the extracellular fluid volume and blood pressure increase (figure 27.5; see figure 27.4).

3. *Atrial natriuretic hormone (ANH) mechanism.* In response to a larger-than-normal blood volume, the heart's atrial walls are stretched to a greater degree. This stretch triggers ANH secretion. ANH reduces Na^+ reabsorption from the distal

HOMEOSTASIS FIGURE 27.4 Regulation of Blood Volume

(1) Blood volume is in the normal range. (2) Blood volume increases outside the normal range, which causes homeostasis to be disturbed. (3) The control centers respond to the change in blood volume. (4) The control centers cause ADH and aldosterone secretion to decrease, which reduces water reabsorption. The control centers also cause dilation of renal arteries, which increases urine production. The heart secretes ANH, which also increases urine production. (5) These changes cause blood volume to decrease. (6) Blood volume returns to the normal range and homeostasis is restored. Observe the responses to a decrease in blood volume outside the normal range by following the *red arrows*.

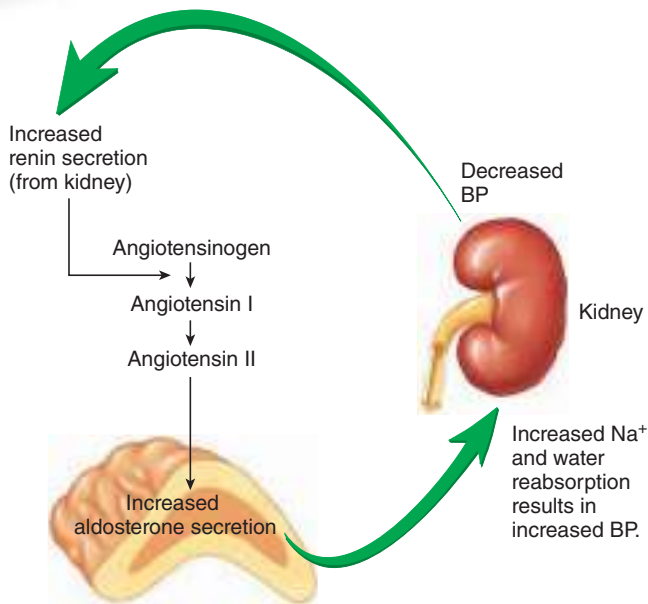

FIGURE 27.5 Effect of Blood Pressure on Na^+ and Water Reabsorption in the Kidneys

Low blood pressure (BP) stimulates renin secretion from the kidneys. Renin converts angiotensinogen to angiotensin I, which is converted to angiotensin II. Angiotensin II stimulates aldosterone secretion from the adrenal cortex. Aldosterone increases Na^+ and water reabsorption in the kidneys.

convoluted tubules and the collecting ducts, increasing the rate of Na^+ and water loss in the urine. Thus, increased ANH secretion decreases extracellular fluid volume and thus blood volume (figure 27.6; see figure 27.4).

ANH does not appear to respond strongly to decreases in blood volume. However, a decrease in pressure in the atria of the heart inhibits the secretion of ANH. Without ANH, Na^+ reabsorption is inhibited in the distal convoluted tubules and collecting ducts. Therefore, the rate of Na^+ reabsorption increases, and water reabsorption increases. Thus, decreased ANH secretion is consistent with a reduced urine volume and an elevated extracellular fluid volume (see figure 27.4).

4. *Antidiuretic hormone (ADH) mechanism.* The ADH mechanism plays an important role in regulating extracellular fluid volume in response to large changes in blood pressure (of 5–10%). Increased blood pressure inhibits ADH secretion. As a result, the reabsorption of water from the lumens of the distal convoluted tubules and collecting ducts decreases, resulting in a larger volume of dilute urine. This response helps decrease extracellular fluid volume, thereby lowering blood pressure (see figures 27.2 and 27.4).

Low blood pressure stimulates ADH secretion. Consequently, the reabsorption of water from the distal convoluted tubules and collecting ducts increases, resulting in a small volume of concentrated urine. This response helps increase

FIGURE 27.6 Effect of Blood Pressure in the Right Atrium on Na^+ and Water Excretion

Increased blood pressure (BP) in the right atrium of the heart causes increased secretion of atrial natriuretic hormone (ANH), which increases Na^+ excretion and water loss in urine.

extracellular fluid volume, thereby increasing blood pressure (see figures 27.2 and 27.4).

The mechanisms that maintain extracellular fluid concentration and volume function together. However, when the mechanisms do not function normally, extracellular fluid volume may increase, even though the extracellular concentration of fluids does not change substantially. For example, excessive aldosterone secretion from an enlarged adrenal cortex increases Na^+ reabsorption by the kidneys, and the total volume of extracellular fluid increases. Certain mechanisms, such as the regulation of ADH secretion, keep the concentration of the body fluids constant. Even if elevated blood pressure causes edema, the osmolality of the extracellular fluid is maintained between 285 and 300 mOsm/kg. Similarly, in people suffering from heart failure, the resulting reduced blood pressure activates mechanisms, such as renin secretion, that increase blood pressure to its normal range. Consequently, aldosterone secretion increases, and the result is increased extracellular fluid volume and edema in the periphery, including the lungs.

ASSESS YOUR PROGRESS

9. What sensory receptors are responsible for activating neural and hormonal mechanisms that regulate extracellular fluid volume?
10. What is the effect on sympathetic stimulation, afferent arterioles, GFR, filtrate volume, urine volume, and extracellular fluid volume when baroreceptors detect an increase in arterial and venous blood pressure?
11. Describe the response of the renin-angiotensin-aldosterone hormone mechanism to a decrease in blood pressure. How are extracellular fluid volume and urine volume affected?

12. What effect does atrial natriuretic hormone (ANH) have on extracellular fluid volume?
13. How does an increase in blood pressure affect the secretion of ADH? How does ADH affect extracellular fluid volume?

27.3 Regulation of Intracellular Fluid Composition

LEARNING OUTCOME

After reading this section, you should be able to

A. Describe how intracellular fluid composition is maintained.

The composition of intracellular fluid is very different from that of extracellular fluid. Recall from chapter 3 that the plasma membrane is selectively permeable; large and polar molecules cannot easily diffuse across the membrane, whereas small and nonpolar molecules can easily diffuse across the membrane. One major reason for the different composition of the intracellular fluid is that many of the molecules synthesized inside the cell are large proteins that cannot exit the cell. Another factor contributing to the difference is that cells

have transport proteins embedded in the plasma membrane. These transport proteins expend ATP to create a concentration gradient of certain ions. Many cells have a Na^+/K^+ ATP pump that moves K^+ into the cell and pumps Na^+ out of the cell. The uneven distribution of molecules and ions creates a charge difference across the plasma membrane. This difference in charge can also influence the concentration of ions across the plasma membrane (figure 27.7).

Because water moves across the plasma membrane by osmosis, the net movement of water is determined by changes in the concentration of solutes in the extracellular and intracellular fluids. For example, as dehydration develops, the concentration of solutes in the extracellular fluid increases, allowing water to move by osmosis out of the cell and into the extracellular fluid. If dehydration is severe, the cells can shrink and will function abnormally. If water intake increases after a period of dehydration, the concentration of solutes in the extracellular fluids decreases, which allows water to move back into the cells.

ASSESS YOUR PROGRESS

14. What factors determine the composition of intracellular fluid?
15. What characteristic of the plasma membrane is responsible for maintaining the differences between intracellular and extracellular fluid?

FUNDAMENTAL Figure

- 1 Large organic molecules, such as proteins, which cannot cross the plasma membrane, are synthesized inside cells and influence the concentration of solutes inside the cells.
- 2 The transport of ions, such as Na^+ , K^+ , and Ca^{2+} , across the plasma membrane influences the concentration of ions inside and outside the cell.
- 3 An electrical charge difference across the plasma membrane influences the distribution of ions inside and outside the cell.
- 4 The distribution of water inside and outside the cell is determined by osmosis.

PROCESS FIGURE 27.7 Regulation of Intracellular Fluid

27.4 Regulation of Specific Electrolytes in the Extracellular Fluid

LEARNING OUTCOMES

After reading this section, you should be able to

- Discuss how sodium ion concentration is achieved.
- Describe the regulation of chloride ions.
- Explain potassium ion homeostasis.
- Demonstrate an understanding of calcium ion homeostasis.
- Relate the mechanisms governing magnesium ion concentration.
- Explain the regulation of phosphate ions.
- Describe the causes and symptoms of abnormal plasma levels of selected electrolytes.

Electrolytes (ē-lek'trō-līts) can be either cations or anions. The major extracellular ions are Na^+ , Cl^- , K^+ , Ca^{2+} , Mg^{2+} , and phosphate ions (PO_4^{3-}). Electrolytes are in the food and water we ingest. Organs—such as the kidneys and, to a lesser degree, the liver, skin, and lungs—remove them from the body. The concentrations of electrolytes in the extracellular fluid are regulated, so that they do not change unless the individual is growing, gaining weight, or losing weight. The regulation of each electrolyte involves the coordinated participation of several organ systems.

Regulation of Sodium Ions

Sodium ions are the dominant extracellular cations. Because of their abundance in the extracellular fluid, they exert substantial osmotic pressure. Osmotic pressure is the tendency for net movement of water molecules toward an area with a higher solute concentration—in this case, the extracellular fluid. Approximately 90–95% of the osmotic pressure of the extracellular fluid is caused by Na^+ and the negative ions associated with it. In the United States, most people consume 20–30 times the amount of sodium chloride (salt) the body needs. Although less than 0.5 g is required to maintain homeostasis, the average individual ingests approximately 10–15 g of sodium chloride daily. Therefore, regulation of the body's Na^+ content depends primarily on the excretion of excess quantities of Na^+ . On the other hand, when Na^+ intake is very low, the mechanisms for conserving Na^+ in the body take effect.

The kidneys are the major route by which Na^+ is excreted. Sodium ions readily pass from the glomerulus into the lumen of the Bowman capsule and are present in the same concentration in the filtrate as in the plasma. The concentration of Na^+ excreted in the urine is determined by the amount of Na^+ and water reabsorbed from filtrate in the renal tubule. If Na^+ reabsorption from the tubule decreases, large quantities are excreted in the urine. If Na^+ reabsorption from the tubule increases, only small quantities are excreted in the urine.

The rate of Na^+ transport in the proximal convoluted tubule is relatively constant, but the Na^+ transport mechanisms of the distal convoluted tubule and the collecting duct are under hormonal control. **Aldosterone** increases Na^+ reabsorption from the distal convoluted tubule and collecting duct. As little as 0.1 g of sodium is excreted in the urine each day in the presence of high blood levels of aldosterone. When aldosterone is absent, Na^+ reabsorption in the renal tubule is greatly reduced, and as much as 30–40 g of sodium can be lost in the urine daily.

Sodium ions are also excreted from the body in sweat. Normally, only a small quantity of Na^+ is lost each day in the form of sweat, but, as noted in section 27.2, the amount increases during heavy exercise in warm environments. The mechanisms that regulate sweating control the quantity of Na^+ excreted through the skin. As body temperature increases, thermoreceptor neurons within the hypothalamus respond by increasing the rate of sweat production. As the rate of sweat production increases, the quantity of Na^+ lost in the urine decreases to keep the extracellular concentration of Na^+ constant. Because of this mechanism, the loss of Na^+ in sweat is rarely physiologically significant.

The primary mechanisms that regulate Na^+ concentrations in the extracellular fluid do not directly monitor Na^+ levels but are sensitive to changes in overall extracellular fluid osmolality or blood pressure (table 27.5; see figure 27.4). The quantity of Na^+ in the body has a dramatic effect on extracellular osmotic pressure and extracellular fluid volume. For example, if the quantity of Na^+ in the extracellular fluid increases, its osmolality also increases. This promotes ADH secretion, which stimulates both water reabsorption in the kidneys and thirst. Overall, ADH is a water conservation hormone. A decrease in the quantity of Na^+ in the body causes an opposite set of responses. ADH secretion decreases, which allows a large volume of dilute urine to be produced and decreases the sensation of thirst. As a result of these changes, extracellular osmolality increases. By regulating extracellular fluid osmolality and extracellular fluid volume, the concentration of Na^+ in the body fluids is maintained within a narrow range of values.

Elevated blood pressure under resting conditions increases Na^+ and water excretion (table 27.5; see figure 27.4). If blood pressure is low, the total Na^+ content of the body is usually also low. In response to low blood pressure, mechanisms such as the renin-angiotensin-aldosterone hormone mechanism are activated, increasing Na^+ concentration and water volume in the extracellular fluid (table 27.5; see figure 27.4).

Predict 2

In response to hemorrhagic shock, the kidneys produce a small volume of very concentrated urine. Explain how the rate of filtrate formation changes and how Na^+ transport is altered in the distal convoluted tubule in response to hemorrhagic shock.

When blood pressure is increased, the walls of the heart, particularly in the right atrium, are stretched. The increased stretch causes specialized cells in the right atrium to secrete the hormone ANH. ANH acts on the kidneys to increase urine production by inhibiting the reabsorption of Na^+ (table 27.5; see figure 27.6). It

TABLE 27.5 Homeostasis: Mechanisms Regulating Blood Sodium

Mechanism	Stimulus	Response to Stimulus	Effect of Response	Result
Response to Changes in Blood Osmolality				
Antidiuretic hormone (ADH); the most important regulator of blood osmolality	Increased blood osmolality (e.g., increased Na ⁺ concentration)	Increased ADH secretion from the posterior pituitary; mediated through cells in the hypothalamus	Increased water reabsorption in the kidney; production of a small volume of concentrated urine	Decreased blood osmolality as reabsorbed water dilutes the blood
	Decreased blood osmolality (e.g., decreased Na ⁺ concentration)	Decreased ADH secretion from the posterior pituitary; mediated through cells in the hypothalamus	Decreased water reabsorption in the kidney; production of a large volume of dilute urine	Increased blood osmolality as water is excreted from the blood into the urine
Response to Changes in Blood Pressure				
Renin-angiotensin-aldosterone hormone mechanism	Decreased blood pressure in the kidney's afferent arterioles	Increased renin release from the juxtaglomerular apparatuses; renin initiates the conversion of angiotensinogen to angiotensin; angiotensin I is converted to angiotensin II, which increases aldosterone secretion from the adrenal cortex	Increased Na ⁺ reabsorption in the kidney (because of increased aldosterone); increased water reabsorption as water follows the Na ⁺ ; decreased urine volume	Increased blood pressure as blood volume increases because of increased water reabsorption; blood osmolality is maintained because both Na ⁺ and water are reabsorbed*
	Increased blood pressure in the kidney's afferent arterioles	Decreased renin release from the juxtaglomerular apparatuses, resulting in reduced formation of angiotensin I; reduced angiotensin I leads to reduced angiotensin II, which causes a decrease in aldosterone secretion from the adrenal cortex	Decreased Na ⁺ reabsorption in the kidney (because of decreased aldosterone); decreased water reabsorption as less Na ⁺ is reabsorbed; increased urine volume	Decreased blood pressure as blood volume decreases because water is excreted in the urine; blood osmolality is maintained because both Na ⁺ and water are excreted in the urine*
Atrial natriuretic hormone (ANH)	Decreased blood pressure in the atria of the heart	Decreased ANH released from the atria	Increased Na ⁺ reabsorption in the kidney; increased water reabsorption as water follows the Na ⁺ ; decreased urinary volume	Increased blood pressure as blood volume increases because of increased water reabsorption; blood osmolality is maintained because both Na ⁺ and water are reabsorbed*
	Increased blood pressure in the atria of the heart	Increased ANH released from the atria	Decreased Na ⁺ reabsorption in the kidney; decreased water reabsorption as water is excreted with Na ⁺ in the urine; increased urinary volume	Decreased blood osmolality as blood volume decreases because water is excreted in the urine; blood osmolality is maintained because both Na ⁺ and water are excreted in the urine*
ADH—activated by significant decreases in blood pressure; normally regulates blood osmolality (see above)	Decreased arterial blood pressure	Increased ADH secretion from the posterior pituitary; mediated through baroreceptors	Increased water reabsorption in the kidney; production of a small volume of concentrated urine	Increased blood pressure resulting from increased blood volume; decreased blood osmolality
	Increased arterial blood pressure	Decreased ADH secretion from the posterior pituitary; mediated through baroreceptors	Decreased water reabsorption in the kidney; production of a large volume of dilute urine	Decreased blood pressure resulting from decreased blood volume; increased blood osmolality

Abbreviation: ADH = antidiuretic hormone.

*Assumes normal levels of ADH.

TABLE 27.6 Consequences of Abnormal Plasma Levels of Sodium Ions

HYPONATREMIA	
Causes	Inadequate dietary intake of sodium Extrarenal losses Dilution Hyperglycemia
Symptoms	Lethargy, confusion, apprehension, seizures, and coma When accompanied by reduced blood volume: reduced blood pressure, tachycardia, and decreased urine output When accompanied by increased blood volume: weight gain, edema, and distension of veins
HYPERNATREMIA	
Causes	High dietary sodium (rarely causes symptoms) Administration of hypertonic saline solutions Oversecretion of aldosterone Water loss
Symptoms	Thirst, fever, dry mucous membranes, and restlessness Most serious symptoms are convulsions and pulmonary edema When occurring with increased water volume: weight gain, edema, elevated blood pressure, and bounding pulse

also inhibits the effect of ADH on the distal convoluted tubules and collecting ducts and inhibits ADH secretion (see chapter 26, section 26.4).

Deviations from the normal concentration range for Na^+ in body fluids result in significant symptoms. **Hyponatremia** (hī'pō-nā-trē'mē-ă) is low plasma Na^+ levels; **hypernatremia** (hī'per-nā-trē'mē-ă) is high plasma levels of Na^+ . The major causes and symptoms of each are listed in table 27.6.

ASSESS YOUR PROGRESS

- Name the substance responsible for most of the osmotic pressure of the extracellular fluid.
- How does aldosterone affect the concentration of Na^+ in the urine?
- What role does sweating play in Na^+ balance?
- How does increased blood pressure result in a loss of water and salt? What happens when blood pressure decreases?
- What effect does ANH have on Na^+ and water loss in urine?
- What are the causes of hypernatremia and hyponatremia? List the symptoms of both conditions.

Regulation of Chloride Ions

Chloride ions are the predominant anions in the extracellular fluid. Because anions and cations are strongly attracted to each

other, the regulatory mechanisms that influence the concentration of cations in the extracellular fluid also influence the concentration of anions. The mechanisms that regulate Na^+ , K^+ , and Ca^{2+} levels in the body are important in influencing Cl^- levels. Because Na^+ is the predominant cation, the mechanisms that regulate its extracellular concentration are the most important for regulation of the extracellular Cl^- concentration.

ASSESS YOUR PROGRESS

- What mechanisms regulate Cl^- concentrations?

Regulation of Potassium Ions

Potassium ion concentration across the plasma membrane is very tightly regulated because K^+ is the critical factor for determining the resting membrane potential for electrically excitable cells. If extracellular K^+ concentrations increase, the cell depolarizes, whereas if extracellular K^+ concentrations decrease, the cell hyperpolarizes. **Hypokalemia** (hī'pō-ka-lē'mē-ă) is an abnormally low level of K^+ in the extracellular fluid; **hyperkalemia** (hī'per-kā-lē'mē-ă) is an abnormally high level of K^+ in the extracellular fluid. Major causes of hypokalemia and hyperkalemia and their symptoms are listed in table 27.7.

TABLE 27.7 Consequences of Abnormal Concentrations of Potassium Ions

HYPOKALEMIA	
Causes	Alkalosis Insulin administration Reduced K^+ intake Increased renal loss
Symptoms	Decreased neuromuscular excitability Decreased smooth muscle tone Delayed ventricular depolarization Bradycardia Atrioventricular block
HYPERKALEMIA	
Causes	Loss of intracellular K^+ due to cell trauma or reduced permeability of plasma membrane Reduced renal excretion
Symptoms	
<i>Mild</i>	Increased neuromuscular irritability Intestinal cramping and diarrhea Rapid cardiac repolarization
<i>Severe</i>	Muscle weakness Loss of muscle tone and paralysis Reduced rate of cardiac action potential conduction

HOMEOSTASIS FIGURE 27.8 Summary of Blood K⁺ Regulation

(1) Blood K⁺ is in the normal range. (2) Blood K⁺ increases outside the normal range, which causes homeostasis to be disturbed. (3) The control center responds to the change in blood K⁺. (4) The control center causes aldosterone to be secreted, which increases K⁺ secretion at the distal convoluted tubule and the collecting duct. (5) These changes cause blood K⁺ to decrease. (6) Blood K⁺ returns to the normal range and homeostasis is restored. Observe the responses to a decrease in blood K⁺ outside the normal range by following the red arrows.

Potassium ions are readily filtered out of the blood in the renal corpuscle. They are actively reabsorbed in the proximal convoluted tubules and actively secreted in the distal convoluted tubules and collecting ducts. Potassium ion secretion into the distal convoluted tubules and collecting ducts is highly regulated and primarily responsible for controlling the extracellular concentration of K^+ .

Aldosterone plays a major role in regulating the concentration of K^+ in the extracellular fluid. It increases the rate of K^+ secretion in the distal convoluted tubules and collecting ducts. Elevated K^+ blood levels stimulate aldosterone secretion from the adrenal cortex (figure 27.8; see chapter 26). Aldosterone secretion is also stimulated in response to increased angiotensin II. Elevated aldosterone concentrations in the circulatory system increase K^+ secretion into the renal tubule, thereby lowering blood levels of K^+ .

Circulatory system shock can result from plasma loss, dehydration, and tissue damage, as occurs in burn patients. This shock causes the extracellular K^+ to be more concentrated than normal, which stimulates aldosterone secretion from the adrenal cortex. Aldosterone is also secreted in response to decreased blood pressure, which stimulates the renin-angiotensin-aldosterone hormone mechanism. Homeostasis is reestablished as K^+ excretion increases. Also, increased Na^+ and water reabsorption stimulated by aldosterone results in an increase in extracellular fluid volume, which dilutes the K^+ in the body fluids. Blood pressure increases toward normal as water reabsorption increases and when vasoconstriction is stimulated by angiotensin II.

ASSESS YOUR PROGRESS

23. What effect does an increase or a decrease in extracellular K^+ concentration have on resting membrane potential?
24. In what portion of the renal tubule is K^+ secreted?
25. How is the secretion of K^+ regulated?

Regulation of Calcium Ions

As with other ions, the extracellular concentration of **calcium ions** is regulated within a narrow range. The normal concentration of Ca^{2+} in plasma is 9.4 mg/100 mL. **Hypocalcemia** (hī'pō-kal-sē'mē-ă) is a below-normal level of Ca^{2+} in the extracellular fluid, and **hypercalcemia** (hī'per-kal-sē'mē-ă) is an above-normal level of Ca^{2+} in the extracellular fluid. Major symptoms develop when the extracellular concentration of Ca^{2+} declines below 6 mg/100 mL or increases above 12 mg/100 mL. Changes in the extracellular concentration of Ca^{2+} markedly affect the electrical properties of excitable tissues. Hypocalcemia increases the plasma membrane's permeability to Na^+ . As a result, nerve and muscle tissues undergo spontaneous action potential generation. Hypercalcemia decreases the plasma membrane's permeability to Na^+ , preventing normal depolarization of nerve and muscle cells. High extracellular Ca^{2+} levels cause the deposition of calcium carbonate salts in soft tissues, resulting in irritation and inflammation of those tissues. Table 27.8 lists the major causes and symptoms of hypocalcemia and hypercalcemia.

The kidneys, digestive tract, and bones are important in maintaining extracellular Ca^{2+} levels (figure 27.9). Almost 99% of total body calcium is contained in bone. Calcium ion regulation partly

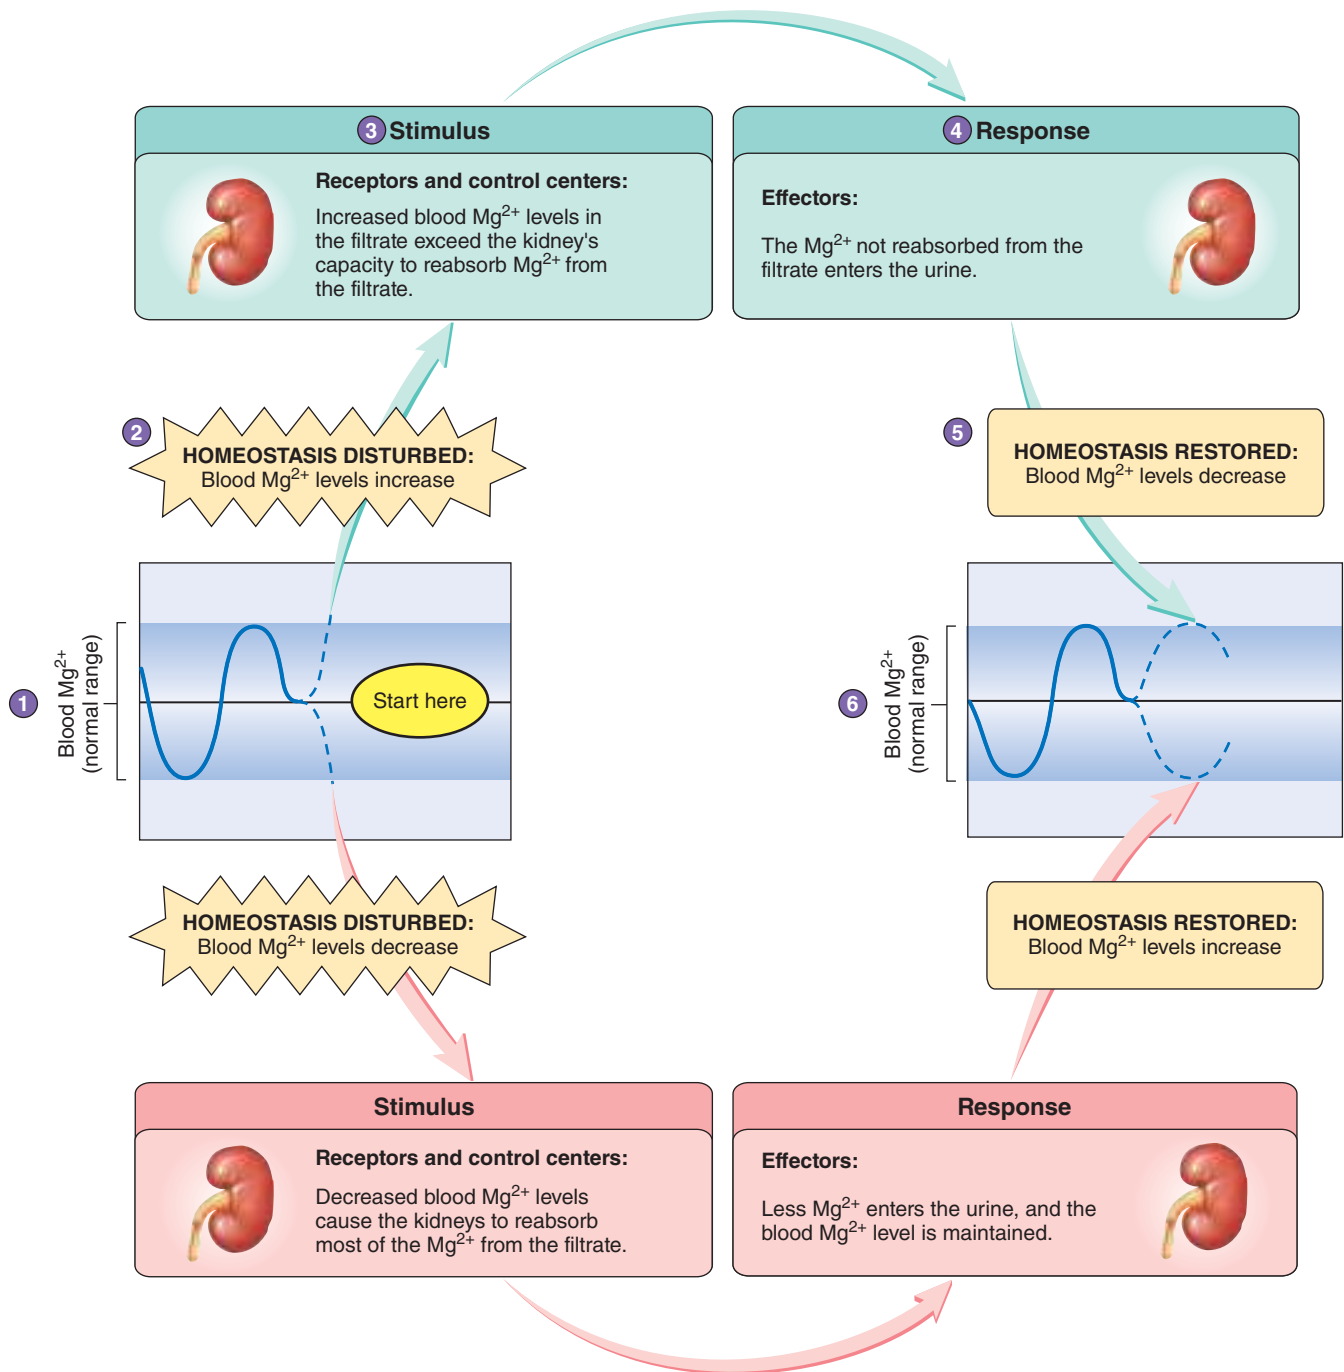

TABLE 27.8

Consequences of Abnormal Concentrations of Calcium Ions

HYPOCALCEMIA	
Causes	Nutritional deficiencies Vitamin D deficiency Decreased PTH secretion Malabsorption of lipids (reduces vitamin D absorption) Bone tumors that increase Ca^{2+} deposition
Symptoms	Confusion Muscle spasms Hyperreflexia Intestinal cramping Convulsions Tetany Inadequate respiratory movements Prolonged cardiac ventricular depolarization
HYPERCALCEMIA	
Causes	Excessive PTH secretion Excess vitamin D
Symptoms	Fatigue Weakness Lethargy Anorexia Nausea Constipation Reduced cardiac ventricular depolarization Kidney stones

involves the regulation of Ca^{2+} deposition into and reabsorption from bone (see chapter 6). However, long-term regulation of Ca^{2+} levels depends on maintaining a balance between Ca^{2+} absorption across the intestinal wall and Ca^{2+} excretion by the kidneys.

Parathyroid (par-ă-thī'royd) hormone (PTH), secreted by the parathyroid glands, increases extracellular Ca^{2+} levels and reduces extracellular phosphate levels. The rate of PTH secretion is regulated by extracellular Ca^{2+} levels. Parathyroid cells directly detect extracellular Ca^{2+} levels. Elevated Ca^{2+} levels inhibit PTH secretion, and reduced levels stimulate it. PTH causes increased osteoclast activity, which results in the degradation of bone, releasing Ca^{2+} and phosphate ions into the blood. PTH increases the rate of Ca^{2+} reabsorption from renal tubules in the kidneys and increases the concentration of phosphate ions in the urine. It also increases the rate at which vitamin D is converted to 1,25-dihydroxycholecalciferol, or **active vitamin D**. Active vitamin D increases Ca^{2+} absorption across the intestinal mucosa.

HOMEOSTASIS FIGURE 27.9 Summary of Blood Mg^{2+} Regulation

(1) Blood Mg^{2+} is in the normal range. (2) Blood Mg^{2+} increases outside the normal range, which causes homeostasis to be disturbed. (3) The control center responds to the change in blood Mg^{2+} . (4) The control center prevents Mg^{2+} reabsorption in the kidney. (5) These changes cause blood Mg^{2+} to decrease. (6) Blood Mg^{2+} returns to the normal range and homeostasis is restored. Observe the responses to a decrease in blood Mg^{2+} outside the normal range by following the *red arrows*.

Lack of PTH secretion results in a rapid decline in extracellular Ca^{2+} concentration. The causes of this decline are a reduced rate of Ca^{2+} absorption from the digestive tract, increased Ca^{2+} excretion by the kidneys, and reduced bone reabsorption. A lack of PTH can result in death because of tetany of the respiratory muscles caused by hypocalcemia.

Vitamin D can be obtained from food or from vitamin D biosynthesis. Normally, vitamin D biosynthesis is adequate; however, because ultraviolet light is required for this process, prolonged lack of sun exposure reduces vitamin D blood levels.

Without vitamin D, the transport of Ca^{2+} across the wall of the digestive tract is negligible. This leads to inadequate Ca^{2+}

absorption, even though the person may be consuming a large amount of this ion. Thus, Ca^{2+} absorption depends on getting adequate amounts of calcium and vitamin D.

Calcitonin (kal-si-tō'nin), which is secreted by the parafollicular cells of the thyroid gland, helps reduce extracellular Ca^{2+} levels. However, greater-than-normal calcitonin levels in the blood do not reduce blood levels of Ca^{2+} to below-normal values. The major effect of calcitonin is in bone, where it inhibits osteoclasts. Thus, calcitonin prevents bone degradation, which keeps blood Ca^{2+} levels from rising (see chapter 6). However, PTH is more important than calcitonin for blood Ca^{2+} regulation.

ASSESS YOUR PROGRESS

26. Describe the effects of hypocalcemia and hypercalcemia on membrane potentials.
27. Explain the role of PTH in regulating extracellular Ca^{2+} concentration.
28. Discuss the role of vitamin D in regulating extracellular Ca^{2+} concentration.
29. Describe the role of calcitonin in regulating extracellular Ca^{2+} concentration.

Regulation of Magnesium Ions

Most of the magnesium in the body is stored in the bones or intracellular fluid. Less than 1% of the total are ions in the extracellular fluid. Approximately one-half of those ions are bound to plasma proteins, and the rest are free. The free **magnesium ion** (Mg^{2+}) concentration is 1.8–2.4 mEq/L. Magnesium ions are cofactors for intracellular enzymes, such as the sodium-potassium pump involved in actively transporting Na^+ out of and K^+ into cells (see the section “Enzymes” in chapter 2). **Hypomagnesemia** is a below-normal blood level of magnesium, and **hypermagnesemia** is an above-normal blood level of magnesium. Low and high levels of plasma magnesium produce symptoms associated with the effect of magnesium on Na^+ – K^+ active transport (table 27.9).

Free Mg^{2+} passes through the filtration membranes of the kidney into the filtrate. About 85–90% of those ions are reabsorbed from the filtrate, and only about 10–15% enter the urine. Of the Mg^{2+} reabsorbed, most is reabsorbed by the loop of Henle. The remainder is reabsorbed by the proximal convoluted tubule, distal convoluted tubule, and collecting duct.

The kidney's capacity to reabsorb Mg^{2+} is limited. If the level of free Mg^{2+} increases in the extracellular fluid, the excess Mg^{2+} remains in the filtrate, and the rate of Mg^{2+} loss in the urine increases. If the level of free Mg^{2+} decreases in the extracellular fluid, nearly all of the Mg^{2+} is reabsorbed, and the rate of Mg^{2+} loss in the urine decreases. The control of Mg^{2+} reabsorption is not clear, but a decreased extracellular concentration of Mg^{2+} causes an increased rate of reabsorption in the renal tubule (figure 27.9).

ASSESS YOUR PROGRESS

30. In what part of the renal tubule is most Mg^{2+} reabsorbed?
31. What effect does a decreased extracellular concentration of Mg^{2+} have on its reabsorption in the renal tubule?

TABLE 27.9

Consequences of Abnormal Concentrations of Magnesium Ions

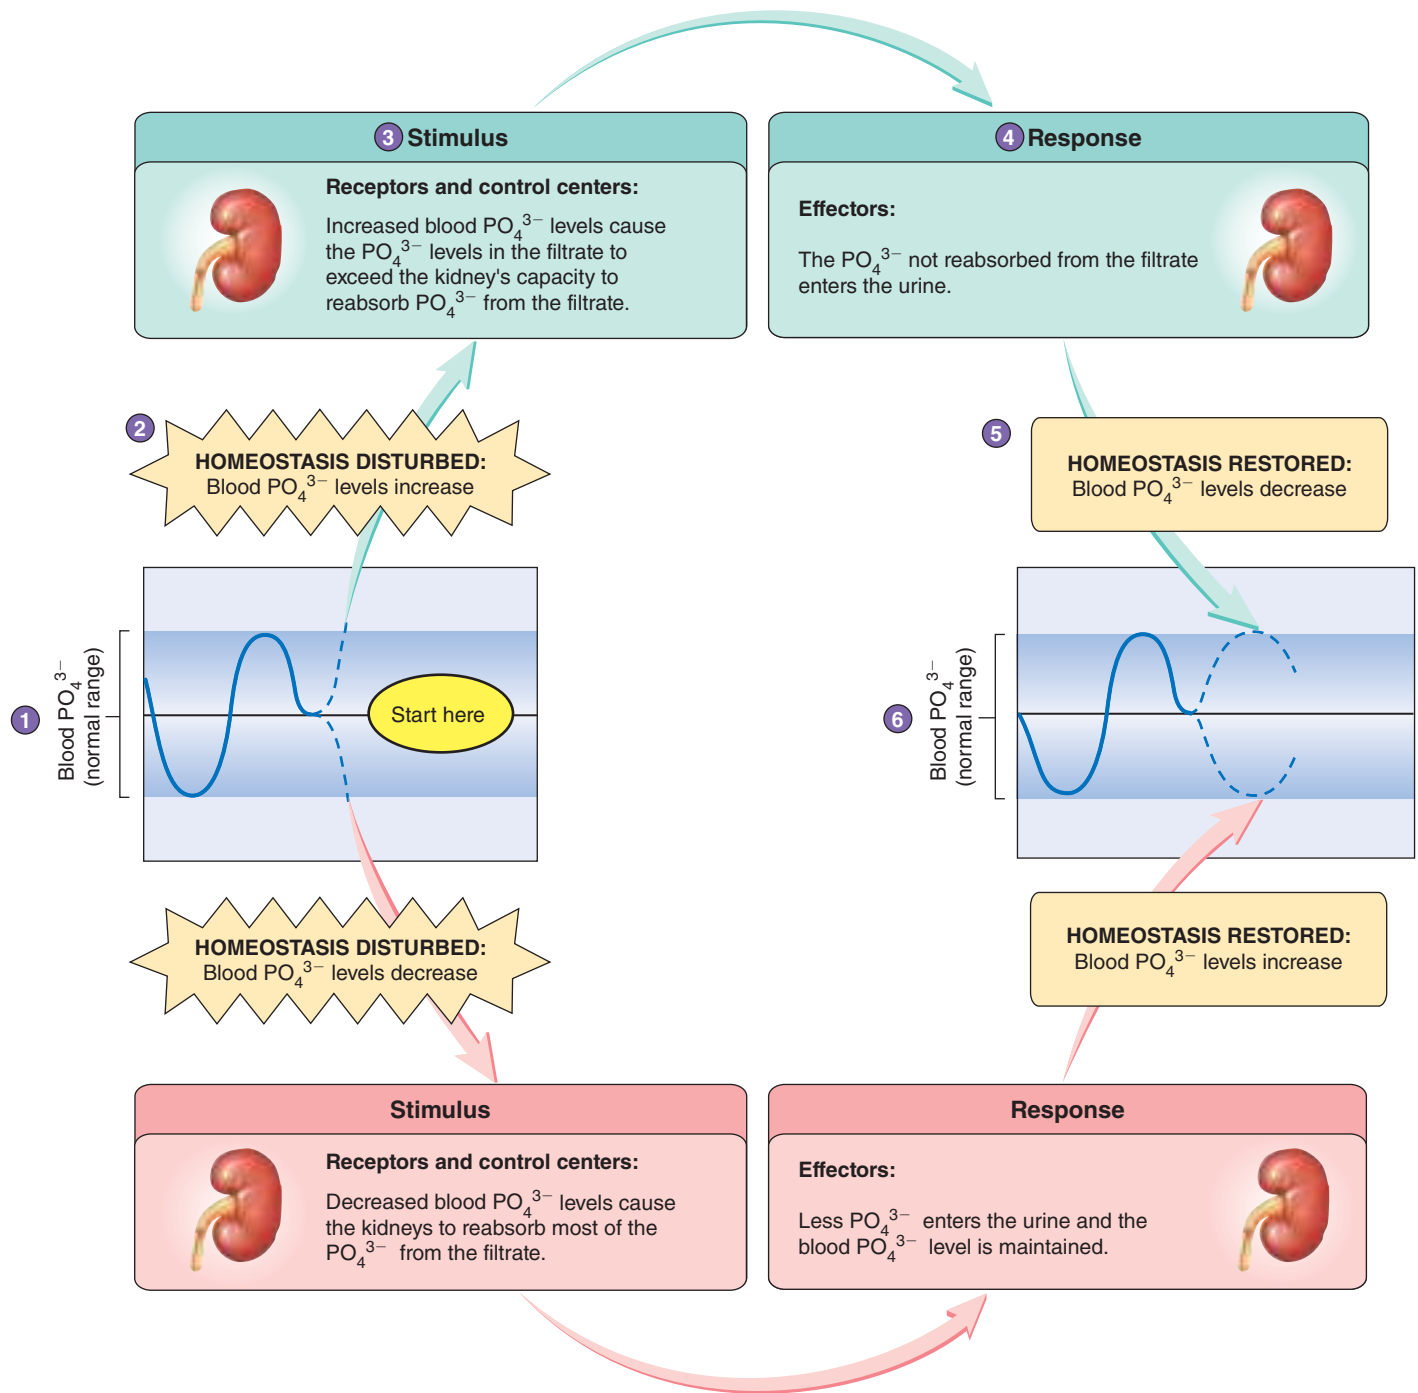

HYPOMAGNESEMIA (rare)

	Hypotension	
	Bradycardia	
	Reduced respiration	

Regulation of Phosphate Ions

About 85% of the phosphate in the body is in the form of calcium phosphate salts in bone (hydroxyapatite) and teeth. Most of the remaining phosphate is inside cells. Many of the phosphate ions are covalently bound to other organic molecules. For example, phosphate ions are bound to lipids (to form phospholipids), proteins, and carbohydrates, and they are important components of DNA, RNA, and ATP. Phosphates also play important roles in regulating enzyme activity, and phosphate ions dissolved in the intracellular fluid act as buffers (see section 27.5). The extracellular concentration of phosphate ions is between 1.7 and 2.6 mEq/L. Phosphate ions are in the form of H_2PO_4^- , HPO_4^{2-} , and PO_4^{3-} . The most common phosphate ion is HPO_4^{2-} .

The kidneys' capacity to reabsorb phosphate ions is limited. If the level of phosphate ions increases in the extracellular fluid, more phosphate is excreted in the urine. If the level of phosphate ions decreases in the extracellular fluid, less phosphate is excreted in the urine (figure 27.10).

Over time, a diet low in phosphate can increase the rate of phosphate reabsorption. Consequently, most of the phosphate that enters the filtrate is reabsorbed to maintain the extracellular phosphate concentration. PTH plays a significant role in regulating extracellular phosphate levels by promoting bone reabsorption, which releases Ca^{2+} and phosphate ions into the extracellular fluid. Thus, the kidneys do not need to conserve phosphate ions,

HOMEOSTASIS FIGURE 27.10 Summary of Blood Phosphate Ion Regulation

(1) Blood PO_4^{3-} is in the normal range. (2) Blood PO_4^{3-} increases outside the normal range, which causes homeostasis to be disturbed. (3) The control center responds to the change in blood PO_4^{3-} . (4) The control center prevents PO_4^{3-} reabsorption in the kidney. (5) These changes cause blood PO_4^{3-} to decrease. (6) Blood PO_4^{3-} returns to the normal range and homeostasis is restored. Observe the responses to a decrease in blood PO_4^{3-} outside the normal range by following the red arrows.

and more are excreted in the urine. If phosphate levels in the extracellular fluid increase above normal levels, Ca^{2+} and phosphate ions precipitate as calcium phosphate salts in soft tissues.

Elevated blood levels of phosphate may occur with acute or chronic renal failure as a result of a critically reduced rate of filtrate formation by the kidneys. The rate of phosphate excretion

is consequently reduced. Also, the chronic use of laxatives containing phosphates may cause elevated blood levels of phosphate. Symptoms of elevated phosphate levels are related to reduced blood Ca^{2+} levels because phosphate ions and Ca^{2+} precipitate out of solution and are deposited in the body's soft tissues. Prolonged elevation of blood levels of phosphate can

TABLE 27.10 Consequences of Abnormal Concentrations of Phosphate Ions

HYPOPHOSPHATEMIA	
Causes	Reduced intestinal absorption due to vitamin D deficiency or alcohol abuse Hyperparathyroidism (elevated renal PO_4^- excretion)
Symptoms	Reduced metabolic rate Reduced O_2 transport Reduced blood clotting Reduced white blood cell functions

Causes	Renal failure Tissue destruction from chemotherapy Hyperparathyroidism (reduced renal PO_4^- excretion)
Symptoms	Formation of calcium phosphate deposits in tissues of lungs, kidneys, and joints Symptoms of reduced Ca^{2+} related to formation of deposits

result in calcium phosphate deposits in the joints and other tissues, such as the lungs and kidneys. A below-normal blood level of phosphate is called **hypophosphatemia** (hī'pō-fos-fā-tē'mē-ă), and an above-normal blood level of phosphate is called **hyperphosphatemia** (hī'per-fos-fā-tē'mē-ă). The consequences of increased and reduced plasma levels of phosphates are presented in table 27.10.

ASSESS YOUR PROGRESS

- Where is most of the phosphate in the body located? What is the most common phosphate ion?
- Explain how the kidneys control plasma levels of phosphate ions.
- How does an increased level of PTH affect tubular phosphate reabsorption?
- What are the consequences of prolonged elevation of blood phosphate ions?

27.5 Regulation of Acid-Base Balance

LEARNING OUTCOMES

After reading this section, you should be able to

- Demonstrate an understanding of acids and bases and their relationship with buffers.
- Explain the actions of the three buffer systems of the body.
- Describe the mechanisms of acid-base balance.
- Explain the causes and effects of acid-base imbalances.

Hydrogen ions affect the activity of enzymes and interact with many electrically charged molecules. Consequently, most chemical reactions within the body are highly sensitive to the H^+ concentration of the fluid in which they occur. Maintaining the H^+ concentration within a narrow range of values is essential for normal metabolic reactions. The H^+ concentration is determined by acids and bases in the body. Recall from chapter 2 that the pH of a solution is a measure of H^+ concentration. However, the pH scale can be a little confusing because the relationship between the pH level and H^+ concentration is an inverse one. The lower the pH level, the greater the H^+ concentration. Likewise, the higher the pH level, the lower the H^+ concentration (see figure 2.13).

Acids and Bases

Acids release H^+ into a solution; bases remove H^+ from a solution. Acids and bases are classified as either strong or weak. A **strong acid** completely dissociates into its separate ions; for example, hydrochloric acid dissociates into H^+ and Cl^- (figure 27.11). A **strong base** also completely dissociates into its separate ions. For example, NaOH dissociates into Na^+ and OH^- . The OH^- can then react with H^+ to form H_2O , thus removing H^+ from the solution.

Like a strong acid, a **weak acid** releases H^+ into a solution; however, it does not completely dissociate into its separate ions. The weak acid releases H^+ until equilibrium with the surrounding solution is reached, and then no more H^+ dissociates. Weak acids are common in living systems, and they play important roles in preventing large changes in body fluid pH. A **weak base**, such as NH_3^+ , reduces the concentration of H^+ ions in a solution by binding to free H^+ .

ASSESS YOUR PROGRESS

- Define acid and base. What is the relationship between pH and H^+ concentration?
- Describe weak acids. Why are weak acids important in living systems?

FIGURE 27.11 Comparison of Strong Acids and Bases with Weak Acids

Strong acids and bases completely dissociate when dissolved in water. Weak acids do not completely dissociate. Instead, weak acids partially dissociate, so that an equilibrium is established between the acid and the dissociated ions.

Mechanisms of Acid-Base Balance Regulation

There are three major mechanisms for regulation of H^+ concentration. These mechanisms are the following: (1) buffer systems, (2) the respiratory system, and (3) the kidneys. Buffers and other mechanisms of acid-base balance regulation work together to regulate acid-base balance (figure 27.12). Buffers almost instantaneously resist changes in the pH of body fluids, but the regulation of respiration and the function of the kidneys also play essential roles. The respiratory system responds within a few minutes to bring the pH of body fluids back toward its normal range. Still, the respiratory system's capacity to regulate pH is not as great as that of the kidneys, nor does the respiratory system have the same ability to return the pH to its precise range of normal values. In contrast, the kidneys respond more slowly, within hours to days, to alterations of body fluid pH, and their capacity to respond is substantial.

Buffer Systems

Buffers (büf'ertz; see chapter 2) prevent extreme changes in the pH of a solution. Buffers within body fluids stabilize the pH by binding to excess H^+ or by releasing H^+ .

Three important buffer systems function together to prevent major changes in the pH of body fluids: the carbonic acid/bicarbonate buffer system; the protein buffer system, such as hemoglobin and plasma proteins; and the phosphate buffer system (table 27.11).

Carbonic Acid/Bicarbonate Buffer System

Carbonic acid (H_2CO_3) is a weak acid formed when CO_2 and water mix. When it is dissolved in water, the following equilibrium is established:

The carbonic acid/bicarbonate buffer system depends on the equilibrium that is quickly established between H_2CO_3 and H^+/HCO_3^- . When H^+ is added to this solution, a large proportion of the H^+ binds to HCO_3^- to form H_2CO_3 , and only a small percentage remains as free H^+ . Thus, the carbonic acid/bicarbonate buffer system resists a large decrease in pH when acidic substances are added to a solution containing H_2CO_3 .

When H^+ is removed from a solution containing H_2CO_3 , much of the H_2CO_3 forms HCO_3^- and H^+ . Thus, a large increase in pH is resisted when basic substances are added to a solution containing H_2CO_3 .

The carbonic acid/bicarbonate buffer system plays an important role in regulating the *extracellular* pH. It quickly responds to the addition of substances such as CO_2 or lactate produced by increased metabolism during exercise (see chapter 23) and to increased fatty acid and ketone body production during periods of elevated lipid metabolism (see chapter 25). It also responds to the addition of basic substances, such as large amounts of $NaHCO_3$ consumed as an antacid. The carbonic acid/bicarbonate buffer system has a limited capacity to resist changes in pH, but it plays an essential role in the control of pH by both the respiratory system and the kidneys.

Protein Buffer System

The high concentration of intracellular proteins and plasma proteins forms a large pool of buffer molecules; they provide approximately three-fourths of the body's buffer capacity. Hemoglobin in red blood cells is one of the most important intracellular proteins. Other intracellular molecules associated with nucleic acids, such as histone proteins, also act as buffers. The capacity of proteins to function as buffers is due to the functional groups of amino acids, such as carboxyl ($-COOH$) or amino ($-NH_2$) groups, which can act as weak acids and bases. Consequently, as the H^+ concentration increases, more H^+ binds to the functional groups; when the H^+ concentration decreases, H^+ is released from the functional groups (table 27.11).

Phosphate Buffer System

The phosphate buffer system is an important *intracellular* buffer system. Phosphate-containing molecules in solution, such as DNA, RNA, ATP, and phosphate ions, act as buffers. When the pH decreases, ions, such as HPO_4^- , bind H^+ to form $H_2PO_4^-$; however, when the pH becomes more basic, $H_2PO_4^-$ releases H^+ into solution. In this way, these two ions fluctuate between gaining and losing H^+ ions, which helps balance the pH (table 27.11).

ASSESS YOUR PROGRESS

38. What are the three major mechanisms that regulate H^+ concentration?
39. Compare the capacity and rate at which the respiratory system and kidneys control body fluid pH.
40. Define buffer. Describe how a buffer works when H^+ is added to a solution or when it is removed from a solution.
41. Name the three buffer systems of the body. Which of these systems provides the largest proportion of buffer capacity?

TABLE 27.11

Characteristics of Buffer Systems

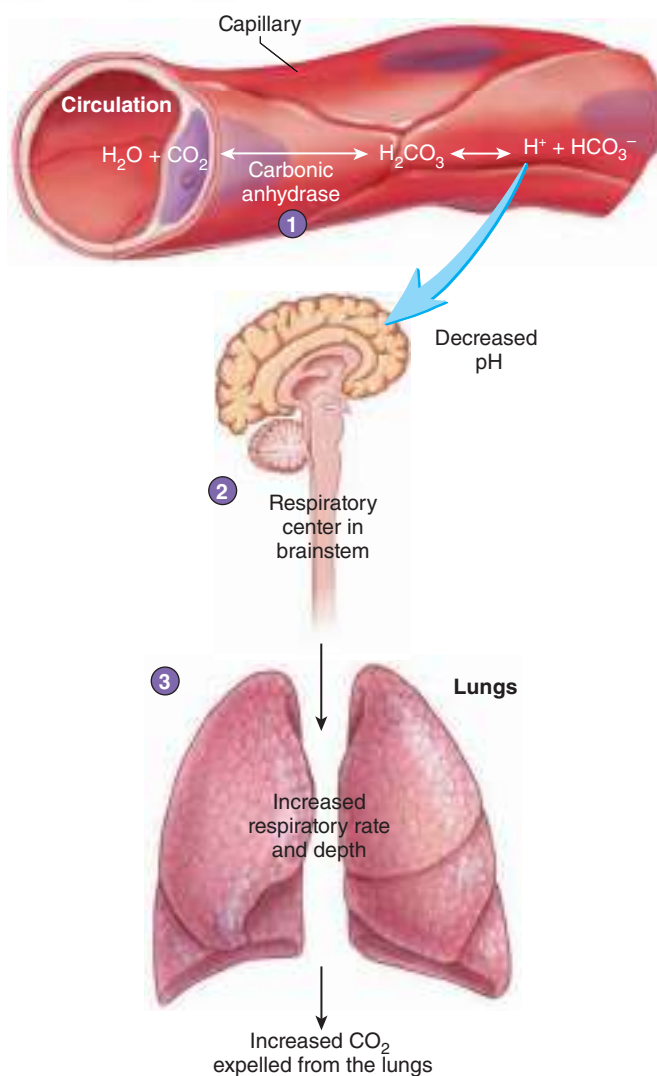

Carbonic acid/bicarbonate buffer system	Components of the carbonic acid/bicarbonate buffer system are not present in high enough concentrations in the extracellular fluid to constitute a powerful buffer system. However, the concentrations of the components of the buffer system are regulated. Therefore, it plays an exceptionally important role in controlling the pH of extracellular fluid.
Protein buffer system	Intracellular proteins and plasma proteins form a large pool of protein molecules that can act as buffer molecules. Because of their high concentration, they provide approximately three-fourths of the body's buffer capacity. Hemoglobin in red blood cells is an important intracellular protein. Other intracellular molecules, such as histone proteins and nucleic acids, also act as buffers.
Phosphate buffer system	Components of the phosphate buffer system are low in the extracellular fluids, compared with the other buffer systems, but it is an important intracellular buffer system.

HOMEOSTASIS FIGURE 27.12 Summary of Acid-Base Balance Regulation

(1) Blood pH is in the normal range. (2) Blood pH increases outside the normal range, which causes homeostasis to be disturbed. (3) The blood pH control centers respond to the change in blood pH. (4) The control centers cause decreased H^+ secretion from the blood and increased carbonic acid production, which increases blood H^+ concentration. (5) These changes cause blood pH to decrease. (6) Blood pH returns to the normal range and homeostasis is restored. Observe the responses to a decrease in blood pH outside the normal range by following the *red arrows*.

- 1 Carbon dioxide reacts with H₂O to form H₂CO₃. An enzyme, carbonic anhydrase, found in red blood cells and on the surface of blood vessel epithelium, catalyzes the reaction. Carbonic acid dissociates to form H⁺ and HCO₃⁻. An equilibrium is quickly established.
- 2 Decreased pH in the extracellular fluid stimulates the respiratory center and causes an increased rate and depth of breathing.
- 3 Increased rate and depth of breathing cause CO₂ to be expelled from the lungs, thus reducing the extracellular CO₂ levels. As CO₂ levels decrease, the extracellular concentration of H⁺ decreases, and the extracellular fluid pH increases.

PROCESS FIGURE 27.13 Respiratory Regulation of Body Fluid Acid-Base Balance

Respiratory Regulation of Acid-Base Balance

The respiratory system regulates acid-base balance through the carbonic acid/bicarbonate buffer system. Carbon dioxide (CO₂) reacts with water (H₂O) to form carbonic acid (H₂CO₃), which dissociates to form H⁺ and HCO₃⁻ as follows:

This reaction is in equilibrium. As CO₂ increases, CO₂ combines with H₂O. The higher the concentration of CO₂, the greater the amount of H₂CO₃ formed. Many H₂CO₃ molecules then dissociate to form H⁺ and HCO₃⁻. However, if CO₂ levels decline, the equilibrium shifts in the opposite direction, so that many H⁺ and HCO₃⁻ ions combine to form H₂CO₃, which then forms CO₂ and H₂O. Thus, both H⁺ and HCO₃⁻ decrease in the solution.

The reaction between CO₂ and H₂O is catalyzed by the enzyme **carbonic anhydrase**, which is found in a relatively high concentration in red blood cells and on the surface of capillary epithelial cells (figure 27.13; see chapter 23). This enzyme does not influence

equilibrium but accelerates the rate at which the reaction proceeds in either direction, so that equilibrium is achieved quickly.

Decreases in body fluid pH, regardless of the cause, stimulate neurons in the respiratory center in the brainstem to increase the rate and depth of ventilation. The increased rate and depth of ventilation cause CO₂ to be eliminated from the body through the lungs at a greater rate, and the concentration of CO₂ in the body fluids decreases. As CO₂ levels decline, the carbonic acid/bicarbonate buffer system reacts. Hydrogen ions react with HCO₃⁻ to form H₂CO₃, which then forms CO₂ and H₂O. Consequently, the concentration of H⁺ decreases toward its normal range as CO₂ exits through the respiratory system (figure 27.13).

Increases in body fluid pH, regardless of the cause, inhibit neurons in the respiratory center in the brainstem to decrease the rate and depth of ventilation. The decreased rate and depth of ventilation cause less CO₂ to be eliminated from the body through the lungs. The concentration of CO₂ in the body fluids increases because CO₂ is continually produced as a by-product of metabolism in all tissues. Thus, the body fluid concentration of H₂CO₃

- 1 When the filtrate or blood pH decreases, H^+ combines with HCO_3^- to form carbonic acid that is converted into CO_2 and H_2O . The CO_2 diffuses into tubule cells.
- 2 In the tubule cells, CO_2 combines with H_2O to form H_2CO_3 that dissociates to form H^+ and HCO_3^- .
- 3 An antiport mechanism secretes H^+ into the filtrate in exchange for Na^+ from the filtrate. As a result, filtrate pH decreases.
- 4 Bicarbonate ions are symported with Na^+ into the interstitial fluid. The HCO_3^- then diffuses into capillaries.
- 5 In capillaries, HCO_3^- combines with H^+ . This decreases the H^+ concentration and increases blood pH.

PROCESS FIGURE 27.14 Kidney Regulation of Body Fluid Acid-Base Balance

As the extracellular pH decreases, the rate of H^+ secretion by the renal tubule cells and HCO_3^- reabsorption increase.

increases also. As H_2CO_3 increases, many H_2CO_3 molecules dissociate to form H^+ and HCO_3^- . This results in an elevated H^+ concentration, and the pH decreases toward its normal range.

Predict 3

Under stressful conditions, some people hyperventilate. What effect does the rapid rate of ventilation have on blood pH? Explain why breathing into a paper bag helps a hyperventilating person.

Renal Regulation of Acid-Base Balance

Cells of the kidney tubules can directly regulate acid-base balance by changing both the rate of H^+ secretion into the filtrate and the rate of HCO_3^- reabsorption (figure 27.14). Carbonic anhydrase within tubule cells catalyzes the formation of H_2CO_3 from CO_2 and H_2O . The carbonic acid molecules dissociate to form H^+ and HCO_3^- . An antiport system then exchanges H^+ for Na^+ across the apical membrane of the cells. Thus, tubule cells secrete H^+ into the filtrate and reabsorb Na^+ . The Na^+ and HCO_3^- are symported across the basal membrane. After the Na^+ and HCO_3^- are symported from the tubule cells, they diffuse into the peritubular capillaries. As a result, H^+ is secreted into the lumens of the tubules, and HCO_3^- passes into the extracellular fluid.

The reabsorbed HCO_3^- combines with excess H^+ in the extracellular fluid to form H_2CO_3 . This combination removes H^+ from the extracellular fluid and increases extracellular pH. The rate of H^+ secretion and HCO_3^- reabsorption increases when the pH of the body fluids decreases, and this process slows when the pH of the body fluids increases (figure 27.14).

Some of the H^+ secreted by cells of the tubules into the filtrate combines with HCO_3^- , which enters the filtrate through the filtration membrane in the form of sodium bicarbonate ($NaHCO_3$).

Within the tubules, H^+ combines with HCO_3^- to form H_2CO_3 , which then dissociates to form CO_2 and H_2O . The CO_2 diffuses from the filtrate into the tubule cells, where it can react with H_2O to form H_2CO_3 , which subsequently dissociates to form H^+ and HCO_3^- (figure 27.15). Once again, H^+ is antiported into the lumens of the kidney tubules in exchange for Na^+ , whereas HCO_3^- enters the extracellular fluid. As a result, much of the HCO_3^- entering the filtrate reenters the extracellular fluid.

Hydrogen ions secreted into the tubule normally exceed the amount of HCO_3^- that enters the tubules through the filtration membrane. Because the H^+ combines with HCO_3^- , almost all the HCO_3^- is reabsorbed from the tubules (figure 27.15). Little HCO_3^- is excreted in the urine unless the pH of the body fluids becomes elevated.

The rate of H^+ secretion into the filtrate and the rate of HCO_3^- reabsorption into the extracellular fluid decrease if the pH of the body fluids increases. As a result, the amount of bicarbonate filtered into the tubules exceeds the amount of secreted H^+ , and the excess HCO_3^- passes into the urine. The excretion of excess HCO_3^- in the urine diminishes the amount of HCO_3^- in the extracellular fluid. This allows the amount of extracellular H^+ to increase; as a consequence, the pH of the body fluids decreases toward its normal range.

Although the tubule cells respond directly to H^+ , the hormone aldosterone can also alter the H^+ permeability of the tubules. Aldosterone increases the rate of Na^+ reabsorption and K^+ secretion by the kidneys, but in high concentrations aldosterone also stimulates H^+ secretion. Elevated aldosterone levels, such as those occurring in patients with Cushing syndrome, can therefore elevate body fluid pH above normal (alkalosis). However, the major influence on the rate of H^+ secretion is the pH of the body fluids.

Predict 4

Predict the effect of aldosterone hyopsecretion on body fluid pH.

The secretion of H^+ into the nephron can decrease the filtrate pH to approximately 4.5. A filtrate pH below 4.5 inhibits the secretion of additional H^+ . The H^+ that passes into the filtrate is more than the amount required to decrease the pH of an unbuffered solution below 4.5. Buffers in the filtrate combine with many of the secreted H^+ . The buffers in the filtrate include HCO_3^- , phosphate ions (HPO_4^{2-}), and **ammonia** (NH_3). HCO_3^- and HPO_4^{2-} enter the filtrate through the filtration membrane, and NH_3 diffuses across the wall of tubule cells into the filtrate. These ions combine with H^+ secreted by the renal tubule, lowering its concentration (figure 27.15).

NH_3 is produced in renal tubule cells when amino acids, such as glutamine, are deaminated. Subsequently, NH_3 diffuses from the tubule cells into the filtrate and combines with H^+ in the filtrate to form **ammonium ions** (NH_4^+ ; see figure 27.15). The rate of NH_3 production increases when the pH of the body fluids has been depressed for 2–3 days, as occurs during prolonged respiratory or metabolic acidosis. The elevated ammonia production increases the buffering capacity of the filtrate, allowing the secretion of additional H^+ into the urine.

HCO_3^- , HPO_4^{2-} , and NH_3 constitute major buffers within the filtrate, but other weak acids, such as lactate in the filtrate, also combine with H^+ and increase the amount of H^+ that can be secreted into the filtrate.

ASSESS YOUR PROGRESS

42. What happens to blood pH when blood CO_2 levels go up or down? What causes this change?
43. What effect do increased CO_2 levels or decreased pH have on ventilation? How does this change in breathing affect blood pH?
44. Describe the process by which tubule cells move H^+ into the tubule lumen and HCO_3^- into the extracellular fluid.

45. Name the factors that cause an increase and a decrease in H^+ secretion.
46. What is the purpose of buffers in the urine? Describe how the ammonia buffer system operates.
47. What is acidosis? What are the two types, and what causes each? How does the body compensate for each of the changes?
48. What is alkalosis? What are the two types, and what causes each? How does the body compensate for each of the changes?

Acidosis and Alkalosis

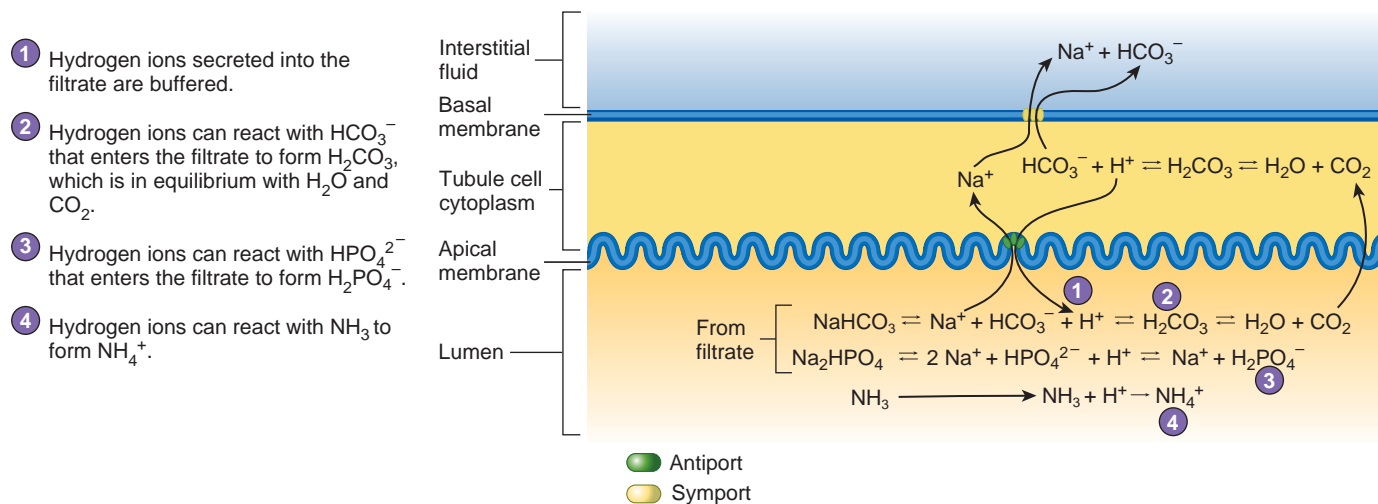

The normal pH of the body fluids is between 7.35 and 7.45. **Acidosis** (as-i-dō'sis) results when the pH falls below 7.35; **alkalosis** (al'kă-lō'sis) occurs when the pH rises above 7.45.

Metabolism produces acidic products that lower the pH of the body fluids. For example, CO_2 is a by-product of metabolism that combines with water to form H_2CO_3 . Likewise, anaerobic respiration produces lactate, protein metabolism produces phosphoric and sulfuric acids, and lipid metabolism produces fatty acids. These acidic substances must continuously be eliminated from the body to maintain homeostatic pH. Failure to eliminate the acidic products of metabolism results in acidosis. Excess elimination of the acidic products of metabolism results in alkalosis.

The major effect of acidosis is depression of the central nervous system. When blood pH falls below 7.35, the central nervous system malfunctions. The individual becomes disoriented, and possibly comatose as the condition worsens.

A major effect of alkalosis is hyperexcitability of the nervous system. Peripheral nerves are affected first, resulting in spontaneous nervous stimulation of muscles. Spasms, tetanic contractions, and possibly extreme nervousness or convulsions result. Severe alkalosis can cause death as a result of tetany of the respiratory muscles.

Although buffers help resist changes in the pH of body fluids, the respiratory system and the kidneys regulate the pH of the body

PROCESS FIGURE 27.15 Hydrogen Ion Buffering in the Filtrate

The secretion of H^+ into the filtrate decreases filtrate pH. As the concentration of H^+ increases in the filtrate, the ability of tubule cells to secrete additional H^+ becomes limited. Buffering the H^+ in the filtrate decreases its concentration and enables tubule cells to secrete additional H^+ .

fluids. Therefore, malfunctions in either the respiratory system or the kidneys can result in acidosis or alkalosis.

Acidosis and alkalosis are categorized according to the cause of the condition. **Respiratory acidosis** and **alkalosis** result from abnormalities in the respiratory system. **Metabolic acidosis** and **alkalosis** result from all causes other than abnormal respiratory functions.

Inadequate ventilation causes respiratory acidosis because CO_2 is retained in the body rather than being eliminated (table 27.12). This increases the concentration of CO_2 in the body fluids. As CO_2 levels increase, CO_2 reacts with water to form H_2CO_3 . Carbonic acid forms H^+ and HCO_3^- . The increase in H^+ concentration causes the pH of the body fluids to decrease. If the pH falls below 7.35, the symptoms of respiratory acidosis appear.

Buffers help resist a decrease in pH, and the kidneys help compensate for the failure of the lungs to prevent respiratory acidosis by increasing the rate at which they secrete H^+ into the filtrate and reabsorb HCO_3^- . However, the capacity of buffers to resist changes in pH can be exceeded, and a period of 1–2 days is required for the kidneys to become maximally functional. Thus, the kidneys are not effective if respiratory acidosis develops quickly. On the other hand, the kidneys are very effective if respiratory acidosis develops slowly, or if it lasts long enough for the kidneys to respond. For example, the kidneys cannot compensate for respiratory acidosis occurring in response to a severe asthma attack that begins quickly and subsides within hours. If, however, respiratory acidosis results from emphysema, which develops over a long time, the kidneys play a significant role in helping compensate.

Respiratory alkalosis results from hyperventilation, which eliminates greater-than-normal CO_2 from the body, resulting in a decreased CO_2 concentration in the body fluids (table 27.12). As CO_2 levels decrease, H^+ reacts with HCO_3^- to form H_2CO_3 . The H_2CO_3 forms H_2O and CO_2 . The resulting decrease in the concentration of H^+ causes the pH of the body fluids to increase. If the pH increases above 7.45, the symptoms of respiratory alkalosis appear.

The kidneys help compensate for respiratory alkalosis by decreasing the rate of H^+ secretion into the filtrate and the rate of HCO_3^- reabsorption. If pH increases, the kidneys need 1–2 days to compensate. Thus, the kidneys are not effective if respiratory alkalosis develops quickly. However, they are very effective if respiratory alkalosis develops slowly. For example, the kidneys are not effective in compensating for respiratory alkalosis that occurs in response to hyperventilation triggered by emotions, which usually begins quickly and subsides within minutes or hours. However, if alkalosis results from staying at a high altitude over a 2- or 3-day period, the kidneys play a significant role in helping compensate.

Metabolic acidosis results from all conditions that decrease the pH of the body fluids below 7.35, except for certain respiratory system conditions (table 27.12). As H^+ accumulates in the body fluids, buffers first resist a decline in pH. If the buffers cannot compensate for the increase in H^+ , the respiratory center helps regulate body fluid pH. The reduced pH stimulates the respiratory center, which causes hyperventilation. During hyperventilation, CO_2 is eliminated at a greater rate. The elimination of CO_2 also eliminates excess H^+ and helps maintain the pH of the body fluids within a normal range.

If metabolic acidosis persists for many hours and if the kidneys are functional, the kidneys can also help compensate for metabolic acidosis by secreting H^+ at a greater rate and increasing the rate of HCO_3^- reabsorption. The symptoms of metabolic acidosis appear if the respiratory and renal systems are not able to maintain the pH of the body fluids within its normal range.

Metabolic alkalosis results from all conditions that increase the pH of the body fluids above 7.45, with the exception of those resulting from altered function of the respiratory system. As H^+ decreases in the body fluids, buffers first resist an increase in pH. If the buffers cannot compensate for the decrease in H^+ , the respiratory center helps regulate body fluid pH. The increased pH inhibits respiration. Reduced respiration allows CO_2 to accumulate in the body fluids. Carbon dioxide reacts with water to produce H_2CO_3 . If metabolic alkalosis persists for several hours and if the kidneys are functional, the kidneys reduce the rate of H^+ secretion to help reverse alkalosis (table 27.12).

TABLE 27.12 Acidosis and Alkalosis

Acidosis

Respiratory Acidosis

Reduced elimination of CO_2 from the body fluids

Asphyxia

Hypoventilation (e.g., impaired respiratory center function due to trauma, tumor, shock, or renal failure)

Advanced asthma

Severe emphysema

Metabolic Acidosis

Elimination of large amounts of HCO_3^- resulting from mucous secretion (e.g., severe diarrhea and vomiting of lower intestinal contents)

Direct reduction of body fluid pH as acid is absorbed (e.g., ingestion of acidic drugs, such as aspirin)

Production of large amounts of fatty acids and other acidic metabolites, such as ketone bodies (e.g., untreated diabetes mellitus)

Inadequate O_2 delivery to tissue, resulting in anaerobic respiration (e.g., exercise, heart failure, or shock)

Alkalosis

Respiratory Alkalosis

Reduced CO_2 levels in the extracellular fluid (e.g., hyperventilation due to emotions)

Decreased atmospheric pressure, causing reduced O_2 levels, which stimulate the chemoreceptor reflex (e.g., cause hyperventilation at high altitudes)

Metabolic Alkalosis

Elimination of H^+ and reabsorption of HCO_3^- in the stomach or kidneys (e.g., severe vomiting or formation of acidic urine in response to excess aldosterone)

Ingestion of alkaline substances (e.g., large amounts of sodium bicarbonate)

Case STUDY

Gastroenteritis

After work on a Friday night, Dan and some friends had a late dinner at a fast-food restaurant. Shortly afterward, Dan began feeling ill, so he went to his dorm room. By midnight, he was very nauseated and vomited repeatedly over the next several hours. The next morning, he was still vomiting at least once each hour, so he went to the student health center. At that point, it was about 12 hours since he had begun feeling nauseated. Each time he vomited, a significant volume of acidic gastric fluid was expelled. A physician examined him and ordered blood tests. The physician then diagnosed gastroenteritis caused by an unknown microorganism and prescribed medication for the infection. The next day, about 36 hours after Dan had begun to feel nauseated, he was reexamined.

Dan began to feel better by the end of the second day (about 48 hours after the nausea had begun). By 72 hours, he felt fairly normal again. After the nauseous feeling disappeared, Dan was very thirsty, and he drank a substantial

TABLE 27A

	12 Hours	36 Hours	Normal
Body Weight	71 kg	68 kg	Not known
Blood Pressure	115/75 mm Hg	90/60 mm Hg	120/80 mm Hg
Heart Rate	77 beats/min	105 beats/min	72 beats/min
Plasma pH	7.48	7.5	7.35 to 7.45
Plasma HCO₃⁻	32 mEq/L	36 mEq/L	22 to 28 mEq/L
Plasma Pco₂	44 mm Hg	48 mm Hg	35 to 43 mm Hg
Skin Color	Pallor	Pallor	

amount of water and juice over several hours. Table 27A shows the results of Dan's physical examinations and blood analyses 12 hours and 36 hours after his illness began and compares them with normal values. After studying this table, explain the meaning of the various changes, as suggested in Predict 5.

► Predict 5

- Explain the changes in weight, blood pressure, heart rate, and skin color that Dan experienced between 12 and 36 hours.
- Explain the changes in plasma pH and plasma HCO₃⁻ between 12 and 36 hours.
- Explain the plasma PCO₂ at 12 and 36 hours.
- Explain why all the parameters had returned to normal by 72 hours.

Learn to Predict ◀ From page 1001

Satish and Kiran suffered from dehydration due to lack of water intake and increased water loss. In this chapter we learned that water is normally lost through urine, sensible and insensible perspiration, respiratory passages, and feces. The students' rate of water loss due to perspiration and through the respiratory passages increased dramatically in the hot, dry environment. As water loss continued, blood volume decreased, and plasma osmolality increased. The decrease in blood volume caused their renal arteries to constrict, reducing renal blood flow and the glomerular filtration rate; stimulated the renin-angiotensin-aldosterone hormone mechanism, increasing Na⁺ reabsorption; and increased ADH secretion, reducing water loss in the urine. Their increased plasma osmolality also increased ADH secretion. ADH and aldosterone together maximize the kidneys' ability to conserve water; thus, their urine was very concentrated and its

volume was small. However, Satish and Kiran continued to lose water by evaporation of perspiration and from the respiratory passages. Their blood osmolality continued to increase and plasma volume continued to decrease. As the plasma volume decreased, Satish and Kiran's hematocrit increased. Consequently, their blood became more viscous, and their hearts had to work harder to pump blood. We also learned in this chapter that increased plasma osmolality causes water to move from cells into the interstitial spaces and into the plasma. As a result, cells became dehydrated and malfunctioned. Satish and Kiran almost died because of the increased workload on their hearts and the decreased ability of their nerve and muscle cells to function.

Answers to the rest of this chapter's Predict questions are in appendix G.

Answer

Summary

27.1 Body Fluids (p. 1002)

1. Intracellular fluid is inside cells.
2. Extracellular fluid is outside cells and includes interstitial fluid and plasma.

27.2 Regulation of Body Fluid Concentration and Volume (p. 1003)

Regulation of Water Content

1. Water crosses the wall of the digestive tract through osmosis.
2. An increase in extracellular osmolality or a decrease in blood pressure stimulates the sense of thirst.
3. Wetting of the oral mucosa or stretch of the digestive tract inhibits thirst.
4. Learned behavior plays a role in the amount of fluid ingested.
5. Water leaves the body by the following routes:
 - Through evaporation from the respiratory system and the skin (insensible perspiration and sweat)
 - Through the digestive tract (this amount is normally small, but vomiting or diarrhea can significantly increase it)
 - Through the kidneys, the primary regulator of water excretion; urine output can vary from a small amount of concentrated urine to a large amount of dilute urine

Regulation of Extracellular Fluid Osmolality

1. Increased water consumption and ADH secretion occur in response to increases in extracellular fluid osmolality. Decreased water consumption and ADH secretion occur in response to decreases in extracellular fluid osmolality.
2. Increased water consumption and ADH decrease extracellular fluid osmolality by increasing water absorption from the intestines and water reabsorption from the renal tubules. Decreased water consumption and ADH increase extracellular fluid osmolality by decreasing absorption from the intestines and water reabsorption from the renal tubules.

Regulation of Extracellular Fluid Volume

1. Increased extracellular fluid volume results in decreased aldosterone secretion, increased ANH secretion, decreased ADH secretion, and decreased sympathetic stimulation of afferent arterioles. These changes decrease Na^+ reabsorption and increase urine volume so as to decrease extracellular fluid volume.
2. Decreased extracellular fluid volume results in increased aldosterone secretion, decreased ANH secretion, increased ADH secretion, and increased sympathetic stimulation of the afferent arterioles. These changes increase Na^+ reabsorption and decrease urine volume so as to increase extracellular fluid volume.

27.3 Regulation of Intracellular Fluid Composition (p. 1009)

1. Substances used or produced inside the cell and substances exchanged with the extracellular fluid determine the composition of intracellular fluid.
2. Intracellular fluid is different from extracellular fluid because the plasma membrane regulates the movement of materials.
3. The difference between intracellular and extracellular fluid concentrations determines water movement.

27.4 Regulation of Specific Electrolytes in the Extracellular Fluid (p. 1010)

The intake and elimination of substances from the body and the exchange of substances between the extracellular and intracellular fluids determine extracellular fluid composition.

Regulation of Sodium Ions

1. Sodium is responsible for 90–95% of extracellular osmotic pressure.
2. The amount of Na^+ excreted in the kidneys is the difference between the amount of Na^+ that enters the renal tubule and the amount that is reabsorbed from the renal tubule.
 - The glomerular filtration rate determines the amount of Na^+ entering the renal tubule.
 - Aldosterone determines the amount of Na^+ reabsorbed.
3. Small quantities of Na^+ are excreted in sweat.
4. Increased blood osmolality leads to the production of a small volume of concentrated urine and to thirst. Decreased blood osmolality leads to the production of a large volume of dilute urine and to decreased thirst.
5. Increased blood pressure increases water and salt loss.
 - Elevated extracellular fluid volume reduces ADH secretion.
 - Renin secretion is inhibited, leading to reduced aldosterone production.

Regulation of Chloride Ions

Chloride ions are the dominant negatively charged ions in extracellular fluid.

Regulation of Potassium Ions

1. The extracellular concentration of K^+ affects resting membrane potentials.
2. The amount of K^+ excreted depends on the amount that enters with the glomerular filtrate, the amount actively reabsorbed by the renal tubule, and the amount secreted into the distal convoluted tubule.
3. Aldosterone increases the amount of K^+ secreted.

Regulation of Calcium Ions

1. Elevated extracellular Ca^{2+} levels prevent membrane depolarization. Decreased levels lead to spontaneous action potential generation.
2. PTH increases extracellular Ca^{2+} levels and decreases extracellular phosphate levels. It stimulates osteoclast activity, increases Ca^{2+} reabsorption from the kidneys, and stimulates active vitamin D production.
3. Vitamin D stimulates Ca^{2+} uptake in the intestines.
4. Calcitonin decreases extracellular Ca^{2+} levels.

Regulation of Magnesium Ions

The kidneys' capacity to reabsorb Mg^{2+} is limited, so excess Mg^{2+} is excreted in the urine, and decreased extracellular Mg^{2+} leads to increased Mg^{2+} reabsorption.

Regulation of Phosphate Ions

1. Under normal conditions, reabsorption of phosphate occurs at a maximum rate in the renal tubule.
2. An increase in plasma phosphate increases the amount of phosphate in the renal tubule beyond that which can be reabsorbed, and the excess is excreted in the urine.

27.5 Regulation of Acid-Base Balance (p. 1018)

Acids and Bases

Acids release H^+ into solution, and bases remove it.

Mechanisms of Acid-Base Balance Regulation

Buffers, the respiratory system, and the kidneys regulate acid-base balance.

Buffer Systems

1. A buffer resists changes in pH.
 - When H^+ is added to a solution, the buffer removes it.
 - When H^+ is removed from a solution, the buffer replaces it.
2. Three important buffers are carbonic acid/bicarbonate, proteins, and phosphate compounds.

Respiratory Regulation of Acid-Base Balance

Respiratory regulation of pH is achieved through the carbonic acid/bicarbonate buffer system.

1. As CO_2 levels increase, pH decreases.
2. As CO_2 levels decrease, pH increases.
3. Carbon dioxide levels and pH affect the respiratory centers. Hypoventilation increases blood CO_2 levels, and hyperventilation decreases blood CO_2 levels.

Renal Regulation of Acid-Base Balance

1. The secretion of H^+ into the filtrate and the reabsorption of HCO_3^- into extracellular fluid cause extracellular pH to increase.
 - Carbonic acid dissociates to form H^+ and HCO_3^- in tubule cells.
 - An antiport mechanism moves H^+ into the tubule lumen and Na^+ into the tubule cell.
 - Sodium ions and HCO_3^- diffuse into the extracellular fluid.
2. Bicarbonate ions in the filtrate are reabsorbed.
 - Bicarbonate ions combine with H^+ to form carbonic acid, which dissociates to form CO_2 and water.
 - Carbon dioxide diffuses into tubule cells and forms carbonic acid, which dissociates to form HCO_3^- and H^+ .
 - Bicarbonate ions diffuse into the extracellular fluid, and H^+ is secreted into the filtrate.
3. The rate of H^+ secretion increases as body fluid pH decreases or as aldosterone levels increase.
4. Secretion of H^+ is inhibited when urine pH falls below 4.5.
 - Ammonia and phosphate buffers in the urine resist a drop in pH.
 - As the buffers absorb H^+ , more H^+ is pumped into the urine.

Acidosis and Alkalosis

Acidosis occurs if pH falls below 7.35 and alkalosis occurs if pH rises above 7.45.

1. Acidosis results in insensitivity of the CNS.
2. Alkalosis results in overexcitability of the CNS.

REVIEW AND COMPREHENSION

1. The sensation of thirst increases when
 - a. the levels of angiotensin II increase.
 - b. the osmolality of the blood decreases.
 - c. blood pressure increases.
 - d. renin secretion decreases.
2. Insensible perspiration
 - a. is lost through sweat glands.
 - b. results in heat loss from the body.
 - c. increases when ADH secretion increases.
 - d. results in the loss of solutes, such as Na^+ and Cl^- .
3. The composition and volume of body fluids are regulated primarily by the
 - a. skin.
 - b. lungs.
 - c. kidneys.
 - d. heart.
 - e. spleen.
4. Which of these conditions *decreases* extracellular fluid volume?
 - a. constriction of afferent arterioles
 - b. increased ADH secretion
 - c. decreased ANH secretion
 - d. decreased aldosterone secretion
 - e. stimulation of sympathetic nerves to the kidneys
5. Which of these results in an increased blood Na^+ concentration?
 - a. decrease in ADH secretion
 - b. decrease in aldosterone secretion
 - c. increase in ANH
 - d. decrease in renin secretion
6. Which of these mechanisms is the most important for regulating blood osmolality?
 - a. ADH
 - b. renin-angiotensin-aldosterone
 - c. ANH
 - d. PTH
7. A decrease in extracellular K^+
 - a. produces depolarization of the plasma membrane.
 - b. results when aldosterone levels increase.
 - c. occurs when tissues are damaged (e.g., in burn patients).
 - d. increases ANH secretion.
 - e. increases PTH secretion.
8. Calcium ion concentration in the blood decreases when
 - a. vitamin D levels are lower than normal.
 - b. calcitonin secretion decreases.
 - c. PTH secretion increases.
 - d. All of these are correct.
9. An acid
 - a. is a solution that has a pH greater than 7.
 - b. is a substance that releases H^+ into a solution.
 - c. is considered weak if it completely dissociates in water.
 - d. All of these are correct.
10. Buffers
 - a. release H^+ when pH increases.
 - b. resist changes in the pH of a solution.
 - c. include the proteins of the blood.
 - d. All of these are correct.
11. An increase in blood CO_2 levels is followed by a(n) _____ in H^+ and a(n) _____ in blood pH.
 - a. increase, increase
 - b. increase, decrease
 - c. decrease, increase
 - d. decrease, decrease

12. High levels of bicarbonate ions in the urine indicate
- a low level of H^+ secretion into the urine.
 - that the kidneys are causing blood pH to increase.
 - that urine pH is decreasing.
 - All of these are correct.
13. High levels of ammonium ions in the urine indicate
- a high level of H^+ secretion into the urine.
 - that the kidneys are causing blood pH to decrease.
 - that urine pH is too basic.
 - All of these are correct.
14. Blood plasma pH is normally
- slightly acidic.
 - strongly acidic.
 - slightly basic.
 - strongly basic.
 - neutral.
15. Acidosis
- increases neuron excitability.
 - can produce tetany by affecting the peripheral nervous system.
 - may lead to coma.
 - may produce convulsions through the central nervous system.
16. Respiratory alkalosis is caused by _____ and can be compensated for by the production of a more _____ urine.
- hypoventilation, basic
 - hyperventilation, acidic
 - hyperventilation, basic
 - hypoventilation, acidic

Answers in appendix E

CRITICAL THINKING

- In patients with diabetes mellitus, not enough insulin is produced; as a consequence, blood glucose levels increase. If blood glucose levels rise high enough, the kidneys are unable to absorb the glucose from the glomerular filtrate, and glucose “spills over” into the urine. What effect does this glucose have on urine concentration and volume? How does the body adjust to the excess glucose in the urine?
- A patient suffering from a tumor in the hypothalamus produces excessive amounts of ADH, a condition called syndrome of inappropriate ADH (SIADH) production. For this patient, the excessive ADH production is chronic and has persisted for many months. A student nurse keeps a fluid intake-output record on the patient. She is surprised to find that fluid intake and urinary output are normal. What effect was she expecting? Can you explain why urinary output is normal?
- Acetazolamide is a diuretic that blocks the activity of the enzyme carbonic anhydrase inside kidney tubule cells. This blockage prevents the formation of carbonic acid from CO_2 and water. Normally, carbonic acid dissociates to form H^+ and HCO_3^- , and the H^+ is exchanged for Na^+ from the urine. Blocking the formation of H^+ in the tubule cells blocks sodium reabsorption, thus inhibiting water reabsorption and producing the diuretic effect. With this information in mind, what effect does acetazolamide have on blood pH, urine pH, and respiratory rate?
- As part of a physiology experiment, an anatomy and physiology student is asked to breathe through a 3-foot-long glass tube. What effect does this action have on his blood pH, urine pH, and respiratory rate?
- Harry ate a late meal at a cheap diner on the way home from work. A couple of hours later, he vomited three times, and then he consumed several packages of an antacid (mostly $NaHCO_3$) over the next several hours. By the evening of the next day, he was feeling better. During this ordeal, his blood pH did not deviate significantly. Select the mechanism(s) that helped maintain Harry’s pH within a normal range.

Reproductive System

Do you know if it is a boy or a girl?” Expectant mothers answer this question continuously throughout their pregnancies. Gender is a common way that we classify people. Just think of all the times you have had to check a box for male or female while filling out a form. The reproductive system controls the development of the structural and functional differences between males and females, and it has profound effects on human behavior. Not only are male and female reproductive structures different, but they also influence structural and functional characteristics in other areas of the body, such as the integumentary, muscular, and skeletal systems.

Although the differences between the male and female reproductive systems are striking, these two systems also have numerous similarities. Many reproductive organs of males and females are derived from the same embryological structures (see chapter 29), and some of the same hormones function in both males and females, even though these hormones act in very different ways.

Learn to Predict

Chase and Christina were studying for their last anatomy and physiology exam of the semester. After reviewing his notes on meiosis, Chase said, “Well, since meiosis is the same in males and females, I don’t need to study the meiosis notes from the female reproductive system lecture.” Christina quickly pointed out that he was wrong and that if he reviewed his notes he would see that meiosis is very different in males and females. **With some information from previous chapters and after reading chapter 28, explain the major differences between meiosis in males and females.**

28.1 Functions of the Reproductive System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the functions of the reproductive system.
- B. Distinguish among the functions that occur in males, females, and both.

Reproduction is an essential characteristic of living organisms, and functional male and female reproductive systems are necessary for humans to reproduce. In addition, even in people who do not reproduce, the reproductive system plays important roles. The reproductive system performs the following functions:

1. *Production of gametes.* Specialized organs of the reproductive system produce gametes: sperm cells in males and oocytes (eggs) in females.
2. *Fertilization.* The reproductive system enables fertilization of the oocyte by the sperm. The duct system in males nourishes sperm cells until they are mature and are deposited in the female reproductive tract by the penis. The female reproductive system receives the sperm cells from the male and transports them to the fertilization site.
3. *Development and nourishment of a new individual.* The female reproductive system nurtures the developing fetus in the uterus until birth and provides nourishment (milk) after birth.
4. *Production of reproductive hormones.* Hormones produced by the reproductive system control its development and the development of the gender-specific body form (table 28.1). These hormones are also essential for the normal function of the reproductive system and for reproductive behavior.

ASSESS YOUR PROGRESS

1. What are the functions of the reproductive system?
2. What functions occur in both males and females, and what functions occur only in females?

28.2 Meiosis

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the process of meiosis, highlighting the change in chromosome number and structure after each division.
- B. Explain why meiosis is necessary in sexually reproducing organisms.
- C. Describe the different events in meiosis that result in genetic variation among gametes.

Meiosis (mī-ō'sis) is a type of cell division specialized for sexual reproduction. During meiosis, one cell undergoes two consecutive

divisions to produce four genetically different daughter cells. Each of these daughter cells contains half as many chromosomes as the parent cell (figure 28.1). In humans, meiosis occurs only in the testes and ovaries and produces sperm cells in males and oocytes in females.

In humans, the somatic cells normally have 46 chromosomes, called the **diploid** (dip'loyd) number ($2n$). Chromosomes exist in 23 **homologous** (hō-mol'ō-gūs) **pairs**—22 autosomal pairs and 1 pair of sex chromosomes. The sex chromosome pair is composed of an X and a Y chromosome in males and two X chromosomes in females. One chromosome of each homologous pair is inherited from the male parent, and the other chromosome of each pair is inherited from the female parent. The chromosomes of each homologous pair are alike in size and shape and contain genes for the same traits.

Sperm cells and oocytes contain the **haploid** (hap'loyd) number (n) of chromosomes, which is half the diploid number, or 23. Each gamete contains one chromosome from each of the homologous pairs. Reduction in the number of chromosomes in sperm cells or oocytes to an n number is important. When a sperm cell and an oocyte fuse to form a fertilized egg, each provides an n number of chromosomes, which reestablishes a $2n$ number. If meiosis did not take place, the number of chromosomes in the fertilized oocyte would double each time fertilization occurred, and the extra chromosomal material would be lethal to the developing offspring.

Upon fertilization, the sex of the baby is determined by the sperm cell. The baby is male if the oocyte is fertilized by a Y-carrying sperm cell or female if it is fertilized by an X-carrying sperm cell.

The two divisions of meiosis are called **meiosis I** and **meiosis II**. The stages of meiosis have the same names as the stages of mitosis—that is, prophase, metaphase, anaphase, and telophase—but distinct differences exist between mitosis and meiosis.

Before meiosis begins, all the chromosomes are duplicated. At the beginning of meiosis, each of the 46 chromosomes consists of two sister **chromatids** (krō'mă-tids) connected by a **centromere** (sen'trō-mēr; figure 28.1, *step 1*). In prophase I, the chromosomes become visible, and the homologous pairs come together in a process called **synapsis** (si-nap'sis). Because each chromosome consists of two chromatids, the pairing of the homologous chromosomes brings two chromatids of each chromosome close together, an arrangement called a **tetrad** (figure 28.1, *step 2*). Occasionally, part of a chromatid of one homologous chromosome breaks off and is exchanged with part of another chromatid from the other homologous chromosome. This exchange of genetic material between maternal and paternal chromosomes is called **crossing over** and may result in new gene combinations on the chromosomes.

During metaphase I, homologous pairs of chromosomes line up near the center of the cell (figure 28.1, *step 3*). For each homologous pair, however, the orientation of the maternal and paternal chromosomes is random. The way the chromosomes align during synapsis results in the random assortment of maternal and paternal chromosomes in the daughter cells during meiosis.

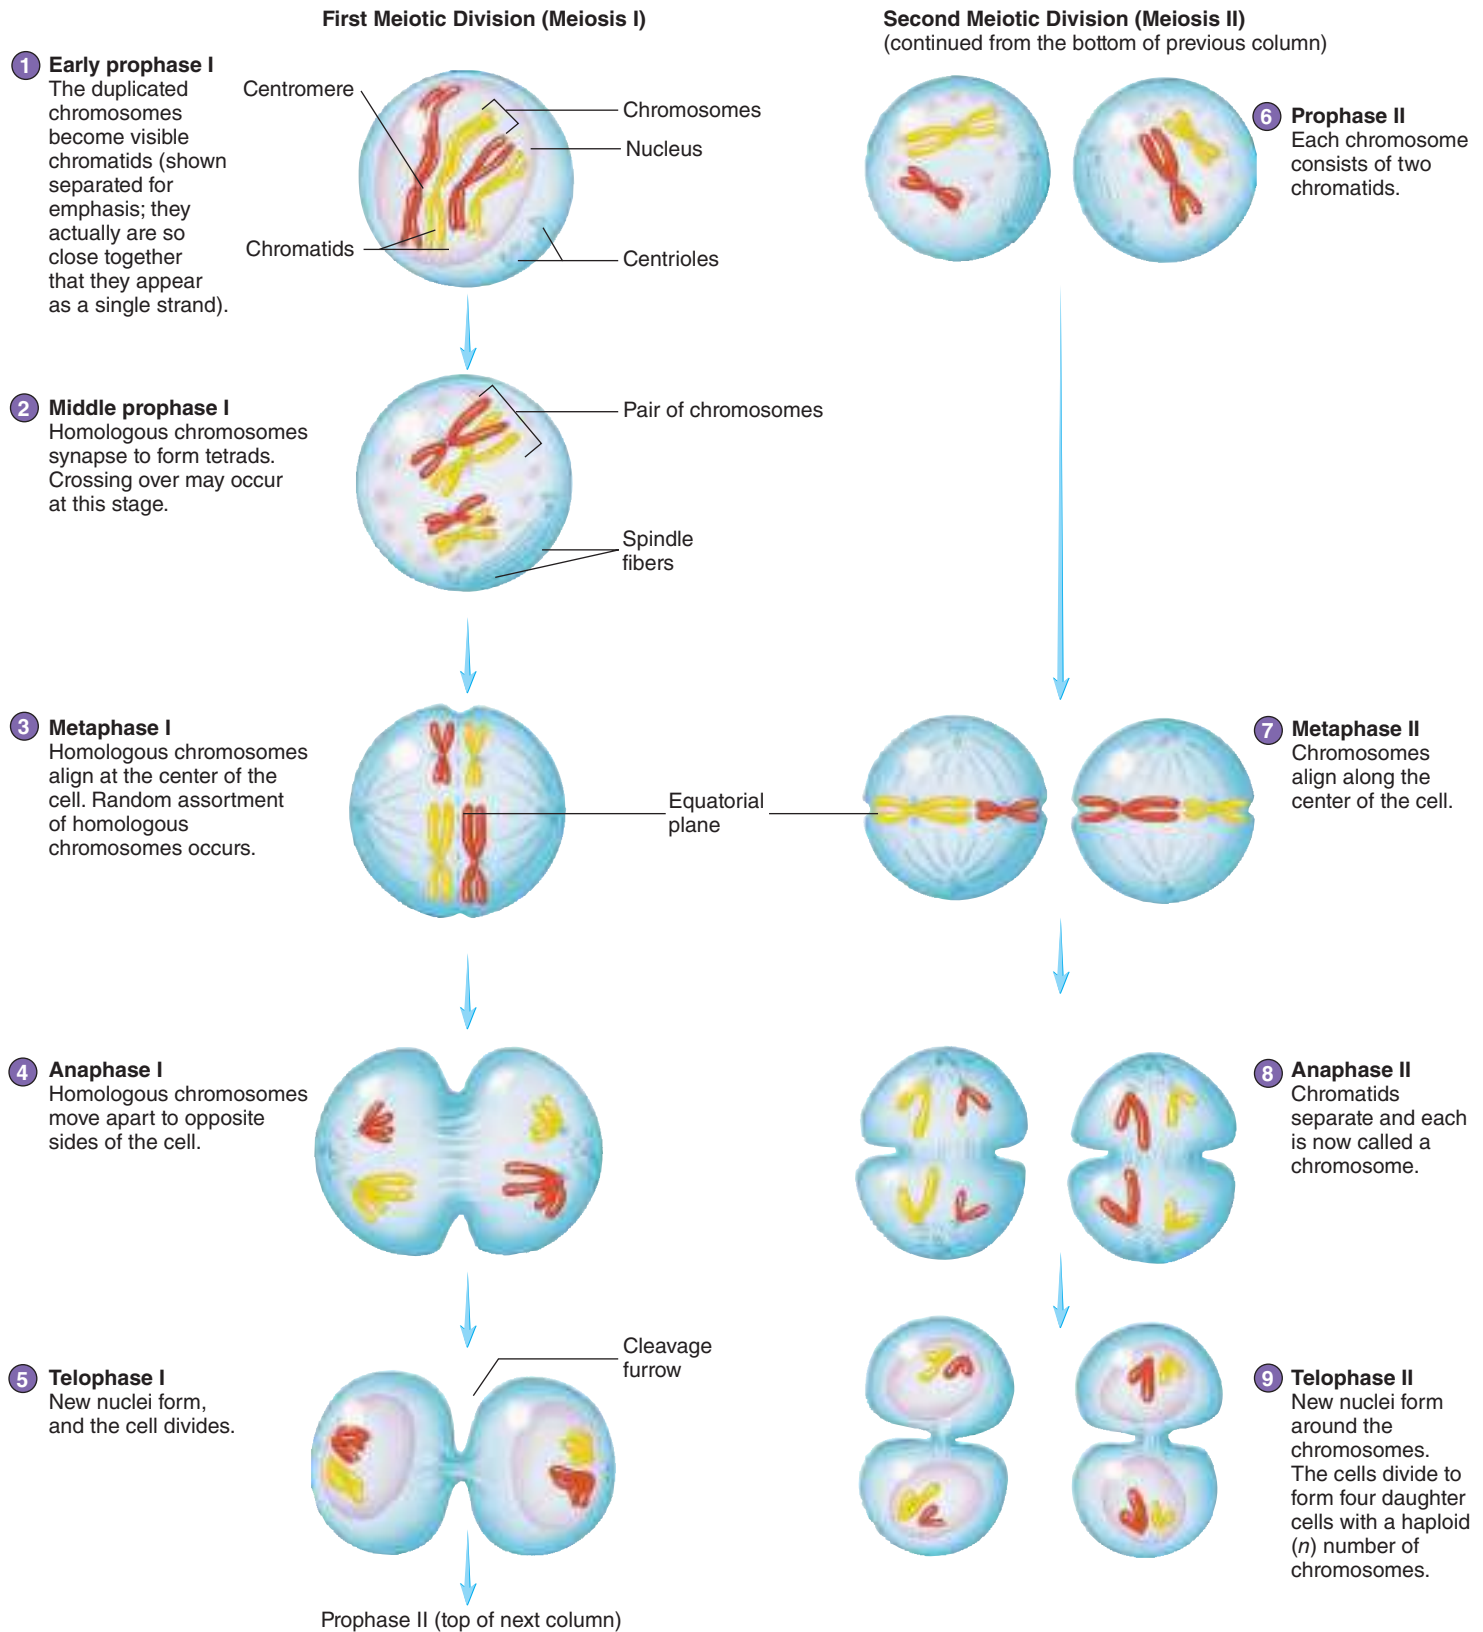

TABLE 28.1 Major Reproductive Hormones and Their Effects

Hormone	Source	Target Tissue	Response
Males			
Gonadotropin-releasing hormone (GnRH)	Hypothalamus	Anterior pituitary	Stimulates secretion of LH and FSH
Luteinizing hormone (LH) (also called interstitial cell–stimulating hormone [ICSH] in males)	Anterior pituitary	Interstitial cells in the testes	Stimulates synthesis and secretion of testosterone
Follicle-stimulating hormone (FSH)	Anterior pituitary	Seminiferous tubules (sustentacular cells)	Supports spermatogenesis
Testosterone	Interstitial cells in the testes	Testes and body tissues	Supports spermatogenesis; stimulates development and maintenance of reproductive organs; causes development of secondary sexual characteristics
		Anterior pituitary and hypothalamus	Inhibits GnRH, LH, and FSH secretion through negative feedback
Females			
Gonadotropin-releasing hormone (GnRH)	Hypothalamus	Anterior pituitary	Stimulates production of LH and FSH
Luteinizing hormone (LH)	Anterior pituitary	Ovaries	Causes follicles to complete maturation and undergo ovulation; causes ovulated follicle to become the corpus luteum
Follicle-stimulating hormone (FSH)	Anterior pituitary	Ovaries	Causes follicles to begin development
Prolactin	Anterior pituitary	Mammary glands	Stimulates milk secretion following childbirth
Estrogen	Follicles of ovaries	Uterus	Causes proliferation of endometrial cells
		Mammary glands	Causes development of mammary glands (especially duct systems)
		Anterior pituitary and hypothalamus	Has a positive-feedback effect before ovulation, resulting in increased LH and FSH secretion; has a negative-feedback effect, with progesterone, on the hypothalamus and anterior pituitary after ovulation, resulting in decreased LH and FSH secretion
Progesterone	Corpus luteum of ovaries	Other tissues	Causes development of secondary sexual characteristics
		Uterus	Causes hypertrophy of endometrial cells and secretion of fluid from uterine glands; helps maintain pregnancy
		Mammary glands	Causes development of mammary glands (especially alveoli)
Oxytocin*	Posterior pituitary	Anterior pituitary	Has a negative-feedback effect, with estrogen, on the hypothalamus and anterior pituitary after ovulation, resulting in decreased LH and FSH secretion
		Other tissues	Causes development of secondary sexual characteristics
Human chorionic gonadotropin (hCG)	Placenta	Uterus and mammary glands	Causes contraction of uterine smooth muscle during intercourse and childbirth; causes contraction of myoepithelial cells in the breast, resulting in milk letdown in lactating women
		Corpus luteum of ovaries	Maintains corpus luteum and increases its rate of progesterone secretion during the first one-third (first trimester) of pregnancy; increases testosterone production in testes of male fetuses

*Covered in chapter 29.

Crossing over and the random assortment of maternal and paternal chromosomes are responsible for the large degree of diversity in the genetic composition of sperm cells and oocytes produced by each individual.

During anaphase I, the homologous pairs are separated to each side of the cell (figure 28.1, *step 4*). During telophase I, new nuclei form, and the cell completes division of the cytoplasm to form two cells (figure 28.1, *step 5*). As a consequence, when

PROCESS FIGURE 28.1 Meiosis **AP R**

meiosis I is complete, each daughter cell has 1 chromosome from each homologous pair. Since the chromosome number is reduced from a $2n$ number (46 chromosomes, or 23 pairs) to an n number (23 chromosomes, or 1 from each homologous pair) during meiosis I, this division is often called a **reduction division**.

At the end of meiosis I, each of the 23 chromosomes in the daughter cells still consists of two chromatids. The separation of the chromatids of the duplicated chromosomes occurs in meiosis II. The second meiotic division is similar to mitosis (figure 28.1, steps 6–9). The duplicated chromosomes line up near the middle of the cell. Then the chromatids separate at the centromere, and each daughter cell receives one of the chromatids from each chromosome. When the centromere separates, each of the chromatids is called a chromosome. Consequently, each of the four daughter cells produced by meiosis contains 23 chromosomes.

ASSESS YOUR PROGRESS

- Describe the events of meiosis I and meiosis II. How are the cells produced by meiosis I different from the cells produced by meiosis II?
- Why is meiosis important in sexually reproducing organisms?
- Describe two mechanisms that occur during meiosis that produce genetic variation among gametes.

28.3 Anatomy of the Male Reproductive System

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the scrotum and its role in regulating the temperature of the testes.
- Describe the structure of the testes, the specialized cells of the testes, and the process of spermatogenesis.
- List the ducts of the male reproductive system and explain their functions.
- Describe the structure of the penis, seminal vesicles, prostate gland, and bulbourethral glands and explain their functions.

The male reproductive system consists of the testes (sing. testis), a series of ducts, accessory glands, and supporting structures. The ducts include the epididymides (sing. epididymis), the ducta deferentia (sing. ductus deferens; also vas deferens), and the urethra. Accessory glands include the seminal vesicles, the prostate gland, and the bulbourethral glands. Supporting structures include the scrotum and the penis (figure 28.2).

The testes and epididymides, in which the sperm cells develop, are located outside the body cavity in the scrotum. The ducta deferentia lead from the testes into the pelvis, where they join the ducts of the seminal vesicles to form the ampullae. Extensions of the ampullae, called the ejaculatory ducts, pass into the prostate and empty into the urethra within the prostate.

The urethra, in turn, exits the pelvis and passes through the penis to the outside of the body.

Scrotum

The **scrotum** (skrō'tŭm) is a saclike structure that contains the testes. It is divided into two internal compartments by an incomplete connective tissue septum. Externally, the compartments of the scrotum are marked by a midline irregular ridge called the **raphe** (rā'fē; a seam). The raphe extends posteriorly to the anus and anteriorly onto the inferior surface of the penis.

The wall of the scrotum includes the skin, a layer of superficial fascia consisting of loose connective tissue, and a layer of smooth muscle called the **dartos** (dar'tōs) **muscle**. In cold temperatures, the dartos muscle contracts, causing the skin of the scrotum to become firm and wrinkled and reducing its overall size. At the same time, the **cremaster** (krē-mas'ter) **muscles** (see figure 28.7), which are extensions of abdominal skeletal muscles into the scrotum, contract and help pull the testes nearer the body. These changes in size and position of the scrotum help keep the testes warm. When temperature increases due to a warmer environment or as a result of exercise or fever, the dartos and cremaster muscles relax, and the skin of the scrotum becomes loose and thin, allowing the testes to descend away from the body and keep cool. The response of the dartos and cremaster muscles is important because sperm cells are very temperature-sensitive and do not develop normally if the testes become too warm or too cool.

Perineum

The **perineum** (per'i-nē'ŭm) is the area between the thighs that is bounded by the symphysis pubis anteriorly, the coccyx posteriorly, and the ischial tuberosities laterally. The perineum is divided into two triangles by the superficial transverse muscles and the deep transverse perineal muscles. These muscles run transversely between the two ischial tuberosities (see figure 10.19). The two triangles are the urogenital triangle and the anal triangle. In males, the **urogenital** (ŭ'rō-jen'i-tāl) **triangle**, or *anterior triangle*, contains the base of the penis and the scrotum, and the smaller **anal triangle**, or *posterior triangle*, contains the anal opening (figure 28.3). The female perineum is described later in the chapter (see section 28.5).

ASSESS YOUR PROGRESS

- List the structures of the male reproductive system.
- Describe the structure of the scrotum.
- Explain the role of the dartos and cremaster muscles in regulating the temperature of the testes.
- Locate the boundaries of the perineum and the two triangles within it.

Testes

Testicular Histology

The **testes** (tes'tēz) are small, oval-shaped organs, each about 4–5 cm long, within the scrotum (see figure 28.2). The testes function as both exocrine and endocrine glands. Their major exocrine

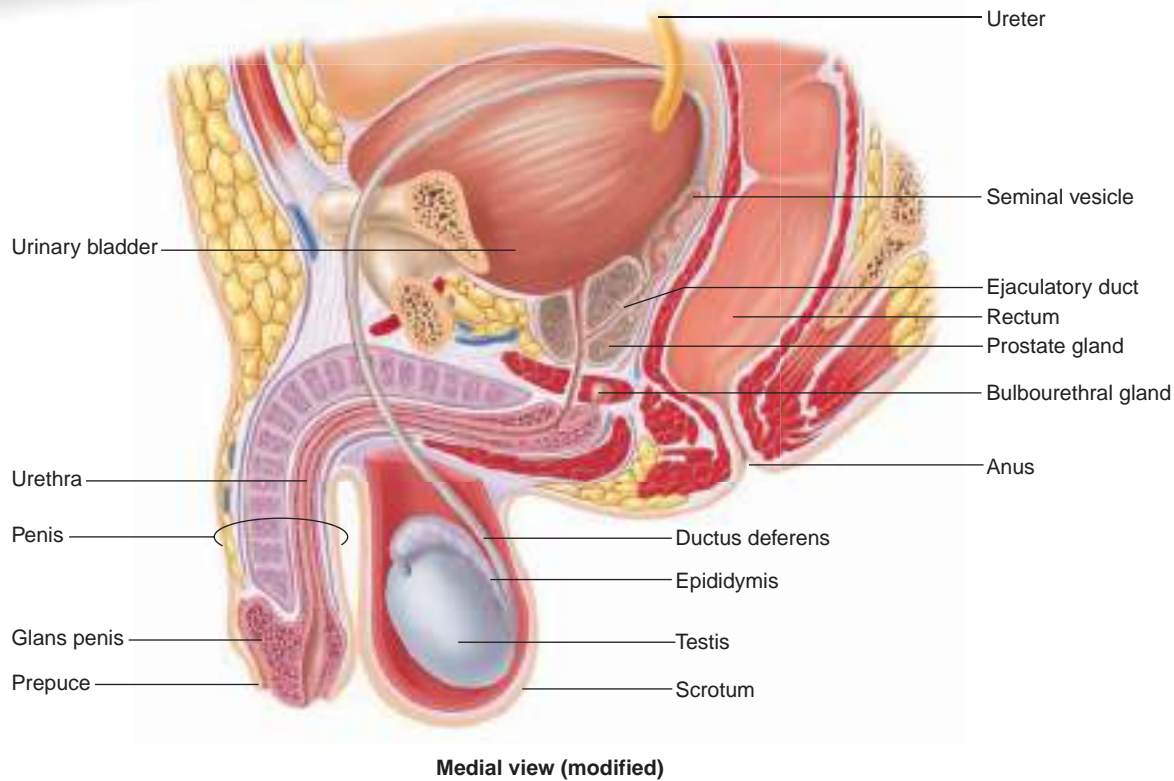

FIGURE 28.2 Male Reproductive System

secretion is sperm cells, and their major endocrine secretion is the hormone testosterone.

The outer part of each testis is a thick, white capsule consisting mostly of fibrous connective tissue called the **tunica albuginea** (al-bū-jin'ē-ă). Extensions of the tunica albuginea extend into the testis and form incomplete **septa** (sep'tă; figure 28.4a). The septa divide each testis into about 300–400 cone-shaped **lobules**. The lobules contain **seminiferous** (sem'i-nif'er-ŭs; seed carriers) **tubules**, in which sperm cells develop. Loose connective tissue surrounding

the seminiferous tubules contains clusters of endocrine cells called **interstitial cells**, or **Leydig cells** (figure 28.4). The interstitial cells secrete testosterone.

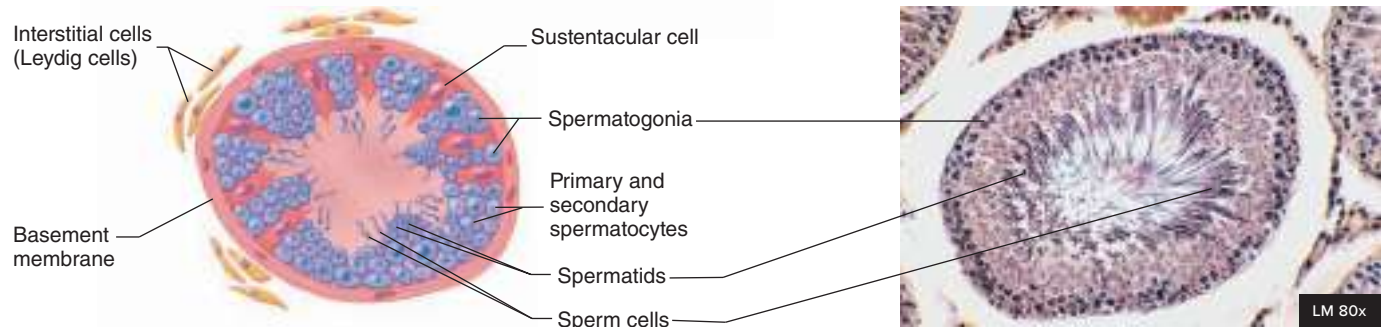

The combined length of the seminiferous tubules in both testes is nearly half a mile. Considering that sperm cells are produced in the seminiferous tubules, it is not surprising that adult males are capable of producing such high numbers of gametes. The seminiferous tubules empty into a set of short, straight tubules called the **tubuli recti**. These in turn empty into a tubular network called the **rete** (rē'tē; net) **testis**. The rete testis empties into 15–20 tubules called **efferent ductules** (dūk'tools) that pass through the tunica albuginea to exit the testis. The efferent ductules have a ciliated pseudostratified columnar epithelium, which helps move sperm cells out of the testis.

Descent of the Testes

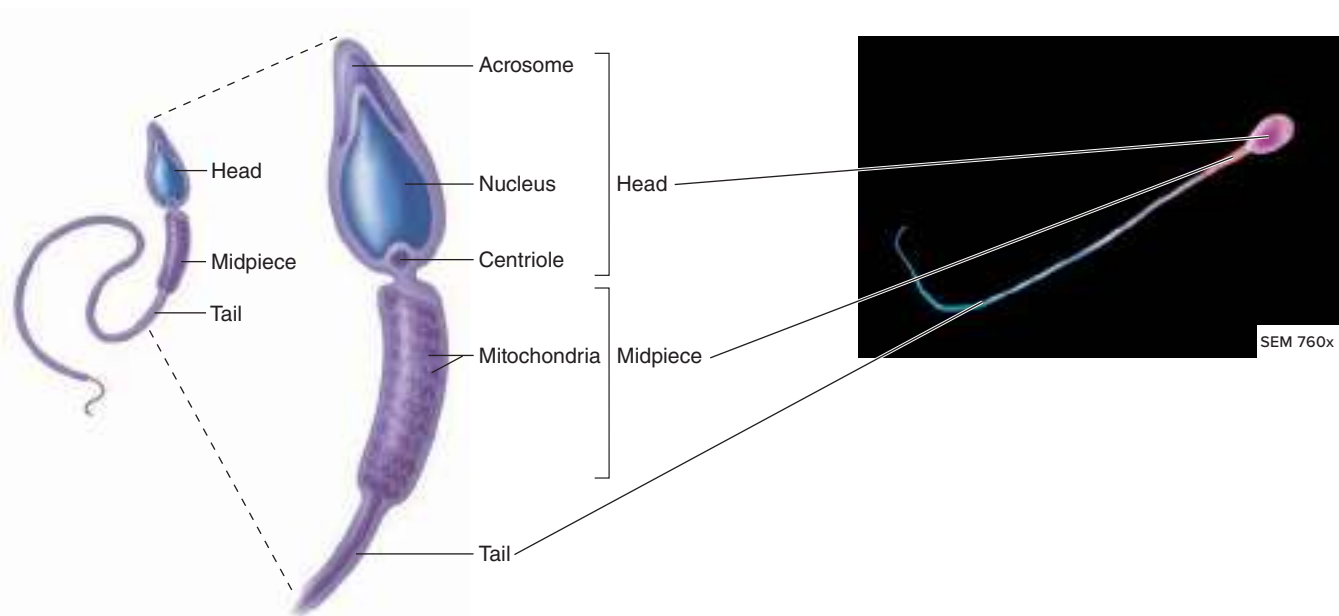

By approximately 8 weeks following fertilization, the testes have developed as retroperitoneal organs. Initially, the testes are located high in the abdominopelvic cavity near the developing kidneys. Each testis is connected to a labioscrotal swelling by a **gubernaculum** (goo'ber-nak'ū-lŭm), a fibromuscular cord (figure 28.5, *step 1*; see chapter 29). The labioscrotal swelling becomes the scrotum. The testes descend toward the area where the **inguinal** (ing'gwi-năl) **canals** will form (figure 28.5, *step 2*). The gubernaculum extends through the inguinal canal, enlarging

FIGURE 28.4 Histology of the Testis **APR**

PROCESS FIGURE 28.5 Descent of the Testes

the canal. Between 7 and 9 months of development, the testes move through the inguinal canals into the scrotum (figure 28.5, *step 3*). As it moves into the scrotum, each testis is preceded by an out-pocketing of the peritoneum called the **process vaginalis** (vaj'i-nā-lis). The superior part of each process vaginalis usually degenerates, and the inferior part remains as a small, closed sac called the **tunica** (too'ni-kā) **vaginalis** (figure 28.5, *step 4*). The tunica vaginalis is a serous membrane consisting of a layer of simple squamous epithelium resting on a basement membrane. The tunica vaginalis surrounds most of the testis in much the same way that the pericardium surrounds the heart. The tunica vaginalis secretes a small amount of fluid, which allows the testes to move in the scrotum, producing little friction.

The testes have descended into the scrotum in approximately 79% of male infants delivered prior to 28 weeks of development. In male infants delivered after 28 weeks, greater than 97% show normal testes descent. By 9 months of age, 98.2% of male infants show normal testes descent.

The inguinal canals are bilateral, oblique passageways in the anterior abdominal wall. They originate at the **deep inguinal rings**, which open through the aponeuroses of the transversus abdominis muscles. The canals extend inferiorly and obliquely and end at the **superficial inguinal rings**, openings in the aponeuroses of the external abdominal oblique muscles. In females, the inguinal canals develop, but they are much smaller than in males, and the ovaries do not normally descend through them.

Cryptorchidism (krip-tōr'ki-dizm) is the failure of one or both of the testes to descend into the scrotum. Because the higher temperature of the abdominal cavity prevents normal sperm cell development, sterility can result if both testes are involved (see chapter 29). In addition, approximately 10% of testicular cancer cases occur in men with a history of cryptorchidism.

ASSESS YOUR PROGRESS

10. Describe the covering and connective tissue of the testis.
11. Where are the seminiferous tubules and interstitial cells located? What are their functions?
12. List the ducts that will move sperm from the seminiferous tubules out of the testis.
13. When and how do the testes descend into the scrotum?
14. What is the function of the tunica vaginalis?

Sperm Cell Development

Before puberty, the testes remain relatively simple and unchanged from the time of their initial development. The interstitial cells are not particularly prominent during this period, and the seminiferous tubules lack a lumen and are not yet functional. At 12–14 years of age, the interstitial cells increase in number and size, a lumen develops in each seminiferous tubule, and sperm cell production begins. It takes approximately 74 days for sperm cells to be produced. For about 50 of those days, the sperm cells are in the seminiferous tubules.

Clinical
IMPACT

Inguinal Hernia

An **inguinal hernia** (her'nē-ă) is an abnormal opening in the abdominal wall in the inguinal region through which a structure, such as a portion of the small intestine, can protrude. Normally, the inguinal canals are closed, but they represent weak spots in the abdominal wall.

Inguinal hernias can be of two types—indirect or direct. If the deep inguinal ring remains open, or if it is weak and enlarges later in life, a loop of intestine can protrude into or even pass through the inguinal canal, resulting in an indirect inguinal hernia. A direct inguinal hernia results from a tear, or rupture, in a weakened area of the anterior abdominal wall near the inguinal canal, but not through the inguinal canal.

Inguinal hernias can be quite painful and even very dangerous, especially if a portion of the small intestine is compressed so that its blood supply is cut off. Fortunately, inguinal hernias can be repaired surgically. Because a male's inguinal canals are larger and weakened as a result of the testes passing through them on their way into the scrotum, males are much more prone to inguinal hernias than are females.

Spermatogenesis (sper'mă'-tō-jen'ě-sis), sperm cell development, occurs in the seminiferous tubules (figure 28.6a; see figure 28.4b). The seminiferous tubules contain two types of cells, germ cells and **sustentacular** (sūs-ten-tak'ū-lăr) **cells**, or **Sertoli** (sēr-tō'lē) **cells** (also sometimes referred to as *nurse cells*).

The germ cells are the ones that divide and differentiate during spermatogenesis to form sperm cells. The sustentacular cells are large cells that extend from the periphery to the lumen of the seminiferous tubule (figure 28.6b; see figure 28.4b). The sustentacular cells nourish the germ cells and probably produce, together with the interstitial cells, a number of hormones, such as androgens, estrogens, and inhibins. In addition, tight junctions between the sustentacular cells form a **blood-testis barrier** between germ cells and sperm cells. The blood-testis barrier isolates the sperm cells from the immune system (figure 28.6b). This barrier is necessary because, as the sperm cells develop, they form surface antigens that could stimulate an immune response, resulting in their destruction.

Interstitial cells secrete testosterone, which passes into the sustentacular cells and binds to intracellular receptors. This binding enables the sustentacular cells to function normally. In addition, testosterone in the sustentacular cells is converted to two other steroids: **dihydrotestosterone** (dī-hī'drō-tes-tos'ter-ōn) and **estradiol**, a specific type of estrogen. These are then secreted as hormones by the sustentacular cells. The sustentacular cells also secrete a protein called **androgen-binding** (an'drō-jen) **protein** into the seminiferous tubules. Testosterone and dihydrotestosterone bind to androgen-binding protein and are carried along with other secretions of the seminiferous tubules to the epididymis. Estradiol and dihydrotestosterone may be the active hormones that promote sperm cell formation.

Germ cells are partially embedded in the sustentacular cells (figure 28.6). The most peripheral cells, those adjacent to the basement membrane of the seminiferous tubules, are **spermatogonia** (sper'mă-tō-gō'nē-ă), which divide by mitosis (figure 28.6a, *step 1*). Some of the daughter cells produced from these mitotic divisions remain spermatogonia and continue to produce additional spermatogonia. Other daughter cells differentiate to form **primary spermatocytes** (sper'mă-tō-sītz), which divide by meiosis (figure 28.6a, *step 2*; see figure 28.1).

Spermatogenesis begins when the primary spermatocytes divide. Each primary spermatocyte passes through the first meiotic division to become two **secondary spermatocytes** (figure 28.6a, *step 2*). Each secondary spermatocyte undergoes a second meiotic division to produce two even smaller cells called **spermatids** (sper'mă-tidz; figure 28.6a, *step 3*). Each spermatid contains one of each of the homologous pairs of chromosomes. Therefore, each sperm cell contains 22 autosomes and either an X or a Y chromosome. Each spermatid undergoes the last phase of spermatogenesis, called **spermiogenesis** (sper'mē-ō-jen'ě-sis), to form a mature **sperm cell**, or **spermatozoon** (sper'mă-tō-zō'on; pl. spermatozoa, sper'mă-tō-zō'ă; figure 28.6a, *step 4*; see figure 28.4c,d). During spermiogenesis, each spermatid develops a head, a midpiece, and a tail, or flagellum. The nucleus of the sperm is located in the head. Just anterior to the nucleus is a vesicle called the **acrosome** (ak'rō-sōm), which contains enzymes necessary for the sperm cell to penetrate the female oocyte (see figure 28.4c). The flagellum is similar to a

- 1 Spermatogonia are the cells that give rise to sperm cells. The spermatogonia divide by mitosis. One daughter cell remains a spermatogonium that can divide again by mitosis. The other daughter cell becomes a primary spermatocyte.
- 2 The primary spermatocyte divides by meiosis to form secondary spermatocytes.
- 3 The secondary spermatocytes divide by meiosis to form spermatids.
- 4 The spermatids differentiate to form sperm cells.
- 5 Sustentacular cells, in which the spermatogonia and developing sperm cells are embedded, maintain the blood-testis barrier.

(a)

(b)

PROCESS FIGURE 28.6 Spermatogenesis

(a) Meiosis during spermatogenesis. A section of a seminiferous tubule illustrating the process of meiosis and sperm cell formation. (b) The sustentacular cells extend from the periphery to the lumen of the seminiferous tubules shown in alternating dark and light shades for emphasis. The tight junctions that form between adjacent sustentacular cells form the blood-testis barrier. Spermatogonia are peripheral to the blood-testis barrier, and spermatocytes are central to it.

cilium (see chapter 3), and microtubules within the flagellum move, propelling the sperm cell forward. The midpiece contains large numbers of mitochondria, which produce the ATP necessary for microtubule movement.

At the end of spermatogenesis, the developing sperm cells gather around the lumen of the seminiferous tubules, with their heads directed toward the surrounding sustentacular cells and their tails directed toward the center of the lumen (figure 28.6; see figure 28.4*b*). Finally, sperm cells are released into the lumen of the seminiferous tubules.

ASSESS YOUR PROGRESS

15. Describe the role of germ cells, sustentacular cells, and the blood-testis barrier in the structure of the seminiferous tubules.
16. Describe the conversion of testosterone to other hormones in the sustentacular cells.
17. Where, specifically, are sperm cells produced in the testis?
18. Describe the role of meiosis in sperm cell formation.
19. List the parts of a mature sperm. What are their functions? Explain the events of spermiogenesis.

Ducts

After being released into the seminiferous tubules, the sperm cells pass through a series of ducts from the interior of the testes until they potentially exit the body through the urethra. Specifically, sperm cells in the seminiferous tubules move through the tubuli recti to the rete testis. From the rete testis, they pass through the efferent ductules, which leave the testis and enter the epididymis. The sperm cells then leave the epididymis, passing through the ductus deferens, ejaculatory duct, and urethra to the exterior of the body.

Epididymis

The efferent ductules from each testis become extremely convoluted and form a comma-shaped structure on the posterior side of the testis called the **epididymis** (ep-i-did'i-mis; pl. epididymides, ep-i-di-dim'i-dēz). Each epididymis consists of a head, a body, and a long tail (figure 28.7). The head contains the convoluted efferent ductules, which empty into the **duct of the epididymis**, a single convoluted tube located primarily within the body of the epididymis (see figure 28.4*a*). This duct alone, if unraveled, would extend for several meters. The duct of the epididymis has a pseudostratified columnar epithelium with elongated microvilli called **stereocilia** (ster'ē-ō-sil'ē-ă). The stereocilia increase the surface area of epithelial cells that absorb fluid from the lumen of the duct of the epididymis. The duct of the epididymis ends at the tail of the epididymis, which is located at the inferior border of the testis.

The final maturation of the sperm cells occurs within the epididymis. It takes 12–16 days for sperm to travel through the epididymis and appear in the ejaculate. Several structural and functional changes occur in sperm cells as they pass through the epididymis. Structural changes include a further reduction in cytoplasm and maturation of the acrosome. Functionally, the sperm cells develop the ability to bind to the zona pellucida of the secondary

oocyte during fertilization (see “Oogenesis and Fertilization” in section 28.5). Sperm cells taken from the head of the epididymis are unable to fertilize secondary oocytes, and they are not yet able to become motile; however, sperm cells taken from the tail of the epididymis are able to perform both functions.

Ductus Deferens and Ejaculatory Duct

The **ductus deferens** (pl. ducta deferentia), or *vas deferens*, emerges from the tail of the epididymis and ascends along the posterior side of the testis medial to the epididymis, where it associates with the blood vessels and nerves that supply the testis to form the **spermatic cord** (figure 28.7; see figures 28.2 and 28.4*a*). The spermatic cord consists of (1) the ductus deferens, (2) the testicular artery and venous plexus, (3) lymphatic vessels, (4) nerves, and (5) fibrous remnants of the process vaginalis. The coverings of the spermatic cord include (1) the **external spermatic fascia** (fash'ē-ă); (2) the cremaster muscle, an extension of the muscle fibers of the internal abdominal oblique muscle of the abdomen; and (3) the **internal spermatic fascia** (figure 28.7).

The ductus deferens and the rest of the spermatic cord structures ascend and pass through the inguinal canal to enter the pelvic cavity (figure 28.7; see figure 28.2). The ductus deferens crosses the lateral and posterior walls of the pelvic cavity, travels over the ureter, and loops over the posterior surface of the urinary bladder to approach the prostate gland. Near the prostate gland, the end of the ductus deferens enlarges to form an **ampulla** (am-pul'lă). The lumen of the ductus deferens is lined with pseudostratified columnar epithelium, which is surrounded by smooth muscle. Peristaltic contractions of the smooth muscle help propel sperm cells through the ductus deferens.

Adjacent to the ampulla of each ductus deferens is a sac-shaped gland called the seminal vesicle. A short duct from each seminal vesicle joins the ampulla of the ductus deferens to form the **ejaculatory** (ē-jak'ū-lă-tōr-ē) **duct**. Each ejaculatory duct is approximately 2.5 cm long. These ducts extend into the prostate gland and open into the urethra (figure 28.7; see figure 28.2).

Urethra

The male **urethra** (ū-rē'thră) is about 20 cm long and extends from the urinary bladder to the distal end of the penis (figure 28.8; see figures 28.2 and 28.7). The urethra is a passageway for both urine and male reproductive fluids. The urethra is divided into three parts: (1) the prostatic urethra, (2) the membranous urethra, and (3) the spongy urethra. The **prostatic** (pros-tat'ik) **urethra** is connected to the bladder and passes through the prostate gland. Fifteen to 30 small ducts from the prostate gland and the two ejaculatory ducts empty into the prostatic urethra. The **membranous urethra** is the shortest part of the urethra, extending from the prostate gland through the perineum. The **spongy urethra**, also called the *penile* (pē'nīl) **urethra**, is the longest part of the urethra; it extends from the membranous urethra through the length of the penis, where it opens to the exterior at the **external urethral orifice** (figure 28.8). In rare cases, the penis does not develop normally, and the urethra may open to the exterior along the inferior surface of the penis (see chapter 29). Stratified

Anterior view

FIGURE 28.7 Male Reproductive Structures

Testes, epididymis, ductus deferens, and glands of the male reproductive system. The urethra is cut open along its dorsal side. **APR**

columnar epithelium lines most of the urethra, but transitional epithelium is in the prostatic urethra near the bladder, and stratified squamous epithelium is near the external urethral orifice of the spongy urethra. Several minute, mucus-secreting **urethral glands** empty into the urethra.

Penis

The **penis** is the male organ of copulation, through which sperm cells are transferred from the male to the female. The penis contains three columns of erectile tissue (figure 28.8). Engorgement of this erectile tissue with blood causes the penis to enlarge and become firm, a process called **erection** (ē-rek'shŭn).

The **corpora cavernosa** (kōr'pōr-ă kav-er-nos'ă) are the erectile columns that form the dorsum and sides of the penis. The third column, the **corpus spongiosum** (kōr'pŭs spŭn'jē-ō'sŭm), forms the ventral portion of the penis. The corpus spongiosum expands to form a cap, the **glans penis**, over the distal end of the penis. The spongy urethra passes through the corpus spongiosum, penetrates the glans penis, and opens as the external urethral orifice.

At the base of the penis, the corpus spongiosum expands to form the **bulb of the penis**. Each corpus cavernosum expands to form the **crus** (kroos; pl. crura, kroo'ră) **of the penis**, which attaches the penis to the pelvic bones. Together, the bulb of the penis and the crura of the penis constitute the **root of the penis**.

FIGURE 28.8 Penis

(a) Section through the spongy, or penile, urethra laid open and viewed from above. The prostate is also cut open to show the prostatic urethra. (b) Cross section of the penis, showing principal nerves, arteries, and veins along the dorsum of the penis. The *black line* and *blue arrows* depict the manner in which (a) is cut and laid open.

Skin is loosely attached to the connective tissue that surrounds the erectile columns in the shaft of the penis. The skin is firmly attached at the base of the glans penis, and a thinner layer of skin tightly covers the glans penis. The skin of the penis, especially the glans penis, is well supplied with sensory receptors. A loose fold of skin called the **prepuce** (prē'poo), or *foreskin*, covers the glans penis (see figure 28.2).

In many cultures, the prepuce is surgically removed shortly after birth, a procedure called **circumcision** (ser-kūm-sizh'ūn). There are no compelling medical reasons for circumcision.

Uncircumcised males have a higher incidence of penile cancer, but the underlying causes seem related to chronic infections and poor hygiene. In the few cases in which the prepuce is “too tight” to be moved over the glans penis, circumcision may be necessary to avoid chronic infections and maintain normal circulation.

The primary nerves, arteries, and veins of the penis pass along its dorsal surface (figure 28.8b). Dorsal arteries, with dorsal nerves lateral to them, exist on each side of a single, midline dorsal vein. Additional deep arteries lie within the corpora cavernosa.

ASSESS YOUR PROGRESS

20. Describe the structure and functions of the epididymis.
21. How do sperm move from the epididymis, and what changes occur in sperm cells while in the epididymis?
22. Describe the structure and functions of the ductus deferens.
23. List the components and coverings of the spermatic cord.
24. Relate the route by which the ductus deferens extends from the testis to the prostate gland.
25. What is the ejaculatory duct?
26. Distinguish among the three parts of the male urethra.
27. Describe the erectile tissue of the penis.
28. Describe the structures and locations of the glans penis, crus, bulb, and prepuce.

Accessory Glands

The male reproductive system also includes three accessory glands that are important for normal reproductive function. The accessory glands are exocrine glands that secrete material into the ducts of the male reproductive tract. These glands are (1) the seminal vesicles, (2) the prostate gland, and (3) the bulbourethral glands.

Seminal Vesicles

The **seminal vesicles** (sem'i-näl ves'i-klz) are sac-shaped glands located next to the ampullae of the ducta deferentia (see figure 28.7). Each gland is about 5 cm long and tapers into a short excretory duct that joins the ampulla of the ductus deferens to form the ejaculatory duct. The seminal vesicles have a capsule containing fibrous connective tissue and smooth muscle cells.

Prostate Gland

The **prostate** (pros'tät; one standing before) **gland** consists of both glandular and muscular tissue. It resembles a walnut in shape and size and is approximately 4 cm long and 2 cm wide. It is dorsal to the symphysis pubis at the base of the urinary bladder, where it surrounds the prostatic urethra and the two ejaculatory ducts (see figure 28.2). The prostate gland is composed of a fibrous connective tissue capsule containing distinct smooth muscle cells and numerous fibrous partitions, also containing smooth muscle, that radiate inward toward the urethra. Covering these muscular partitions is a layer of columnar epithelial cells that form saccular dilations. The columnar cells secrete prostatic fluid into the saccular dilations. Fifteen to 30 small prostatic ducts carry these secretions into the prostatic urethra.

Case STUDY

Prostate Cancer

Sixty-five-year-old Vern has a physical examination every year. Eight years ago, a test indicated that Vern's blood **prostate specific antigen (PSA)** levels were elevated compared with his previous tests. His physician performed a digital examination and reported moderate enlargement of the prostate gland but no obvious tumorlike structures. Because of the increased PSA levels, needle biopsies of Vern's prostate gland were taken through his rectum. Suspicious cells consistent with prostate cancer were detected in one of the tissue samples. Vern's physician had the biopsy samples examined by another pathology laboratory, which did not confirm the first pathology report. As a consequence, Vern's physician explained that, since prostate cancer typically develops slowly, one option was to do nothing and continue having regular checkups.

Eight years later, a routine blood test showed another substantial increase in Vern's PSA levels, although, again, no tumor could be detected by a digital exam. Also, Vern had no symptoms associated with prostate tumors, such as difficulty urinating. Needle biopsies of

the prostate gland were taken again, and cancer cells were found in two of the six biopsy samples. The physician explained that, since the cancer had been discovered before it had metastasized, Vern's chances of surviving were high. Vern could choose to do nothing, have his prostate gland surgically removed, or treat the cancer with radiation therapy, hormonal therapy, or chemotherapy. Vern's physician indicated that doing nothing is a reasonable option for men who are significantly older than Vern because older men diagnosed with prostate cancer often die of other conditions before they succumb to prostate cancer.

Vern elected to have radiation therapy, which focuses radiation on the prostate gland to kill the cancer cells. Statistics indicate that surgery and radiation therapy have similar success rates for small, localized tumors like Vern's. The trauma of surgery and the higher probability of erectile dysfunction following surgery convinced Vern that radiation therapy was preferable. The physician explained that approximately 85% of patients like Vern are cancer-free 5 years after radiation treatments.

Vern was glad that he had continued having annual physical examinations. Prostate cancer represents 29% of cancers in males in the United States and 14% of the deaths due to cancer. Only lung cancer causes more cancer deaths in men.

Predict 2

- a. Given the elevated PSA levels and the suspicious cells appearing in the first biopsy, was it reasonable to conclude that cancer cells were not present in Vern's prostate gland, or was it an error? (*Hint:* See chapter 4.)
- b. Explain why, following the first biopsy, the second pathology report did not confirm the results of the first pathology report.
- c. Explain why cancer cells were present in only two of the six needle biopsy samples.
- d. Since increased blood levels of PSA are a common diagnostic tool for prostate cancer, explain why Vern's PSA levels were elevated prior to the first biopsy.

Bulbourethral Glands

The **bulbourethral** (bŭl' bō-ŭ-rē' thrāl) **glands**, or *Cowper glands*, are a pair of small glands located near the membranous urethra (see figures 28.2 and 28.7). In young males, each gland is about the size of a pea, but they decrease in size with age and are almost impossible to detect in older men. Each bulbourethral gland is a compound mucous gland (see chapter 4). The small ducts of each gland unite to form a single duct, which empties into the spongy urethra at the base of the penis.

Semen

Collectively, the sperm cells and secretions from the accessory glands are called **semen** (sē'men). The seminal vesicles produce about 60% of the fluid, the prostate gland contributes about 30%, the testes contribute 5%, and the bulbourethral glands contribute 5%. **Emission** (ē-mish' ūn) is the discharge of all these secretions from the ducta deferentia into the urethra. **Ejaculation** (ē-jak-ŭ-lā'shŭn) is the forceful expulsion of semen from the urethra caused by contraction of the urethra, the skeletal muscles in the pelvic floor, and the muscles at the base of the penis.

The major component of the testicular secretions is sperm cells. In addition to the sperm cells, the testes also secrete a small amount of fluid necessary for moving the sperm cells through the reproductive tract. Metabolic by-products are also included in this fluid, as sperm cells carry out basic cellular processes.

The bulbourethral glands and urethral mucous glands produce a mucous secretion just before ejaculation. This alkaline mucous secretion lubricates the urethra, neutralizes the contents of the normally acidic spongy urethra, provides a small amount of lubrication during intercourse, and helps reduce vaginal acidity.

The thick, mucuslike secretions of the seminal vesicles contain large amounts of fructose, citric acid, and other nutrients that nourish the sperm cells. The seminal vesicle secretions also contain fibrinogen, which is involved in a weak coagulation reaction of the semen immediately after ejaculation. In addition, seminal vesicle secretions contain prostaglandins that can cause uterine contractions, which help transport sperm cells through the female reproductive tract to the site of fertilization.

The prostate produces a thin, milky, alkaline secretion. In combination with secretions of the seminal vesicles, bulbourethral glands, and urethral mucous glands, the prostatic secretions help neutralize the acidic urethra. The secretions of the prostate and seminal vesicles also help neutralize the acidic secretions of the testes and the vagina. In addition, the prostatic secretions are important in the transient coagulation of semen because they contain clotting factors that convert fibrinogen from the seminal vesicles to fibrin, resulting in coagulation. The coagulated material keeps the semen a sticky mass for a few minutes after ejaculation, and then fibrinolysin, also secreted by the prostate, causes the mass to dissolve. This releases the sperm cells to make their way up the female reproductive tract.

Before ejaculation, the ductus deferens begins to contract rhythmically to propel sperm cells and testicular and epididymal secretions from the tail of the epididymis to the ampulla of the ductus deferens. Contractions of the ampullae, seminal vesicles, and ejaculatory ducts cause the sperm cells, along with testicular and epididymal secretions, to move into the prostatic urethra with the prostatic secretions. Secretions of the seminal vesicles then enter the prostatic urethra, where they mix with the other secretions.

Normal sperm cell counts in the semen range from 75 to 400 million sperm cells per milliliter of semen, and a normal ejaculation usually consists of about 2–5 mL of semen. The semen with the highest sperm count is expelled from the penis first because it contains the greater percentage of sperm-containing fluid from the epididymis. Sperm cells become motile after ejaculation once they are mixed with secretions of the male accessory glands and the female reproductive tract. The alkaline pH (an average of 7.5), nutrients, and removal of inhibitory substances from the surface of sperm cells appear to increase sperm cell motility. Enzymes carried in the acrosomal cap of each sperm cell help digest a path through the mucoid fluids of the female reproductive tract and through materials surrounding the oocyte. Once the acrosomal fluid is depleted from a sperm cell, the sperm cell is no longer capable of fertilization. As a result, most of the sperm cells (millions) are expended in moving the general group of sperm cells through the female reproductive tract.

29. State where the seminal vesicles, prostate gland, and bulbourethral glands empty into the male reproductive duct system.
30. Define emission and ejaculation.
31. Describe the contributions to semen from the accessory glands.
32. What is the function of the secretions of each of the accessory glands?

28.4 Physiology of Male Reproduction

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the hormones that influence the male reproductive system and describe their functions.
- B. Demonstrate an understanding of the changes that occur in males during puberty.
- C. Explain the events that occur during the male sexual act.

The male reproductive system is under hormonal and nervous control. Hormones are primarily responsible for the development of reproductive structures and the maintenance of their functional capacities, the development of secondary sexual characteristics, and the control of sperm cell formation. Hormones also influence

Predict 3

Explain a possible function of the coagulation reaction.

sexual behavior. Neural mechanisms are primarily involved in sexual behavior and control of the sexual act.

Regulation of Reproductive Hormone Secretion

Hormonal mechanisms that influence the male reproductive system involve the hypothalamus, the pituitary gland, and the testes (figure 28.9). A small peptide hormone called **gonadotropin-releasing hormone (GnRH)** is released from neurons in the hypothalamus. GnRH passes through the hypothalamohypophysial portal system to the anterior pituitary gland (see chapter 18). In response to GnRH, cells within the anterior pituitary gland secrete two hormones, referred to as **gonadotropins** (*gō'nad-ō-trō'pinz*, *gon'ă-dō-trō'pinz*) because they influence the function of the **gonads** (*gō'nadz*; testes or ovaries).

The two gonadotropins are **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**. They are named for their functions in females, but they also have important functions in males. When discussing the male reproductive system, LH is sometimes called **interstitial cell-stimulating hormone (ICSH)**. LH binds to the interstitial cells in the testes and causes them to increase their

rate of testosterone synthesis and secretion. FSH binds primarily to sustentacular cells in the seminiferous tubules and promotes sperm cell development. Both gonadotropins bind to specific receptor molecules on the membranes of the cells they influence, and cyclic adenosine monophosphate (cAMP) is an important intracellular mediator in those cells.

For GnRH to stimulate the secretion of large quantities of LH and FSH and thereby influence sperm cell production, the anterior pituitary must be exposed to a series of pulses, or brief increases and decreases in GnRH. Interestingly, GnRH can be produced synthetically; if administered in small amounts in frequent pulses or surges, it can be useful in treating male infertility. However, chronically elevated GnRH levels in the blood cause the anterior pituitary cells to become insensitive to stimulation by GnRH molecules, and little LH or FSH is secreted. Long-term administration of synthetic GnRH, therefore, can reduce sperm cell production, causing infertility.

Testosterone is the major male hormone secreted by the testes. It is classified as an **androgen** (Gr. *andros*, male human) because it stimulates the development of male reproductive structures (see chapter 29) and male secondary sexual characteristics. The testes secrete other androgens, but they are produced in smaller

PROCESS FIGURE 28.9 Regulation of Reproductive Hormone Secretion in Males

Clinical IMPACT

Male Infertility

Infertility (in-fer-til'i-tē) is the inability or the reduced ability to produce offspring. The most common cause of infertility in males is a low sperm cell count. A count of less than 20 million sperm cells per milliliter usually indicates infertility.

The sperm cell count can decrease because of damage to the testes as a result of trauma, radiation, cryptorchidism, or an infection, such as mumps. **Varicocele** (var'i-kō-sēl) is an abnormal dilation of a spermatic vein that results from incompetent or absent valves in spermatic veins, from thrombi, or from tumors. As a result, both testicular blood flow and spermatogenesis decrease. Reduced

sperm cell counts can also result from inadequate secretion of LH and FSH, which can be caused by hypothyroidism, trauma to the hypothalamus, infarctions of the hypothalamus or anterior pituitary gland, or tumors. Decreased testosterone secretion reduces the sperm cell count as well. Some reports suggest that the average sperm cell count has decreased substantially since the end of World War II (1945), although there is some controversy about the accuracy of these reports. Researchers speculate that certain synthetic chemicals are responsible.

Even when the sperm cell count is normal, fertility can be reduced if sperm cell structure

is abnormal, as occurs due to chromosomal abnormalities or other genetic factors. Reduced sperm cell motility also results in infertility. A major cause of reduced sperm cell motility is the presence of antisperm antibodies, which are produced by the immune system and bind to sperm cells.

In cases of infertility due to low sperm count or reduced motility, fertility can sometimes be achieved by collecting several ejaculations and concentrating the sperm cells before inserting them into the female reproductive tract, a process called **artificial insemination** (in-sem-i-nā'shūn).

concentrations and are less potent than testosterone. In addition, the testes secrete small amounts of estrogen and progesterone.

Testosterone has a major influence on many tissues. It plays an essential role in the embryonic development of reproductive structures, their further development during puberty, the development of secondary sexual characteristics during puberty, the maintenance of sperm cell production, and the regulation of gonadotropin secretion. It also influences behavior.

Inside some target tissue cells, such as cells of the scrotum and penis, an enzyme converts testosterone to dihydrotestosterone, which is the active hormone for these cells. If the enzyme is not active, these structures do not fully develop normally. In other target tissue cells, an enzyme converts testosterone to estrogen, and estrogen becomes the active hormone. Some brain cells convert testosterone to estrogen. In these cells, estrogen may be the active hormone responsible for certain aspects of male sexual behavior.

The sustentacular cells of the testes secrete a polypeptide hormone called **inhibin** (in-hib'in), which inhibits FSH secretion from the anterior pituitary.

Puberty in Males

Before birth, a gonadotropin-like hormone called **human chorionic** (kō-rē-on'ik) **gonadotropin (hCG)**, secreted by the placenta, stimulates the synthesis and secretion of testosterone by the fetal testes. After birth, however, no source of stimulation is present, and the testes of the newborn baby atrophy slightly and secrete only small amounts of testosterone until puberty, which normally begins when a boy is 12–14 years old.

Puberty (pū'ber-tē) is the age at which individuals become capable of sexual reproduction. Before puberty, GnRH release from the hypothalamus is inhibited by small amounts of testosterone and other androgens. At puberty, the hypothalamus becomes

much less sensitive to the inhibitory effect of these androgens, and the rate of GnRH secretion increases. This causes an increase in LH and FSH secretion from the anterior pituitary gland. Elevated FSH levels promote sperm cell formation, and elevated LH levels cause the interstitial cells to secrete larger amounts of testosterone. Testosterone still has a negative-feedback effect on GnRH secretion after puberty but is not capable of completely suppressing it.

Effects of Testosterone

Testosterone is by far the major androgen in males. Nearly all the androgens, including testosterone, are produced by the interstitial cells, with small amounts produced by the adrenal cortex and possibly by the sustentacular cells. Testosterone causes the enlargement and differentiation of the male genitals and reproductive duct system and is necessary for sperm cell formation. Testosterone also stimulates growth of thicker, coarser, pigmented hair in the pubic area and extending up the linea alba, as well as on the legs, chest, axillary region, face, and back. Testosterone causes existing vellus hair to be converted to terminal hair, which is coarser and more pigmented.

Testosterone also affects the appearance of the skin. Specifically, it causes the texture of the skin to become rougher or coarser. The quantity of melanin in the skin also increases, making the skin darker. In addition, testosterone increases the rate of secretion from the sebaceous glands, especially on the face. Near puberty, the increased testosterone level and increased sebaceous gland secretion frequently cause acne (see chapter 5).

Testosterone also causes hypertrophy of the larynx and reduced tension on the vocal folds, beginning near puberty. At first, the structural changes can make the voice difficult to control, but ultimately its normal masculine quality is achieved.

Testosterone stimulates metabolism so that males have a slightly higher metabolic rate than females. The red blood cell

Clinical IMPACT

Anabolic Steroids

In an attempt to improve their performance, some athletes, especially those who depend on muscle strength, may either ingest or inject synthetic androgens, commonly called **anabolic steroids**, or simply *steroids*. These hormones have testosterone-like effects, such as stimulating the development of male secondary sexual characteristics, but many anabolic steroids are structurally different from testosterone, and their effect on muscle is greater than their effect on the reproductive organs. However, when taken in large amounts, they can influence the reproductive system. Large doses of anabolic steroids have a negative-feedback effect on the hypothalamus and anterior pituitary, reducing GnRH, LH, and FSH levels. As a result, the testes can atrophy and sterility can develop. Other side effects of large doses of anabolic steroids include kidney and liver damage, heart attack, and stroke. In addition, anabolic steroids cause abrupt mood swings, usually toward intense anger and rage. Taking anabolic steroids is highly discouraged by medical professionals, violates the rules of most athletic organizations, and is illegal without a prescription.

count increases by nearly 20% as a result of testosterone's effect on erythropoietin production. Testosterone also has a minor mineralocorticoid-like effect, causing Na^+ to be retained in the body and, consequently, an increased volume of body fluids. Testosterone promotes protein synthesis in most tissues; as a result, skeletal muscle mass increases at puberty. The average percentage of the body weight composed of skeletal muscle is greater for males than for females because of the effect of androgens.

Testosterone causes rapid bone growth and increases the deposition of Ca^{2+} in bone, resulting in increased height. However, the growth in height is limited because testosterone also stimulates ossification of the epiphyseal plates of long bones (see chapter 6). Males who mature sexually at an earlier age grow rapidly but reach their maximum height earlier. Males who mature sexually at a later age do not exhibit a rapid period of growth, but they grow for a longer period and can become taller than those who mature sexually at an earlier age.

Male Sexual Behavior and the Male Sexual Act

Testosterone is required to initiate and maintain male sexual behavior. Testosterone enters cells within the hypothalamus and the surrounding areas of the brain and influences their function, resulting in sexual behavior. However, male sexual behavior may depend, in part, on the conversion of testosterone to other steroids, such as estrogen, in cells of the brain.

The blood levels of testosterone remain relatively constant in a male from puberty until about 40 years of age. Thereafter, the

levels slowly decline to about 20% of this value by 80 years of age, causing a slow decrease in sex drive and fertility.

The male sexual act is a complex series of reflexes that result in erection of the penis, secretion of mucus into the urethra, emission, and ejaculation. Sensations that are normally interpreted as pleasurable occur during the male sexual act and result in a climactic sensation, called **orgasm** (*ōr'gāzm*), associated with ejaculation. After ejaculation, a phase called **resolution** occurs. Resolution is characterized by a flaccid penis, an overall feeling of satisfaction, and the inability to achieve erection and a second ejaculation for a period that can range from many minutes to many hours or longer.

Sensory Action Potentials and Integration

Male sexual reflexes are initiated by a variety of sensory stimuli. Action potentials are conducted by sensory neurons from the genitals through the pudendal nerve to the sacral region of the spinal cord, where reflexes that result in the male sexual act are integrated. Action potentials travel from the spinal cord to the cerebrum to produce conscious sexual sensations.

Rhythmic massage of the penis, especially the glans penis, produces extremely important sensory action potentials that initiate erection and ejaculation. In addition, sensory action potentials produced in surrounding tissues, such as the scrotum and the anal, perineal, and pubic regions, reinforce sexual sensations. Engorgement of the prostate and seminal vesicles with their secretions also causes sexual sensations. In some cases, mild irritation of the urethra, as may result from an infection, can cause sexual sensations.

Psychic stimuli, including sight, sound, odor, and thoughts, have a major effect on sexual reflexes. Thinking sexual thoughts or dreaming about erotic events tends to reinforce stimuli that trigger sexual reflexes, such as erection and ejaculation. Ejaculation while sleeping is a relatively common event in young males and is thought to be triggered by psychic stimuli associated with dreaming. Psychic stimuli can also inhibit the sexual act, and thoughts that are not sexual tend to decrease the effectiveness of the male sexual act.

Action potentials from the cerebrum that reinforce the sacral reflexes are not absolutely required for the culmination of the male sexual act. The sexual act can be performed by males who have suffered spinal cord injuries superior to the sacral region.

Erection, Emission, and Ejaculation

When erection occurs, the penis becomes enlarged and rigid. Erection is the first major component of the male sexual act. Figure 28.10 illustrates the neural events that lead to an erection. First, action potentials travel from the spinal cord through the pudendal nerve to the arteries that supply blood to the erectile tissues. The nerve fibers release acetylcholine and nitric oxide (NO) as neurotransmitters. Acetylcholine binds to muscarinic receptors and activates a G protein mechanism that causes smooth muscle relaxation. Nitric oxide diffuses into the smooth muscle cells of blood vessels and combines with the enzyme guanylate cyclase, which converts guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). The cGMP causes smooth muscle cells to relax and blood vessels to dilate (figure 28.10). At the same time, other arteries of the penis constrict to shunt blood to the erectile tissues. As a consequence, blood fills the sinusoids of the erectile

- 1 Action potentials in parasympathetic neurons cause voltage-gated Ca^{2+} channels to open, and Ca^{2+} diffuses into the presynaptic terminals.
- 2 Calcium ions initiate the release of acetylcholine (ACh) from presynaptic vesicles.
- 3 Calcium ions also activate nitric oxide synthase, which promotes the synthesis of nitric oxide (NO) from arginine.
- 4 ACh binds to ACh receptors on the smooth muscle cells and activates a G protein mechanism. The activated G protein causes the relaxation of smooth muscle cells and erection of the penis.
- 5 NO binds to guanylate cyclase enzymes and activates them. The activated enzymes convert GTP to cGMP, which causes relaxation of the smooth muscle cells and erection of the penis.

PROCESS FIGURE 28.10 Nervous Control of Erection

tissue and compresses the veins. Because venous outflow is partially occluded, the blood pressure in the sinusoids causes inflation and rigidity of the erectile tissue. Nerve action potentials that result in erection come from parasympathetic centers (S2–S4) or sympathetic centers (T2–L1) in the spinal cord. Normally, the parasympathetic centers are more important for erection; however, in cases of damage to the sacral region of the spinal cord, erection can occur through the sympathetic system.

Parasympathetic action potentials also cause the mucous glands within the penile urethra and the bulbourethral glands at the base of the penis to secrete mucus.

As mentioned in section 28.3, emission is the accumulation of sperm cells and secretions of the accessory glands in the urethra.

Clinical IMPACT

Erectile Dysfunction

Failure to achieve erection, or **erectile dysfunction (ED)**, sometimes called *impotence*, can be a major source of frustration for some men. ED can be due to reduced testosterone secretion resulting from hypothalamic, pituitary, or testicular complications. In other cases, ED is due to defective stimulation of the erectile tissue by nerve fibers or reduced response of the blood vessels to neural stimulation.

Some men can achieve erections by taking oral medication, such as sildenafil (Viagra), tadalafil (Cialis), or vardenafil (Levitra). Sildenafil is a drug that blocks the activity of the enzyme that converts cGMP to GMP. Consequently, it allows cGMP to accumulate in smooth muscle cells in the arteries of erectile tissues and causes them to relax. This response is effective in enhancing erection in males. Sildenafil's action is not specific to the erectile tissue of the penis, however. It causes vasodilation in other tissues and can increase the workload of the heart.

Sympathetic centers in the spinal cord (T12–L1), which are stimulated as the level of sexual tension increases, control emission. Sympathetic action potentials cause peristaltic contractions of the reproductive ducts and stimulate the seminal vesicles and the prostate gland to release their secretions. Consequently, semen accumulates in the prostatic urethra and produces sensory action potentials that pass through the pudendal nerves to the spinal cord. Integration of these action potentials results in both sympathetic and somatic motor output. Sympathetic action potentials cause the internal sphincter of the urinary bladder to constrict, so that semen and urine are not mixed. Somatic motor action potentials travel to the skeletal muscles of the urogenital diaphragm and the base of the penis, causing ejaculation by several rhythmic contractions that force the semen out of the urethra. Muscle tension increases throughout the body as well.

Predict 4

Mr. Grover suffers from the periodic inability to achieve an erection. His doctor could find no structural or physiological abnormalities, so he prescribed sildenafil. After taking the pills, Mr. Grover could sometimes, but not always, achieve an erection. Assuming no pathology affected Mr. Grover, explain his experiences.

39. Describe the processes of erection, emission, ejaculation, orgasm, and resolution.

28.5 Anatomy of the Female Reproductive System

LEARNING OUTCOMES

After reading this section, you should be able to

- Name the organs of the female reproductive system and describe their functions.
- Describe the anatomy and histology of the ovaries.
- Discuss the development of the oocyte and the follicle and describe ovulation and fertilization.
- Describe the structure of the uterine tubes, uterus, vagina, external genitalia, and mammary glands.

The female reproductive organs are the ovaries, the uterine tubes, the uterus, the vagina, the external genital organs, and the mammary glands. The internal reproductive organs are within the pelvis between the urinary bladder and the rectum (figure 28.11). The uterus and the vagina are in the midline, with the ovaries to each side of the uterus. A group of ligaments holds the internal reproductive organs in place. The most conspicuous of these ligaments is the **broad ligament**, an extension of the peritoneum that spreads out on both sides of the uterus and attaches to the ovaries and uterine tubes (figure 28.12).

Ovaries

The two **ovaries** (*ō'var-ēz*) are small organs about 2–3.5 cm long and 1–1.5 cm wide (figure 28.12). A peritoneal fold called the **mesovarium** (*mez'ō-vā'rē-ŭm*; mesentery of the ovary) attaches each ovary to the posterior surface of the broad ligament. Two other ligaments are associated with the ovary: (1) the **suspensory ligament**, which extends from the mesovarium to the body wall, and (2) the **ovarian ligament**, which attaches the ovary to the superior margin

FUNDAMENTAL Figure

FIGURE 28.11 Female Reproductive Structures

The structures are depicted in sagittal section.

FIGURE 28.12 Uterus, Vagina, Uterine Tubes, Ovaries, and Supporting Ligaments

The uterus and uterine tubes are cut in section (on the left side), and the vagina is cut to show the internal anatomy. The inset (top, left) shows the relationships among the ovary, the uterine tube, and the ligaments that suspend them in the pelvic cavity.

of the uterus. The ovarian arteries, veins, and nerves traverse the suspensory ligament and enter the ovary through the mesovarium.

Ovarian Histology

The ovary is covered by a portion of the visceral peritoneum, made up of simple cuboidal epithelium, called the **ovarian epithelium**, or *germinal epithelium*. Immediately below the ovarian epithelium is a capsule of dense fibrous connective tissue called the **tunica albuginea** (al-bū-jin'ē-ă). The tissue of the ovary is divided into two areas: the cortex and the medulla. The **cortex** is the denser, outer part of the ovary, and the **medulla** is the looser, inner part of the ovary (figure 28.13). The connective tissue of the ovary is called the **stroma**. Numerous **ovarian follicles**, each of which contains an **oocyte** (ō'ō-sīt), are distributed throughout the stroma of the cortex. Blood vessels, lymphatic vessels, and nerves from the mesovarium enter the medulla.

Oogenesis and Fertilization

The process of gamete production in females is called **oogenesis**. This process begins in the fetus. By the fourth month of development, the ovaries contain 5 million **oogonia** (ō-ō-gō'nē-ă; *oon*, egg + *gone*, generation), the cells from which oocytes develop (figure 28.14). By the time of birth, many of the oogonia have degenerated, and the remaining ones have begun meiosis.

Oogonia can form after birth from stem cells, but the extent to which this occurs, and how long it occurs, is not clear. Meiosis stops, however, during the first meiotic division at prophase I (see figure 28.1). The cell at this stage is called a **primary oocyte**. At birth a female possesses about 2 million primary oocytes. From birth to puberty, the number of primary oocytes decreases to around 300,000–400,000. On average, about 400 primary oocytes will actually complete development and give rise to the secondary oocytes that are eventually released from the ovaries.

Ovulation (ov'ū-lā'shŭn, ō'vū-lā'shŭn) is the release of a **secondary oocyte** from an ovary (figure 28.14, *step 8*). Just before ovulation, the primary oocyte completes the first meiotic division to produce a secondary oocyte and a **first polar body**. Unlike meiosis in males, cytoplasm is not split evenly between the two cells. Most of the cytoplasm of the primary oocyte remains with the secondary oocyte. As a result, the secondary oocyte is much larger than the first polar body. The cytoplasm contains organelles, such as mitochondria, and nutrients that increase the viability of the secondary oocyte. The first polar body either degenerates or divides to form two second polar bodies. Eventually, the polar bodies degenerate. The secondary oocyte begins the second meiotic division, but it stops in metaphase II.

After ovulation, the secondary oocyte may be fertilized by a sperm cell (figure 28.14, *step 9*). **Fertilization** (fer'til-i-zā-shŭn)

FIGURE 28.13 Histology of the Ovary

The ovary is sectioned to illustrate its internal structure (the inset shows plane of section). Ovarian follicles from each major stage of development are shown. **APR**

begins when a sperm cell binds to the plasma membrane and penetrates the plasma membrane of a secondary oocyte. Subsequently, the secondary oocyte completes the second meiotic division to form two cells, each containing 23 chromosomes. One of these cells has very little cytoplasm and is called the second polar body, which degenerates. In the other, larger cell, the 23 chromosomes from the sperm cell nucleus join with the 23 chromosomes from the oocyte to form a **zygote** (zī'gōt), completing fertilization. The zygote has 23 pairs of chromosomes (a total of 46 chromosomes). All cells of the human body contain 23 pairs of chromosomes, except for the male and female gametes. The zygote divides by mitosis to form two cells, which divide to form four cells, and so on. Seven days after ovulation, the mass of cells may implant in or attach to the uterine wall. The implanted mass of cells continues to develop for approximately 9 months to form a new individual (see chapter 29).

Follicle Development

Within the cortex of the ovary are specialized structures called ovarian follicles. These follicles contain the developing primary oocytes. As the primary oocytes progress through meiosis I, the ovarian follicle undergoes development, changing in size and structure (figure 28.14).

As discussed earlier, oogenesis begins when a female is in her mother's uterus. The primary oocytes present at birth are located in primordial follicles. A **primordial follicle** is a primary oocyte surrounded by a single layer of flat cells, called **granulosa cells** (figure 28.14). Once puberty begins, some of the primordial follicles become **primary follicles**. This transition to a primary follicle occurs as the oocyte enlarges and the single layer of granulosa cells becomes thicker and the cells become cuboidal in shape. Subsequently, several layers of granulosa cells form, and a layer of clear material called the **zona pellucida** (zō'nā pellū'sid-dā;

FUNDAMENTAL Figure

- Oogonia give rise to primary oocytes. Before birth, oogonia multiply by mitosis. During development of the fetus, many oogonia begin meiosis, but stop in prophase I and are now called primary oocytes. They remain in this state until puberty.
- Before birth, the primary oocytes become surrounded by a single layer of granulosa cells, creating a primordial follicle. These are present until puberty.
- After puberty, primordial follicles develop into primary follicles when the granulosa cells enlarge and increase in number.
- Secondary follicles form when fluid-filled vesicles develop and thecal cells arise on the outside of the follicle.
- Mature follicles form when the vesicles create a single antrum.
- Just before ovulation, the primary oocyte completes meiosis I, creating a secondary oocyte and a first polar body.
- The secondary oocyte begins meiosis II, but stops at metaphase II.
- During ovulation, the secondary oocyte is released from the ovary.
- The secondary oocyte only completes meiosis II if it is fertilized by a sperm cell. The completion of meiosis II forms an oocyte and a second polar body. Fertilization is complete when the oocyte nucleus and the sperm cell nucleus unite, creating a zygote.
- Following ovulation, the granulosa cells divide rapidly and enlarge to form the corpus luteum.
- The corpus luteum degenerates to form a scar, or corpus albicans.

PROCESS FIGURE 28.14 Oogenesis and Follicle Development

The events of oogenesis and follicle development are closely linked. Once these structures are mature, fertilization can result. The numbers written in the cells are total numbers of chromosomes.

girdle + *pellucidus*, passage of light) is deposited around the primary oocyte.

Approximately every 28 days, hormonal changes stimulate some of the primary follicles to continue to develop (figure 28.14). The primary follicle becomes a **secondary follicle** as fluid-filled spaces called **vesicles** form among the granulosa cells, and a capsule called the **theca** (thē'kā; a box) forms around the follicle (see figure 28.13). Cells of the **theca interna** surround the granulosa cells, where they participate in the synthesis of ovarian hormones. The **theca externa** is primarily connective tissue that merges with the stroma of the ovary.

The secondary follicle continues to enlarge. When the fluid-filled vesicles fuse to form a single, fluid-filled chamber called the **antrum** (an'trūm), the follicle is called a **mature follicle**, or *Graafian* (graf'ē-ăn) *follicle*. In the mature follicle, the oocyte is pushed off to one side and lies in a mass of granulosa cells called the **cumulus cells**, or *cumulus oophorus* (kū'mū-lūs ō-of'ōr-ūs).

The mature follicle forms a lump on the surface of the ovary. During ovulation, the mature follicle ruptures, releasing a small amount of blood, follicular fluid, and the oocyte, surrounded by the cumulus cells, into the peritoneal cavity. The cumulus cells resemble a crown radiating from the oocyte and are thus called the **corona radiata**.

Usually, only one mature follicle reaches the most advanced stages of development and is ovulated. The other follicles that were undergoing this maturation process degenerate, a process called **atresia**.

Fate of the Follicle

After ovulation, the ruptured mature follicle still has an important function. It is transformed into an endocrine structure called the **corpus luteum** (kōr'pūs loo'tē-ūm; yellow body). The corpus luteum has a convoluted appearance as a result of its collapse after ovulation (figure 28.14). The granulosa cells and the theca interna, now called **luteal cells**, enlarge and begin to secrete hormones—progesterone and smaller amounts of estrogen.

If pregnancy occurs, the corpus luteum enlarges and remains active throughout pregnancy as the **corpus luteum of pregnancy**. If pregnancy does not occur, the corpus luteum remains functional for about 10–12 days and then begins to degenerate. As the corpus luteum degenerates, progesterone and estrogen secretion decreases. Within the corpus luteum, connective tissue cells become enlarged and clear, giving the whole structure a whitish color. The structure is then called the **corpus albicans** (al'bī-kanz; white body). The corpus albicans continues to shrink and eventually disappears after several months or even years.

ASSESS YOUR PROGRESS

40. List the organs of the female reproductive system.
41. Name and describe the ligaments that hold the ovaries in place.
42. Discuss the coverings and structure of the ovary.
43. Starting with oogonia, describe the formation of secondary oocytes by meiosis. What are polar bodies?

44. Describe the formation of a zygote. How many pairs of chromosomes are in a zygote, and where do the chromosomes within a pair come from?
45. Distinguish among primordial, primary, secondary, and mature follicles.
46. Describe the process of ovulation.
47. What is the corpus luteum? What happens to it if fertilization occurs? If fertilization does not occur?

Uterine Tubes

A **uterine tube**, also called a *fallopian* (fa-lō'pē-an) *tube* or *oviduct* (ō'vi-dūkt), is associated with each ovary. It extends from the area of the ovary to the uterus (see figure 28.12). Each uterine tube is located along the superior margin of the broad ligament. The part of the broad ligament most directly associated with the uterine tube is called the **mesosalpinx** (mez'ō-sal'pink).

The uterine tube opens directly into the peritoneal cavity to receive the secondary oocyte released from the ovary during ovulation. Near the ovary, the uterine tube expands to form the **infundibulum** (in-fūn-dib'ū-lūm; funnel). Long, thin processes called **fimbriae** (fim'brē-ē; fringe) surround the opening of the infundibulum. The inner surfaces of the fimbriae consist of a ciliated mucous membrane.

The part of the uterine tube that is nearest the infundibulum is called the **ampulla**. It is the widest and longest part of the tube and accounts for about 7.5–8 cm of the total 10 cm length of the tube. Fertilization usually occurs in the ampulla. The part of the uterine tube nearest the uterus is the **isthmus**. It is much narrower and has thicker walls than the ampulla. The **uterine part**, or *intramural part*, of the uterine tube passes through the uterine wall and ends in a very small uterine opening.

The wall of each uterine tube consists of three layers: (1) the serosa, (2) the muscular layer, and (3) the mucosa (see figure 28.12). The outer **serosa** is formed by the peritoneum, the middle **muscular layer** consists of longitudinal and circular smooth muscle cells, and the inner **mucosa** consists of a mucous membrane of simple ciliated columnar epithelium. The mucosa is arranged into numerous longitudinal folds.

The mucosa of the uterine tubes provides nutrients for the oocyte or, if fertilization has occurred, for the developing embryonic mass (see chapter 29) as it passes through the uterine tube. The ciliated epithelium helps move the small amount of fluid and the oocyte, or the developing embryonic mass, through the uterine tubes.

Uterus

The **uterus** (ū'ter-ūs) is the size and shape of a medium-sized pear—about 7.5 cm long and 5 cm wide (see figures 28.11 and 28.12). It is slightly flattened anteroposteriorly and is oriented in the pelvic cavity with the larger, rounded part, the **fundus** (fūn'dūs), directed superiorly and the narrower part, the **cervix** (ser'viks), directed inferiorly. The main part of the uterus, the **body**, is the region between the fundus and the cervix. A slight constriction called the **isthmus** marks the junction of the cervix and the body. Internally, the uterine cavity continues as the **cervical canal**, which opens through the **ostium** into the vagina.

MICROBES In Your Body

Human Papillomavirus and Cancer

In the majority of the “Microbes in Your Body” features, we have focused on bacteria. However, recall from chapter 1 that the human microbiota also includes viruses, protists, and fungi. Human papillomaviruses (HPV) belong to a family of DNA viruses that are naturally found on the skin soon after birth. Over 200 types of HPV have been identified, and most are not harmful. However, more than 10 types have been shown to be oncogenic, or cancer-causing, with two types, HPV 16 and HPV 18, being linked to 70% of all cervical cancer cases. In addition, the number of cases of mouth and throat cancers caused by HPV is on the rise, especially in men.

Viruses take over their host cell’s machinery to replicate and form thousands of new individual viruses. In the case of HPV, the virus targets undifferentiated cells in the stratified squamous epithelium of the outer body skin, as well as the stratified squamous epithelium of the mucosal lining of the reproductive tract or pharynx (see chapter 4). Once the virus is inside the host cell nucleus, its DNA is replicated at the same time the host cell DNA is replicated. HPV induces uncontrolled division in its host’s cells. The continued division causes an accumulation of mutations, and eventually the cell becomes cancerous. New

HPV are released through normal shedding of cells. Fortunately, full-blown metastasizing cancer from an HPV infection takes more than 10 years to develop, which gives enough time for screening, identification, and treatment.

Because HPV is present for years with no clinical symptoms, the most effective way to avoid the oncogenic forms is to be vaccinated against them. Acquisition of HPV is often through sexual transmission, but the virus can also be passed from mother to child or from very close contact with an infected individual, such as providing personal hygienic care. Even so, HPV is the most common sexually transmitted disease, with some high-risk types. The high-risk types can develop into cervical cancer or several forms of head and neck cancers, particularly oropharyngeal cancer. In addition, naturally acquired HPV does not usually elicit a strong immune response, which prevents memory immune response to protect from potential future exposures. Thus, the vaccine Gardasil® has been developed to vaccinate against HPV types 16 and 18. Additional HPV vaccines also protect against several other types of HPV. Vaccination for all preteens and previously unvaccinated people through age 26 is recommended by the Centers for Disease Control and Prevention.

Recently, the Food and Drug Administration approved an HPV screening test for use in combination with the traditional Pap test for women. The Pap test involves collecting cells from the surface of the cervix for examination under a microscope. If the cells are abnormally shaped, as precancerous or cancerous cells would be, it is indicative that further testing should be done. However, the Pap test can be negative for abnormal cells even if the woman has HPV. If that is the case, the HPV test is recommended to test if HPV is present. The HPV test is also recommended for women over 30 years of age even if the woman has been vaccinated for HPV, since the vaccine does not target all oncogenic forms of HPV. Eventually, with continued vaccination, the oncogenic types may become less relevant to human health.

Predict 5

The identity of the cell surface receptors used by HPV to enter their host cell has not been completely identified but will most likely be known within the next several years. Propose a future mechanism that could use the cell surface receptor protein to prevent HPV uptake and the subsequent development of cancer-inducing uncontrolled cell division.

The uterus is supported by the broad ligament, the **round ligaments** (see figure 28.12), and the **uterosacral ligaments**. The broad ligament is a peritoneal fold extending from the lateral margins of the uterus to the wall of the pelvis on either side. It also surrounds and supports the ovaries and the uterine tubes. The round ligaments extend from the uterus through the inguinal canals to the labia majora of the external genitalia, and the uterosacral ligaments attach the lateral wall of the uterus to the sacrum. Normally, the uterus is *anteverted*, meaning that the body of the uterus is tipped slightly anteriorly. However, in some women, the uterus is retroverted, or tipped posteriorly.

In addition to the ligaments, skeletal muscles of the pelvic floor support the uterus inferiorly. If these muscles are weakened (e.g., in childbirth), the uterus can extend inferiorly into the vagina, a condition called a **prolapsed uterus**.

The uterine wall is composed of three layers: (1) the perimetrium, (2) the myometrium, and (3) the endometrium (see figure 28.12). The **perimetrium** (per-i-mē'trē-ŭm), or *serous layer*, is the peritoneum that covers the uterus. The next layer, just deep to the perimetrium, is the **myometrium** (mī'ō-mē'trē-ŭm), or *muscular layer*, composed of a thick layer of

smooth muscle. The myometrium accounts for the bulk of the uterine wall and is the thickest layer of smooth muscle in the body. In the cervix, the muscular layer contains less muscle and more dense connective tissue. The cervix is therefore more rigid and less contractile than the rest of the uterus. The innermost layer of the uterus is the **endometrium** (en'dō-mē'trē-ŭm), or *mucous membrane*, which consists of a simple columnar epithelial lining and a connective tissue layer called the lamina propria. Simple tubular glands, called spiral glands, are scattered about the lamina propria and open through the epithelium into the uterine cavity. The endometrium consists of two layers: (1) the basal layer and (2) the functional layer. The thin, deep **basal layer** is the deepest part of the lamina propria and is continuous with the myometrium. The thicker, superficial **functional layer** consists of most of the lamina propria and the endothelium and lines the uterine cavity itself. The functional layer is so named because it undergoes changes and sloughing during the female menstrual cycle. Small **spiral arteries** of the lamina propria supply blood to the functional layer of the endometrium. These blood vessels play an important role in the cyclic changes of the endometrium.

Columnar epithelial cells line the cervical canal, which contains **cervical mucous glands**. The mucus fills the cervical canal and acts as a barrier to substances that could pass from the vagina into the uterus. Near ovulation, the consistency of the mucus changes, easing the passage of sperm cells from the vagina into the uterus.

49. How are the uterine tubes involved in moving the oocyte or the zygote?
50. Name the parts of the uterus.
51. Describe the major ligaments holding the uterus in place.
52. Describe the layers of the uterine wall.

Vagina

The **vagina** (vā-jī'nā) is the female organ of copulation, receiving the penis during intercourse. It also allows menstrual flow and childbirth. The vagina is a tube about 10 cm long that extends from the uterus to the outside of the body (see figure 28.12). Longitudinal ridges called **columns** extend the length of the anterior and posterior vaginal walls, and several transverse ridges called **rugae** (roo'gē) extend between the anterior and posterior columns. The superior, domed part of the vagina, the **fornix** (fōr'niks), is attached to the sides of the cervix, so that a part of the cervix extends into the vagina.

The wall of the vagina consists of an outer muscular layer and an inner mucous membrane. The muscular layer is smooth muscle that allows the vagina to increase in size to accommodate the penis during intercourse and to stretch greatly during childbirth. The mucous membrane is moist stratified squamous epithelium that forms a protective surface layer. The vaginal mucous membrane releases most of the lubricating secretions produced by the female during intercourse.

The **hymen** (hī'men) is a thin mucous membrane that covers the **vaginal opening**, or **orifice**. Sometimes, the hymen completely closes the vaginal opening (a condition called imperforate hymen), and it must be removed to allow menstrual flow. More commonly, the hymen is perforated by one or several holes. The openings in the hymen are usually greatly enlarged during the first sexual intercourse. In addition, the hymen can be perforated earlier in a young woman's life, such as during strenuous physical exercise. Thus, the absence of an intact hymen does not necessarily indicate that a woman has had sexual intercourse, as was once thought.

55. What is the hymen?

External Genitalia

The external female genitalia is the **vulva** (vūl'vă), or *pudendum* (pū-den'dūm). It consists of the vestibule and its surrounding structures (figure 28.15). The **vestibule** (ves'ti-bool) is the space

FIGURE 28.15 Female External Genitalia

into which the vagina opens posteriorly and the urethra opens anteriorly. A pair of thin, longitudinal skin folds called the **labia** (lā'bē-ă; lips) **minora** (sing. labium minus) form a border on each side of the vestibule. A small, erectile structure called the **clitoris** (klit'ō-ris) is located in the anterior margin of the vestibule. Anteriorly, the two labia minora unite over the clitoris to form a fold of skin called the **prepuce**.

The clitoris is usually less than 2 cm in length and consists of a shaft and a distal glans. Well supplied with sensory receptors, it initiates and intensifies levels of sexual sensation. The clitoris contains two erectile structures, the **corpora cavernosa**, each of which expands at the base end of the clitoris to form the **crus of the clitoris** and attaches the clitoris to the pelvic bones. The corpora cavernosa of the clitoris are comparable to the corpora cavernosa of the penis, and they become engorged with blood as a result of sexual excitement. In most women, this engorgement results in an increase in the diameter, but not the length, of the clitoris. With increased diameter, the clitoris makes better contact with the prepuce and surrounding tissues and is more easily stimulated.

Erectile tissue that corresponds to the corpus spongiosum of the male lies deep to and on the lateral margins of the vestibular floor on each side of the vaginal orifice. Each erectile body is called a **bulb of the vestibule**. Like other erectile tissue, it becomes engorged with blood and is more sensitive during sexual arousal. Expansion of the bulbs causes narrowing of the vaginal orifice and allows better contact of the vagina with the penis during intercourse.

Glands associated with the vestibule secrete a lubricating fluid that prevents drying of the vestibule. The ducts of the greater vestibular glands open on each side of the vestibule, between the vaginal opening and the labia minora. Additional small mucous glands, the **lesser vestibular glands**, or *paraurethral glands*, are located near the clitoris and urethral opening.

Lateral to the labia minora are two prominent, rounded folds of skin called the **labia majora**. Subcutaneous adipose tissue is primarily responsible for the prominence of the labia majora. The two labia majora unite anteriorly in an elevation over the symphysis pubis called the **mons pubis** (monz pū'bis). The lateral surfaces of the labia majora and the surface of the mons pubis are covered with coarse hair. The medial surfaces are covered with numerous sebaceous and sweat glands. The space between the labia majora is called the **puddental cleft**. Most of the time, the labia majora are in contact with each other across the midline, closing the pudental cleft and concealing the deeper structures within the vestibule.

Perineum

Similar to the male perineum, the female **perineum** is divided into two triangles by the superficial and deep transverse perineal muscles (figure 28.16; see figure 28.2). The anterior urogenital triangle contains the external genitalia, and the posterior anal triangle contains the anal opening. The region between the vagina and the anus is the **clinical perineum**. The skin and muscle of this region can tear during childbirth. To prevent such tearing, an incision called an **episiotomy** (e-piz-ē-ot'ō-mē, e-pis-ē-ot'ō-mē) is sometimes made in the clinical perineum. This clean, straight incision is easier to repair than a tear would be. Alternatively, allowing the perineum to stretch slowly during delivery may prevent tearing, thereby making an episiotomy unnecessary.

Mammary Glands

The **mammary glands** are the organs of milk production and they are located within the **breasts** (figure 28.17). The mammary glands are modified sweat glands. Externally, the breasts of both males and females have a raised **nipple** surrounded by a circular, pigmented region called the **areola** (ă-rē'ō-lă). The areolae normally have a slightly bumpy surface caused by **areolar glands** just below the surface. The areolar glands are actually rudimentary mammary glands. Secretions from these glands lubricate and protect the nipple and the areola from chafing during nursing.

Before puberty, the general structure of the breasts is similar in both males and females. The breasts possess a rudimentary glandular system, which consists mainly of ducts with sparse alveoli. The female breasts begin to enlarge during puberty, primarily under the influence of estrogen and progesterone. Increased sensitivity or pain in the breasts often accompanies this enlargement. Males often experience the same sensations during early puberty, and their breasts can even develop slight swellings; however, these symptoms usually disappear fairly quickly. On rare occasions, the breasts of a male become enlarged, a condition called **gynecomastia** (gī'ne-kō-mas'tē-ă).

Each adult female mammary gland usually consists of 15–20 glandular **lobes** covered by a considerable amount of adipose tissue. It is primarily this superficial adipose tissue that gives the breast its form. The lobes of each mammary gland form a conical mass, with the nipple located at the apex. Each lobe has a single **lactiferous** (lak-tif'er-ūs; milk-producing) **duct**, which opens independently of other lactiferous ducts on the surface of the nipple. Just deep to the surface, each lactiferous duct enlarges to form a small, spindle-shaped **lactiferous sinus**. In lactating females, milk accumulates in the lactiferous sinuses during milk letdown. The lactiferous duct supplying a lobe subdivides to form smaller ducts, each of which supplies a **lobule**. Within a lobule, the ducts branch and become even smaller. In milk-producing, or lactating, mammary glands, the ends of these small ducts expand to form secretory sacs called **alveoli**.

FIGURE 28.17 Anatomy of the Breast

(a) Lactiferous ducts divide to supply lobules, which form lobes. (b) In the nonlactating breast, only the duct system is present. (c) In the lactating breast, the ends of the mammary gland ducts have secretory sacs, called alveoli, that produce milk. Surrounding the alveoli are myoepithelial cells, which can contract, causing the milk to move out of the alveoli. **APR**

Myoepithelial cells surround the alveoli and contract to expel milk (see chapter 29). In non-lactating mammary glands, only the duct system is present.

A group of **suspensory ligaments**, or *Cooper ligaments*, support and hold the breasts in place. These ligaments extend from the fascia over the pectoralis major muscles to the skin over the mammary glands and prevent the breasts from excessive sagging.

The nipples are very sensitive to tactile stimulation and contain smooth muscle cells that contract, causing the nipple to become erect in response to stimulation. These smooth muscle cells respond to stimuli such as touch, cold, and sexual arousal.

ASSESS YOUR PROGRESS

63. Describe the anatomy of the mammary glands.
64. Trace the route taken by a drop of milk from its site of production to the outside of the body.

Clinical IMPACT

Fibrocystic Changes in the Breast

Fibrocystic changes in the breast are benign and include the formation of fluid-filled cysts, hyperplasia (accelerated growth) of the duct system of the breast, and the deposition of fibrous connective tissue. Breast pain sometimes occurs, especially during the luteal phase of the menstrual cycle and continuing until menstruation. These changes occur in approximately 10% of women who are less than 21 years of age, 25% of women in their reproductive years, and 50% of women who are postmenopausal. The cause of the condition is not known.

Some evidence suggests that women with certain types of duct hyperplasia, along with a family history of breast cancer, have an increased likelihood of developing breast cancer.

Clinical GENETICS

Breast Cancer

Breast cancer is a serious, often fatal disease that most often occurs in women. It is the most common cancer in North American women. Greater than 75% of the breast cancer cases occur in women older than 50 years of age, and 85% involve cancer of the epithelium of the mammary gland ducts (ductal carcinoma).

The risk for breast cancer appears to be lower if a woman has had a child. Women who have never given birth are at a greater risk than those who have given birth. The younger a woman is when her first child is born, the lower her risk of developing breast cancer. However, the risk for breast cancer is not lowered in young women who become pregnant but do not carry to full term. It appears that differentiation of the breast epithelium caused by the first pregnancy decreases the risk for cancer by reducing the amount of undifferentiated epithelium in the breast.

Breast cancer development correlates with long-term exposure to high levels of estrogen. Since pregnancy delays the menstrual cycle and decreases estrogen secretion, this may explain its effect on breast cancer risk. In addition, decreased exposure of breast tissue to estrogen explains a reduced cancer risk because of early menopause or removal of the ovaries. Unfortunately, hormone replacement therapy for postmenopausal women correlates with an increased incidence of cancer; however, breast cancer incidence decreases with the use of drugs that block the effect of estrogen receptors.

A number of environmental factors have been associated with the development of

breast cancer. Exposure to ionizing radiation, especially during adolescence and during pregnancy when epithelial cells are dividing more rapidly, is correlated with breast cancer. High dietary fat intake and obesity are also linked to breast cancer, although the fish oil-derived omega-3 fatty acids may help prevent cancer. Breast cancer rates are low in Japanese women; however, Japanese women who immigrate to the United States and adopt a Western diet have breast cancer rates close to those of women in the United States. A number of environmental factors that mimic estrogen, such as components of plastics, fuels, pharmaceuticals, and chlorine-based chemicals (such as DDT, PCBs, and chlorofluorocarbons), may increase the incidence of breast cancer.

Between 5% and 10% of breast cancers are hereditary. Women who have inherited specific gene mutations have an increased risk for breast cancer. Therefore, a history of breast cancer in a close relative, such as a mother or sister, makes breast cancer more likely, and the risk increases further if more than one close relative has had breast cancer, especially if the cancer affected both breasts and if it occurred before menopause. Genetic tests can identify breast cancer genes. However, the presence of breast cancer genes does not mean that cancer will develop. Some women who are known to be at high risk because of their genetic makeup have frequent breast examinations, whereas others elect to have their breasts surgically removed before cancer develops.

Mutations in the *BRCA1* and *BRCA2* genes are responsible for about 30–40% of

inherited breast cancers. The *BRCA* genes are tumor suppressor genes, which normally suppress cell division (see Clinical Genetics, “Genetic Changes in Cancer Cells,” chapter 3). A person who has two mutated *BRCA* alleles is much more likely to develop breast cancer. Although a person with one normal and one mutated *BRCA* allele may have sufficient tumor suppressor activity, she has a greater risk of developing cancer because only one mutation in the remaining normal *BRCA* allele is necessary to eliminate tumor suppressor activity. Consequently, a person who has inherited two normal alleles is much less likely to develop breast cancer than a person who has inherited one or two mutated alleles.

Another tumor suppressor gene is called *p53*. The cells of almost 50% of all cancers have a mutated *p53* gene, and these cancers are more aggressive and more often fatal than cancers without a mutated *p53* gene. Approximately 20–40% of individuals with hereditary breast cancer have a mutated *p53* gene. *P53* is a regulatory gene that has been called the “guardian of the genome,” since *p53* is activated when DNA is damaged. Once activated, *p53* arrests the cell cycle and initiates the repair of damaged DNA before the cell cycle continues. If the DNA damage is too extensive, *p53* causes cell death. Thus, the *p53* gene normally helps repair or eliminate cells that may become cancer cells. When *p53* is mutated, this protection against aberrant cell proliferation is reduced and there is a greatly increased risk for tumor formation.

28.6 Physiology of Female Reproduction

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the changes that occur in females during puberty.
- Explain the changes in the ovary and uterus during the menstrual and ovarian cycles.
- List the hormones of the female reproductive system and explain their functions and how their secretion is regulated.

- Explain the events that occur during the female sexual act.
- Describe the events that occur following fertilization of the oocyte and the process of implantation of the embryo.
- Discuss menopause, including the changes that result from it.

Female reproduction is under hormonal and nervous control. The development of the female reproductive organs and their normal function depend on a number of hormones. Estrogen and progesterone are the female reproductive hormones. The term *estrogen* actually refers to several hormones, including estradiol, estrone, and estrinol. Estradiol is the primary estrogen in humans and the most prevalent in the blood.

Puberty in Females

The first episode of menstrual bleeding, called **menarche** (me-nar'kē), occurs during puberty, between ages 11 and 16. At this time, the vagina, uterus, uterine tubes, and external genitalia begin to enlarge as well. Adipose tissue is deposited in the breasts and around the hips, causing them to enlarge and assume adult form. The ducts of the breasts develop, pubic and axillary hair grows, and the voice changes, although more subtly than in males. The development of sex drive is also associated with puberty.

The changes associated with puberty are primarily the result of elevated rates of estrogen and progesterone secretion by the ovaries. Before puberty, estrogen and progesterone are secreted in very small amounts, and LH and FSH levels remain very low due to a lack of GnRH released from the hypothalamus. At puberty, not only are GnRH, LH, and FSH secreted in greater quantities than before puberty but also the adult cyclic pattern of FSH and LH secretion is established.

ASSESS YOUR PROGRESS

65. Define menarche. Describe other physical changes that occur during female puberty.
66. What changes occur in LH, FSH, estrogen, and progesterone secretion during puberty?

Menstrual Cycle

The term **menstrual** (men'stroo-äl) **cycle** technically refers to the cyclic changes in sexually mature, nonpregnant females that begin with menses. Typically, the menstrual cycle is about 28 days long, although it can be as short as 18 days in some women and as long as 40 days in others (figure 28.18). **Menses** (men'sēz) is a period of mild hemorrhage that occurs approximately once each month, during which the functional layer of the endometrium is sloughed and expelled from the uterus. **Menstruation** (men-stroo-ā'shūn) is the discharge of the blood and other elements of the endometrium. Although the term *menstrual cycle* refers specifically to changes in the uterus, the term is often used to refer to all the cyclic events in the female reproductive system, including alterations in hormone secretion and changes in the ovaries (table 28.2).

The first day of menses is considered day 1 of the menstrual cycle, and menses typically lasts 4–5 days. Ovulation occurs on about day 14 of a 28-day menstrual cycle; however, the timing of ovulation varies from individual to individual and even within a single individual from one menstrual cycle to the next. The time between ovulation (day 14) and the next menses is typically 14 days. The time between the first day of menses and the day of ovulation is more variable than the time between ovulation and the next menses. The time between the ending of menses and ovulation is called the **proliferative phase**, because of the rapid proliferation of the uterine mucosa, or the **follicular phase**, because of the rapid development of ovarian follicles. The period after ovulation and before the next menses is called the **secretory phase**, because of the maturation of and secretion by uterine glands, or the **luteal phase**, because of the existence of the corpus luteum.

So that it is easier to discuss the processes occurring in different components of the female reproductive system, the menstrual cycle is divided into the ovarian cycle and the uterine cycle. The *ovarian cycle* describes the changes that are associated specifically with the ovaries, and the *uterine cycle* describes the changes that are associated specifically with the uterus.

Ovarian Cycle

The term **ovarian cycle** refers to the regular events that occur in the ovaries of sexually mature, nonpregnant women during the menstrual cycle. This cycle can be divided into the follicular phase, which occurs before ovulation, and the luteal phase, which occurs after ovulation. The hypothalamus and anterior pituitary release hormones that control the events of the ovarian cycle. FSH from the anterior pituitary is primarily responsible for initiating the development of primary follicles, and as many as 25 follicles begin to mature during each ovarian cycle. However, normally only 1 is ovulated. The follicles that start to develop in response to FSH may not ovulate during the same ovarian cycle in which they begin to mature, but they may ovulate one or two cycles later. The remaining follicles degenerate. Larger, more mature follicles appear to secrete estrogen and other substances that have an inhibitory effect on other, less mature follicles.

Early in the ovarian cycle, the release of GnRH from the hypothalamus increases, as does the sensitivity of the anterior pituitary to GnRH. These changes stimulate the anterior pituitary to produce and release small amounts of FSH and LH. FSH and LH stimulate follicular growth and maturation. They also cause an increase in estrogen secretion by the developing follicles. FSH exerts its main effect on the granulosa cells, whereas LH exerts its initial effect on the theca interna cells and later on the granulosa cells.

LH stimulates the theca interna cells to produce androgens, which diffuse from these cells to the granulosa cells. FSH stimulates the granulosa cells to convert androgens to estrogen. In addition, FSH gradually increases LH receptors in the granulosa cells. Estrogen produced by the granulosa cells increases LH receptors in the theca interna cells. Consequently, theca interna cells and granulosa cells cooperate to produce estrogen. Estrogen, in turn, increases receptors for LH in both theca interna cells and granulosa cells.

After LH receptors in the granulosa cells have increased, LH stimulates the granulosa cells to produce progesterone, which diffuses from the granulosa cells to the theca interna cells, where it is converted to androgens. These androgens are also converted to estrogen by the granulosa cells. Thus, the production of androgens by the theca interna cells increases, resulting in a gradual increase in estrogen secretion by granulosa cells throughout the follicular phase, even though only a small increase in LH secretion occurs. FSH levels actually decrease during the follicular phase because developing follicles produce inhibin, which has a negative-feedback effect on FSH secretion.

The gradual increase in estrogen levels, especially late in the follicular phase, begins to have a positive-feedback effect on LH and FSH release from the anterior pituitary. Consequently, as the estrogen level in the blood increases, it stimulates greater LH and FSH secretion. The sustained increase in estrogen is necessary for this positive-feedback effect. In response, LH and FSH secretion

FUNDAMENTAL Figure

FIGURE 28.18 Menstrual Cycle

This graph depicts the changes that occur in blood hormone levels, follicles, and the endometrium during the menstrual cycle.

increases rapidly and in large amounts just before ovulation (figure 28.19). The increase in blood levels of both LH and FSH is called the **LH surge**, and the increase in FSH is called the **FSH surge**. The LH surge occurs several hours earlier and to a greater degree than the FSH surge, and the LH surge can last up to 24 hours.

Ovulation is initiated by the LH surge and causes the ovulated follicle to become the corpus luteum. FSH can make the follicle more sensitive to the influence of LH by stimulating the synthesis of additional LH receptors in the follicles and by

stimulating the development of follicles that may ovulate during later ovarian cycles.

The LH surge causes the primary oocyte to complete the first meiotic division just before or during the process of ovulation. Also, the LH surge triggers several events that are very much like inflammation in a mature follicle. These events result in ovulation. The follicle enlarges due to edema. Proteolytic enzymes break down the ovarian tissue around the follicle, causing the follicle to rupture, and the oocyte and some surrounding follicle cells are slowly released from the ovary.

TABLE 28.2 Hormone Secretion During the Menstrual Cycle

Menses	Proliferative Phase	Ovulation	Secretory Phase
Pituitary Hormones			
LH levels are low and remain low; FSH increases somewhat.	Near the end of the proliferative phase, LH and FSH levels begin to increase rapidly in response to increases in estrogen.	Increasing levels of LH trigger ovulation. Ovulation generally occurs after LH levels have reached their peak. FSH reaches a peak about the time of ovulation and initiates the development of follicles that may complete maturation during a later cycle.	LH and FSH levels decline to low levels following ovulation and remain low during the secretory phase in response to increases in estrogen and progesterone.
Developing Follicles			
FSH secreted during menses causes several follicles to begin to enlarge.	As several follicles continue to enlarge, they begin to secrete estrogen. In addition, many follicles degenerate. By the end of the proliferative phase, only one of the follicles has become a mature follicle that is capable of ovulation.	Normally, a single follicle reaches maturity and ovulates in response to LH. The oocyte and some cumulus cells are released during ovulation.	Following ovulation, the granulosa cells of the ovulated follicle change to luteal cells and begin secreting large amounts of progesterone and some estrogen.
Estrogen			
The ovarian follicles secrete very little estrogen.	Near the end of the proliferative phase, the enlarging follicles begin to secrete increasing amounts of estrogen. The estrogen causes the pituitary gland to secrete increasing quantities of LH and smaller quantities of FSH. The positive-feedback relationship between estrogen and LH results in rapidly increasing LH and estrogen levels several days prior to ovulation. The rapid increase in LH triggers ovulation.	Estrogen, secreted by developing follicles, reaches a peak at ovulation.	Following ovulation, estrogen levels decline. After the luteal cells have been established, smaller amounts of estrogen are secreted by the corpus luteum.
Progesterone			
The ovarian follicles secrete very little progesterone.	Progesterone levels are low during the proliferative phase.	Progesterone levels are low.	Following ovulation, progesterone levels increase due to progesterone secretion by the corpus luteum. Progesterone levels remain high throughout the secretory phase and fall rapidly just before menses unless pregnancy occurs.
Uterine Endometrium			
The endometrium of the uterus undergoes necrosis and is eliminated during menses. The necrosis is a result of decreasing progesterone concentrations near the end of the proliferative phase.	In response to estrogen, endometrial cells of the uterus undergo rapid cell division and proliferate rapidly. In addition, the number of progesterone receptors in the endometrial cells increases in response to estrogen.	Ovulation occurs over a short time. It signals the end of the proliferative phase, as estrogen levels decline, and the onset of the secretory phase, as progesterone levels begin to increase.	Progesterone causes the endometrial cells to enlarge and secrete a small amount of fluid. The endometrium continues to thicken throughout the secretory phase. Near the end of the secretory phase, declining progesterone levels allow the spiral arteries of the endometrium to constrict, causing ischemia, and the endometrium becomes necrotic unless pregnancy occurs.

PROCESS FIGURE 28.19 Regulation of Hormone Secretion During the Ovarian Cycle

Hormone secretion is regulated from the anterior pituitary and the ovary before and after ovulation.

Shortly after ovulation, the follicle's production of estrogen decreases. The remaining granulosa cells of the ovulated follicle are converted to corpus luteum cells and begin to secrete progesterone. After the corpus luteum forms, progesterone levels become much higher than before ovulation, and some estrogen is produced. The increased progesterone and estrogen have a negative-feedback effect on GnRH release from the hypothalamus. As a result, LH and FSH release from the anterior pituitary decreases. Estrogen and progesterone also cause the down-regulation of GnRH receptors in the anterior pituitary, and the anterior pituitary cells become less sensitive to GnRH. Because of the decreased secretion of GnRH and decreased sensitivity of the anterior pituitary to GnRH, the rate of LH and FSH secretion declines to very low levels after ovulation (figure 28.19; see figure 28.18).

If the ovulated oocyte is fertilized, the developing embryo secretes the LH-like substance **human chorionic gonadotropin (hCG)**, which keeps the corpus luteum from degenerating. As a

result, blood levels of estrogen and progesterone do not decrease, and menses does not occur. If fertilization does not occur, hCG is not produced. The cells of the corpus luteum begin to atrophy after day 25 or 26, and the blood levels of estrogen and progesterone decrease rapidly, resulting in menses.

➤ Predict 6

Predict the effect on the ovarian cycle of administering a relatively large amount of estrogen and progesterone just before the preovulatory LH surge. Also predict the consequences of continually administering high concentrations of GnRH.

Uterine Cycle

The term **uterine cycle** refers to changes that occur primarily in the endometrium of the uterus during the menstrual cycle (figure 28.20; see figure 28.18). Other, more subtle changes also take place in the vagina and other structures during the menstrual cycle. Cyclic

Clinical IMPACT

Menstrual Cramps and Amenorrhea

Menstrual cramps are the result of strong myometrial contractions that occur before and during menstruation. The cramps can result from excessive prostaglandin secretion. As the endometrium of the uterus sloughs off, it becomes inflamed, and prostaglandins are produced as part of the inflammatory process. Sloughing of the endometrium and uterine contractions are inhibited by progesterone but stimulated by estrogen. Many women can alleviate painful cramps by taking nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin or ibuprofen, which inhibit prostaglandin biosynthesis, just before the onset of menstruation. These medications, however, are not effective in treating all painful menstruation, especially when the pain is not due to inflammation but to other conditions, such as tumors of the myometrium or obstruction of the cervical canal.

The absence of a menstrual cycle is called **amenorrhea** (ă-men-ō-rē-ă). If the pituitary gland does not function properly because of abnormal development, a female does not begin to menstruate at puberty. This condition is called **primary amenorrhea**. In contrast, if a female has had normal menstrual cycles and later stops menstruating, the condition is called **secondary amenorrhea**. One cause of secondary amenorrhea is anorexia, in which lack of food causes the hypothalamus to decrease GnRH secretion to levels so low that the menstrual cycle cannot occur. Many female athletes and ballet dancers who pursue rigorous training schedules have secondary amenorrhea. Physical stress coupled with inadequate food intake also result in very low GnRH secretion. Increased food intake, for anorexic women, and reduced training, for women who exercise intensely, generally restore normal hormone secretion and normal menstrual cycles.

Secondary amenorrhea can also result from a pituitary tumor that decreases FSH and LH secretion or from a lack of GnRH secretion from the hypothalamus due to head trauma or a tumor. In addition, secondary amenorrhea can occur due to a lack of normal hormone secretion from the ovaries, which can be caused by autoimmune diseases that attack the ovary or by polycystic ovarian disease, in which cysts in the ovary produce large amounts of androgens that are converted to estrogens by other body tissues. The increased estrogen prevents the normal cycle of FSH and LH secretion required for ovulation. Other hormone-secreting tumors of the ovary can also disrupt the normal menstrual cycle and result in amenorrhea.

secretions of estrogen and progesterone are the primary cause of these changes.

The uterine cycle can be divided into three phases: (1) menses, (2) the proliferative phase, and (3) the secretory phase. As described earlier, menses is the time when the functional layer of the endometrium is sloughed and expelled from the uterus. The proliferative phase and secretory phase involve the regeneration of and changes in the endometrium following menses.

During the proliferative phase, the endometrium of the uterus begins to regenerate after menses. The remaining epithelial cells

rapidly divide and replace the cells of the functional layer that were sloughed during the last menses. A relatively uniform layer of low cuboidal endometrial cells is produced. The cells later become columnar, and the layer of cells folds to form tubular **spiral glands**. Blood vessels called **spiral arteries** project through the delicate connective tissue that separates the individual spiral glands to supply nutrients to the endometrial cells. After ovulation, during the secretory phase, the endometrium becomes thicker, and the spiral glands develop to a greater extent and begin to secrete small amounts of a fluid rich in glycogen. Approximately 7 days after ovulation, or about day 21 of the menstrual cycle, the endometrium is prepared to receive a developing embryonic mass, if fertilization has occurred. If the developing embryonic mass arrives in the uterus too early or too late, the endometrium does not provide a suitable environment for it.

Estrogen causes the endometrial cells and, to a lesser degree, the myometrial cells to divide during the proliferative phase. It also makes the uterine tissue more sensitive to progesterone by stimulating the synthesis of progesterone receptor molecules within the uterine cells. After ovulation, during the secretory phase, progesterone from the corpus luteum binds to the progesterone receptors, resulting in cellular hypertrophy in the endometrium and myometrium and causing the endometrial cells to become secretory. Estrogen increases the tendency of the smooth muscle cells of the uterus to contract in response to stimuli, but progesterone inhibits smooth muscle contractions. When progesterone levels increase while estrogen levels are low, contractions of the uterine smooth muscle are reduced.

In uterine cycles in which pregnancy does not occur, progesterone and estrogen levels decline to low levels as the corpus luteum degenerates. The drop in these hormones initiates the beginning of the next uterine cycle, beginning with the next menses. As a consequence of low progesterone and estrogen levels, the uterine lining begins to degenerate. The spiral arteries constrict in a rhythmic pattern for longer and longer periods as progesterone levels fall. As a result, all but the basal parts of the spiral glands become ischemic and then necrotic. As the cells become necrotic, they slough into the uterine lumen. The necrotic endometrium, mucous secretions, and a small amount of blood released from the spiral arteries make up the menstrual fluid. Decreases in progesterone levels and increases in inflammatory substances that stimulate myometrial smooth muscle cells cause uterine contractions, which expel the menstrual fluid from the uterus through the cervix and into the vagina.

➤ Predict 7

Predict the effect on the endometrium of maintaining high progesterone levels in the blood, including the period of time during which estrogen normally increases following menstruation.

ASSESS YOUR PROGRESS

67. What are the major events of the menstrual cycle?
68. What is the length of a typical menstrual cycle? What event marks the beginning of a cycle?
69. On which day does ovulation occur?
70. Where do the proliferative and secretory phases occur? What happens during these phases?

1 Menses

The apical portion of the endometrium is the functional layer. It sloughs off as the spiral arteries remain in a constricted state in response to low levels of progesterone, depriving the functional layer of an adequate blood supply. Functional layer tissue and some blood make up most of the menstrual fluid. The basal layer of the endometrium remains intact.

2 Proliferative phase

Epithelial cells of the basal layer of the endometrium proliferate in response to estrogen. As a result, the epithelial cells and loose connective tissue on which they rest form the tubular, spiral glands. The spiral arteries found in the loose connective tissue between the spiral glands nourish the functional layer.

3 Secretory phase

Epithelial cells of the basal and functional layers undergo hypertrophy in response to progesterone. As a result, the spiral glands become more elongated and more spiral. Consequently, the endometrial layer reaches its greatest thickness. The spiral arteries can be seen in the loose connective tissue between the spiral glands. The spiral arteries remain dilated due to the presence of progesterone.

71. Where do the follicular and luteal phases occur? What happens during these phases?
72. What roles do FSH and LH play in the ovarian cycle?
73. Describe how the cyclic increase and decrease in FSH and LH is produced.
74. What is the importance of the LH surge and the FSH surge?
75. Where is hCG produced, and what effect does it have on the ovary?
76. What are the effects of estrogen and progesterone on the uterus?

Female Sexual Behavior and the Female Sexual Act

The female sex drive, like the sex drive in males, depends on hormones. The adrenal gland and other tissues, such as the liver, convert steroids, such as progesterone, to androgens. Androgens and possibly estrogens affect cells in the brain, especially in the hypothalamus, to influence sexual behavior. However, androgens and estrogen alone do not control sex drive. In other words, sex drive cannot be predictably increased simply by injecting these hormones into healthy women or men. Psychological factors also affect sexual behavior. For example, after removal of the ovaries or after menopause, many women report an increased sex drive because they no longer fear pregnancy.

The neural pathways, both sensory and motor, involved in controlling sexual responses are the same for males and females. Sensory action potentials are conducted from the genitals to the sacral region of the spinal cord, where reflexes that govern sexual responses are integrated. Ascending pathways, primarily the spinothalamic tracts (see chapter 14), conduct sensory information through the spinal cord to the brain, and descending pathways conduct action potentials back to the sacral region of the spinal cord. As a result, cerebral influences modulate the sacral reflexes. Motor action potentials are conducted from the spinal cord to the reproductive organs by both parasympathetic and sympathetic nerve fibers and to skeletal muscles by the somatic motor nerve fibers.

During sexual excitement, as a result of parasympathetic stimulation, erectile tissue within the clitoris and around the vaginal opening becomes engorged with blood. The nipples of the breast often become erect as well. The mucous glands within the vestibule, especially the vestibular glands, secrete small amounts of mucus. Large amounts of mucuslike fluid are also extruded into the vagina through its wall, although no well-developed mucous glands are within the vaginal wall. These secretions provide lubrication that allows for easy entry of the penis into the vagina and easy movement of the penis during intercourse. Tactile stimulation of the female's genitals that occurs during sexual intercourse, along with psychological stimuli, normally triggers an orgasm. The vaginal, uterine, and perineal muscles contract rhythmically, and muscle tension increases throughout much of the body. After the sexual act, a period of resolution characterized by an overall sense of satisfaction and relaxation occurs. In contrast to males, females can be receptive to further stimulation and can experience

successive orgasms. Although orgasm is a pleasurable component of sexual intercourse, it is not necessary for females to experience an orgasm for fertilization to occur.

Female Fertility and Pregnancy

After sperm cells are ejaculated into the vagina during sexual intercourse, they are transported through the cervix, the body of the uterus, and the uterine tubes to the ampulla (figure 28.21). The forces responsible for moving sperm cells through the female reproductive tract include the swimming ability of the sperm cells and possibly the muscular contractions of the uterus and the uterine tubes. During sexual intercourse, oxytocin is released from the posterior pituitary of the female, and the semen introduced into the vagina contains prostaglandins. Both of these substances stimulate smooth muscle contractions in the uterus and uterine tubes, which may also enhance the movement of sperm cells through the female reproductive tract.

While passing through the vagina, uterus, and uterine tubes, the sperm cells undergo **capacitation** (kă-pas'i-tă'shŭn), which involves the removal of proteins and the modification of glycoproteins of the sperm cell plasma membranes. Following capacitation, as the sperm cells move through the female reproductive tract, some of them release acrosomal enzymes. These enzymes help the sperm cells penetrate the cervical mucus, cumulus mass, zona pellucida, and oocyte plasma membrane.

FIGURE 28.21 Sperm Cell Movement

Sperm cells are deposited into the vagina as part of the semen when the male ejaculates. Sperm cells pass through the cervix, the body of the uterus, and the uterine tube. Fertilization normally occurs when the oocyte is in the upper one-third of the uterine tube (the ampulla).

Clinical IMPACT

Ectopic Pregnancy

If implantation occurs anywhere other than in the uterine cavity, an ectopic pregnancy results. The most common site of ectopic pregnancy is the uterine tube. Implantation in the uterine tube is eventually fatal to the fetus and can cause the tube to rupture. The possibility of hemorrhage makes ectopic pregnancy dangerous to the mother as well.

In rare cases, implantation occurs in the mesenteries of the abdominal cavity. Although the fetus may develop normally, the pregnancy is considered extremely high-risk due to the serious threat to the mother's life and that of the fetus. Severe hemorrhaging at or near the time of delivery is the most serious concern. Delivery by cesarean section, with special precautions to prevent uncontrolled bleeding, can result in a successful outcome for this type of ectopic pregnancy. However, maternal mortality rates for abdominal pregnancies are significantly higher than for uterine tube ectopic pregnancies.

One sperm cell enters the secondary oocyte, and fertilization occurs (see chapter 29). The oocyte can be fertilized for up to 24 hours after ovulation, and some sperm cells remain viable in the female reproductive tract for up to 6 days, although most of them have degenerated after 24 hours. For fertilization to occur successfully, sexual intercourse must occur between 5 days before and 1 day after ovulation.

For the next several days following fertilization, a sequence of cell divisions occurs while the developing embryo passes through the uterine tube to the uterus. By 7 or 8 days after ovulation, which is day 21 or 22 of the average menstrual cycle, the endometrium of the uterus has been prepared for implantation. Estrogen and progesterone have caused it to reach its maximum thickness and secretory activity, and the developing embryo begins to implant. The outer layer of the developing embryo, the **trophoblast** (trof'ō-blast, trō'fō-blast), secretes proteolytic enzymes that digest the cells of the thickened endometrium (see chapter 29), and the developing embryo digests its way into the endometrium.

The trophoblast secretes hCG, which is transported in the blood to the ovary and causes the corpus luteum to remain functional. As a consequence, both estrogen and progesterone levels continue to increase rather than decrease. The secretion of hCG increases rapidly and reaches a peak about 8–9 weeks after fertilization. Subsequently, hCG levels in the circulatory system have declined to a lower level by 16 weeks and remain at a relatively constant level throughout the remainder of pregnancy. The detection of hCG in the urine is the basis for some pregnancy tests.

The estrogen and progesterone secreted by the corpus luteum are essential for the maintenance of pregnancy. After the **placenta** (plă-sen'tă) forms from the trophoblast and uterine tissue, however, it also begins to secrete estrogen and progesterone. After the first

3 months of pregnancy the corpus luteum is no longer needed to maintain pregnancy. Instead, the placenta, in addition to its function of nutrient and waste exchange between the fetus and the mother, functions as an endocrine gland that secretes sufficient quantities of estrogen and progesterone to maintain pregnancy. Estrogen and progesterone levels increase in the woman's blood throughout pregnancy (figure 28.22).

Menopause

When a woman is 40–50 years old, menstrual cycles become less regular, and ovulation often does not occur consistently. Eventually, menstrual cycles stop completely. The cessation of menstrual cycles is called **menopause** (men'ō-pawz). The time from the onset of irregular cycles to the complete cessation, which is often 3 to 5 years, is called the **female climacteric** (klī-mak'ter-ik, klī-mak-ter'ik), or *perimenopause*.

Menopause is associated with changes in the ovaries. The number of follicles remaining in the ovaries of menopausal women is small. In addition, the follicles that remain become less sensitive to stimulation by LH and FSH; therefore, fewer mature follicles and corpora lutea are produced.

Older women experience gradual changes in response to the reduced amount of estrogen and progesterone produced by the ovaries (table 28.3). For example, some women experience sudden episodes of uncomfortable sweating (hot flashes), fatigue, anxiety, temporary decreases in sex drive, and occasionally severe emotional disturbances. Many of these symptoms can be treated successfully with hormone replacement therapy (HRT). HRT usually involves administering small amounts of estrogen, or estrogen in combination with progesterone, and then gradually decreasing the treatment over time. It appears that administering estrogen following menopause also helps prevent osteoporosis and may reduce colorectal cancer. However, although estrogen therapy has been successful, it prolongs the symptoms associated with menopause, in many women and some potential side effects are of concern, including an increased risk for breast, ovarian, and uterine cancer. In addition, HRT does not reduce the risk for heart disease for the first few years after the beginning of menopause. Some data indicate that the risk for heart attacks, strokes, and blood clots is also increased.

ASSESS YOUR PROGRESS

77. Compare the female sexual act with the male sexual act.
78. Is an orgasm required for fertilization to occur?
79. Describe the transport of sperm cells through the female reproductive system.
80. What is capacitation of sperm cells?
81. Describe the events that follow fertilization.
82. Describe implantation of the embryo and formation of the placenta.
83. Differentiate between menopause and the female climacteric.
84. What causes the changes that lead to menopause?

① Human chorionic gonadotropin (hCG; red line) increases until it reaches a maximum concentration near the end of the first 3 months of pregnancy and then decreases to a low level thereafter.

② Progesterone (blue line) continues to increase until it levels off near the end of pregnancy. Early in pregnancy, progesterone is produced by the corpus luteum in the ovary; by the second trimester, production shifts to the placenta.

③ Estrogen (green line) increases slowly throughout pregnancy but increases more rapidly as the end of pregnancy approaches. Early in pregnancy, estrogen is produced only in the ovary; by the second trimester, production shifts to the placenta.

PROCESS FIGURE 28.22 Changes in Hormone Concentration and Changes in Hormone Secretion During Pregnancy

TABLE 28.3 Possible Changes Caused by Decreased Ovarian Hormone Secretion in Postmenopausal Women

Affected Structures and Functions	Changes
Menstrual cycle	Five to seven years before menopause, the cycle becomes less regular; finally, the number of cycles in which ovulation occurs decreases, and corpora lutea do not develop.
Uterine tubes	Little change occurs.
Uterus	Irregular menstruation is gradually followed by no menstruation; the chance of cystic glandular hypertrophy of the endometrium increases; the endometrium finally atrophies, and the uterus becomes smaller.
Vagina and external genitalia	The dermis and epithelial lining become thinner; the vulva becomes thinner and less elastic; the labia majora become smaller; pubic hair decreases; the vaginal epithelium produces less glycogen; vaginal pH increases; reduced secretion leads to dryness; the vagina is more easily inflamed and infected.
Skin	The epidermis becomes thinner; melanin synthesis increases.
Cardiovascular system	Hypertension and atherosclerosis occur more frequently.
Vasomotor instability	Hot flashes and increased sweating are correlated with the vasodilation of cutaneous blood vessels; hot flashes are not caused by abnormal FSH and LH secretion but are related to decreased estrogen levels.
Sex drive	Temporary changes, such as either decreases or increases in sex drive, are often associated with the onset of menopause.
Fertility	Fertility begins to decline approximately 10 years before the onset of menopause; by age 50, almost all oocytes and follicles have been lost; the loss is gradual, and no increased follicular degeneration is associated with the onset of menopause.

28.7 Effects of Aging on the Reproductive System

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe the major age-related changes in the male and female reproductive systems.**

Age-Related Changes in Males

Several age-related changes occur in the male reproductive system. In some but not all men, the size and weight of the testes decrease. In addition, there is an associated decrease in the number of interstitial cells and a thinning of the wall of the seminiferous tubules. These changes may be secondary to a decrease in blood flow to the testes or to a gradual decrease in reproductive hormone production. In addition, the rate of sperm cell production is reduced, and the number of abnormal sperm cells produced increases. However, sperm cell production does not stop, and it remains adequate for fertility for most men.

Age-related changes become obvious in the prostate gland by age 40. By age 60, there is a clear decrease in blood flow to the prostate gland, an increased thickness in the epithelial cell lining of the prostate gland, and a decrease in the number of functional smooth muscle cells in the wall of the prostate. The changes in the prostate

Clinical IMPACT

Causes of Female Infertility

The causes of infertility in females include malfunctions of the uterine tubes, reduced hormone secretion from the pituitary gland or the ovaries, and interruption of implantation.

Uterine tube malfunction can occur when infections result in pelvic inflammatory disease (PID), which causes adhesions to form in one or both uterine tubes.

Inadequate secretion of LH and FSH can result in reduced ovulation. The insufficient amount of hormones may be caused by hypothyroidism, trauma to the hypothalamus, infarctions of the hypothalamus or anterior pituitary gland, or tumors.

Interruption of implantation may result from uterine tumors or conditions causing abnormal ovarian hormone secretion.

Endometriosis (en'dō-mē-trē-ō'sis), in which endometrial tissue is present in abnormal locations, also reduces fertility. Generally, endometriosis is thought to result when some endometrial cells pass from the uterus through the uterine tubes into the pelvic cavity, where they invade the peritoneum. Because the endometrium is sensitive to estrogen and progesterone, the areas where the endometrial cells have invaded periodically become inflamed. Endometriosis is one possible cause of abdominal pain associated with menstruation.

Diseases and Disorders

TABLE 28.4 Reproductive System

Condition	Description
Infectious Diseases	
Pelvic inflammatory disease (PID)	Bacterial infection of the female pelvic organs; commonly caused by vaginal or uterine infection by the bacteria that cause gonorrhea or chlamydia; early symptoms include increased vaginal discharge and pelvic pain; antibiotics are effective; if untreated, can lead to sterility or be life-threatening
Sexually Transmitted Diseases	
Nongonococcal urethritis (non-gon'ō-kok'ā'l u-rē-thrī'tis)	Inflammation of the urethra that is not caused by gonorrhea; can be caused by trauma, insertion of a nonsterile catheter, or sexual contact; usually due to infection with the bacterium <i>Chlamydia trachomatis</i> (kla-mid'ē-ā tra-kō'mā-tis); may go unnoticed and result in pelvic inflammatory disease or sterility; antibiotics are effective treatment
Trichomoniasis (trik-ō-mō-nī'ā-sis)	Caused by <i>Trichomonas</i> (trik'ō-mō'nas), a protozoan commonly found in the vagina of women and in the urethra of men; results in a greenish-yellow discharge with a foul odor; more common in women than in men
Gonorrhea (gon-ō-rē'ā)	Caused by the bacterium <i>Neisseria gonorrhoeae</i> (nī-sē'rē-ā gon-ō-rē'ā), which attaches to the epithelial cells of the vagina or male urethra and causes pus to form; pain and discharge from the penis occur in men; asymptomatic in women in the early stages; can lead to sterility in men and pelvic inflammatory disease in women
Genital herpes (her'pēz)	Caused by herpes simplex 2 virus; characterized by lesions on the genitals that progress into blisterlike areas, making urination, sitting, and walking painful; antiviral drugs can be effective
Genital warts	Caused by a viral infection; very contagious; warts vary from separate, small growths to large, cauliflower-like clusters; lesions are not painful, but sexual intercourse with lesions is; treatments include topical medicines and surgery to remove the lesions
Syphilis (sif'i-lis)	Caused by the bacterium <i>Treponema pallidum</i> (trep-ō-nē'mā pal'i-dūm); can be spread by sexual contact; multiple disease stages occur; children born to infected mothers may be developmentally delayed; antibiotics are effective
Acquired immunodeficiency syndrome (AIDS)	Caused by the human immunodeficiency virus (HIV), which ultimately destroys the immune system (see chapter 22); transmitted through intimate sexual contact or by allowing infected body fluids into the interior of another person

Clinical IMPACT

Control of Pregnancy

Many methods are used to prevent pregnancy (figure 28A), either by preventing fertilization or by preventing implantation of the developing embryo. Many of these techniques are quite effective when used perfectly and consistently. But most of these methods also have disadvantages, and the use of some of them is controversial.

Behavioral Methods

Abstinence, or refraining from sexual intercourse, is 100% effective in preventing pregnancy when practiced consistently. It is not an effective method when used only occasionally.

Coitus (kō'i-tūs) **interruptus**, or *withdrawal*, is removal of the penis from the vagina just before ejaculation. This is a very unreliable method of preventing pregnancy because it requires perfect awareness and willingness to withdraw the penis at the correct time. It also ignores the fact that some sperm cells are present in preejaculatory emissions. Statistically, about 23 women out of 100 become pregnant while relying on this method.

The **calendar method**, also called *natural family planning* or *rhythm method*, requires abstaining from sexual intercourse near the time of ovulation. Although the calendar method provides some protection against becoming pregnant, it has a relatively high failure rate because of both the inability to predict the time of ovulation and the failure to abstain around that time. About 9 women out of 100 become pregnant while using the calendar method.

Continuous breastfeeding, or lactation (also known as *lactation amenorrhea*, or *LAM*), often stops the menstrual cycle for a few months after childbirth. Action potentials sent to the hypothalamus in response to suckling inhibit GnRH release from the hypothalamus, thus also inhibiting FSH and LH release from the anterior pituitary. Lactation, therefore, prevents the development of ovarian follicles and ovulation. This method is 98% effective as long as the baby is *exclusively* and frequently breastfed and the mother has not resumed menstruation. Supplemental feeding and introduction of solid food reduce the amount of suckling, the stimulus that reduces fertility. Furthermore, despite continuous lactation, the ovarian and uterine cycles eventually resume. Because ovulation occurs before menstruation, relying on lactation to prevent pregnancy is not consistently effective.

Barrier Methods

A **male condom** (kon'dom; figure 28Aa) is a sheath made of animal membrane, rubber, or latex. When placed over the erect penis, a condom acts as a barrier by collecting semen instead of allowing it to be released into the vagina. Condoms also provide protection against sexually transmitted diseases. Male condoms alone are 98% effective; when used with spermicide, they are 99% effective. A **vaginal condom**, or *female condom*, also acts as a barrier. A woman can place the vaginal condom into the vagina before sexual intercourse. Female condoms are 95% effective; using spermicide further increases their effectiveness.

Methods to prevent sperm cells from reaching the oocyte once they are in the vagina include a diaphragm, a cervical cap, spermicidal agents, and a vaginal sponge. The **diaphragm** and **cervical cap** (figure 28Ab) are flexible latex domes that are placed over the cervix within the vagina, where they prevent sperm cells from passing from the vagina through the cervical canal of the uterus. The diaphragm is a larger, shallow latex cup, and the cervical cap is a smaller, thimble-shaped cup. Diaphragms are 94% effective, whereas cervical cap effectiveness ranges from 71% in a woman who has previously been pregnant to 86% in a woman who has never been pregnant. The most commonly used **spermicidal agents** (figure 28Ac) are foams, creams, and gels that kill the sperm cells. They are inserted into the vagina before sexual intercourse, often in conjunction with diaphragm or condom use. Alone, spermicidal agents are only about 85% effective.

Intrauterine (in'tră-yū'ter-in) **devices** (**IUDs**; figure 28Ad) are inserted into the uterus through the cervix. The two types of IUDs now available in the United States are the copper-containing ParaGard and the progestin hormone-coated Mirena. The ParaGard may be left in place for 12 years, whereas the Mirena may be left in place for 5 years. Both types of IUDs thicken cervical mucus, which bars sperm cells from entering the uterus. Some women stop ovulating when they have an IUD implanted. IUDs also alter the endometrium, which in theory may prevent implantation of an embryo. IUDs are 99.99% effective in preventing pregnancy.

Chemical Methods

Synthetic estrogen and progesterone in **oral contraceptives** (birth control pills; figure 28Ae) are among the most effective contraceptives, providing 99.9% effectiveness. The synthetic hormones may have more than one action, but they reduce LH and FSH release from the anterior pituitary. Estrogen and progesterone are present in high enough concentrations to have a negative-feedback effect on the pituitary gland, which prevents the large increase in LH and FSH secretion that triggers ovulation. Over the years, the dose of estrogen and progesterone in birth control pills has been reduced. The current lower dose has fewer side effects than earlier doses. For most women, the pill is effective and has a minimum frequency of complications, until at least age 35. However, the risk for heart attack or stroke increases in women who smoke or have a history of hypertension or coagulation disorders.

The **mini-pill** is an oral contraceptive that contains only synthetic progesterone. It reduces and thickens the mucus of the cervix, which prevents sperm cells from reaching the oocyte. It also prevents blastocysts from implanting in the uterus.

Progesterone-like chemicals, such as medroxyprogesterone (Depo-Provera), which are injected intramuscularly and slowly released into the circulatory system, can act as effective contraceptives. These injections can protect against pregnancy for approximately 1 month, depending on the amount injected, and are 99.9% effective. The **patch** is an adhesive skin patch containing synthetic estrogen and progesterone. It is worn on the lower abdomen, buttocks, or upper body and is 99.9% effective. The **vaginal contraceptive ring** (NuvaRing) is inserted into the vagina, where it releases synthetic estrogen and progesterone, and is 99.9% effective.

A drug called **mifepristone** (mif'pris-tōn), formerly *RU486*, blocks the action of progesterone, causing the endometrium of the uterus to slough off, as it does at the time of menstruation. It can therefore be used to induce menstruation and reduce the possibility of implantation when sexual intercourse has occurred near the time of ovulation. It can also be used to terminate pregnancies.

Chemical techniques to be used after intercourse have been developed, but they are only about 75% effective. **Morning-after pills**, similar in composition to birth control pills, are available. Alternatively doubling the number of birth control pills after sexual intercourse within 3 days and again after 12 more hours is sometimes recommended. The elevated estrogen and progesterone levels may inhibit the increase in LH that causes ovulation, alter the rate at which the fertilized oocyte is transported through the uterine tube to the uterus, or inhibit implantation. The precise effect of the elevated estrogen-like and progesterone-like substances depends on the stage of the menstrual cycle when they are taken.

Surgical Methods

Vasectomy (va-sek'tō-mē; figure 28Af) is a common method of rendering males permanently infertile without affecting the performance of the sexual act. Vasectomy is a surgical procedure in which the ductus deferens from each testis is cut and tied off within the scrotal sac. This

procedure prevents sperm cells from passing through the ductus deferens and becoming part of the ejaculate. Because such a small volume of ejaculate comes from the testis and epididymis, vasectomy has little effect on the volume of the ejaculated semen. The sequestered sperm cells are reabsorbed in the epididymis. Only 1–4 in 1000 surgeries of this type fail.

A common method of permanent birth control in females is **tubal ligation** (lī-gā'shūn;

figure 28Ag), in which the uterine tubes are tied and cut or clamped by means of an incision through the wall of the abdomen. This procedure closes off the pathway between the sperm cells and the oocyte. Commonly, tubal ligation is performed by **laparoscopy** (lap-ă-ros'kō-pē), in which an instrument is inserted into the abdomen through a small incision, so that only small openings need to be made to perform the operation.

Name: Molly
Gender: Female
Age: 43

Comments

Molly has four children. She noticed that menstruation was becoming gradually more severe and lasting

up to several days longer each time. After menstruating almost continuously for 2 months, Molly made an appointment with her physician. The physician performed a pelvic examination, including tests for conditions such as cervical and uterine cancers. Palpation of the uterus indicated the presence of enlarged masses in Molly's uterus. The doctor performed a D&C, which is dilation of the cervix and scraping (curettage) of the endometrium to remove growths or other abnormal tissues. The results of the D&C indicated that Molly had developed leiomyomas.

Background Information

Leiomyomas (lī'-ō-mī-ō'mās; figure 28B) are also called fibroid tumors of the uterus. They are one of the most common disorders of the uterus and are the most frequent tumor in women, affecting one of every four. However, three-fourths of the women with this condition experience no symptoms. The enlarged masses that originate from smooth muscle tissue compress the uterine lining (endometrium), resulting in ischemia and inflammation. The increased inflammation, which shares some characteristics with menstruation, results in frequent and severe menses, with associated abdominal cramping due to strong uterine contractions. Constant menstruation is a frequent manifestation of these tumors, and it is one of the most common reasons women elect to have the uterus removed, a procedure called a **hysterectomy** (his-ter-ek'tō-mē).

► Predict 8

When discussing her condition with her mother, Molly discovered that her mother had experienced frequent menses that were irregular and prolonged when she was in her late forties. Molly's mother did not have a hysterectomy, and in a few years the frequency of menstruation gradually began to subside. Explain.

Figure 28B Leiomyomas

Leiomyomas, or fibroid tumors, are enlarged masses of smooth muscle. They can be located near the mucosa (submucous), within the myometrium (interstitial), or near the serosa (subserous).

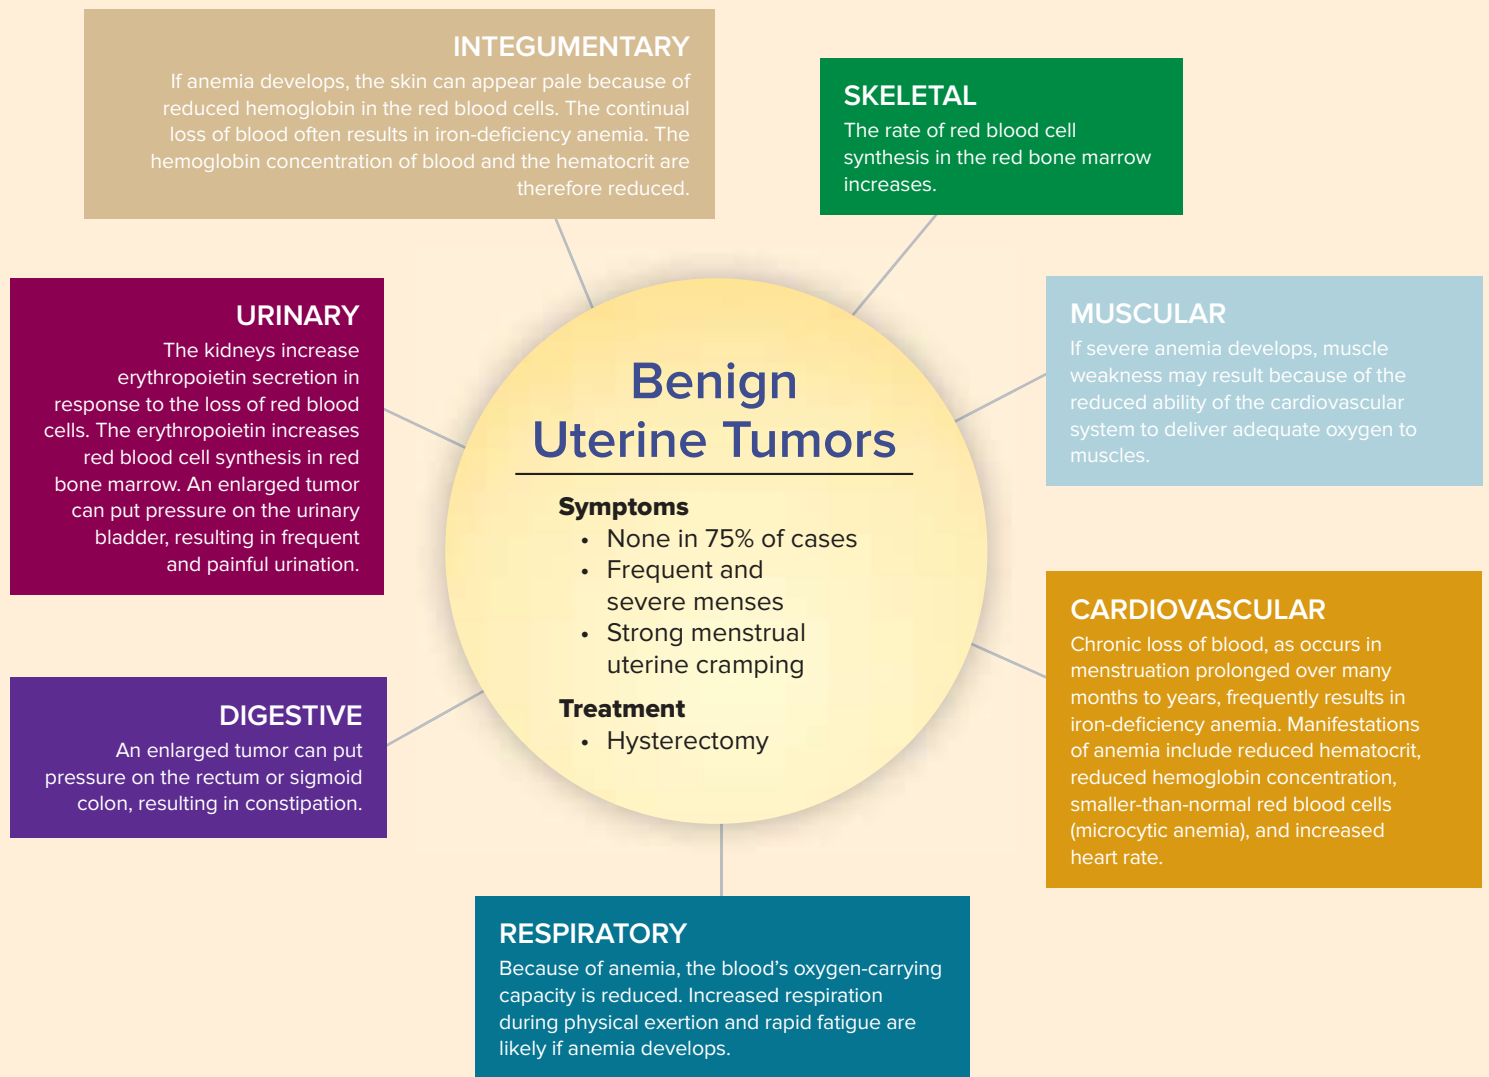

gland do not decrease fertility, but the incidence of benign prostatic hypertrophy (enlargement of the prostate) increases substantially and can lead to difficulty in urination due to compression of the prostatic urethra. A significant number (approximately 15%) of men older than 60 require medical treatment for benign prostatic hypertrophy; by age 80, this number is 50%. Before age 50, prostate cancer is rare. After 55, it is the third leading cause of death from cancer in men.

Erectile dysfunction increases in men with age. By age 60, approximately 15% of men have ED; by 80, 50% do. In addition,

the amount of fibrous connective tissue in the erectile tissue of the penis increases, which generally decreases the speed of erection by age 60.

Although there is great variation among males, many exhibit decreases in the frequency of sexual activity and in sexual performance. Psychological changes, age-related changes in the nervous system, and decreased blood flow explain some of the decline. The side effects of medications taken for other conditions are responsible for decreased sexual activity in many older men.

Age-Related Changes in Females

The most significant age-related change in females is menopause. By age 50, few viable follicles remain in the ovaries. As a result, the amount of estrogen and progesterone produced by the ovaries has decreased.

The uterus decreases in size, and the endometrium decreases in thickness. The time between menses becomes irregular and longer. Finally, menstruations stop. As the uterus decreases in size, it tips posteriorly and assumes a lower position in the pelvic cavity. Occasionally, uterine prolapse, in which the ligaments of

the uterus allow it to descend and protrude into the vagina, occurs. Within 15 years after menopause, the uterus is 50% of its original size.

The vaginal wall becomes thinner and less elastic. There is less lubrication of the vagina, and the epithelial lining is more fragile, resulting in an increased tendency for vaginal infections. Vaginal contractions during intercourse decrease, and the vagina narrows with age. In healthy females, sexual excitement requires greater time to develop, the peak levels of sexual activity are lower, and return to the resting state occurs more quickly.

The incidence of breast cancer is greatest between 45 and 65 years of age and is greater for women who have a family history of breast cancer. Approximately 10% of all women will develop breast cancer. The most important measure to guard against death from breast cancer is early detection through breast self-exams and annual mammograms after age 40. The incidences of uterine cancer and cervical cancer increase between 50 and 65 years of age. Ovarian cancer increases in frequency in older women, and it is the second most common cancer of the reproductive system in older women. Annual medical checkups, including Pap smears, are important for early detection and treatment of these cancers.

ASSESS YOUR PROGRESS

85. List the major age-related changes that occur in the male reproductive system.
86. What are the age-related changes in the prostate gland?
87. List the major age-related changes that occur in the female reproductive system.
88. What are some of the long-term consequences of menopause?

Answer

Learn to Predict From page 1029

In this chapter, we learned that meiosis is cell division that produces haploid cells. When comparing meiosis in males and females, we find that the processes differ in several ways: the stage in an individual's life when meiosis begins, the types of cells produced, the number of functional cells produced with each cell division, and the stage of life when meiosis ceases to occur.

In males, meiosis begins at puberty in the seminiferous tubules. Spermatogonia give rise to primary spermatocytes, which will undergo the process of meiosis. During this process, each primary spermatocyte eventually gives rise to four mature sperm cells. Males continue to produce sperm until death.

Meiosis in females is more complex. The process actually begins before a female is born. During fetal development, many of the oogonia in the ovaries degenerate. The remaining oogonia actually begin meiosis I and are called primary oocytes. At birth, the

existing primary oocytes stop meiosis. After puberty and just before the ovulation of each oocyte, the primary oocyte that is ovulated completes the first meiotic division to produce one secondary oocyte and one polar body. The secondary oocyte begins the second meiotic division but will complete the process only if fertilized by a sperm cell. In the case of fertilization, the secondary oocyte divides to form two cells. One cell is another polar body and degenerates. In the other cell, the haploid sperm nucleus combines with the haploid oocyte nucleus to form a zygote. Thus, in females, each primary oocyte produces only one functional cell. For females, the process of meiosis stops at menopause.

Answers to the rest of this chapter's Predict questions are in appendix G.

Summary

28.1 Functions of the Reproductive System (p. 1030)

The reproductive systems produce male and female gametes, enhance fertilization of an oocyte by a sperm cell, and produce reproductive hormones. In addition, the female reproductive system nurtures the new individual until birth.

28.2 Meiosis (p. 1030)

The reproductive organs in males and females produce gametes by meiosis.

1. Two consecutive cell divisions halve the chromosome number from 46 total chromosomes to 23 total chromosomes.
2. Meiosis ensures that the diploid number (46, in humans) is maintained in each generation.
3. Crossing over and random sorting of chromosomes during meiosis I produce genetic variation in gametes.

28.3 Anatomy of the Male Reproductive System (p. 1033)

The male reproductive system includes the testes, ducts, accessory glands, and supporting structures.

Scrotum

1. The scrotum is a two-chambered sac that contains the testes.
2. The dartos and cremaster muscles help regulate testicular temperature.

Perineum

The perineum, the diamond-shaped area between the thighs, consists of a urogenital triangle and an anal triangle.

Testes

1. The tunica albuginea is the outer connective tissue capsule of the testes.
2. The testes are divided by septa into lobules that contain the seminiferous tubules and the interstitial cells.

- The seminiferous tubules straighten to form the tubuli recti, which lead to the rete testis. The rete testis opens into the efferent ductules of the epididymis.
- During development, the testes pass from the abdominal cavity through the inguinal canal to the scrotum.

Sperm Cell Development

- Spermatogenesis begins in the seminiferous tubules at the time of puberty.
- Spermatogonia divide (mitosis) to form primary spermatocytes.
- Primary spermatocytes divide (first division of meiosis) to form secondary spermatocytes, which divide (second division of meiosis) to form spermatids.
- Spermatids develop an acrosome and a flagellum to become sperm cells.
- Sustentacular cells nourish the sperm cells, form a blood-testis barrier, and produce hormones.

Ducts

- Efferent ductules extend from the testes to the head of the epididymis.
- The epididymis, a coiled tube system, is located on the testis and is the site of sperm cell maturation. It consists of a head, a body, and a tail.
- The ductus deferens passes from the epididymis into the abdominal cavity.
- The end of the ductus deferens, called the ampulla, and the seminal vesicle join to form the ejaculatory duct.
- The prostatic urethra extends from the urinary bladder and joins with the ejaculatory ducts to form the membranous urethra.
- The membranous urethra extends through the urogenital diaphragm and becomes the spongy urethra, which continues through the penis.
- The spermatic cord consists of the ductus deferens, blood and lymphatic vessels, nerves, and remnants of the process vaginalis. Coverings of the spermatic cord consist of the external spermatic fascia, cremaster muscle, and internal spermatic fascia.
- The spermatic cord passes through the inguinal canal into the abdominal cavity.

Penis

- The penis consists of erectile tissue.
 - The two corpora cavernosa form the dorsum and the sides of the penis.
 - The corpus spongiosum forms the ventral part and the glans penis.
- The bulb of the penis and the crura form the root of the penis, and the crura attaches the penis to the pelvic bones.
- The prepuce covers the glans penis.

Accessory Glands

- The seminal vesicles empty into the ejaculatory ducts.
- The prostate gland consists of glandular and muscular tissue and empties into the prostatic urethra.
- The bulbourethral glands are compound mucous glands that empty into the spongy urethra.

Semen

- Semen is a mixture of sperm cells and glandular secretions.
- The bulbourethral glands and the urethral mucous glands produce mucus, which neutralizes the acidic pH of the urethra.
- The testicular secretions contain sperm cells.
- The seminal vesicle fluid contains fructose and fibrinogen.
- The prostate secretions make the seminal fluid more pH-neutral. Clotting factors activate fibrinogen, and fibrinolysin breaks down fibrin.

28.4 Physiology of Male Reproduction (p. 1043)

Normal function of the male reproductive system depends on hormonal and neural mechanisms.

Regulation of Reproductive Hormone Secretion

- GnRH is produced in the hypothalamus and released in surges.
- GnRH stimulates LH and FSH release from the anterior pituitary.
 - LH stimulates the interstitial cells to produce testosterone.
 - FSH stimulates sperm cell formation.
- Inhibin, produced by sustentacular cells, inhibits FSH secretion.

Puberty in Males

- Before puberty, small amounts of testosterone inhibit GnRH release.
- During puberty, testosterone does not completely suppress GnRH release, resulting in increased production of FSH, LH, and testosterone.

Effects of Testosterone

- Interstitial cells, the adrenal cortex, and possibly the sustentacular cells produce testosterone.
- Testosterone causes the development of male sex organs in the embryo and stimulates the descent of the testes.
- Testosterone causes enlargement of the genitals and is necessary for sperm cell formation.
- Other effects of testosterone
 - Hair growth stimulation (pubic area, axilla, and beard) and inhibition (male pattern baldness)
 - Enlargement of the larynx and deepening of the voice
 - Increased skin thickness and melanin and sebum production
 - Increased protein synthesis (muscle), bone growth, blood cell synthesis, and blood volume
 - Increased metabolic rate

Male Sexual Behavior and the Male Sexual Act

- Testosterone is required for normal sex drive.
- Stimulation of the sexual act can be tactile or psychological.
- Afferent action potentials pass through the pudendal nerve to the sacral region of the spinal cord.
- Parasympathetic stimulation
 - Erection is due to vasodilation of the blood vessels that supply the erectile tissue.
 - The glands of the urethra and the bulbourethral glands produce mucus.
- Sympathetic stimulation causes erection, emission, and ejaculation.

28.5 Anatomy of the Female Reproductive System (p. 1048)

The female reproductive system includes the ovaries, uterine tubes, uterus, vagina, external genitals, and mammary glands.

Ovaries

- The broad ligament, the mesovarium, the suspensory ligaments, and the ovarian ligaments hold the ovaries in place.
- The peritoneum (ovarian epithelium) covers the surface of the ovaries.
- The ovary has an outer capsule called the tunica albuginea and is divided internally into a cortex, which contains follicles, and a medulla, which receives blood and lymphatic vessels and nerves.

- Oocyte development and fertilization
 - Oogonia proliferate and become primary oocytes that are in prophase I of meiosis.
 - Ovulation is the release of an oocyte from an ovary.
 - Prior to ovulation, a primary oocyte continues meiosis I and produces a secondary oocyte, which begins meiosis II, and a polar body, which either degenerates or divides to form two polar bodies.
 - Fertilization is the joining of a sperm cell and a secondary oocyte to form a zygote. A sperm cell enters a secondary oocyte, which then completes the second meiotic division and produces a polar body. A zygote is formed when the nuclei of the sperm cell and the oocyte fuse to form a diploid nucleus.
- Follicle development
 - Primordial follicles are surrounded by a single layer of flat granulosa cells.
 - Primary follicles are primary oocytes surrounded by cuboidal granulosa cells.
 - The primary follicles become secondary follicles as granulosa cells increase in number and fluid begins to accumulate in the vesicles. The granulosa cells increase in number, and a theca forms around the secondary follicles.
 - Mature follicles are enlarged secondary follicles at the surface of the ovary.
- Ovulation occurs when the follicle swells and ruptures and the secondary oocyte is released from the ovary.
- Fate of the follicle
 - The mature follicle becomes the corpus luteum.
 - If pregnancy occurs, the corpus luteum persists. If no pregnancy occurs, it becomes the corpus albicans.

Uterine Tubes

- The mesosalpinx holds the uterine tubes.
- The uterine tubes transport the oocyte or zygote from the ovary to the uterus.
- Structures
 - The ovarian end of the uterine tube is expanded as the infundibulum. The opening of the infundibulum is the ostium, which is surrounded by fimbriae.
 - The infundibulum connects to the ampulla, which narrows to become the isthmus. The isthmus is the part of the uterine tube nearest the uterus.
- The uterine tube consists of an outer serosa, a middle muscular layer, and an inner mucosa composed of simple ciliated columnar epithelium.
- Movement of the oocyte
 - Cilia move the oocyte over the fimbriae surface into the infundibulum.
 - Peristaltic contractions and cilia move the oocyte within the uterine tube.
 - Fertilization occurs in the ampulla, where the zygote remains for several days.

Uterus

- The uterus consists of the body, the isthmus, and the cervix. The uterine cavity and the cervical canal are the spaces formed by the uterus.
- The uterus is held in place by the broad, round, and uterosacral ligaments.
- The wall of the uterus consists of the perimetrium (serous membrane), the myometrium (smooth muscle), and the endometrium (mucous membrane).

Vagina

- The vagina connects the uterus (cervix) to the outside of the body.
- The vagina consists of a layer of smooth muscle and an inner lining of moist stratified squamous epithelium.

- The vagina is folded into rugae and longitudinal folds.
- The hymen covers the opening of the vagina.

External Genitalia

- The vulva, or pudendum, comprises the external genitalia.
- The vestibule is the space into which the vagina and the urethra open.
- Erectile tissue
 - The two corpora cavernosa form the clitoris.
 - The corpora spongiosa form the bulbs of the vestibule.
- The labia minora are folds that cover the vestibule and form the prepuce.
- The greater and lesser vestibular glands produce a mucous fluid.
- When closed, the labia majora cover the labia minora.
 - The pudendal cleft is a space between the labia majora.
 - The mons pubis is an elevated fat deposit superior to the labia majora.

Perineum

The clinical perineum is the region between the vagina and the anus.

Mammary Glands

- The mammary glands are modified sweat glands located in the breasts.
 - The mammary glands consist of glandular lobes and adipose tissue.
 - The lobes consist of lobules that are divided into alveoli.
 - The lobes connect to the nipple through the lactiferous ducts.
 - The areola surrounds the nipple.
- Suspensory ligaments support the breasts.

28.6 Physiology of Female Reproduction (p. 1057)

Puberty in Females

- The first menstrual bleeding (menarche) occurs during puberty.
- Puberty begins when GnRH levels increase.

Menstrual Cycle

- Ovarian cycle
 - FSH initiates the development of the primary follicles.
 - The follicles secrete a substance that inhibits the development of other follicles.
 - LH stimulates ovulation and completion of the first meiotic division by the primary oocyte.
 - The LH surge stimulates the formation of the corpus luteum. If fertilization occurs, hCG stimulates the corpus luteum to persist. If fertilization does not occur, the corpus luteum becomes the corpus albicans.
- A positive-feedback mechanism causes FSH and LH levels to increase near the time of ovulation.
 - Estrogen produced by the theca cells of the follicle stimulates GnRH secretion.
 - GnRH stimulates the production and release of FSH and LH, which stimulate more estrogen secretion, and so on.
 - Inhibition of GnRH levels causes FSH and LH levels to decrease after ovulation. Inhibition is due to the high levels of estrogen and progesterone produced by the corpus luteum.
- Uterine cycle
 - Menses (from day 1 to day 4 or 5). The spiral arteries constrict, and endometrial cells die. The menstrual fluid is composed of sloughed cells, secretions, and blood.
 - Proliferative phase (from day 5 to day 14). Epithelial cells multiply and form glands, and the spiral arteries supply the glands.

- Secretory phase (from day 15 to day 28). The endometrium becomes thicker, and the endometrial glands secrete.
- Estrogen stimulates proliferation of the endometrium and synthesis of progesterone receptors.
- Increased progesterone levels cause hypertrophy of the endometrium, stimulate gland secretion, and inhibit uterine contractions. Decreased progesterone levels cause the spiral arteries to constrict and start menses.

Female Sexual Behavior and the Female Sexual Act

1. Female sex drive is partially influenced by androgens (produced by the adrenal gland) and other steroids (produced by the ovaries).
2. Parasympathetic effects
 - The erectile tissue of the clitoris and the bulbs of the vestibule become filled with blood.
 - The vestibular glands secrete mucus, and the vagina extrudes a mucuslike substance.

Female Fertility and Pregnancy

1. If fertilization is to occur, intercourse must take place between 5 days before and 1 day after ovulation.
2. Sperm cell transport to the ampulla depends on the ability of the sperm cells to swim and possibly on contractions of the uterus and the uterine tubes.
3. Implantation of the developing embryo into the uterine wall occurs when the uterus is most receptive.

4. Estrogen and progesterone, secreted first by the corpus luteum and later by the placenta, are essential for the maintenance of pregnancy.

Menopause

The female climacteric begins with irregular menstrual cycles and ends with menopause, the cessation of the menstrual cycle.

28.7 Effects of Aging on the Reproductive System (p. 1067)

Several age-related changes occur in the male and female reproductive systems.

Age-Related Changes in Males

1. Decreases occur in the size and weight of the testes, the number of interstitial cells, and the number of sperm produced, but sperm cell production is still adequate for fertilization. The wall of the seminiferous tubule becomes thin.
2. The prostate gland enlarges, and the incidence of prostate cancer increases.
3. Erectile dysfunction becomes more common, and sexual activity gradually decreases.

Age-Related Changes in Females

1. The most significant age-related change in females is menopause.
2. The uterus decreases in size, and the vaginal wall thins.
3. The incidence of breast, uterine, and ovarian cancer increases.

REVIEW AND COMPREHENSION

1. During meiosis I,
 - a. homologous chromosomes synapse.
 - b. crossing over between homologous chromosomes occurs.
 - c. the chromosomal number is reduced by half.
 - d. two haploid cells are produced.
 - e. All of these are correct.
2. Testosterone is produced in the
 - a. interstitial cells.
 - b. seminiferous tubules of the testes.
 - c. anterior lobe of the pituitary gland.
 - d. sperm cells.
3. Early in development (4 months after fertilization), the testes
 - a. are found in the abdominal cavity.
 - b. move through the inguinal canal.
 - c. produce a membrane that becomes the scrotum.
 - d. produce sperm cells.
 - e. All of these are correct.
4. The site of spermatogenesis in the male is the
 - a. ductus deferens.
 - b. seminiferous tubules.
 - c. epididymis.
 - d. rete testis.
 - e. efferent ductule.
5. The site of final maturation and storage of sperm cells before their ejaculation is the
 - a. seminal vesicles.
 - b. seminiferous tubules.
 - c. glans penis.
 - d. epididymis.
 - e. sperm bank.
6. Given these structures:

(1) ductus deferens	(4) ejaculatory duct
(2) efferent ductule	(5) rete testis
(3) epididymis	

Choose the arrangement that lists the structures in the order a sperm cell passes through them from the seminiferous tubules to the urethra.

 - a. 2,3,5,4,1
 - b. 2,5,3,4,1
 - c. 3,2,4,1,5
 - d. 3,4,2,1,5
 - e. 5,2,3,1,4
7. Concerning the penis,
 - a. the membranous urethra passes through the corpora cavernosa.
 - b. the glans penis is formed by the corpus spongiosum.
 - c. the penis contains four columns of erectile tissue.
 - d. the crus of the penis is part of the corpus spongiosum.
 - e. the bulb of the penis is covered by the prepuce.
8. Which of these glands is correctly matched with the function of its secretions?
 - a. bulbourethral gland—neutralizes acidic contents of the urethra
 - b. seminal vesicles—contain large amounts of fructose, which nourishes the sperm cells
 - c. prostate gland—contains clotting factors that cause coagulation of the semen
 - d. All of these are correct.
9. LH in the male stimulates
 - a. the development of the seminiferous tubules.
 - b. spermatogenesis.
 - c. testosterone production.
 - d. Both a and b are correct.
 - e. All of these are correct.

10. Which of these factors causes a decrease in GnRH release?
 a. decreased inhibin
 b. increased testosterone
 c. decreased FSH
 d. decreased LH
11. In the male, before puberty
 a. FSH levels are higher than after puberty.
 b. LH levels are higher than after puberty.
 c. GnRH release is inhibited by testosterone.
 d. All of these are correct.
12. Testosterone
 a. stimulates the development of terminal hairs.
 b. decreases red blood cell count.
 c. prevents closure of the epiphyseal plate.
 d. decreases blood volume.
 e. All of these are correct.
13. Which of these events is consistent with erection of the penis?
 a. parasympathetic stimulation
 b. dilation of arterioles
 c. engorgement of sinusoids with blood
 d. occlusion of veins
 e. All of these are correct.
14. After ovulation, the mature follicle collapses, taking on a yellowish appearance to become the
 a. degenerating follicle.
 b. corpus luteum.
 c. corpus albicans.
 d. tunica albuginea.
 e. cumulus mass.
15. The ampulla of the uterine tube
 a. is the opening of the uterine tube into the uterus.
 b. has long, thin projections called the ostium.
 c. is connected to the isthmus of the uterine tube.
 d. is lined with simple cuboidal epithelium.
16. The layer of the uterus that undergoes the greatest change during the menstrual cycle is the
 a. perimetrium. c. endometrium. e. broad ligament.
 b. hymen. d. myometrium.
17. The vagina
 a. consists of skeletal muscle.
 b. has ridges called rugae.
 c. is lined with simple squamous epithelium.
 d. All of these are correct.
18. During sexual excitement, which of these structures fills with blood and causes the vaginal opening to narrow?
 a. bulbs of the vestibule d. labia majora
 b. clitoris e. prepuce
 c. mons pubis
19. Concerning the breasts,
 a. lactiferous ducts open on the areola.
 b. each lactiferous duct supplies an alveolus.
 c. they are attached to the pectoralis major muscles by suspensory ligaments.
 d. even before puberty, the female breast is quite different from the male breast.
20. The major secretory product of the mature follicle is
 a. estrogen.
 b. progesterone.
 c. LH.
 d. FSH.
 e. relaxin.
21. In the average adult female, ovulation occurs at day _____ of the menstrual cycle.
 a. 1 c. 14 e. 28
 b. 7 d. 21
22. Which of these processes or phases in the monthly reproductive cycle of the human female occur at the same time?
 a. maximal LH secretion and menstruation
 b. early follicular development and the secretory phase of the uterus
 c. regression of the corpus luteum and an increase in ovarian progesterone secretion
 d. ovulation and menstruation
 e. proliferative stage of the uterus and increased estrogen production
23. During the proliferative phase of the uterine cycle, one would normally expect
 a. the highest levels of estrogen that occur during the menstrual cycle.
 b. the mature follicle to be present in the ovary.
 c. an increase in the thickness of the endometrium.
 d. Both a and b are correct.
 e. All of these are correct.
24. The cause of menses in the uterine cycle appears to be
 a. increased progesterone secretion from the ovary, which produces blood clotting.
 b. increased estrogen secretion from the ovary, which stimulates the muscles of the uterus to contract.
 c. decreased progesterone secretion by the ovary.
 d. decreased production of oxytocin, causing the muscles of the uterus to relax.
25. After fertilization, the successful development of a mature, full-term fetus depends on
 a. the release of human chorionic gonadotropin (hCG) by the developing placenta.
 b. the production of estrogen and progesterone by the placental tissues.
 c. maintenance of the corpus luteum for all 9 months.
 d. Both a and b are correct.
 e. All of these are correct.
26. A woman with a 28-day menstrual cycle is most likely to become pregnant as a result of intercourse on days
 a. 1–3.
 b. 5–8.
 c. 9–14.
 d. 15–20.
 e. 21–28.
27. Menopause
 a. develops when follicles become less responsive to FSH and LH.
 b. results from elevated estrogen levels in 40- to 50-year-old women.
 c. occurs because too many follicles develop during each cycle.
 d. results when follicles develop but contain no oocytes.
 e. occurs because FSH and LH levels decline.

CRITICAL THINKING

1. If an adult male were castrated (testes were removed), what would happen to the levels of GnRH, FSH, LH, and testosterone in his blood? What effect would these hormonal changes have on his sexual characteristics and sexual behavior?
2. If a 9-year-old boy were castrated, what would happen to the levels of GnRH, FSH, LH, and testosterone in his blood? What effect would these hormonal changes have on his sexual characteristics and sexual behavior as an adult?
3. Suppose you want to produce a birth control pill for men. On the basis of what you know about the male hormone system, what process should the pill affect? Discuss any possible side effects of the pill.
4. If the ovaries are removed from a postmenopausal woman, what happens to the levels of GnRH, FSH, LH, estrogen, and progesterone in her blood? What symptoms would you expect to observe?
5. If the ovaries are removed from a 20-year-old woman, what happens to the levels of GnRH, FSH, LH, estrogen, and progesterone in her blood? What side effects would these hormonal changes have on her sexual characteristics and sexual behavior?
6. A study divides healthy women into two groups (A and B). Both groups are composed of women who have been sexually active for at least 2 years and are not pregnant at the beginning of the experiment. The subjects weigh about the same amount, and none smoke cigarettes, although some drink alcohol occasionally. Group A women receive a placebo in the form of a sugar pill each morning of their menstrual cycles. Group B women receive a pill containing estrogen and progesterone each morning of their menstrual cycles. Then plasma LH levels are measured before, during, and after ovulation. The results are as follows:

Group	4 Days Before Ovulation	Day of Ovulation	4 Days After Ovulation
A	18 mg/100 mL	300 mg/100 mL	17 mg/100 mL
B	21 mg/100 mL	157 mg/100 mL	15 mg/100 mL

The number of pregnancies in group A is 37/100 women/year. The number of pregnancies in group B is 1.5/100 women/year. What conclusion can you reach on the basis of these data? Explain the mechanism involved.

7. A woman who is taking birth control pills that consist of only progesterone experiences the hot flashes of menopause. Explain why.
8. GnRH can be used to treat some women who want to have children but have not been able to get pregnant. Explain why it is critical to

administer the correct concentration of GnRH at the right time during the menstrual cycle.

9. Dr. Procter has two patients, one of whom has elevated blood PSA. A digital exam reveals that both patient 1 and patient 2 have enlarged prostate glands. Patient 1's enlarged prostate has the same shape as a smaller prostate, except that it is larger than normal, with a smooth contour. Patient 2's prostate is enlarged and asymmetrical, with a rough contour. In what way are these patients' lives probably being affected by their enlarged prostates? Explain how the doctor was able to conclude that one of the patients is likely to have prostate cancer.
10. The left testis of a newborn baby failed to descend into his scrotal sac. For some reason, the condition was not treated, and the testis remained in that position until after puberty. Select the observation consistent with the fate of the left testis after puberty.
 - (1) normal testosterone secretion
 - (2) no interstitial cells in the testis
 - (3) no sustentacular cells in the testis
 - (4) no spermatogonia in the testis
 - (5) increased number of interstitial cells
 - (6) normal LH secretion
 - a. 1
 - b. 1,2,3,4
 - c. 1,2,3,6
 - d. 1,4,6
 - e. 4,6
11. Norman had a stroke that decreased blood flow to his anterior pituitary gland. The condition had a sudden onset, and the manifestations lasted for about a week before collateral circulation developed and the manifestations disappeared. Which of the following are most consistent with this temporary interruption of anterior pituitary function?
 - (1) increased testosterone levels in the blood
 - (2) reduced sperm counts during the week Norman was in the hospital
 - (3) decreased testosterone levels in the blood
 - (4) normal sperm counts during the week Norman was in the hospital
 - (5) increased LH secretion
 - (6) decreased LH secretion
 - a. 1,5
 - b. 3,5
 - c. 2,3,6
 - d. 3,4,6
 - e. 1,4,5

Learn to Predict

After reading about the benefits of breast milk, Ming was determined to breastfeed her baby until he was a year old. Unfortunately, 2 weeks after her son's birth, Ming developed a serious urinary tract infection. Her physician prescribed an antibiotic and explained that she must not breastfeed her son while taking it. **After reviewing chapter 28 and reading chapter 29, explain the effect on Ming if she stops breastfeeding for an extended time, and propose a strategy that would allow her to cease breastfeeding for a while but resume after she has finished the antibiotic.**

Development, Growth, Aging, and Genetics

The stages of life and associated activities are issues of great interest in today's society. We tend to view life stages very differently today than in the past. For example, in 1960, 20% of males and 12% of females graduating from high school attended college. Today, over half of all people 25 and older have attended some college. In addition, there are many more nontraditional college students than there were 30 years ago.

The life span is usually considered the period between birth and death; however, the 9 months before birth are a critical part of a person's existence. What happens in these 9 months profoundly affects the rest of a person's life. Although most people develop normally and are born without defects, approximately 3 out of every 100 people are born with a birth defect so severe that it requires medical attention during the first year of life. Later in life, many more people discover previously unknown problems, such as the tendency to develop asthma, certain brain disorders, or cancer. This chapter discusses the topics of development, growth, aging, and genetics.

29.1 Prenatal Development

LEARNING OUTCOMES

After reading this section, you should be able to

- List the prenatal periods and state the major developmental events associated with each.
- List the postnatal periods and state the age range for each.
- Describe the process of fertilization.
- Describe the blastocyst, the process of implantation, and placental formation.
- List the three germ layers, describe their formation, and list the adult derivatives of each layer.
- Discuss the formation of the neural tube and the neural crest cells.
- Explain the formation of the digestive tract, the limbs, and the face.
- Demonstrate knowledge of the formation of the major organ systems.

We recognize that during our lifetime we have and will pass through many different stages. Those stages may be characterized by many factors, such as biological factors or social factors. When discussing the human life span from a biological perspective, we subdivide it in multiple ways. From the broadest perspective, we divide the human life span into two major periods: prenatal (before birth) and postnatal (after birth). Each of these periods is then subdivided based on specific criteria. The prenatal period, which extends from conception until birth, is subdivided into three stages:

- The **germinal period** begins at fertilization and ends at 14 days (weeks 1 and 2 of development). This is the stage when the primitive germ layers form.
- The **embryonic period** occurs during days 14–56 after fertilization (weeks 3–8 of development) and is the time when the major organ systems form. The developing human is called an **embryo** (em'brē-ō) at this stage.
- The **fetal period** extends from 56 days after fertilization to birth (the last 30 weeks of development). During this stage, the organ systems grow and become more mature, and the developing human is called a **fetus** (fē'tus).

Altogether, the prenatal period extends about 9 months. The above description characterizes each period based on days from fertilization, or the postovulatory age. Most embryologists use this method to describe events of prenatal development. However, the medical community uses the mother's last **menstrual period (LMP)** to calculate the clinical age of the unborn child. Postovulatory age is used in this book. Because ovulation occurs about 14 days after LMP and fertilization occurs near the time of ovulation, postovulatory age is 14 days less than clinical age.

The prenatal period is acutely important for the remainder of a person's life. Essentially, the foundation of the human body is established early in this period and the first important steps of growth

begin. Though these first 9 months of life are extremely important, the prenatal period is only a small part of the total life span.

The postnatal period begins at birth. This period is commonly divided into five stages:

- Neonatal period** extends from birth to 1 month after birth.
- Infancy** includes the time from 1 month to 1 or 2 years of age. The end of infancy is sometimes set at the time the child begins to walk.
- Childhood** includes the time from age 1 or 2 to puberty. During childhood, the individual develops considerably and forms many of the emotional characteristics that last throughout life.
- Adolescence** extends from puberty (age 11–14) to 20 years. Puberty usually occurs somewhat earlier in females (about 11–13 years) than in males (about 12–14 years). A period of rapid growth usually accompanies the onset of puberty.
- Adult** is the time from age 20 to death. Full adult stature is usually achieved by age 17 or 18 in females and by 19 or 20 years in males. Adulthood is sometimes divided into three periods: (1) young adult, age 20–40; (2) middle age, age 40–65; and (3) older adult, age 65 to death.

ASSESS YOUR PROGRESS

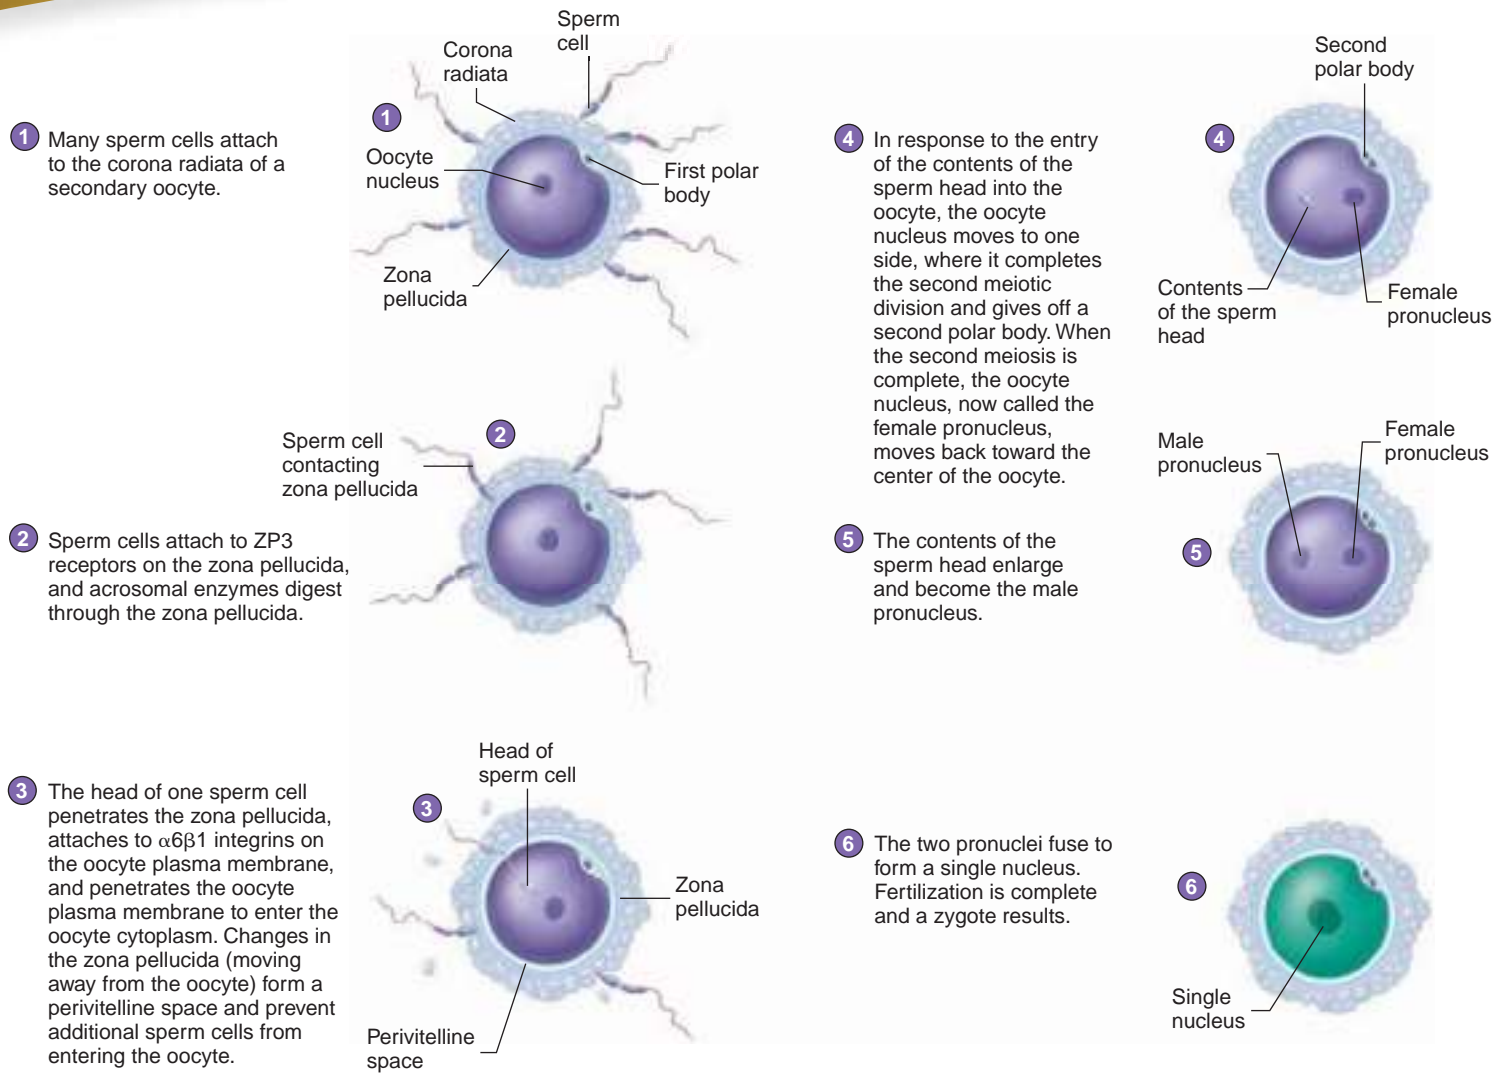

- Describe the three parts of the prenatal period, including the length of time for each part.
- Distinguish between clinical age and postovulatory age.
- List the stages of postnatal development, including the age range for each.

Fertilization

Prenatal development begins at **fertilization**. Fertilization occurs when a sperm cell attaches to a secondary oocyte, and the contents of the sperm head enter the oocyte cytoplasm and join with the oocyte pronucleus (figure 29.1). Of the several hundred million sperm cells deposited in the vagina during sexual intercourse, only a few dozen reach the vicinity of the secondary oocyte in the ampulla of the uterine tube. The **corona radiata**, composed of cumulus cells expelled from the follicle with the oocyte during ovulation (see figure 28.14), acts as a sort of barrier to those sperm cells that reach the oocyte; however, this barrier is not effective at blocking the sperm cells but rather slowing them down. The flagella on the sperm cells propel them through the loose matrix between the follicular cells of the corona radiata. Between the corona radiata and the oocyte is the **zona pellucida**, an extracellular membrane comprised mostly of glycoproteins. One particular zona pellucida glycoprotein, called **ZP3**, is a species-specific sperm cell receptor, to which molecules on the acrosomal cap of the sperm cell bind. This binding initiates the **acrosomal reaction**, which activates digestive enzymes in the acrosome, primarily hyaluronidase.

The first sperm cell through the zona pellucida attaches to a receptor molecule (integrin $\alpha\beta 1$) on the surface of the oocyte plasma membrane and causes depolarization of the membrane within 2–3 seconds. This depolarization, called the **fast block to polyspermy**, prevents additional sperm cells from attaching

FUNDAMENTAL Figure

PROCESS FIGURE 29.1 Fertilization 

to the oocyte plasma membrane. Depolarization also stimulates the intracellular release of Ca^{2+} . This in turn causes the oocyte to release water and other molecules from secretory vesicles, referred to as cortical granules. These granules are located on the inner surface of the oocyte plasma membrane. The released fluid causes the oocyte to shrink and the zona pellucida to denature and expand away from the oocyte. This results in a fluid-filled space between the oocyte plasma membrane and the zona pellucida called the **perivitelline space**. As the result of denaturation of the zona pellucida, ZP3 is inactivated, and no additional sperm cells can attach. This reaction is referred to as the **slow block to polyspermy**. Together, the fast block and the slow block ensure that the oocyte is fertilized by only one sperm cell.

The entrance of a sperm cell into the oocyte stimulates the female nucleus to undergo the second meiotic division, and the second polar body is formed. The nucleus that remains after the second meiotic division, called the **female pronucleus**, moves to the center of the oocyte, where it meets the **male pronucleus**

of the sperm cell. Both the male and female pronuclei are haploid, each having one chromosome of each homologous pair (see chapter 28). Fusion of the pronuclei completes the process of fertilization and restores the diploid number of chromosomes. The product of fertilization is a single diploid cell, the **zygote** ($z\gamma'g\delta t$; figure 29.2a).

Early Cell Division

About 18–36 hours after fertilization, the zygote divides to form two cells. Those two cells divide to form four cells, which divide to form eight cells, and so on (figure 29.2b–d). In the very early stages of development (days 1–4), the cells are said to be **totipotent** ($t\delta-t\text{ip}'\delta-tent$; whole-powered), meaning that each cell has the potential to give rise to any tissue type necessary for development. However, the cells of the developing embryo soon undergo **differentiation**, or specialization. Once differentiation occurs, the dividing cells of the embryo are referred to as

FIGURE 29.2 Development of the Blastocyst and Implantation

Successive cell divisions produce a multicellular morula by day 5, which becomes a hollow blastocyst on day 6. In the figure of the blastocyst, *green* cells are trophoblastic, and *orange* cells form the embryo proper. (a) Zygote (120 μm in diameter) with two polar bodies attached. (b–e) During the early cell divisions, the embryo divides into more and more cells, but the total size of the embryo remains relatively constant. **APR**

pluripotent (ploo-rip'ō-tent; multiple-powered), which means that any given cell has the ability to develop into a wide range of tissues, but not into all the tissues necessary for development. From this point on, the total number of embryonic cells can decrease, increase, or reorganize without affecting the normal development of the embryo.

Morula and Blastocyst

Once the dividing embryo consists of 12 or more cells, it is a solid mass of cells called a **morula** (mōr'oo-lă, mōr'u-lă; mulberry; figure 29.2d). Four or 5 days after ovulation, the morula consists of about 32 cells. Near this time, a fluid-filled cavity called the **blastocoele** (blas'tō-sēl) begins to form near the center of the cellular mass. The embryo then becomes a hollow sphere called a **blastocyst** (blas'tō-sist; figure 29.2e). A single layer of cells, the **trophoblast** (trof'ō-blast, trō'fō-blast; feeding layer), surrounds most of the blastocoele. At one end of the blastocyst, however, the

Clinical IMPACT

Twins

In rare cases, following early cell divisions, a totipotent cell separates from the embryo and develops to form another individual, producing “identical twins,” or **monozygotic twins**. Identical twins have identical genetic information in their cells. Other mechanisms that occur a little later in development can also cause identical twins.

Occasionally, a woman ovulates two or more secondary oocytes at the same time. Fertilization of two oocytes by different sperm cells results in “fraternal twins,” or **dizygotic twins**. Dizygotic twins are not genetically identical. Multiple ovulations can occur naturally or result from the injection of drugs that stimulate gonadotropin release. These drugs are used to treat certain forms of infertility, and they sometimes result in multiple fetuses.

cells are several layers thick. The thickened area, called the **inner cell mass**, is the tissue from which the embryo proper develops. The pluripotent cells of the inner cell mass do not form all the tissues necessary for normal development. The placenta and the membranes (chorion and amnion) surrounding the embryo form from the trophoblast.

Implantation of the Blastocyst and Development of the Placenta

All the events of the early germinal phase, from the first cell division through formation of the blastocoele and the inner cell mass, occur as the embryo moves from the site of fertilization in the ampulla of the uterine tube to the uterus, where **implantation** (im-plan-tā'shun) occurs. During implantation, the blastocyst essentially burrows into the uterine wall. Implantation occurs about 7 days after fertilization, usually in the area of the uterine fundus.

As the blastocyst invades the uterine wall, two populations of trophoblast cells develop and form the embryonic portion of the **placenta** (figure 29.3), the organ of nutrient and waste exchange between the embryo and the mother. The first proliferating population of individual trophoblast cells is called the **cytotrophoblast** (sī-tō-trof'ō-blast). The other trophoblast population is a nondividing syncytium, or multinucleated cell, called the **syncytiotrophoblast** (sin-sish'ē-ō-trō'fō-blast). The cytotrophoblast remains nearer the other embryonic tissues, and the syncytiotrophoblast invades the endometrium of the uterus. The syncytiotrophoblast is nonantigenic, meaning that, as it invades the maternal tissue, no immune reaction is triggered.

As the syncytiotrophoblast encounters maternal blood vessels, it surrounds them and digests the vessel wall, forming cavities called **lacunae** (lă-koo'nē), which contain maternal blood (figure 29.3, *step 3*). The lacunae are still connected to intact maternal vessels, so that blood circulates from the maternal

Clinical IMPACT

Stem Cell Research

During growth and development, many cells differentiate for a particular function, and many lose the ability to divide. However, some cells do not become fully specialized and retain the ability to undergo mitosis and differentiation. Such cells are called **stem cells**. Currently, stem cells are a hot topic for discussion, not only in the scientific community but also in the political arena. Stem cells have the potential to treat many diseases by replacing dysfunctional cells with normal cells. For example, bone marrow transplants have become a common treatment for certain types of leukemia. In this procedure, blood stem cells, found in the red bone marrow, are harvested from a donor and introduced into a leukemia patient. The stem cells provide a new source of normal blood cells for that individual. Investigations as to whether stem cells can be isolated and used to treat other diseases are under way.

Stem cells can be obtained from different sources, including adult tissues. Adult stem cells, however, produce only a limited number of cell types, depending on the tissue source of the stem cell. For example, adult liver stem cells can give rise to many cell types found in the liver, but they cannot give rise to other tissue cell types, such as blood cells. The most versatile stem cell is the totipotent zygote because it can give rise to all cell types, including placental tissue.

The pluripotent cells of the inner cell mass, called **embryonic stem cells**, are also

very versatile because they can give rise to all tissues, but they do not produce placental tissue. Embryonic stem cells were first isolated in 1998. Theoretically, embryonic stem cells have great potential for treating diseases. One problem, however, lies in the ability to artificially stimulate embryonic stem cells to differentiate into the right type of cell. Scientists are still in the early stages of determining the biochemical processes of how embryonic stem cells communicate to allow for the proper development of all tissues in multicellular organisms. Ideally, scientists would prefer to limit the number of cell types a particular stem cell can give rise to; otherwise, when these stem cells are grown in the lab, further work must be completed to isolate the correct cell type for a given treatment procedure.

Adult stem cells have had limited success in treating certain diseases. For example, stem cells obtained from adult blood can treat the complications associated with coronary heart disease, particularly the growth of new vessels around areas of blockage. However, it appears that adult stem cells are not effective for treating other diseases, such as type 1 diabetes mellitus and Parkinson disease. In these cases, embryonic stem cells may have a greater potential for providing a long-lasting cure.

Important ethical questions surround the use of embryonic stem cells. To harvest the embryonic cells, an embryo must be destroyed, which is unacceptable to opponents of the procedure, who argue that the zygote is a living

human whose cells should not be destroyed. They believe that human life extends into the earliest stages of development. Conversely, proponents of embryonic stem cell use maintain that the definition of a human life does not extend to the zygote and that preserving the sanctity and quality of human life for people suffering from debilitating, often fatal, and currently incurable diseases is worth the price. Furthermore, proponents argue that the zygotes providing the embryonic stem cells were produced for some other reason, such as infertility treatment, and will more than likely be destroyed.

The debate will probably not end soon. Current research is attempting to obtain embryonic stem cells without needing to destroy embryos. Indeed, the recent development of **induced pluripotent stem (iPS)** cells has raised the exciting prospect that fully differentiated adult cells—for example, skin cells—can be reprogrammed to create stem cells similar to embryonic stem cells. Alternatively, the possibility of bypassing iPS cells by directly transdifferentiating, or reprogramming, readily accessible adult skin cells to generate specific cell types, such as neurons, affected by a disease may soon be possible. Whether iPS or transdifferentiated cells will be useful in treatment remains to be established, although in the near future the ability to create patient-specific cells will provide scientists with useful tools for researching disease mechanisms and possibly for screening new drugs.

- 1 Frontal section of the uterus and uterine tube, showing development 7 days after fertilization.

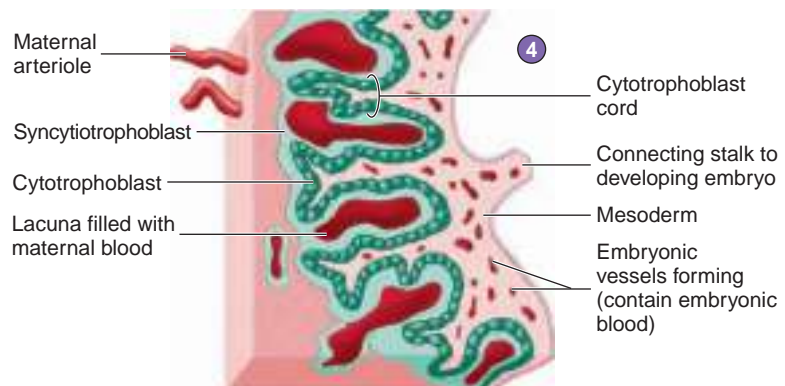

- 2 Implantation of the blastocyst, with syncytiotrophoblast beginning to invade the uterine wall (at about 8–12 days).

- 3 Intermediate stage of placental formation (at about 14–20 days). As maternal blood vessels are encountered by the syncytiotrophoblast, lacunae form and are filled with maternal blood.

- 4 Cytotrophoblast cords surround the syncytiotrophoblast and lacunae, and embryonic blood vessels enter the cord (at about 1 month).

PROCESS FIGURE 29.3 Implantation of the Blastocyst and Formation of the Placenta

As the blastocyst is implanted, syncytiotrophoblasts and cytotrophoblasts invade to form the placenta.

vessels through the lacunae. Cords of cytotrophoblast surround the syncytiotrophoblast and lacunae (figure 29.3, *step 4*).

Branches, called **chorionic** (kō-rē-on'ik) **villi**, sprout from the cords of cytotrophoblasts and protrude into the lacunae, like fingers (figure 29.4a). This entire embryonic structure facing the maternal tissues is called the **chorion** (kō'rē-on). Embryonic mesoderm and blood vessels grow into the cords and villi as they protrude into the lacunae. In the mature placenta, the cytotrophoblast disappears, so that the embryonic blood supply is separated from the maternal blood supply by only the embryonic capillary wall, a basement membrane, and a thin layer of syncytiotrophoblast (figure 29.4b).

The site of implantation and the integrity of the placental attachment are both very important for a successful pregnancy. If the blastocyst implants near the cervix, a condition called **placenta previa** (prē'vĕ-ă) occurs. As the placenta grows, it may extend partially or completely across the internal cervical opening. As the fetus and placenta continue to grow and the uterus stretches, the region of the placenta over the cervical opening may tear, and hemorrhaging may occur. A second condition, **abruptio** (ab-rŭp'shĕ-ō) **placentae**, occurs when the placental attachment is not strong. In this case, a normally positioned placenta tears away from the uterine wall, which also involves hemorrhaging. Both conditions can result in miscarriage and threaten the life of the mother.

ASSESS YOUR PROGRESS

- Describe the events of fertilization. Where does fertilization occur?
- Explain what occurs to prevent polyspermy.
- What events occur during the first week after fertilization? Use the terms zygote, morula, blastocyst, blastocle, totipotent, and pluripotent in your explanation.
- Describe the trophoblast and inner cell mass, and explain what develops from each.
- Explain the process of implantation and the development of the placenta.

Formation of the Germ Layers

After implantation, an **amniotic** (am-nĕ-ot'ik) **cavity** forms inside the inner cell mass. The amniotic cavity is surrounded by a layer of cells called the **amnion** (am'nĕ-on), or **amniotic sac**. Formation of the amniotic cavity causes part of the inner cell mass nearest the blastocle to separate as a flat disk of tissue called the **embryonic disk** (figure 29.5). This embryonic disk is composed of two layers of cells: an **epiblast** adjacent to the amniotic cavity and a **hypoblast** on the side opposite the amnion. The epiblast gives rise to the three germ layers, whereas the hypoblast gives rise to extra-embryonic membranes. A third cavity, the **yolk sac**, forms inside the blastocle from the hypoblast. The amniotic sac and the yolk

FIGURE 29.4 Mature Placenta and Fetus

Fetal blood vessels and maternal blood vessels are in close contact, and nutrients are exchanged between fetal and maternal blood. However, fetal and maternal blood do not mix.

FIGURE 29.5 Embryonic Disk

The embryonic disk consists of epiblast (*blue*) and hypoblast (*yellow*), surrounded by the amniotic cavity and yolk sac. The connecting stalk, which attaches the embryo to the uterus, becomes part of the umbilical cord.

sac can be compared to two balloons pushed together, with the circular double layer where the two balloons meet representing the embryonic disk. The amniotic sac eventually enlarges to surround the developing embryo, providing a protective fluid environment, the “bag of waters,” where the embryo forms.

About 13 or 14 days after fertilization, the embryonic disk becomes a slightly elongated, oval structure. This phase of development, known as **gastrulation**, involves the movement of epiblast cells and results in the formation of three distinct germ layers that eventually give rise to the many body structures.

Clinical IMPACT

In Vitro Fertilization and Embryo Transfer

In a small number of women, normal pregnancy is not possible because of an anatomical or physiological condition. In 87% of these cases, the uterine tubes are incapable of allowing sperm cells to reach the oocyte or transporting the zygote to the uterus. Since 1978, two techniques—in vitro fertilization and embryo transfer—have made pregnancy possible in hundreds of such women. **In vitro fertilization (IVF)** involves removing secondary oocytes from a woman, placing the oocytes into a petri dish, and adding sperm cells to the dish, where fertilization and early development occur *in vitro*, which means “in glass.” **Embryo transfer** involves removing the developing embryo from the petri dish and introducing the embryo into the uterus of a recipient woman.

For IVF and embryo transfer to be accomplished, a woman is first injected with a substance similar to luteinizing hormone (LH), which causes more than one follicle to ovulate at a time. Just before the follicles rupture, the

secondary oocytes are surgically removed from the ovary. The oocytes are then incubated in a dish and maintained at body temperature for 6 hours, when sperm cells are added to the dish. At that time, different techniques may be used to enhance sperm entry into the oocyte.

After 24–48 hours, when the embryos have divided to form cell masses of two to eight cells, several of the embryos are transferred to the uterus. Typically, three embryos are introduced into the uterus at a time to increase the success rate, since only a small percentage of the embryos are expected to survive. However, the rate of complications, such as multiple pregnancies, miscarriage, and prematurity, also increases with the greater number of transferred embryos.

About one-third of transfers of three embryos end in multiple pregnancies. Of triplets born as a result of IVF, 64% require intensive care after birth, and 75% of quadruplets require intensive care, often for several weeks.

Prematurity from IVF pregnancies in the United Kingdom results in newborn mortality in 2.7% of cases, a rate three times that of natural pregnancies. As a result of the possible complications, no more than two or three embryos are transferred per IVF in the United Kingdom. In 2009, the birth of octuplets to a California woman with six other children led to serious discussions of the regulation of embryo transfers in the United States.

The success of IVF is dependent on many factors, including the reason for infertility, the mother’s age, and the physician’s expertise. The success rate for achieving pregnancy following IVF treatment has increased dramatically in recent years and is currently 31%. Of these pregnancies, 83% result in live births. By comparison, only 50% or fewer natural fertilizations result in successful delivery. The improved success rate is probably due to the fact that abnormal-appearing embryos are not used for IVF and more than one embryo is transferred.

Proliferating cells of the epiblast migrate toward the center and the caudal end of the disk, forming a thickened line called the **primitive streak**. Some epiblast cells migrate through the primitive streak. A portion of these cells migrates toward and displaces the hypoblast to form the **endoderm** (en'dō-derm; inside layer). Other cells emerge between the epiblast and the endoderm as the **mesoderm** (mez'ō-derm; middle layer; figure 29.6). Those epiblast cells that do not migrate form the **ectoderm** (ek'tō-derm; outside layer). These three germ layers, the endoderm, mesoderm, and ectoderm, are the beginning of the embryo proper. All tissues of the adult can be traced to the three germ layers (table 29.1). The **notochord**, a rodlike structure, extends from the cephalic end of the primitive streak.

The development of the germ layers and the subsequent development of the organ systems is heavily dependent on cell communication. Some communication requires direct cell-to-cell contact, whereas other communication depends on diffusible molecules, such as **growth factors**. Two important families of growth factors are epidermal growth factors (EGF) and fibroblast growth factors (FGF).

► Predict 2

Occasionally, two primitive streaks form in one embryonic disk. Predict the result. What happens if the two primitive streaks are touching each other?

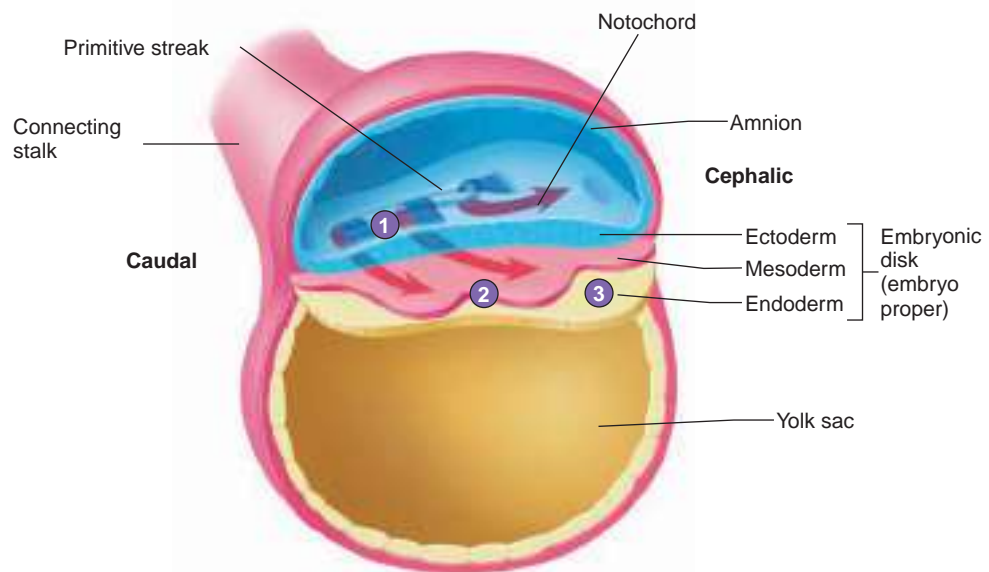

Neural Tube and Neural Crest Formation

About 18 days after fertilization, the ectoderm near the cephalic end of the primitive streak is stimulated to form a thickened **neural plate**. The lateral edges of the plate begin to rise, like two ocean waves coming together. These edges are called the **neural folds**, and between them lies a **neural groove** (figure 29.7, *step 1*). The underlying notochord stimulates the folding of the neural plate at the neural groove. The crests of the neural folds begin to meet in the midline and fuse into a **neural tube** (figure 29.7, *steps 2–4*). The cells of the neural tube are called **neuroectoderm** (table 29.1). Neuroectoderm becomes the brain, the spinal cord, and parts of the peripheral nervous system. The neural tube becomes completely closed by day 26. If the neural tube fails to close, major defects of the central nervous system can result (see Clinical Impact, “Neural Tube Defects,” later in this chapter).

As the neural folds come together and fuse, a population of cells breaks away from the neuroectoderm all along the crests of the folds. These cells are called **neural crest cells**. They migrate along one of three distinct routes as they leave the neural folds. Those that migrate down along the side of the developing neural tube become autonomic ganglia neurons, adrenal medullary cells, or enteric nervous system neurons. Those that migrate into the somites (see the next section, “Somite Formation”) become sensory ganglia neurons. Those that migrate laterally between the somites and the ectoderm become melanocytes. In the head, neural crest cells contribute to the

**PROCESS FIGURE 29.7** Formation of the Neural Tube

The neural folds come together in the midline and fuse to form a neural tube. This fusion begins in the center and moves both cranially and caudally. Shown is an embryo at about 21 days after fertilization. The insets to the right show progressive closure of the neural tube at various levels of cross section.

skull, the dentin of teeth, a few small skeletal muscles, and general connective tissue. Because neural crest cells in the head give rise to many of the same tissues as the mesoderm in the head and trunk, the general term **mesenchyme** (mez/en-kīm) is sometimes applied to cells of either neural crest or mesoderm origin.

Somite Formation

As the neural tube develops, distinct segments, called somites (sō'mītz), form from the mesoderm immediately adjacent to the tube (figure 29.7). In the head, the first few somites do not become clearly divided, but develop into indistinct, segmented structures called **somitomeres**. The somites and somitomeres eventually give rise to a part of the skull, the vertebral column, and skeletal muscle. Most of the head muscles are derived from the somitomeres.

ASSESS YOUR PROGRESS

9. Describe the process of gastrulation and the role of the primitive streak.
10. List the major body tissues, organs, and systems that originate from each of the three germ layers.
11. Describe the formation of the neural tube. What are the three routes taken by neural crest cells?
12. What is a somite? What do they develop into?

Formation of the Gut and Body Cavities

At the same time the neural tube is forming, the embryo itself is becoming a tube along the upper part of the yolk sac. The cephalic and caudal ends of the yolk sac separate from the main part of the sac to form the **foregut** and **hindgut**, respectively. This is the beginning of the digestive tract (figure 29.8a). The developing digestive tract pinches off from the yolk sac as a tube but remains attached to the yolk sac by a yolk stalk.

The ends of the foregut and hindgut (figure 29.8b) are in close relationship to the overlying ectoderm and form membranes called the oropharyngeal membrane and the cloacal membrane, respectively. The **oropharyngeal membrane** opens to form the mouth, and the **cloacal membrane** opens to form the urethra and anus. Thus, the digestive tract becomes a tube with openings at both ends.

A considerable number of outpocketings, or **evaginations** (ē-vaj-i-nā'shūnz), occur along the early digestive tract. The first to form is the allantois (figure 29.8b), part of which will form the urinary bladder. Other evaginations develop into structures such as the anterior pituitary, the thyroid gland, the lungs, the liver, the pancreas, and the urinary bladder. At the same time, solid bars of tissue known as **branchial arches** (figure 29.8c; see figure 29.9) form along the lateral sides of the head. The sides of the foregut expand as pockets between these branchial arches. The central expanded foregut is called the **pharynx**, and the pockets along both sides of the pharynx are called **pharyngeal pouches**. Adult derivatives of the pharyngeal pouches include the auditory tubes, tonsils, thymus, and parathyroids.

At about the same time the gut is developing, the **coelom** (sē'lom), or body cavities, begins to form as a series of isolated

Clinical IMPACT

Environmental Influences on Development

During the first 2 weeks of development, the embryo is quite resistant to environmental influences that may cause malformations. Factors that adversely affect the embryo at this age are more likely to kill it than cause malformations. However, between 2 weeks and the next 4–7 weeks (depending on the structure considered), the embryo is more sensitive to outside influences that cause malformations than at any other time.

A number of drugs and other environmental influences are known to affect the embryo and fetus during development. The two most common are alcohol and cigarette smoke. Alcohol consumption can result in **fetal alcohol syndrome**, which is primarily characterized by decreased mental function. Although excessive alcohol consumption, as occurs with alcoholism and binge drinking, is known to cause fetal alcohol syndrome, research results are inconsistent about the effects of lower levels of consumption. Most physicians recommend that alcohol not be consumed at all during pregnancy. Studies have shown that exposure to cigarette smoke throughout pregnancy can stunt the physical growth and mental development of the fetus.

Isotretinoin, more commonly known as Accutane[®], is a drug used to treat severe acne; however, it has been shown to cause severe birth defects, including malformation of the ears, eyes, face, skull, heart, and brain. The risk of detrimental effects on the developing embryo and fetus is so great that the manufacturer of Accutane[®] requires both medical professionals who prescribe Accutane and their patients to participate in a pregnancy risk management program in order to obtain the medication. The program requires that woman prescribed Accutane[®] agree to use two forms of birth control and take monthly pregnancy tests while using the drug.

cavities within the embryo (figure 29.8). The most cranial group of cavities enlarges and fuses to form the **pericardial cavity**. Shortly thereafter, the coelomic cavity extends toward the caudal end of the embryo as the **pleural cavities** and the **peritoneal cavity**. Initially, these cavities are continuous, but they eventually separate into distinct adult cavities (see chapter 1).

Limb Bud Development

At about 28 days, the arms and legs appear as limb buds (figure 29.9). The **apical ectodermal ridge**, a specialized thickening of the ectoderm, develops on the lateral margin of each limb bud and stimulates its outgrowth. As the buds elongate, limb tissues are laid down in a proximal-to-distal sequence. For example, in the upper limb, the arm forms before the forearm, which in turn forms before the hand.

Development of the Face

The face develops by the fusion of five embryonic structures, which include the single frontonasal process, a pair of maxillary

FIGURE 29.8 Formation of the Digestive Tract

Blue arrows show the folding of the digestive tract into a tube. Dashed lines show the plane from which the cross sections were taken. (a) Twenty days after fertilization. (b) Twenty-five days after fertilization. (c) Thirty days after fertilization. Evaginations are identified along the pharynx and the liver and pancreas.

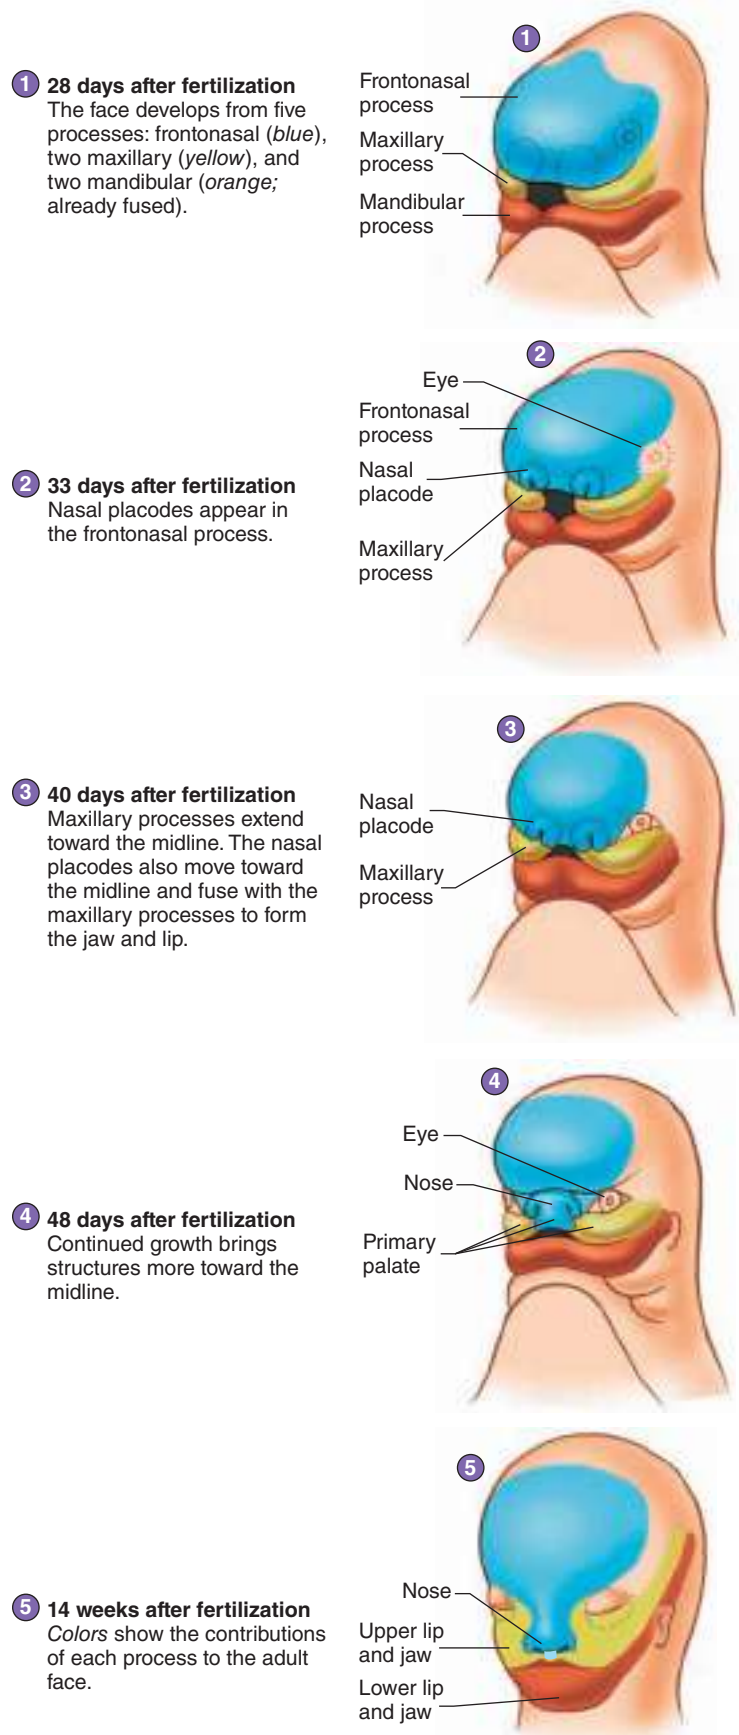

FIGURE 29.9 Human Embryo 35 Days After Fertilization

processes, and a pair of mandibular processes. The **frontonasal process** forms the forehead, nose, and midportion of the upper jaw and lip. The **maxillary processes** form the lateral parts of the upper jaw and lip. The **mandibular processes** form the lower jaw and lip (figure 29.10, *step 1*).

Nasal placodes (plak'ōdz), areas of thickening, which develop at the lateral margins of the frontonasal process, develop into the nose and the center of the upper jaw and lip (figure 29.10, *step 2*). As the brain enlarges and the face matures, the nasal placodes approach each other in the midline. The medial edges of the placodes fuse to form the midportion of the upper jaw and lip (figure 29.10, *steps 3 and 4*). This part of the frontonasal process is between the two maxillary processes, which are expanding toward the midline, and fuses with them to form the upper jaw and lip, known as the **primary palate** (figure 29.10, *step 4*). When the frontonasal and one or both maxillary processes fail to fuse, a **cleft lip** results. Because the frontonasal process is a midline structure that normally fuses with the two lateral maxillary processes during formation of the primary palate, cleft lips usually do not occur in the midline but to one side (or both sides). The cleft can vary in severity from a slight indentation in the lip to a fissure that extends from the mouth to the nares (nostril).

At about the same time the primary palate is forming, the lateral edges of the nasal placodes fuse with the maxillary processes to close off the groove extending from the mouth to the eye (figure 29.10, *steps 4 and 5*). On rare occasions, these structures fail to meet, resulting in a facial cleft extending from the mouth to the eye. The inferior margins of the maxillary processes fuse with the superior margins of the mandibular processes to decrease the size of the mouth.

PROCESS FIGURE 29.10 Development of the Face

All of the previously described fusions and the growth of the brain give the face a recognizably “human” appearance by about 50 days. The roof of the mouth, known as the **secondary palate**, begins as vertical shelves, which swing to a horizontal position and begin to fuse with each other at about 56 days of development. Fusion of the entire palate is not completed until about 90 days. If the secondary palate does not fuse, a midline fissure in the roof of the mouth, called a **cleft palate**, results. A cleft palate can range in severity from a slight cleft of the uvula (see figure 24.6) to a fissure extending the entire length of the palate. A cleft lip and cleft palate can occur together, forming a continuous fissure.

ASSESS YOUR PROGRESS

13. Describe the formation of the gut and the body cavities.
14. How do limb buds develop? What does proximal-to-distal growth sequence mean?
15. Describe the process involved in forming the face. What clefts may result if these tissues fail to fuse?

Development of the Organ Systems

Organogenesis is the appearance and development of organs. The period of organogenesis occurs between 14 and 60 days after fertilization, which is primarily during the embryonic period of development (table 29.2).

Skin

Recall from chapter 5 that the skin is comprised of the epidermis and the dermis. The **epidermis** of the skin is derived from ectoderm, and the **dermis** is derived from mesoderm or, in the case of the face, from neural crest cells. Accessory organs, such as the nails, hair, and glands, develop from the epidermis (see chapter 5). Melanocytes and sensory receptors in the skin are derived from neural crest cells.

Skeleton

The process of bone development was discussed in chapter 6. The bones of the skeleton develop from either mesoderm or the neural crest cells through intramembranous or endochondral bone formation (see chapter 6). The bones of the face develop from neural crest cells, whereas the rest of the skull, the vertebral column, and the ribs develop from somite- or somitomere-derived mesoderm. The appendicular skeleton develops from limb bud mesoderm.

Muscle

Recall from chapter 9 that skeletal muscles are comprised of multinucleated cells called muscle fibers. **Myoblasts** (mī'ō-blastz) are the early embryonic cells that give rise to skeletal muscle fibers. Myoblasts migrate from somites or somitomeres to sites of future muscle development, where they continue to divide and begin to fuse to form multinuclear cells called **myotubes**. Myotubes enlarge to become the muscle fibers of the skeletal muscles. Shortly after myotubes form, nerves grow into the area and innervate the developing muscle fibers. After the basic form of each

muscle is established, muscle growth continues as the number of muscle fibers increases. The total number of muscle fibers is established before birth and remains relatively constant thereafter. Muscle enlargement after birth results from an increase in the size of individual fibers.

Nervous System

The nervous system is derived from the neural tube and the neural crest cells. Neural tube closure begins at about 21 days of development in the upper cervical region and proceeds into the head and down the spinal cord. Soon after the neural tube has closed at about 25 days of development, the part of the neural tube that becomes the brain begins to expand and develop a series of pouches (see figure 13.13). The central cavity of the neural tube becomes the ventricles of the brain and the central canal of the spinal cord.

Within the neural tube are the neuron cell bodies of somatic motor neurons and preganglionic neurons of the autonomic nervous system, which provide axons to the peripheral nervous system. Sensory neurons and postganglionic neurons of the autonomic nervous system are derived from neural crest cells.

Special Senses

Recall from chapter 15 that the special senses are those senses where the receptors are localized to a specific organ. The sense of olfaction (smell) includes the olfactory organ, olfactory bulb, and olfactory nerves. The **olfactory bulbs** and **olfactory nerves** develop as an evagination from the telencephalon (see figure 13.15). The eyes, the organs of vision, develop as evaginations from the diencephalon. Each evagination elongates to form an **optic stalk**, and a bulb called the **optic vesicle** develops at the terminal end of each optic stalk. The optic vesicle reaches the side of the head and stimulates the overlying ectoderm to thicken into a **lens**. The sensory part of the ear, the organ of hearing and equilibrium, appears as an ectodermal thickening, or placode, that invaginates and pinches off from the overlying ectoderm.

Endocrine System

The structures of the endocrine system are found in many areas of the body (see chapter 18). A downward growth from the floor of the diencephalon forms the **posterior pituitary gland**. The **anterior pituitary gland** develops from an evagination of ectoderm in the roof of the embryonic oral cavity and grows toward the floor of the brain. It eventually loses its connection with the oral cavity and becomes attached to the posterior pituitary gland (see chapter 18).

The **thyroid gland** originates as an evagination from the floor of the pharynx in the region of the developing tongue and moves into the lower neck, eventually losing its connection with the pharynx. The **parathyroid glands**, which are derived from the third and fourth pharyngeal pouches, migrate inferiorly and become associated with the thyroid gland.

The **adrenal medulla** arises from neural crest cells and consists of specialized postganglionic neurons of the sympathetic division of the autonomic nervous system (see chapter 16). The **adrenal cortex** is derived from mesoderm.

TABLE 29.2 Development of the Organ Systems

	Age (Days Since Fertilization)					
	1–5	6–10	11–15	16–20	21–25	26–30
General Features	Fertilization, morula, blastocyst	Blastocyst implants.	Primitive streak, three germ layers	Neural plate	Neural tube closed	Limb buds and other “buds” appear.
Integumentary System			Ectoderm, mesoderm			Melanocytes form from neural crest.
Skeletal System			Mesoderm		Neural crest (will form facial bones)	Limb buds
Muscular System			Mesoderm	Somites begin to form.		Somites are all present.
Nervous System			Ectoderm	Neural plate	Neural tube complete; neural crest forms; eyes and ears begin to form	Lens begins to form.
Endocrine System			Ectoderm, mesoderm, endoderm	Thyroid begins to develop.		Parathyroid glands and pancreas appear.
Cardiovascular System			Mesoderm	Blood islands form; two-tubed heart forms.	Single-tubed heart begins to beat.	Interatrial septum begins to form.
Lymphatic System			Mesoderm			Thymus appears.
Respiratory System			Mesoderm, endoderm		Diaphragm begins to form.	Trachea forms as single bud; lung buds (primary bronchi) form.
Digestive System			Mesoderm		Neural crest forms tooth dentin.	Liver and pancreas appear as buds.
			Endoderm		Foregut and hindgut form.	Tongue bud appears.
Urinary System			Mesoderm, endoderm		Pronephros develops; allantois appears.	Mesonephros appears.
Reproductive System			Mesoderm, endoderm		Primordial germ cells form on yolk sac.	Mesonephros appears; genital tubercle forms.

The **pancreas** originates as two evaginations from the duodenum, which come together to form a single gland (see figure 29.8c).

Cardiovascular System

The cardiovascular system includes the heart, blood vessels, and blood (see chapters 19–21). The heart develops from two endothelial tubes (figure 29.11, *step 1*), which fuse into a single, midline heart tube (figure 29.11, *step 2*). A series of dilations appears

along the length of the primitive heart tube, and four major regions can be identified: the **sinus venosus**, the site where blood enters the heart; a single **atrium**; a single **ventricle**; and the **bulbus cordis**, where blood exits the heart (figure 29.11, *step 2*). The elongating heart, confined within the pericardium, becomes bent into a loop, the apex of which is the ventricle.

The major chambers of the heart, the atrium and the ventricle, expand rapidly. The right part of the sinus venosus becomes

Age (Days Since Fertilization)					
31–35	36–40	41–45	46–50	51–55	56–60
Hand and foot plates on limbs	Fingers and toes appear; lips form; embryo is 15 mm long.	External ear is forming; embryo is 20 mm long.	Embryo is 25 mm long.	Limbs elongate to adult proportions; embryo is 35 mm long.	Face is distinctly human in appearance.
Sensory receptors appear in skin.		Collagen fibers are clearly present in skin.		Extensive sensory endings are present in skin.	
Mesoderm condenses in areas of future bone.	Cartilage in site of future humerus	Cartilage in site of future ulna and radius	Cartilage in site of hand and fingers		Ossification begins in clavicle and then in other bones.
Muscle precursor cells enter limb buds.			Functional muscle		Nearly all muscles are appearing in an adult form.
Nerve processes enter limb buds.		External ear is forming; olfactory nerves begin to form.		Semicircular canals in inner ear are complete.	Eyelids form; cochlea in inner ear is complete.
Pituitary gland appears as evaginations from brain and mouth.	Gonadal ridges form; adrenal glands are forming.		Pineal gland appears.	Thyroid gland is in adult position, and its attachment to tongue is lost.	Anterior pituitary loses its connection to mouth.
Interventricular septum begins to form.		Interventricular septum is complete.	Interatrial septum is complete but still has opening until birth.		
Large lymphatic vessels form in neck.	Spleen appears.			Adult lymph pattern forms.	
Secondary bronchi to lobes form.	Tertiary bronchi to bronchopulmonary segments form.		Tracheal cartilage begins to form.		
Oropharyngeal membrane ruptures.		Secondary palate begins to form; tooth buds begin to form.			Secondary palate begins to fuse (fusion complete by 90 days).
Metanephros begins to develop.				Mesonephros degenerates.	Anal portion of cloacal membrane ruptures.
	Gonadal ridges form.	Primordial germ cells enter gonadal ridges.	Paramesonephric ducts appear.		Uterus is forming; external genitalia begin to differentiate in male and female.

absorbed into the atrium, and the bulbus cordis is absorbed into the ventricle. The embryonic sinus venosus initiates contraction at one end of the tubular heart. Later in development, part of the sinus venosus becomes the sinoatrial node, the pacemaker in the adult heart.

The **interatrial septum**, which separates the two atria in the adult heart, is formed from two parts: the **septum primum** (primary septum) and the **septum secundum** (secondary

septum). An opening in the interatrial septum called the **foramen ovale** (*ō-val'ē*) connects the two atria and allows blood to flow from the right to the left atrium in the embryo and fetus. An **interventricular septum** (figure 29.11, *steps 3–5*) develops, which divides the single ventricle into two chambers.

Blood vessels and blood cells form from blood islands on the surface of the yolk sac and inside the embryo. Blood islands are small masses of mesoderm that become blood vessels on the

Clinical IMPACT

Neural Tube Defects

Proper neural tube formation is necessary for the development of the nervous system; otherwise, several birth defects can occur. **Anencephaly** (an'en-sef'ă-lē; no brain) is a birth defect in which much of the brain fails to form. It results because the neural tube did not close in the region of the head. A baby born with anencephaly cannot survive.

Spina bifida (spī'nă bi'fī-dă; split spine) is a general term describing defects of the spinal cord, vertebral column, or both (figure 29A). Spina bifida can range from a simple defect, in which one or more vertebral spinous processes are split or missing but there is no clinical manifestation, to a severe defect that results in paralysis of the limbs or the bowels and bladder, depending on where the defect occurs.

The inclusion of **folic acid**, the B vitamin folate, in a woman's diet during the early stages of her pregnancy significantly reduces the risk for neural tube defects in her developing embryo.

FIGURE 29A Spina Bifida

outside and blood cells on the inside. These islands expand and fuse to form the blood vessels.

Respiratory System

The respiratory system includes the lungs and the structures of the respiratory tract (see chapter 23). The lungs develop as a single, midline evagination from the foregut in the region of the future esophagus. This evagination branches to form two **lung buds** (figure 29.12, *step 1*). The lung buds elongate and branch, first forming the bronchi that project to the lobes of the lungs (figure 29.12, *step 2*) and then forming the bronchi that project to the bronchopulmonary segments of the lungs (figure 29.12, *step 3*). This branching continues (figure 29.12, *step 4*) until, by the end of the sixth month, about 17 generations of branching have occurred. Even after birth, some branching continues as the lungs

grow larger and, in the adult, about 24 generations of branches have been established.

Urinary System

The urinary system consists of the kidneys, ureters, urinary bladder, and urethra (see chapter 26). The kidneys develop from mesoderm located between the somites and the lateral part of the embryo. About 21 days after fertilization, the mesoderm in the cervical region differentiates into a structure called the **pronephros** (figure 29.13a). The pronephros consists of a duct and simple tubules connecting the duct to the open coelomic cavity. This type of kidney is the functional adult kidney in some lower chordates, but it is probably not functional in the human embryo and soon disappears.

The **mesonephros** (figure 29.13a) is a functional organ in the embryo. It consists of a caudal extension of the pronephric duct and a number of minute tubules, which are smaller and more complex than those of the pronephros. One end of each tubule opens into the mesonephric duct, and the other end forms a glomerulus (see chapter 26).

As the mesonephros is developing, the caudal end of the hindgut begins to enlarge to form the **cloaca** (klō-ă'kă; sewer), the common junction of the digestive, urinary, and genital systems (figure 29.13b). The cloaca is divided into two parts by a **urorectal septum**: a digestive part called the **rectum** and a urogenital part called the **urethra** (figure 29.13c). The cloaca is associated with two tubes: the hindgut and the **allantois** (ă-lan'tō-is), a blind tube extending into the umbilical cord (see figure 29.8). The part of the allantois nearest the cloaca enlarges to form the urinary bladder, and the remainder, from the bladder to the umbilicus, forms the median umbilical ligament.

The mesonephric duct extends caudally as it develops and eventually joins the cloaca. At the point of junction, another tube, the **ureter**, begins to form. Its distal end enlarges and branches to form the duct system of the **metanephros** (last kidney), which is the adult kidney. The metanephros takes over the function of the degenerating mesonephros (figure 29.13d).

Reproductive System

The term **gonads** refers to the organs in which gametogenesis occurs. The female gonad is the ovary, and the male gonad is the testis (see chapter 28). The male and female gonads appear as **gonadal ridges** along the ventral border of each mesonephros (figure 29.14a). **Primordial germ cells**, destined to become oocytes or sperm cells, form on the surface of the yolk sac, migrate into the embryo, and enter the gonadal ridge.

In the female, the ovaries descend from their original position high in the abdomen to a location within the pelvis. In the male, the testes descend even farther. As the testes reach the anteroinferior abdominal wall, two tunnels called the **inguinal canals** form through the abdominal musculature. The testes pass through these canals, leaving the abdominal cavity and coming to lie within the **scrotum** (see figure 28.5). Descent of the testes through the inguinal canals begins about 7 months after conception, and the testes enter the scrotum about 1 month before the infant is born.

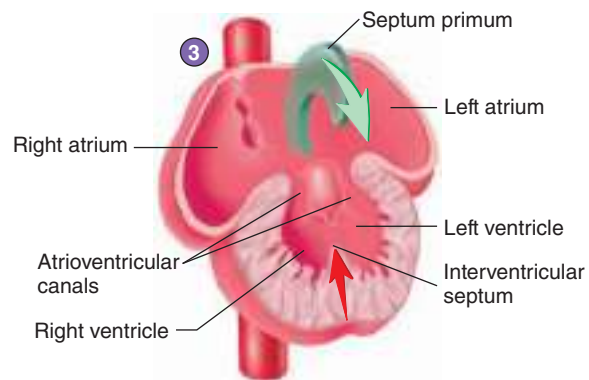

- 1 20 days after fertilization**
At this age, the heart consists of two parallel tubes that will fuse into a single, midline heart.

- 2 22 days after fertilization**
The two parallel tubes have fused to form one tube. This tube bends as it elongates (*blue arrows* suggest the direction of bending) within the confined space of the pericardium.

- 3 31 days after fertilization**
The interatrial septum (septum primum, *green*) and the interventricular septum grow toward the center of the heart.

- 4 35 days after fertilization**
The interventricular septum is nearly complete. A foramen opens in the septum primum (*green*) as the septum secundum begins to form (*blue*).

- 5 Final embryonic condition of the interatrial septum**
Blood from the right atrium can flow through the foramen ovale into the left atrium. After birth, as blood begins to flow in the other direction, the septum primum is forced against the septum secundum, closing the foramen ovale.

1 28 days after fertilization
A single bud forms and divides into two buds, which will become the lungs and primary bronchi.

2 32 days after fertilization
Primary bronchi branch to form secondary bronchi, which supply the lung lobes.

3 35 days after fertilization
Secondary bronchi branch to form tertiary bronchi, which supply the bronchopulmonary segments.

4 50 days after fertilization
The branching will continue to eventually form the extensive respiratory passages in the lungs.

Clinical IMPACT

Heart Defects

If the septum secundum fails to grow far enough or if the foramen ovale becomes too large, an **atrial septal defect (ASD)** develops, allowing blood to flow from the left atrium to the right atrium in the newborn. If the interventricular septum does not grow enough to completely separate the ventricles, a **ventricular septal defect (VSD)** results. VSDs are more common than ASDs. Both ASDs and VSDs result in abnormal heart sounds, called a **heart murmur**. Blood passes through the ASD or the VSD from the left to the right side of the heart. The right side of the heart usually hypertrophies. In many cases, septal defects are not serious. However, in severe cases of VSD (Eisenmenger syndrome), increased pressure in the pulmonary blood vessels and decreased blood flow through the systemic blood vessels result in pulmonary edema, cyanosis (a bluish color to the skin due to deficient blood oxygenation), or heart failure.

In approximately 3% of male children, one or both testes fail to enter the scrotum. This condition is called undescended testes, or **cryptorchidism** (krip-tōr'ki-dizm). Because testosterone is required for the testes to descend into the scrotum, cryptorchidism is often the result of inadequate testosterone secreted by the fetal testes. If neither testis descends and the defect is not corrected, the male will be infertile because the slightly higher temperature of the body cavity, compared with that of the scrotal sac, causes the spermatogonia to degenerate. Cryptorchidism is treated with hormone therapy, or it can be surgically corrected. Cryptorchidism is an important risk factor for testicular cancer.

Paramesonephric ducts (also called müllerian ducts) are the precursors for the segments of the female reproductive tract. They begin to develop just lateral to the **mesonephric ducts** (also called wolffian ducts), which are the precursor for the segments of the male reproductive tract. These two ducts grow inferiorly until they meet one another and enter the cloaca as a single, midline tube.

In male embryos, testosterone is secreted by the testes. It causes the mesonephric duct system to enlarge and differentiate to form the epididymis, ductus deferens, seminal vesicles, and prostate gland (figure 29.14*b*). Müllerian-inhibiting hormone, also secreted by the testes, causes the paramesonephric ducts to degenerate. In female embryos, neither testosterone nor müllerian-inhibiting hormone is secreted. As a result, the mesonephric duct system atrophies, and the paramesonephric duct system develops to form the uterine tubes, the uterus, and part of the vagina in females (figure 29.14*c*).

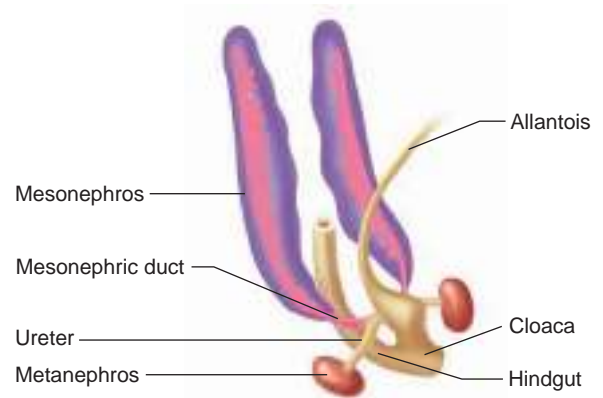

Like the other sex organs, the external genitalia begin as the same structures in the male and female and then diverge (figure 29.15). An enlargement called the **genital tubercle** develops in the groin of the embryo. **Genital folds** develop on each side of a **urethral groove**, and **labioscrotal swellings** develop lateral to the folds.

In the male, under the influence of dihydrotestosterone, derived from testosterone, the genital tubercle and the genital

(c) The kidney continues to grow and develop.

(d) Final duct relationships

FIGURE 29.13 Development of the Kidneys and Urinary Bladder

folds close over the urethral groove to form the penis. The testes move into the labioscrotal swellings, which become the scrotum of the male. If closure of the urethral groove does not proceed all the way to the end of the penis, a defect known as **hypospadias** (hī'pō-spā'dē-ās) results.

In the female, in the absence of testosterone, the genital tubercle becomes the clitoris. The urethral groove disappears; genital folds do not fuse. As a result, the urethra opens somewhat posterior to the clitoris but anterior to the vaginal opening. The unfused genital folds become the labia minora, and the labioscrotal folds become the labia majora.

➤ Predict 3

How would the failure to produce müllerian-inhibiting hormone affect the development of the internal reproductive system and external genitalia in a male embryo?

Growth of the Fetus

At approximately 60 days after fertilization, the embryo becomes a fetus (a 50-day-old embryo is shown in figure 29.16a). In the embryo, most of the organ systems are forming, whereas in the fetus the organs are present and continue to develop during the fetal period. Most morphological changes occur in the embryonic phase of development, whereas the fetal period is primarily a “growing phase.”

The fetus grows from about 3 cm and 2.5 g at 60 days to 50 cm and 3300 g at term—more than a 15-fold increase in length and a 1300-fold increase in weight. The growth of the fetus also causes an increase in the size of the uterus (figure 29.17).

The fetus is covered with fine, soft hair called **lanugo** (la-noo'gō). The fetus is also covered with a waxy coat of sloughed epithelial cells called the **vernix caseosa** (ver'niks kā-se-ō'sä). The vernix caseosa protects the fetus from the somewhat toxic amniotic fluid formed by the accumulation of fetal waste products.

FIGURE 29.14 Differentiation of the Reproductive Systems

(a) Indifferent stage. (b) The male, under the influence of male hormones, develops a ductus deferens from the mesonephric duct, and the paramesonephric duct degenerates. (c) The female, without male hormones, develops a uterus and uterine tubes from the paramesonephric duct, and the mesonephros disappears.

Subcutaneous adipose tissue accumulates in the older fetus. This tissue provides nutrients and helps insulate the fetus after it is born. In addition, the subcutaneous adipose tissue aids the baby in sucking by strengthening and supporting the cheeks, so that negative pressure can be developed in the oral cavity.

Peak body growth occurs late in gestation, but growth of the placenta essentially stops at about 35 weeks, thus restricting further intrauterine growth.

At about 38 weeks of development, the fetus can survive outside the mother and is ready to be delivered. The average weight at this point is 3250 g for a female fetus and 3300 g for a male fetus.

ASSESS YOUR PROGRESS

- Describe the formation of the following major organs and organ systems: skin, bones, skeletal muscles, nervous system, eyes, and respiratory system. When does each of these events occur?
- Explain the formation of the following endocrine glands: anterior pituitary, posterior pituitary, thyroid, parathyroid, adrenal medulla, adrenal cortex, and pancreas.
- Explain the process by which a one-chambered heart becomes a four-chambered heart.

- Describe how the pronephros, mesonephros, and metanephros lead to the development of the kidneys.
- Demonstrate your understanding of the effect hormones have on the development of the male and female reproductive systems.
- Compare the male and female structures formed from each of the following: genital tubercle, genital folds, and labioscrotal swellings.
- What major events distinguish between embryonic and fetal development?

29.2 Parturition

LEARNING OUTCOMES

After reading this section, you should be able to

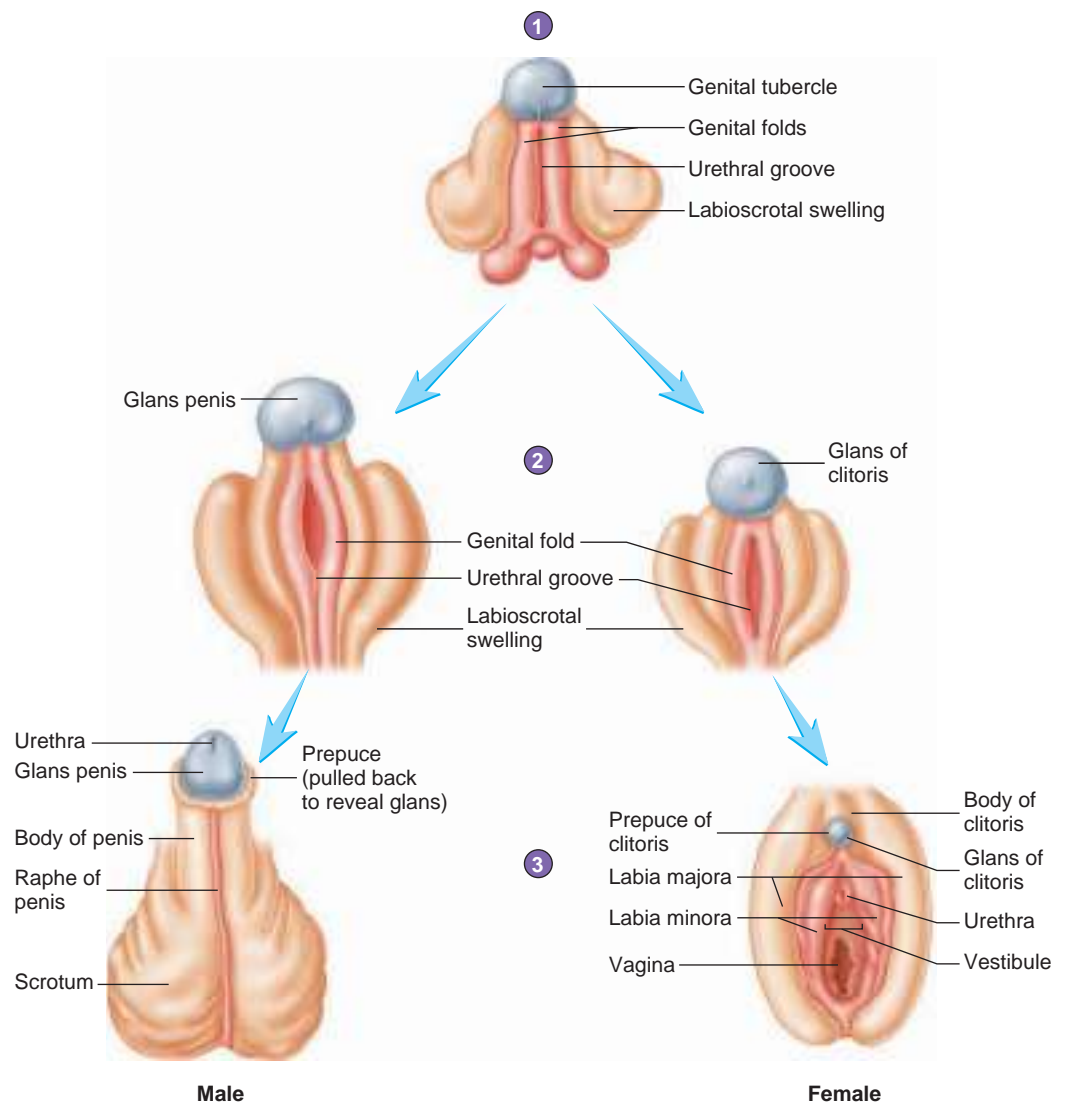

- Explain the events that occur during the three stages of parturition.
- Discuss the hormonal changes of parturition for both the fetus and the mother.

Parturition (par-toor-ish'ün) is the process by which a baby is born. Physicians usually calculate the **gestation period**, or length

1 At approximately 5 weeks after fertilization, the genital tubercle, genital folds, and labioscrotal swellings are the same for the male and female.

2 By 10 weeks of development, the male penile structures are somewhat larger than those of the female clitoris. The urethral groove is still open in the male and female.

3 Near term, the general adult condition is achieved. The labioscrotal swellings become the scrotum in the male and the labia majora in the female. The genital folds fuse in the male to form the body of the penis, whereas they form the labia minora in the female. The urethral groove in the male is closed by the raphe of the penis. It remains open in the female as the vestibule.

PROCESS FIGURE 29.15 Development of the External Genitalia

of the pregnancy, as 280 days (40 weeks) from the last menstrual period (LMP) to the date of delivery of the infant. (In terms of post-ovulatory age, the fetus is ready for birth at 38 weeks.)

Predict 4

Compare and contrast clinical age and postovulatory age for fertilization, implantation, the beginning of the fetal period, and parturition.

Near the end of pregnancy, the uterus becomes progressively more excitable and usually exhibits occasional contractions, which become stronger and more frequent until parturition is initiated. The cervix gradually dilates, and strong uterine contractions help expel the fetus from the uterus through the vagina (figure 29.18).

Stages of Labor

Labor is the period during which uterine contractions occur that eventually expel the fetus and placenta from the uterus. Labor occurs as three stages:

1. **First stage.** The first stage of labor, often called the *dilation stage*, begins with the onset of regular uterine contractions. This stage extends until the cervix has dilated to a diameter about the size of the fetus's head. This stage of labor commonly lasts 8–24 hours, but it may be as short as a few minutes, especially in women who have had more than one child. Normally during labor (95% of the time), the head of the fetus is in an inferior position within the woman's pelvis, so that the head acts as a wedge, forcing the cervix and vagina to open as the uterine contractions push against the fetus. During this stage of labor, the amniotic sac ruptures, releasing the amniotic fluid.

The **central tendon of the perineum** (see figure 10.19) is very important in supporting the uterus and vagina. Tearing or stretching of the tendon during childbirth may weaken the inferior support of these organs, and prolapse of the uterus may occur. **Prolapse** is a "sinking" of the uterus, so that the uterine cervix moves down into the vagina (first degree), moves down near the vaginal orifice (second degree), or protrudes through the vaginal orifice (third degree).

(a)

(b)

(c)

FIGURE 29.16 Embryos and Fetuses at Different Ages

(a) Fifty days after fertilization. (b) Three months after fertilization. (c) Four months after fertilization.

2. *Second stage.* The second stage of labor, often called the *expulsion stage*, lasts from the time of maximum cervical dilation until the fetus exits the vagina. This stage may last from a minute to an hour or more. During this stage, contractions of the abdominal muscles assist the uterine contractions.

**FIGURE 29.17 Enlargement of the Uterus During Fetal Development**

Clinical IMPACT

Fetal Monitoring

Monitoring of the fetus during pregnancy allows physicians to determine the likelihood of complications during delivery, as well as possible health conditions the fetus may have as a result of either genetics or a developmental error. **Amniocentesis** (am'nē-ō-sen-tē'sis) is the removal and analysis of amniotic fluid (figure 29B). As the fetus develops, it expels molecules of various types, as well as living cells, into the amniotic fluid. These molecules and cells can be collected and analyzed to detect a number of metabolic disorders. Furthermore, if the cells collected by amniocentesis are grown in culture, additional metabolic disorders can be detected. Chromosome analysis, called **karyotyping**, can also be performed on the cultured cells. Amniocentesis has been done as early as 10 weeks after fertilization, but the success rate in detecting disorders at that time is quite low. It is most commonly performed at 13–16 weeks after fertilization.

Fetal tissue samples can also be obtained by **chorionic villus sampling**, in which a probe introduced into the uterine cavity through the cervix removes a small piece of the chorion. This technique has an advantage over amniocentesis in that it can be used as early as 8–10 weeks after fertilization. Furthermore, cells can be analyzed directly, as in karyotyping, rather than having to be cultured, as is required in amniocentesis.

One of the molecules normally produced by the fetus and released into the amniotic fluid is **α -fetoprotein**. This protein shows up in the amniotic fluid if fetal tissues that are normally covered by skin are directly exposed to the amniotic fluid. This can happen with nervous tissue due to failure of the neural tube to close, or with abdominal tissues due to failure of the abdominal wall to fully form.

Some of the metabolic products from the fetus, such as α -fetoprotein and estriol, a weak form of estrogen produced in the placenta after 20 weeks of gestation, can enter the maternal blood. In some cases, the products are processed and passed to the maternal urine. The levels of these fetal products can then be measured in the mother's blood or urine to screen for possible conditions of the fetus. Further tests are required to verify suspected fetal conditions

FIGURE 29B Removal of Amniotic Fluid for Amniocentesis

indicated by elevated levels of fetal metabolic products in the maternal blood or urine.

New maternal blood tests have also been developed to screen for certain chromosomal abnormalities, such as Down syndrome (trisomy 21). Conducted in the first trimester of pregnancy, these procedures detect fetal DNA, referred to as **cell-free fetal DNA (cffDNA)**, within the maternal blood. Certain cffDNA characteristics are valid indicators of specific chromosomal abnormalities. The benefit of this type of fetal monitoring is that it is less invasive than amniocentesis or chorionic villus sampling. Also, the detection rate is very high, as high as 99% in some studies. As with other types of fetal genetic testing, this procedure is reserved for at-risk or high-risk pregnancies as determined by the physician.

The fetus can be seen within the uterus by **ultrasound**, in which sound waves are bounced off the fetus like sonar and then analyzed and enhanced by computer. In another technique, called **fetoscopy**, a fiberoptic probe is introduced into the amniotic cavity and used to view the fetus. Because of the constantly increasing resolution in ultrasound technology and because it is noninvasive compared with

fetoscopy, ultrasound is usually the preferred technique. However, some fetal defects cannot be adequately assessed by ultrasound and require fetoscopy. In that case, ultrasound is used to guide the fetoscope.

Ultrasound has not been found to pose any risk to the fetus or the mother. It is accomplished by placing a transducer on the mother's abdominal wall (transabdominal method) or by inserting the transducer into the woman's vagina (transvaginal method). The latter technique produces much higher resolution because fewer layers of tissue exist between the transducer and the uterine cavity. Transvaginal ultrasound can be used to identify the yolk sac of a developing embryo as early as 17 days after fertilization, and the embryo can be visualized at 25 days. Transabdominal ultrasound allows for fetal monitoring by 6–8 weeks after fertilization.

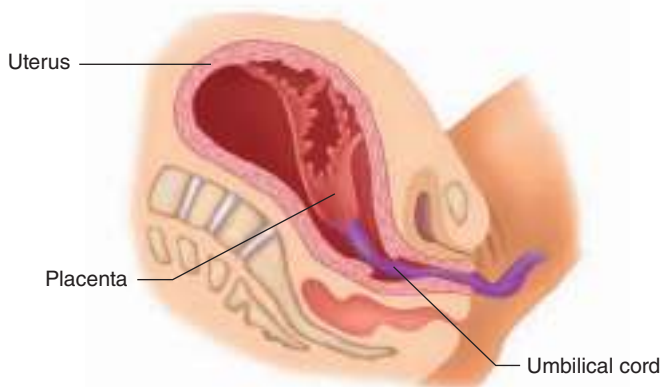

Fetal heart rate can be detected with an ultrasound stethoscope by the tenth week after fertilization and with a conventional stethoscope by 20 weeks. Fetal heart rate is most commonly monitored electronically, either indirectly by transducers on the mother's abdomen or by a probe attached to the skin of the fetus. The normal fetal heart rate range is 110–160 bpm.

1 **First stage.** The cervix dilates, and the amniotic sac ruptures.

2 **Second stage.** The fetus is expelled from the uterus.

3 **Third stage.** The placenta is expelled.

PROCESS FIGURE 29.18 Parturition

The contractions generate enough pressure to compress blood vessels in the placenta that blood flow to the fetus is stopped. During periods of relaxation, blood flow to the placenta resumes. Occasionally, synthetic oxytocin (pitocin) is administered to women during labor to increase the force of the uterine contractions. However, caution must be exercised in using this drug, so that tetanic contractions, which would drastically reduce blood flow through the placenta, do not occur.

3. *Third stage.* The third stage of labor actually occurs after the birth of the fetus. This stage is often called the *placental stage* because during this stage the placenta is expelled from the uterus. Uterine contractions cause the placenta to tear away from the wall of the uterus. Some bleeding from the uterine wall occurs as a consequence of the intimate contact between the placenta and the uterus, but the bleeding is normally limited because uterine smooth muscle contractions compress the blood vessels to the placenta.

Blood levels of estrogen and progesterone fall dramatically after parturition because the source of these hormones is gone once the placenta has been dislodged from the uterus. In addition, during the 4 or 5 weeks after parturition, the uterus becomes much smaller, although it remains somewhat larger than it was before pregnancy. The cells of the uterine lining become smaller, and many of them degenerate. A vaginal discharge composed of small amounts of blood and degenerating endometrium persists for 1 week or more after parturition.

Hormonal Stimulation of Parturition

The precise signal that triggers parturition is unknown, but many supporting factors have been identified (figure 29.19). Before parturition, the progesterone concentration in the maternal blood is at its highest level and is exerting an inhibitory effect on uterine smooth

Clinical IMPACT

Prematurity

Occasionally, the fetus is delivered before it has sufficiently matured and is therefore considered **premature**. Prematurity is one of the most significant problems in pediatrics, the branch of medicine dealing with children, because many complications can result. The most significant complication is **infant respiratory distress syndrome**, which occurs because very young premature infants cannot produce **surfactant**, a mixture of phospholipids and protein that lines the inner surface of the lungs and allows them to expand as we breathe. Each year, 65,000 premature infants suffer from respiratory distress syndrome in the United States. Until recently, 10% of those infants died. Now, surfactant substitutes are being developed, and glucocorticoid administration can stimulate surfactant production. These therapies have cut the death rate in half, and more effective replacements are being investigated.

- 1 The fetal hypothalamus secretes a releasing hormone, corticotropin-releasing hormone (CRH), which stimulates adrenocorticotropic hormone (ACTH) secretion from the pituitary. The fetal pituitary secretes ACTH in greater amounts near parturition.
- 2 ACTH causes the fetal adrenal gland to secrete greater quantities of adrenal cortical steroids.
- 3 Adrenal cortical steroids travel in the umbilical blood to the placenta.
- 4 In the placenta, the adrenal cortical steroids cause progesterone synthesis to level off and estrogen and prostaglandin synthesis to increase, making the uterus more excitable.
- 5 The stretching of the uterus produces action potentials that are transmitted to the brain through ascending pathways.
- 6 Action potentials stimulate the secretion of oxytocin from the posterior pituitary.
- 7 Oxytocin causes the uterine smooth muscle to contract.

PROCESS FIGURE 29.19 Factors That Influence Parturition

Although the precise control of parturition is unknown, these changes appear to play a role.

muscle cells. Near the end of pregnancy, however, estrogen levels rapidly increase in the maternal blood, and their excitatory influence overcomes the inhibitory influence of progesterone.

Before parturition, the adrenal glands of the fetus are greatly enlarged, and the rate of adrenocorticotropic hormone (ACTH) secretion by the fetus's anterior pituitary gland increases. The increase in ACTH is due to the stress of the confined space and limited oxygen supply created in the uterus by the growing fetus. ACTH causes the fetal adrenal cortex to produce glucocorticoids, which travel to the placenta, where they decrease the rate of progesterone secretion and increase the rate of estrogen synthesis. Also, prostaglandin synthesis is initiated, which strongly stimulates uterine contractions.

During parturition, stretching of the uterine cervix stimulates the release of oxytocin from the maternal posterior pituitary gland. Oxytocin stimulates uterine contractions, which move the fetus farther into the cervix, causing further stretch. Thus, by a positive-feedback mechanism, stretch stimulates oxytocin release and oxytocin causes further stretch until the time of delivery. After delivery of the fetus, the cervix is no longer stretched and oxytocin secretion decreases.

Besides the effects already described, progesterone and estrogen also influence the secretion of oxytocin. Progesterone inhibits oxytocin release and decreases the number of oxytocin receptors.

Therefore, decreased progesterone levels in the maternal blood result in increased oxytocin secretion and more oxytocin receptors in the uterus. In addition, estrogen makes the uterus more sensitive to oxytocin stimulation by increasing the synthesis of oxytocin receptor sites. Estrogen may also increase the formation of gap junctions between myometrial cells, thereby enhancing the contractility of the uterus. Some evidence suggests that oxytocin also stimulates prostaglandin synthesis in the uterus. All these events support the development of strong uterine contractions.

Predict 5

A woman is having an extremely prolonged labor. From her anatomy and physiology course, she remembers the role of calcium in muscle contraction and asks the doctor to give her a calcium injection to speed the delivery. Explain why the doctor would or would not do as she requests.

ASSESS YOUR PROGRESS

23. List the stages of labor; indicate when each stage begins and its approximate length.
24. Describe the hormonal changes that take place before and during delivery. How is stretch of the cervix involved in delivery?

29.3 The Newborn

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Discuss the respiratory, cardiovascular, and digestive changes that occur in the newborn.
- B. Explain the significance of the Apgar score.
- C. List the causes of congenital disorders.

The newborn baby, which is also called a **neonate**, immediately experiences several dramatic changes due to being separated from the maternal blood and transferred from a fluid to a gaseous environment.

Respiratory and Cardiovascular Changes

The large, forced gasps of air taken in when the infant cries at the time of delivery help inflate the lungs. This initial inflation of the lungs causes important changes in the cardiovascular system (figure 29.20). Before birth, very little blood flows through the fetus's pulmonary arteries to the lungs and back to the heart through the pulmonary veins. As a result, the left atrium has little blood and very low blood pressure. Recall that the fetal heart has an opening between the right and left atria, called the foramen ovale. Because of the low pressure in the left atrium, blood flows from the right atrium, through the foramen ovale, and into the left atrium.

Expansion of the lungs following the baby's first breath reduces the resistance to blood flow through the lungs, resulting in increased blood flow through the pulmonary arteries. Consequently, more blood flows from the right atrium to the right ventricle and into the pulmonary arteries, and less blood flows from the right atrium through the foramen ovale to the left atrium. In addition, more blood returns from the lungs through the pulmonary veins to the left atrium, which increases the pressure in the left atrium. The increased left atrial pressure and decreased right atrial pressure, resulting from decreased pulmonary resistance, force blood against the septum primum, causing the foramen ovale to close. This action functionally completes the separation of the heart into two pumps: the right side of the heart and the left side of the heart. The closed foramen ovale becomes the **fossa ovalis**.

Prior to birth, a vessel called the **ductus arteriosus** connects the pulmonary trunk to the aorta and allows blood to flow from the pulmonary trunk to the systemic circulation. Within 1 or 2 days after birth, the ductus arteriosus closes off. This closure occurs because of the sphincterlike constriction of the artery and is probably stimulated by local changes in blood pressure and blood oxygen. Once closed, the ductus arteriosus is replaced by connective tissue and is known as the **ligamentum arteriosum**. If the ductus arteriosus does not close completely, it is said to be **patent**. This is a serious birth defect, resulting in marked elevation in pulmonary blood pressure because blood flows from the left ventricle to the aorta, through the ductus arteriosus, and to the pulmonary arteries. If not corrected, it can lead to irreversible degenerative changes in the heart and lungs.

Before birth, the fetal blood passes to the placenta through umbilical arteries from the internal iliac arteries and returns through an umbilical vein. The blood passes through the liver via the ductus venosus, which joins the inferior vena cava. At birth, when the umbilical cord is tied and cut, no more blood flows through the umbilical vein and arteries, and they degenerate. The remnant of the umbilical vein becomes the **ligamentum teres**, or *round ligament*, of the liver, and the ductus venosus becomes the **ligamentum venosum**. The remnants of the umbilical arteries become the cords of the umbilical arteries.

Digestive Changes

When a baby is born, it is suddenly separated from its source of nutrients, the maternal blood. Because of this separation and the stress of birth and new life, the neonate usually loses 5–10% of its total body weight during the first few days of life.

Although the digestive system of the fetus becomes somewhat functional late in development, it is still very immature, compared with that of an adult. Late in gestation, the fetus swallows amniotic fluid from time to time. Shortly after birth, this swallowed fluid plus intestinal cells, intestinal mucus, and bile pass from the digestive tract as a greenish anal discharge called **meconium** (mē-kō'nē-ŭm).

The pH of the stomach at birth is nearly neutral because of the swallowed basic amniotic fluid. Within the first 8 hours of life, gastric acid secretion increases, causing the stomach pH to decrease. Maximum acidity is reached at 4–10 days, and the pH gradually increases for the next 10–30 days.

The neonatal liver is also functionally immature. It lacks adequate amounts of the enzyme required to process bilirubin. This enzyme system usually develops within 2 weeks after birth in a healthy neonate; however, because it is not fully developed at birth, some full-term babies temporarily develop jaundice, characterized by elevated blood levels of bilirubin and a slightly yellowish cast to the skin or whites of the eye. Jaundice is also common in premature babies.

The newborn digestive system is capable of digesting lactose (milk sugar) from the time of birth. The pancreatic secretions are sufficiently mature for a milk diet, but the digestive system only gradually develops the ability to digest more solid foods over the first year or two; therefore, new foods should be introduced gradually during the first 2 years. Parents are also advised to introduce only one new food at a time, so that, if an allergic reaction occurs, the cause is more easily determined.

Amylase secretion by the salivary glands and the pancreas remains low until after the first year. Lactase activity in the small intestine is high at birth but declines during infancy, although the levels still exceed those in adults. In many adults, lactase activity is lost, and an intolerance for milk develops (see chapter 24).

Apgar Scores

A physiological assessment tool known as the **Apgar score** is used to evaluate a newborn baby soon after birth. The

FUNDAMENTAL Figure

1 Blood bypasses the lungs by flowing from the pulmonary trunk through the ductus arteriosus to the aorta.

2 Blood also bypasses the lungs by flowing from the right to the left atrium through the foramen ovale.

3 Blood bypasses the liver sinusoids by flowing through the ductus venosus.

4 Oxygenated blood is returned to the fetus from the placenta by the umbilical vein.

5 Deoxygenated blood is carried from the fetus to the placenta through the umbilical arteries.

(a)

PROCESS FIGURE 29.20 Circulatory Changes at Birth

(a) Circulatory conditions in the fetus.

Apgar test is named for Virginia Apgar, the physician who developed it. This score evaluates five characteristics of the newborn: (1) **A**ppearance, (2) **P**ulse, (3) **G**rimace, (4) **A**ctivity, and (5) **R**espiratory effort. Each of these characteristics is rated on a scale of 0–2, with 2 denoting normal function; 1, reduced function; and 0, seriously impaired function. More specific descriptions of the rankings for each characteristic are shown in table 29.3. For example, a newborn who has a pink complexion at birth is ranked 2 for appearance. The total Apgar score is the sum of the scores from the five characteristics, ranging from

0 to 10. A total Apgar score of 8–10 at 1–5 minutes after birth is considered normal. Other systems that assess neonatal growth and development, including general external appearance and neurological development, also exist.

Congenital Disorders

The term *congenital* means “present at birth,” and **congenital disorders** are abnormalities commonly referred to as birth defects. Approximately 70% of all congenital disorders are the

FUNDAMENTAL Figure

1 When air enters the lungs, blood is forced through the pulmonary arteries to the lungs. The ductus arteriosus closes and becomes the ligamentum arteriosum (*gray*).

2 The foramen ovale closes and becomes the fossa ovalis. Blood can no longer flow from the right to the left atrium.

3 The ductus venosus degenerates and becomes the ligamentum venosum (*gray*).

4 The umbilical arteries and vein are cut. The umbilical vein becomes the round ligament of the liver (*gray*).

5 The umbilical arteries also degenerate and become the cords of the umbilical arteries (*gray*).

(b)

PROCESS FIGURE 29.20 (continued)

(b) Circulatory changes that occur at birth.

result of an unknown cause, 15% have a known genetic cause, and the remaining 15% result from environmental factors or a combination of environmental and genetic factors. Environmental factors, referred to as **teratogens** (ter'ă-tō-jenz), damage the fetus during development. An example of a known teratogen is alcohol. Fetal alcohol syndrome results when a pregnant woman drinks alcohol, which crosses the placenta and damages the fetus. The baby is born with a smaller-than-normal head, intellectual disability, and possibly other defects. Researchers are working to identify various other teratogens, so that women can avoid known teratogens and reduce the risk for congenital disorders.

ASSESS YOUR PROGRESS

25. What changes occur in the newborn's cardiovascular system shortly after birth? What do each of the following fetal structures become: foramen ovale, ductus arteriosus, umbilical vein, and ductus venosus?
26. What changes take place in the newborn's digestive system shortly after birth?
27. What does the Apgar score measure?
28. What are congenital disorders? What are some causes of these disorders?
29. What is a teratogen? Give an example.

TABLE 29.3 Apgar Rating Scales

Physiological Conditions	0	1	2
Appearance (skin color)	White or blue	Limbs blue, body pink	Pink
Pulse (rate)	No pulse	100 bpm	>100 bpm
Grimace (reflexive grimace initiated by stimulating the plantar surface of the foot)	No response	Facial grimaces, slight body movement	Facial grimaces, extensive body movement
Activity (muscle tone)	No movement, muscles flaccid	Limbs partially flexed, little movement, poor muscle tone	Active movement, good muscle tone
Respiratory effort (amount of breathing)	No breathing	Slow, irregular breathing	Good, regular breathing; strong cry

29.4 Lactation

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the events of lactation.
- Relate the roles of hormones in milk production and release.

Lactation is the production of milk by the mother's breasts (mammary glands; figure 29.21) following parturition.

During pregnancy, the duct system and the secretory units of the breast expand as a result of the high concentration and

continuous presence of estrogens and progesterone. The ducts grow and branch repeatedly to form an extensive network. Additional adipose tissue is deposited also; thus, the size of the breasts increases throughout pregnancy. Estrogen is primarily responsible for this breast growth, but normal development of the breast does not occur without the influence of several other hormones. Progesterone causes development of the breasts' secretory alveoli, which enlarge but do not usually secrete milk during pregnancy. The other necessary hormones are growth hormone, prolactin, thyroid hormones, glucocorticoids, and insulin. In addition, the placenta secretes a growth hormone–like substance (human somatotropin) and a prolactin-like substance (human placental lactogen), both of which support development of the breasts.

PROCESS FIGURE 29.21 Hormonal Control of Lactation

Prolactin, produced by the anterior pituitary gland, is responsible for milk production. Before parturition, high levels of estrogen stimulate increased prolactin production, but no milk is produced because high levels of estrogen and progesterone inhibit prolactin's effect on the mammary glands. After parturition, estrogen, progesterone, and prolactin levels decrease. However, these decreased levels of prolactin are still sufficient to stimulate milk production. Despite this overall decrease in the basal levels of prolactin following parturition, a reflex response produces surges of prolactin release. During suckling, mechanical stimulation of the breasts initiates nerve impulses that reach the hypothalamus, causing the secretion of **prolactin-releasing factor (PRF)** and inhibiting the release of **prolactin-inhibiting factor (PIF)**. Consequently, prolactin levels temporarily increase and stimulate additional milk production.

For the first few days after birth, the mammary glands secrete a high-protein material called **colostrum** (kō-lo's'trūm), which also contains many antibodies. Although colostrum is high in protein, it contains few lipids and less lactose than milk. Eventually, the breasts produce milk with a higher lipid and lactose content. The presence of maternal antibodies in the colostrum as well as milk helps protect the nursing baby from infections (see chapter 22).

At the time of nursing, stored milk is released as a result of a reflex response. Mechanical stimulation of the breasts produces nerve impulses that cause the release of oxytocin from the posterior pituitary, which stimulates cells surrounding the alveoli to contract. Milk is then released from the breasts, a process called **milk letdown** or *milk ejection*. In addition, higher brain centers can stimulate oxytocin release, and stimuli such as hearing an infant cry can result in milk letdown.

Milk production in the breast takes time. Suckling also stimulates a surge in prolactin, as described earlier. This increase in prolactin results in the production of milk for the next feeding time. Repeated stimulation of prolactin release by suckling makes nursing (breastfeeding) possible for several years. If nursing stops, however, the ability to produce prolactin ceases, and milk production stops within a few days.

➤ Predict 6

A first-time mother was breastfeeding her baby when she felt uterine cramps. Concerned, she consulted a nurse. What was the nurse's explanation?

31. Describe the events of milk production and milk letdown.
32. What is in colostrum?

29.5 First Year After Birth

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe the changes that occur during the first year after birth.

Clinical IMPACT

HIV and the Newborn

The human immunodeficiency virus (HIV) can be transmitted from a mother to her child in utero, during parturition, or during breastfeeding. HIV has been isolated from human breast milk and colostrum. In developed countries, HIV patients are advised not to breastfeed but to bottle-feed using formula instead. However, in underdeveloped countries, bottle-feeding is not yet a viable option. Evidence indicates that newborn babies given a single dose of an AIDS drug at birth have half the risk for HIV infection as long as they are not breastfed. Therefore, the current proposal for underdeveloped countries is that daily AIDS drug treatment be continued for newborns of HIV patients as long as the child is breastfeeding. In one study, treated infants had a 1% risk for HIV infection, compared with a 15% rate in untreated infants.

The infant experiences many changes from birth until 1 year of age. During this first year, the brain is still developing, and much of what the infant can do depends on how much brain development has occurred. It is estimated that the newborn's central nervous system contains the adult number of neurons, but subsequent brain growth and maturation add new glial cells, myelin sheaths, and new connections between neurons that may remain throughout life.

During the first year of life, infants typically pass certain developmental milestones. However, the timing of these events varies considerably from child to child, and the following time frames are only rough estimates. By 6 weeks of age, the infant usually can hold up his head when placed in a prone position and begins to smile in response to people or objects. At 3 months, the infant exercises his limbs aimlessly, but he can control his arms and hands enough to voluntarily suck his thumb. The infant can follow a moving person with his eyes. At 4 months, the infant begins to raise himself by his arms. He can begin to grasp objects placed in his hand, coo and gurgle, roll from back to side, listen quietly to a person's voice or to music, hold his head erect, and play with his hands.

At 5 months, an infant can usually laugh, reach for objects, turn her head to follow an object, lift her head and shoulders, sit with support, and roll over. At 8 months, the infant recognizes familiar people, sits up without support, and reaches for specific objects. At 12 months, the infant may pull herself to a standing position and may be able to walk without support. She can pick up objects with her hands and examine them carefully. She can understand much of what is said and may say several words of her own.

ASSESS YOUR PROGRESS

33. List the major changes that occur during the first year of life. What do most of these activities depend on?

29.6 Aging and Death

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the process of aging.
- B. Explain the events that occur at the time of death.

As with development, the process of aging begins at fertilization. Cells proliferate at an extremely rapid rate during early development, and then the process begins to slow as various cells become committed to specific body functions.

Many body cells, such as liver and skin cells, continue to proliferate throughout life, replacing dead or damaged tissue. However, many other cells, such as the neurons in the central nervous system, cease to proliferate once a certain number exist, and dead cells are not replaced. Though increases in the number of glial cells, myelin sheaths, and neuronal connections occur during the first year of life, the number of neurons reaches a peak, at about the time of birth. At that time, neuron numbers begin to decline. Neuronal loss is most rapid early in life and later decreases to a slower, steadier rate.

A natural, but as yet unexplained, decline occurs in mitochondrial DNA function with age. If this decline reaches a threshold, which apparently differs from tissue to tissue, the normal mitochondrial function is lost, and the tissue or organ may exhibit disease. In a small number of people, this mitochondrial degeneration occurs very early in life, resulting in premature aging.

The physical plasticity (i.e., the state of being soft and pliable) of young embryonic tissues results largely from the presence of large amounts of hyaluronate and relatively small amounts of collagen. Furthermore, the collagen and other related proteins that are present are not highly cross-linked; thus, the tissues are very flexible and elastic. Many of these proteins produced during development are permanent body components; as the person ages, more and more cross-links form between these protein molecules, thereby rendering the tissues more rigid and less elastic.

Because cross-linking of proteins is a normal part of the aging process, it is not surprising that the tissues with the highest content of collagen and other related proteins are the tissues that display the most tissue rigidity associated with aging. One of the first structures to exhibit pathological changes as a result of this increased rigidity is the lens of the eye. Seeing close objects becomes more difficult with advancing age until most middle-aged people require reading glasses. Loss of elasticity also affects other tissues, including the joints, blood vessels, kidneys, lungs, and heart, and greatly reduces their ability to function.

Like nervous tissue, mature muscle cells do not normally proliferate after terminal differentiation occurs before birth. As a result, the total number of skeletal and cardiac muscle fibers declines with age. The strength of skeletal muscle reaches a peak between 20 and 30 years of life and declines steadily thereafter. Furthermore, like the collagen of connective tissue, the macromolecules of muscle undergo biochemical changes during aging and render the muscle tissue less functional. A good exercise program, however, can slow or even reverse this process (figure 29.22).

FIGURE 29.22 Active Older Adults

The population of older adults exhibits a range of variability. In some adults over 70 years, many systems are beginning to fail, whereas others can look forward to at least 10 more years of healthy living.

A decline in cardiac function with advanced aging is also related to the decline in muscular function. The heart loses elastic recoil ability and muscular contractility. As a result, total cardiac output declines, and less oxygen and fewer nutrients reach cells, such as neurons in the brain and chondrocytes in the joints. The lower amounts of oxygen and nutrients contribute to the decline in these tissues. Reduced cardiac function also may result in decreased blood flow to the kidneys, which decreases their filtration ability. Degeneration of the connective tissues as a result of collagen cross-linking and other factors also decreases the filtration efficiency of the glomerular basement membrane.

Atherosclerosis (ath'er-ō-skler-ō'sis) is the deposit and subsequent hardening of a soft, gruel-like material, containing lipids, cholesterol, calcium, and other materials, in lesions of the tunica intima of large and medium-sized arteries. These deposits then become fibrotic and calcified, resulting in **arteriosclerosis** (ar-tēr'ē-ō-skler-ō'sis; hardening of the arteries). Arteriosclerosis interferes with normal blood flow and can result in a **thrombus**, the formation of a clot or plaque inside a vessel. A piece of the plaque, called an **embolus** (em'bō-lūs), can break loose, float through the circulation, and lodge in smaller arteries, where it may cause myocardial infarctions or strokes. Atherosclerosis affects all middle-aged and older people to some extent and may even occur in young people. People with high blood cholesterol appear to be at increased risk of developing atherosclerosis. In addition to dietary influences, this condition seems to have a heritable component, and blood tests are available to screen people for high blood cholesterol.

Many other organs, including the liver, pancreas, stomach, and colon, undergo degenerative changes with age. The ingestion of harmful agents may accelerate such changes. For example, cigarette smoke induces degenerative changes in the lungs, and excessive alcohol consumption can cause sclerotic changes in the liver.

In addition to the previously described changes, cellular wear and tear contributes to aging. Progressive damage from many sources, including radiation and toxic substances, may result in irreversible cellular insults and may be one of the major factors leading to aging. Researchers have speculated that ingesting the antioxidant vitamins C and E in combination may help slow this

part of aging by stimulating cell repair. Vitamin C also stimulates collagen production and may slow the loss of tissue plasticity associated with aging collagen.

One explanation for aging is the **free radical theory of aging**. Free radicals are atoms or molecules with an unpaired electron that can react with and alter the structure of molecules that are critical for normal cell function. Alteration of these molecules can result in cell dysfunction, cancer, or other types of cellular damage. Free radicals are produced as a normal part of metabolism and introduced into the body from the environment through the air we breathe and the food we eat. The damage caused by free radicals may accumulate with age. Antioxidants, such as beta carotene (provitamin A), vitamin C, and vitamin E, can donate electrons to free radicals, without themselves becoming harmful. Thus, antioxidants may prevent the damage caused by the free radicals and may ward off age-related disorders, ranging from wrinkles to cancer. Experiments designed to test this hypothesis, however, have not consistently produced positive results.

As a result of poor diet, many people over age 50 do not get the minimum daily allotment of several vitamins and minerals. Feeling “bad” is not necessarily a part of aging but is mostly a result of poor nutrition and lack of exercise. Engaging in moderate exercise and avoiding overeating can prolong life. Moderate exercise can reduce the risk for heart attack by as much as 20%. It can also reduce the risk for stroke, high blood pressure, and some forms of cancer. Exercise can also increase a person’s ability to reason and remember. Walking 30 minutes a day is recommended.

One characteristic of aging is an overall decrease in ATP production. This decrease is associated with a decline in oxidative phosphorylation, which has been shown in many cases to result from **mitochondrial DNA mutations**. Mitochondria lack the DNA repair mechanisms that exist in the nucleus for nuclear DNA, and thus mutations can accumulate in mitochondrial DNA.

Immune system changes may also contribute to the effects of aging. The aging immune system loses its ability to respond to outside antigens but becomes more sensitive to the body’s own antigens. These autoimmune changes add to the degeneration of the tissues and may be responsible for conditions such as arthritis, chronic glomerular nephritis, and hyperthyroidism. In addition, T lymphocytes tend to lose their functional capacity with aging and cannot destroy abnormal cells as efficiently. This change may be one reason that certain types of cancer occur more readily in older people.

Genetic traits may also cause many of the changes associated with aging. As a general rule, animals with a very high metabolic rate have a shorter life span than those with a lower metabolic rate. In humans, a very small number of exceptional people have a slightly reduced normal body temperature, suggesting a lower metabolic rate. The same people often have an unusually long life span. This tendency appears to run in families and probably has some genetic basis. Studies of the general population suggest that, if your parents and grandparents have lived a long time, so will you.

The genetic disorder **progeria** (prō-jēr’ē-ă; premature aging) also provides evidence of a strong genetic component to aging. This genetic disorder causes the degenerative changes of aging to begin shortly after the first year of life, and the child may look like a very old person by age 7.

One of the greatest disadvantages of aging is the increasing inability to adjust to stress. Older people have a far more precarious homeostatic balance than younger people, and eventually the body encounters some stressor so great that it cannot recover, and death results. Death is usually not attributed to old age. Another problem, such as heart failure, renal failure, or stroke, is usually the cause.

Death was once defined as the loss of heartbeat and respiration. In recent years, however, more precise definitions of death have been developed because medical science has learned how to keep both the heart and lungs working artificially, and the heart can even be replaced by an artificial device. Modern definitions of death are based on the permanent cessation of life functions and the cessation of integrated tissue and organ function. The most widely accepted indication of death in humans is **brain death**, which is defined as irreparable brain damage manifested clinically by the absence of (1) response to stimulation, (2) spontaneous breathing and heartbeat, and (3) brainstem reflexes, in addition to an electroencephalogram that remains isoelectric (“flat”) for at least 30 minutes.

29.7 Genetics

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Define **genetics** and explain how chromosomes are related to inheritance.
- B. Explain how Mendel’s theories of genetics compare to modern concepts of genetics.
- C. Define and give examples of **phenotypes** and **genotypes**.
- D. Explain what a **karyotype** is.
- E. Describe major patterns of inheritance.
- F. Relate how mitosis differs from meiosis.
- G. Explain how various genetic disorders can occur.

Children resemble their parents in so many ways, whether it be appearance or behavior. This resemblance among relatives is due in large part to heredity. **Genetics** is the study of heredity—that is, the characteristics children inherit from their parents. Although

the environment can influence gene expression, many of a person's physical characteristics, abilities, susceptibility to disease, and even life span are influenced by the genes inherited from his or her parents. Because many of the diseases caused by microorganisms are now preventable or treatable, diseases that have a genetic basis are receiving more attention.

An understanding of genetics is important for medical professionals. Knowing a patient's family medical history helps diagnose many diseases. The family medical history also allows a physician to determine the probability that a patient will develop certain diseases, such as heart disease or cancer, and to suggest preventive measures. Recent advances in genetics have shown how genes influence health and can provide new methods for treating certain diseases.

Some genetic diseases, such as hemophilia, have a simple pattern of inheritance, usually involving one or a few genes, and it is easy to predict whether a person will develop the disease. However, other genetic diseases have a more complex pattern of inheritance involving many more genes. **Mendelian genetics** is the study of how genetic traits are passed from parent to offspring. Mendelian genetics allows us to make predictions about the patterns of how traits are passed from one generation to the next. Understanding these patterns also allows us to make predictions of the probability that a trait will be inherited. From a medical perspective, Mendelian genetics has been used to determine an individual's risk of developing certain genetic diseases.

With the completion of the Human Genome Project in 2003, more than 99% of the genes in human chromosomes, collectively known as the *human genome*, have been sequenced. The results of this project have provided a wealth of useful information, allowing researchers to better identify the genes associated with particular diseases, to understand the biochemical relationship between genes and diseases, and to create new treatments. The genetic approach to the diagnosis and management of disease is known as **genomic medicine**. Mendelian genetics has indeed come a long way since its early beginnings.

Mendelian Genetics

Mendelian genetics is based on the studies of Gregor Mendel (1822–1884), an Austrian monk who made revolutionary discoveries about inheritance patterns in pea plants. Because of his discoveries, Mendel is known as the “father of genetics.” Mendel found that certain traits, such as purple versus white flowers, are transmitted from one generation of pea plants to another by means of discrete units he called “heritable factors.” He concluded that each pea plant has two heritable factors for a characteristic, such as flower color. He proposed that, during the production of **gametes**, or sex cells, each gamete receives one of these factors. Then two gametes combine to produce the next generation, so that each member of the next generation of pea plants has two heritable factors for each characteristic. Mendel's “heritable factors” are now called genes.

Notice that these studies focused on two different characteristics: the genes an individual possessed and how those genes influenced a particular trait. In the language of genetics, these two characteristics are referred to as the genotype and the phenotype. The

genotype (jēn'ō-tīp) is the genes an organism has for a given trait. The **phenotype** (fē'nō-tīp) is the expression of the genes as a trait.

Environmental effects can influence gene expression to determine the phenotype of many traits. Even genetically identical twins can have different phenotypes because of environmental effects. For example, in addition to genes, height is affected by nutrition, and skin color is affected by exposure to the sun. Knowledge of environmental influences can be used to improve our genetic potential and to prevent harmful effects. For example, a healthy diet can promote growth or help prevent diabetes, and refraining from smoking can reduce the risk of developing cancer.

Mendel proposed that a gene for a given trait can exist in different forms, depending on how it is expressed. Specifically, Mendel stated that genes occur in dominant and recessive forms. Alternate forms of genes are now called **alleles** (ă-lēlz'). By definition, the effects of a **dominant allele** for a trait mask the effects of the **recessive allele** for that trait. For example, in pea plants, the allele for purple flowers is dominant over the allele for white flowers. By convention, dominant alleles are indicated by uppercase letters, and recessive alleles are indicated by lowercase letters. For example, the letter *P* designates the dominant allele for purple flower color, and the letter *p* represents the recessive allele for white flower color. A plant with the *Pp* genotype has purple flowers because purple is dominant over white.

Recall that genes are located on chromosomes, which exist in homologous pairs (see chapter 28). Because we possess pairs of alleles for a given gene, the combination of alleles can be two of the same alleles or two different alleles. An organism is **homozygous** (hō-mō-zī'gūs) for a trait if the two alleles for the trait are identical. On the other hand, an organism is **heterozygous** (het'er-ō-zī'gūs) for a trait if the two alleles for the trait are different. The possible genotypes and phenotypes for purple flower color are

Alleles	Genotype	Phenotype
<i>PP</i>	Homozygous dominant	Purple
<i>Pp</i>	Heterozygous	Purple
<i>pp</i>	Homozygous recessive	White

Note that the recessive trait is expressed only when it is not masked by the dominant trait.

The various alleles for a given trait provide information for protein synthesis in the cells of the body (see chapter 3). The relationship between genotype and phenotype can be understood on the molecular level if we consider how different alleles affect this protein synthesis. For example, a recessive trait in humans called **albinism** (al'bi-nīzm) results in a lack of normal coloring of the skin, hair, and eyes. Several human genes produce the enzymes that are necessary for the synthesis of melanin, the pigment responsible for skin, hair, and eye color (see chapter 5). Alleles for these enzymes that do not produce a functional enzyme will result in the lack or complete absence of the pigment. An **albino**, a person with albinism, lacks the ability to produce the pigment melanin. Individuals with albinism have light blonde or white hair and light-colored eyes and skin, with shades of pink, blue, and yellow (figure 29.23). The pink and blue colors result from blood seen in the eyes or through the skin. The yellow is from the natural accumulation of ingested yellow plant pigments in the skin (see chapter 5).

FIGURE 29.23 Albinism

An albino male with his normally pigmented father.

The normal alleles for the melanin-synthesizing enzymes produce normal, functional enzymes capable of catalyzing the steps in melanin synthesis. When normal enzymes are produced, a person has normal pigmentation. But an abnormal allele for any one of the enzymes in the melanin pathway produces a defective enzyme, which blocks the pathway and stops the production of melanin. Type 1 albinism results from a defective enzyme that fails to initiate the synthesis of melanin from tyrosine. The normal allele of the gene for this enzyme, designated *A*, is dominant over the abnormal allele, designated *a*. The possible genotypes and phenotypes for albinism are

Alleles	Genotype	Phenotype
AA	Homozygous dominant	Normal pigmentation
Aa	Heterozygous	Normal pigmentation
aa	Homozygous recessive	Albino

A person with the genotype *AA* has the phenotype of normal pigmentation because the functional enzyme for melanin synthesis is produced by both alleles. A person with the genotype *Aa* also has the phenotype of normal pigmentation. Even though the *a* allele produces an abnormal, nonfunctional enzyme for melanin synthesis, the *A* allele produces sufficient amounts of the normal enzyme to keep pigmentation normal. A person with the genotype *aa* has the phenotype of albinism because only the abnormal, nonfunctional enzyme for melanin synthesis is produced.

Not all dominant traits are the normal condition, and not all recessive traits are abnormal. In some cases, the dominant trait is abnormal. For example, a person with **polydactyly** (pol-ē-dak'ti-lē) has extra fingers or toes (figure 29.24). One allele for polydactyly is dominant over the recessive, normal allele that results in the normal number of fingers or toes.

➤ Predict 7

List all the possible genotypes and phenotypes for polydactyly. Use the letters *D* and *d* for the alleles.

Modern Concepts of Genetics

Although the existence of chromosomes was known in Mendel's time, the relationship between genes and chromosomes was not

FIGURE 29.24 Polydactyly

Polydactyly, having extra fingers or toes, is determined by a dominant gene.

confirmed until the studies of T. H. Morgan were able to connect different mutant traits to the pattern of chromosome inheritance in fruit flies in 1910. Researchers first isolated DNA as the genetic material in 1944, and James Watson and Francis Crick resolved the structure of DNA in 1953, which led to an understanding of the genetic code and protein synthesis (see chapter 3). The sequence of nucleotides of a human gene, specifically the gene that causes cystic fibrosis, was determined for the first time in 1989. The sequencing of more than 99% of the human genome was accomplished in 2003 (see Clinical Genetics, “The Human Genome Project,” later in this chapter).

Chromosomes

In modern terminology, Mendel hypothesized that organisms have genes that control the expression of traits. Most genes, which are segments of DNA, occur in pairs of alleles. Chromosomes are made up of DNA and associated proteins found in the nuclei of cells of the body. The cells of the body can be divided into two major categories: somatic cells and gametes. **Somatic** (sō-mat'ik) **cells** are all the cells of the body except the gametes. Examples of somatic cells are epithelial cells, muscle cells, neurons, fibroblasts, lymphocytes, and macrophages. In males, the gametes are **sperm cells**; in females, the gametes are **oocytes** (egg cells; see chapter 28).

The somatic cells have a normal number of chromosomes called the **diploid** (dip'loid; twofold) number. In chapter 28, we learned that the process of meiosis produces gametes with half the number of chromosomes as a somatic cell. The normal number of chromosomes in a gamete is the **haploid** (hap'loid; single) number. In humans, the diploid number of chromosomes is 46. The haploid number of chromosomes is 23.

➤ Predict 8

Why does it make sense that the number of chromosomes in a gamete is half the number in a somatic cell?

The 23 pairs of chromosomes are divided into autosomal and sex chromosomes. Humans have 22 pairs of **autosomal** (aw-tō-sō'māl) **chromosomes**, which are all the chromosomes except the sex chromosomes, and 1 pair of **sex chromosomes**, which determines the sex of the individual. Sex chromosomes are denoted as **X** or **Y chromosomes**. A normal female has two X chromosomes (XX) in each somatic cell. One X chromosome of a female is derived from her mother; the other is derived from her father. A normal male has one X chromosome and one Y chromosome (XY) in each somatic cell. The X chromosome of a male is derived from his mother; the Y chromosome is derived from his father.

Genetic traits can be classified by the type of chromosome their alleles are located on and by whether their alleles are dominant or recessive. Thus, traits can be autosomal dominant or autosomal recessive, or they can be sex-linked dominant or sex-linked recessive. For example, albinism is an autosomal recessive trait.

When studying the chromosomes of a cell, it is helpful to organize the chromosomes in a specific way. A **karyotype** (kar'ē-ō-tīp) is a display of the chromosomes of a somatic cell during metaphase of mitosis. It is produced by photographing the cell's stained chromosomes through a microscope and arranging the photographed chromosomes in pairs (figure 29.25). For convenience, the autosomal chromosomes are numbered, from largest to smallest, 1 through 22. The sex chromosomes are denoted with an X or a Y. Note that a chromosome in a karyotype is a replicated mitotic chromosome—that is, it has two chromatids

FIGURE 29.25 Human Karyotype

The 23 pairs of chromosomes in a human cell consist of 22 pairs of autosomal chromosomes (numbered 1–22) and 1 pair of sex chromosomes. This is the karyotype of a male, as evidenced by the presence of an X and a Y sex chromosome. A female karyotype would have two X chromosomes.

(figure 29.25). The chromatids of each chromosome are attached at the centromere, so that each replicated chromosome appears as a single structure.

Earlier you learned that chromosomes exist in pairs. Chromosome pairs are called **homologous** (hō-mōl'ō-gūs) **chromosomes**, and each member of the pair is considered a **homolog** (hōm'ō-lōg). One homolog is derived from a person's father, and the other is derived from a person's mother. A **genome** (jē'nōm, jě'nōm) consists of all the genes found in the haploid number of chromosomes from one parent. The combined genomes from both parents are responsible for all of a person's genetic traits. Each gene of the genome occupies a specific location on a chromosome. This location is referred to as a **locus** (figure 29.26). The locus on one chromosome may have one allele type, whereas the locus on its homolog may have another allele type.

ASSESS YOUR PROGRESS

41. What is genetics?
42. What is the difference between genotype and phenotype? Give an example of each.
43. What are alleles? If tall (T) plants are dominant over short (t) plants, what would the alleles and phenotypes be for homozygous dominant, heterozygous, and homozygous recessive?
44. How do the chromosomes in somatic cells and gametes differ from each other?
45. What are the number and type of chromosomes in the karyotype of a human somatic cell? How do the chromosomes of a male and a female differ?
46. What are homologous chromosomes?

FIGURE 29.26 Homologous Chromosomes

This drawing of a pair of unduplicated homologous chromosomes depicts them as compact bodies for simplicity. In the unduplicated state, chromosomes are dispersed within the nucleus as chromatin.

Multiple Alleles

Mendel believed that alleles came in two forms, dominant and recessive. We now know that alleles can exist in many forms, called **multiple alleles**. An individual has only two alleles for a given gene, one on each homologous chromosome. At the population level, however, many forms of an allele may exist.

Differences in alleles arise by mutation (see “Genetic Disorders,” later in this section), in which the DNA nucleotide sequence is altered. Many alleles are possible in a population because any change in the nucleotide sequence of DNA, even in one base pair, potentially produces a different allele. A different form of an allele is called an **allelic variant**, a *mutated allele (gene)*, or a *polymorphism* (“many forms”).

Allelic variants can result in either no effect on the phenotype or minor to major phenotypic changes. Allelic variants at a locus may encode for different sequences of amino acids in proteins. Recall from chapter 2 that the sequence of amino acids in a protein affects the shape of the protein, including the protein’s domain, which is the functional part of the protein. An allelic variant that causes an amino acid change in a protein that does not significantly change protein shape may not affect the phenotype. However, the greater the effect of an amino acid change on a protein’s shape, the greater the effect on the protein’s function and the greater the effect on the phenotype. Millions of allelic variants have been identified. The significance of most of them is unknown.

The allelic variant present at a locus can affect a person’s phenotype. For example, **phenylketonuria** (fen’il-kē’tō-noo’rē-ă; **PKU**) is an autosomal recessive trait with multiple alleles. A gene on chromosome 12 encodes for an enzyme that converts the amino acid phenylalanine to the amino acid tyrosine. If phenylalanine is not converted to tyrosine, high levels of phenylalanine can accumulate, leading to brain cell damage. The more defective the enzyme, the greater the accumulation of phenylalanine and the greater the damage to the brain, in most cases. Over 400 disease-causing allelic variants of the PKU gene are known. The severity of PKU depends in part on which two allelic variants are present. The less severe of the two alleles determines the severity of the disorder. Symptoms of untreated PKU can vary from profound intellectual disability to nearly normal mental abilities. Thus, even though PKU is an autosomal recessive trait, the expression of the recessive condition exhibits considerable variability because of multiple alleles. Furthermore, reducing phenylalanine in the diet can prevent the development of intellectual disability.

► Predict 9

Paula is a woman with PKU. In her case, the conversion of the amino acid phenylalanine to tyrosine is quite limited. Intellectual disability, a common consequence of this condition, can be avoided if people who have PKU consume food containing very small amounts of phenylalanine. Paula is healthy even though she has PKU because from the time she was very small, her diet has been monitored so that it contains little phenylalanine. Paula is engaged to be married to a man named Marvin. No PKU has been identified in his family for many generations. What are the possible genotype(s) for Paula and Marvin’s children?

Gene Dominance

In the Mendelian example of pea flower color, heterozygous individuals cannot be distinguished from homozygous individuals by just viewing the phenotype. This suggests that the one dominant allele present in the heterozygote produces enough protein product to cause the maximum phenotypic response in the heterozygote. This type of inheritance pattern in which the dominant allele is fully expressed over the recessive allele is called **complete dominance**. Though Mendel’s work seems to suggest that complete dominance is the common type of gene expression, we now know that many other types exist.

Complete dominance is at one end of a continuum of genetic expression. At the other end is codominance, and between them is incomplete dominance. In **codominance**, two alleles at the same locus are expressed, so that separate, distinguishable phenotypes occur at the same time. ABO blood types are an example of codominance. A gene with three alleles on chromosome 9 encodes for enzymes that add sugar molecules to certain carbohydrates found on the surface of red blood cells. The carbohydrates are part of glycoproteins (see figure 3.4), called A and B antigens (see chapter 19). These carbohydrates consist of different sugars joined together. Traditionally, in designating alleles for blood type, the A and B alleles are superscripted to a capital letter *I*, and the O allele is designated by the lowercase letter *i*. The I^A allele encodes for an enzyme that adds a particular sugar to the ends of the carbohydrate, producing the A antigen. The I^B allele encodes for a different enzyme that adds a different sugar to the ends of the carbohydrate, producing the B antigen. The *i* allele encodes for no functional enzyme and therefore is recessive to A and B. The possible genotypes and phenotypes for the ABO blood group are

Genotype	Phenotype
$I^A I^A$ or $I^A i$	Type A blood (A antigen only)
$I^B I^B$ or $I^B i$	Type B blood (B antigen only)
$I^A I^B$	Type AB blood (A and B antigens)
<i>ii</i>	Type O blood (neither A nor B antigen)

Type A blood results from the expression of only the I^A allele, type B blood from the expression of only the I^B allele, and type O blood from the expression of neither the I^A allele nor the I^B allele. Type AB blood illustrates codominance and results from the expression of both the I^A allele and the I^B allele at the same time.

In **incomplete dominance**, the dominant allele does not completely mask the effects of the recessive allele in the heterozygote. The heterozygote produces less of the protein product than the homozygous dominant and has phenotypic characteristics intermediate between the homozygous dominant and the homozygous recessive. For example, **beta thalassemia** (thäl-ă-sē’mē-ă) is a disorder of a gene on chromosome 11. It affects the synthesis of β -globulin polypeptide chains, which are part of the hemoglobin in red blood cells. Hemoglobin is a protein that transports oxygen. If normal amounts of the β -globulin polypeptide are produced, the β -globulin polypeptides join with other proteins to form hemoglobin. If lower-than-normal amounts of β -globulin polypeptide are synthesized, lower-than-normal amounts of hemoglobin are produced. In the homozygous dominant state, two normal alleles for β -globulin synthesis are present,

normal amounts of hemoglobin are produced, and the phenotype is normal, meaning that normal oxygen transport is occurring. In the homozygous recessive condition, called **major thalassemia**, two abnormal alleles are present, and much lower-than-normal amounts of β -globulin polypeptide chains are synthesized. The result is severe **anemia** (ă-nĕ'mĕ-ă), which is a deficiency of hemoglobin in the blood. Symptoms include pallor, weakness, fatigue, and spleen enlargement. Blood transfusions are necessary to maintain hemoglobin levels. In the heterozygous condition, called **minor thalassemia**, one normal allele and one abnormal allele are present. The production of hemoglobin is intermediate between the normal phenotype and major thalassemia, and mild anemia results.

Polygenic Traits

The examples discussed thus far involve one gene (usually with two alleles) that determines one phenotype. In other cases, many genes determine a single phenotype. This is called a **polygenic trait**. Polygenic traits result from the interactions of many genes. Although all the genes contribute to the phenotype without being dominant or recessive to each other, each gene has its own characteristics, such as multiple alleles or incomplete dominance. Some of the genes may be more important than others for the expression of the phenotype, and the genes can be on different chromosomes. The result of all the gene interactions is a phenotype with a great amount of variability. Examples of polygenic traits are height, intelligence, eye color, and skin color.

Even though a complex combination of genes determines a polygenic trait, a defect in one of these genes can sometimes have a dramatic effect on phenotype. For example, even though many genes contribute to skin color, one defective gene can eliminate skin color completely, resulting in albinism.

Sex-Linked Traits

Sex-linked traits are traits affected by genes on the sex chromosomes; **X-linked traits** are affected by genes on the X chromosome, and **Y-linked traits** are affected by genes on the Y chromosome. In humans, the X chromosome is much larger than the Y chromosome. Also, the X chromosome carries many different genes that affect traits as varied as blood clotting, muscle activity, and color vision. Due to the size difference, it is probably no surprise that most sex-linked traits are X-linked, whereas only a few Y-linked traits exist. An example of an X-linked recessive trait is **hemophilia A** (classic hemophilia), in which the body is unable to produce certain blood clotting factors (see chapter 19). Consequently, clotting is impaired, and persistent bleeding can occur either spontaneously or as a result of an injury. Traditionally, X-linked genes are designated by letters superscripted to the letter X. The possible genotypes and phenotypes for hemophilia A are

Genotype	Phenotype
$X^H X^H$ or $X^H X^h$	Normal female
$X^h X^h$	Hemophiliac female
$X^H Y$	Normal male
$X^h Y$	Hemophiliac male

Clinical IMPACT

Sex Chromosome Abnormalities

A wide range of sex chromosome abnormalities exist. The presence of a Y chromosome makes a person genetically a male, and the absence of a Y chromosome makes a person genetically a female, regardless of the number of X chromosomes. Therefore, individuals with XO (Turner syndrome), XX, XXX, or XXXX karyotypes are females, and individuals with XY, XXY, XXXY, or XYY karyotypes are males. A YO condition is lethal because the genes on the X chromosome are necessary for survival. Secondary sexual characteristics are usually underdeveloped in both the XO female and the XXY male (called Klinefelter syndrome), and additional X chromosomes (XXXX or XXXY) are often associated with some degree of intellectual disability. Due to hormonal imbalances, the morphological features (phenotype) may be reversed from the genetic constitution (genotype). For example, a male with Klinefelter syndrome may display swelling of the breast.

Note that a female must have both recessive alleles ($X^h X^h$) to exhibit hemophilia, whereas a male, because he has only one X chromosome, has hemophilia if he has only one of the recessive alleles. For this reason, X-linked recessive traits are seen more frequently in males than in females.

Predict 10

Wilma and Wally have one male child who has been diagnosed with Duchenne muscular dystrophy, an X-linked condition that results in severe atrophy of skeletal muscle. Neither parent has this condition. What is the probability that their next child will have Duchenne muscular dystrophy?

47. Explain multiple allelism.
48. Distinguish among complete dominance, incomplete dominance, and codominance. Give examples of each.
49. What is the difference between multiple allelism and polygenic traits?
50. How are sex-linked traits inherited? Give an example.

Meiosis and the Transmission of Genes

Gametes are haploid cells that are derived from diploid cells. In **meiosis** (mĭ-ō'sĭs), haploid gametes are produced that have one chromosome from each of the homologous pairs of chromosomes. Therefore, gametes have one-half the number of chromosomes and one-half as many alleles as the original diploid cells.

Before meiosis begins, DNA replication occurs, forming replicated chromosomes that each consist of two chromatids (figure 29.27). As a result of the first meiotic division, each daughter cell receives one replicated member of a homologous

- 1 A pair of unduplicated homologous chromosomes lie in the nucleus of a somatic cell. For simplicity, the chromosomes are shown as compact bodies. In the unduplicated state, chromosomes are dispersed within the nucleus as chromatin.
- 2 The dominant (*A*) and recessive (*a*) alleles for albinism are shown on the homologous chromosomes.
- 3 The DNA has replicated, and each replicated chromosome consists of two chromatids (see figure 3.40).
- 4 Each replicated homologous chromosome has two alleles because the DNA has replicated.
- 5 As a result of the first meiotic division, each new nucleus has a replicated homologous chromosome.
- 6 DNA is not replicated between the first and second meiotic divisions. As a result of the second meiotic division, the chromatids separate and are now called chromosomes.
- 7 Each homologous chromosome has an allele for albinism. Two types of gametes have been produced, those carrying the *A* allele and those carrying the *a* allele.

PROCESS FIGURE 29.27 Meiosis and the Distribution of Alleles **AP R**

pair. No DNA replication takes place between the first and second meiotic divisions. During the second meiotic division, the chromatids of each chromosome separate. As a result of the second meiotic division, each cell receives one chromatid from each chromosome. That single chromatid is now referred to as a chromosome. Each gamete now has a haploid number of chromosomes. See chapter 28 for a more detailed discussion of gamete production.

Figure 29.27 shows the alleles for albinism on a pair of homologous chromosomes. On one homolog, the normal, dominant allele is indicated with an uppercase *A*; on the other homolog, the abnormal allele is indicated with a lowercase *a*. Figure 29.27 illustrates how the alleles on homologous chromosomes are distributed to gametes. In this case, the gametes have either an *A* or an *a* allele.

The probability of transmitting particular alleles to the next generation can be determined using a **Punnett square** if the genotypes of the parents are known (figure 29.28). The possible alleles in the gametes of one parent form the rows of the square, and the possible alleles in the gametes of the other parent form the columns. The body of the Punnett square shows all possible combinations of the parents' gametes. For example, suppose both parents are heterozygous (*Aa*) for albinism. The heterozygous parents can produce two types of gametes. One gamete has the *A* allele, and the other has the *a* allele. The probability that the

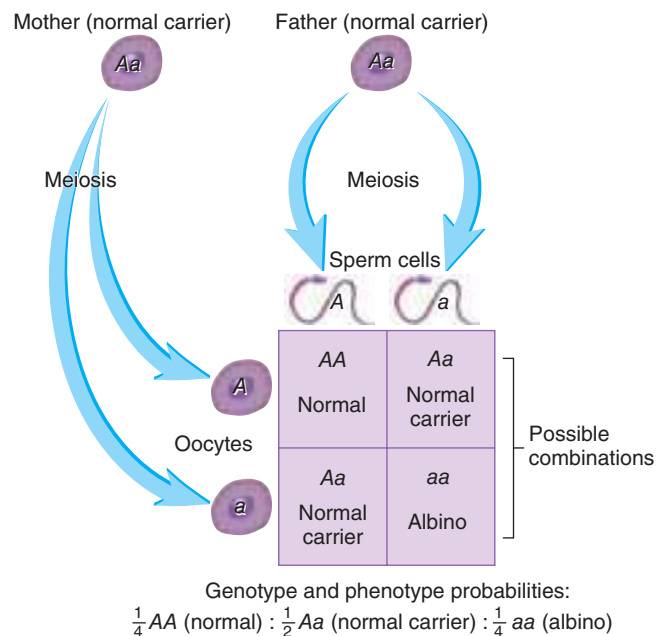

FIGURE 29.28 Inheritance of a Recessive Trait: Albinism

In this Punnett square of a mating between two normal carriers, *A* represents the normal, pigmented condition, and *a* represents the recessive, unpigmented condition.

child will be homozygous dominant (AA) is one out of four; heterozygous (Aa), two out of four; and homozygous recessive (aa), one out of four.

Albinism is an autosomal recessive trait. The homozygous dominant and heterozygous conditions result in normal pigmentation, whereas the homozygous recessive condition results in albinism. Both heterozygous parents have normal pigmentation, but there is a one out of four chance that any one of their children will be an albino. A person who is heterozygous for that trait is called a **carrier**, because he or she has one normal allele and one disorder-causing allele. The carrier does not exhibit the disorder but can pass it on to his or her children.

Genetic Disorders

A **genetic disorder** is a failure of structure, function, or both as a result of abnormalities in a person's genetic makeup—that is, his or her DNA. Humans may have a variety of genetic disorders (table 29.4), some of which were highlighted throughout this text. Genetic disorders determined by one gene are described by Mendelian characteristics—for example, as autosomal recessive. In some cases, this type of description is accurate, but in other cases the reality is more complex. For example, PKU is said to be autosomal recessive, but PKU has multiple alleles, which result in a spectrum of defects.

TABLE 29.4 Genetic Disorders

Disorder	Description
Dominant Traits	
Achondroplasia	Dwarfism characterized by shortening of the upper and lower limbs
Huntington disease	Severe degeneration of the basal nuclei and frontal cerebral cortex; characterized by purposeless movements and mental deterioration; onset is usually between 40 and 50 years of age
Hypercholesterolemia	Elevated blood cholesterol levels that contribute to atherosclerosis and cardiovascular disease
Marfan syndrome	Abnormal connective tissue, resulting in increased height, elongated digits, and weakness in the aortic wall
Neurofibromatosis	Small, pigmented lesions (café-au-lait spots) in the skin and disfiguring tumors (noncancerous) caused by the proliferation of Schwann cells along nerves
Osteogenesis imperfecta	Abnormal collagen synthesis, resulting in brittle bones that break repeatedly
Recessive Traits	
Albinism	Lack of an enzyme necessary to produce the pigment melanin; characterized by lack of coloration in skin, hair, and eyes
Cystic fibrosis	Impaired transport of chloride ions across plasma membranes; results in excessive production of thick mucus, which blocks the respiratory and gastrointestinal tracts; the most common fatal genetic disorder
Phenylketonuria	Lack of the enzyme necessary to convert the amino acid phenylalanine to the amino acid tyrosine; an accumulation of phenylalanine leads to intellectual disability
Severe combined immune deficiency	Inability to form the white blood cells (B cells, T cells, and phagocytes) necessary for an immune system response
Sickle-cell disease	Inability to produce normal hemoglobin; results in abnormally shaped red blood cells that clog capillaries or rupture
Tay-Sachs disease	Lack of the enzyme necessary to break down certain lipids; an accumulation of lipids impairs action potential propagation, resulting in deterioration of mental and physical functions and death by 3–4 years of age
Thalassemia	Decreased rate of hemoglobin synthesis; results in anemia, enlarged spleen, increased cell numbers in red bone marrow, and congestive heart failure
Sex-Linked Traits	
Duchenne muscular dystrophy	Deletion or alteration of part of the X chromosome; results in progressive weakness and wasting of muscles
Hemophilia	Most commonly, failure to produce blood clotting factors, caused by a recessive gene; results in prolonged bleeding
Red-green color blindness	Most commonly, deficiency in functional green-sensitive cones, caused by a recessive gene; inability to distinguish between red and green colors
Chromosomal Disorders	
Down syndrome	Caused by having three chromosomes 21; results in intellectual disability, short stature, and poor muscle tone
Klinefelter syndrome	Caused by two or more X chromosomes in a male (XXY); results in small testes, sterility, and development of female-like breasts
Turner syndrome	Caused by having only one X chromosome; results in immature uterus, lack of ovaries, and short stature

Clinical GENETICS

The Human Genome Project

The human genome consists of all the genes found in one homologous set of human chromosomes. Geneticists estimate that humans have about 20,000 genes. A **genomic map** depicts the DNA nucleotide sequences of the genes and their locations on

the chromosomes (figure 29C). The **Human Genome Project** led to the complete sequencing of the genome. From this sequence, it was firmly established that the haploid genome is 3.2 billion base pairs and that, remarkably, 99.9% of these nucleotides are identical

between individuals. However, that 0.1% difference can account for a lot of changes. Online Mendelian Inheritance in Man (OMIM) is a database that contains information about many human genes and genetic disorders (www.ncbi.nlm.nih.gov/omim). Perhaps one

Representative genetic defects mapped to date. The bars and lines indicate the location of the genes listed for each chromosome.

of the biggest surprises from the Human Genome Project was how few genes we have. Original estimates were as high as 100,000 protein-coding genes. However, after the genome sequence was known, the number has steadily dropped to about 20,000. The mystery deepened when it was realized that these genes make up only about 1.5% of our genome. So what is the other 98.5% of the genome doing? Originally viewed as “junk DNA,” the non-protein-coding DNA is now known to harbor new types of genes, which are collectively called *noncoding RNA genes*. The RNA made from these genes is never made into protein. The roles of these new genes are quickly being uncovered. Many are important for regulating the transcription and translation of protein-coding genes and some have been associated with genetic disorders and diseases. The relatively small number of protein-coding genes is

also compensated for by alternative splicing (see chapter 3), which occurs with both protein-coding and noncoding RNA genes. From protein-coding genes alone, it is estimated that each gene encodes at least three distinct proteins. Although the human genome sequence is now known, there clearly is still much to be learned about its complexity.

Armed with knowledge of the human genome and its effects on a person’s physical, mental, and behavioral abilities, medicine and society are being transformed in many ways. From a medical perspective, we are on the threshold of determining the disease(s) and disease susceptibilities that are associated with each gene in our genome. Knowledge of the genes involved in a disorder may result in new drugs and techniques to compensate for a genetic disorder and **gene therapy** or **genetic engineering** that repairs or replaces defective

genes or gene products. From the perspective of society, the Human Genome Project has raised a number of ethical, legal, and social issues for society. Should a person’s genomic information be public knowledge? Should persons with a genome that predisposes them to cancer or behavioral disorders be barred from certain types of employment or be refused medical insurance because they are at high risk? Can a person demand to know a prospective mate’s genome? Should parents know the genome of their fetus and be allowed to make decisions regarding abortion based on this knowledge? Should the same genetic-engineering techniques that alter the genome to cure genetic disorders be used to create genomes that are deemed superior? Such questions are likely to only intensify as we learn more about the genetic blueprints of the human body.

Genetic disorders involve either a single gene or an entire chromosome, as in the case of aneuploidy. Recall that a mutation is a change in a gene that usually involves a change in the number or kinds of nucleotides composing the DNA (see chapter 2). Mutations are known to occur by chance (randomly without known cause), but they can also be caused by chemicals, radiation, and viruses. Anything that causes mutations is called a **mutagen** (mū’tă-jen). In most cases, the specific cause of a mutation cannot be determined. Once a mutation has occurred, however, the abnormal trait can be passed from one generation to the next.

Mutations can vary in the amount of DNA that is affected. In some cases, a single nucleotide change in the gene can lead to changes in the function of the protein. A mutation involving a single nucleotide change is called a *point mutation*. In other cases, mutations can change the sequence or number of nucleotides. This type of mutation involves changes in chromosome structure and therefore are called *structural mutations*. Structural mutations can result from deletions, the loss of part of a chromosome; duplications, the addition of a copied section of a chromosome; translocations, in which part of one chromosome becomes attached to another chromosome; and inversions, in which the DNA sequence of a section of a chromosome is reversed.

Some large-scale mutations may result from changes in actual chromosome numbers. Segregation errors that occur during meiosis result in changes in the chromosome number in the gametes. As the chromosomes separate during meiosis, the two members of a homologous pair may not separate as they normally do. As a result, one of the daughter cells receives both chromosomes, and the other daughter cell receives none. The failure of chromosomes to separate during meiosis is called **nondisjunction**. When the

gametes are fertilized, the resulting zygote has either 47 chromosomes or 45 chromosomes, rather than the normal 46, a condition called **aneuploidy** (an’ū-ploy-dē). Aneuploidies include monosomies, in which a chromosome is missing, and trisomies, in which an extra chromosome is present. Aneuploidies are usually lethal and are one reason for a high rate of early embryo loss. **Down syndrome**, or *trisomy 21*, is a type of aneuploidy in which three chromosomes 21 are present. A **syndrome** (sīn’drōm) is a set of signs and symptoms occurring together as the result of a single cause, such as a single mutation or one extra chromosome (a trisomy). Down syndrome is an aneuploidy that is not always lethal. However, individuals with this genetic disorder exhibit physical and mental developmental problems, as well as an increased probability of developing certain cancers. These individuals also have a shortened life span.

➤ Predict 11

Mr. and Mrs. Smith, both 40 years of age, are healthy with no known genetic conditions. Their newborn child has Down syndrome (trisomy 21). Explain the events that caused this condition.

ASSESS YOUR PROGRESS

51. What is meiosis? How does it differ from mitosis? What is the end result of meiosis?
52. What is a carrier?
53. What is a mutagen? Describe a point mutation, structural mutation, and nondisjunction.
54. What causes the genetic disorder Down syndrome?

Answer

Learn to Predict From page 1078

In this chapter, we learned that the production of breast milk depends on a number of hormones. Estrogen causes the duct system of the breast to develop and is mainly responsible for the enlargement of the breasts during pregnancy. Progesterone causes the development of the breasts' secretory alveoli, which enlarge but do not usually secrete milk during pregnancy. Other hormones necessary for development of the breast include growth hormone, prolactin, thyroid hormones, glucocorticoids, and insulin. Human somatotropin and human placental lactogen are secreted from the placenta. The high levels of estrogen and progesterone inhibit the effect of prolactin on milk secretion during pregnancy. After parturition, blood levels of estrogen, progesterone, and prolactin decrease.

This chapter also explained that suckling stimulates the periodic pulses of prolactin and oxytocin. The pulses of prolactin,

in the absence of high blood levels of estrogen and progesterone, cause the secretory units of the breasts to secrete milk. Oxytocin causes expulsion of the milk from the breast in response to suckling. Refraining from breastfeeding for a period of time results in no prolactin pulses. Consequently, the secretory units fail to secrete milk and quickly lose the capacity to do so. Ming can retain the capacity to breastfeed her baby by using a breast pump while she takes the prescribed antibiotic. The breast pump simulates suckling and stimulates the pulses of prolactin secretion. After finishing the antibiotic, Ming can then continue to breastfeed her baby.

Answers to the rest of this chapter's Predict questions are in appendix G.

29.1 Prenatal Development (p. 1079)

1. Prenatal development is divided into three parts: the germinal period, during which the germ layers form; the embryonic period, when the organ systems form; and the fetal period, characterized by growth and maturation.
2. Postovulatory age is 14 days less than clinical age.
3. The stages of postnatal development are the neonatal period (birth to 1 month), infancy (1 month to 1–2 years), childhood (1–2 years to puberty), adolescence (puberty to 20 years), and adulthood (20 years to death).

Fertilization

Fertilization, the union of the oocyte and sperm, results in a zygote.

Early Cell Division

The cells of the early embryo are pluripotent (capable of making any cell of the body). In the very early stages of development, the cells are totipotent, meaning that each cell can give rise to any tissue necessary for development.

Morula and Blastocyst

The product of fertilization undergoes divisions until it becomes a mass called a morula and then a hollow ball of cells called a blastocyst.

Implantation of the Blastocyst and Development of the Placenta

The blastocyst implants into the uterus about 7 days after fertilization. The placenta is derived from the trophoblast of the blastocyst.

Formation of the Germ Layers

All body tissues are derived from three primary germ layers: endoderm, mesoderm, and ectoderm.

Neural Tube and Neural Crest Formation

The nervous system develops from a neural tube that forms in the ectodermal surface of the embryo and from neural crest cells derived from the developing neural tube.

Summary

Somite Formation

Segments called somites, which develop along the neural tube, give rise to the musculature, vertebral column, and ribs.

Formation of the Gut and Body Cavities

1. The digestive tract forms as the developing embryo closes off part of the yolk sac.
2. The coelom develops from small cavities that fuse within the embryo.

Limb Bud Development

The limbs develop from proximal to distal as outgrowths called limb buds.

Development of the Face

The face develops from the fusion of five major tissue processes.

Development of the Organ Systems

1. The epidermis of the skin develops from the ectoderm, and the dermis develops from the mesoderm or from neural crest cells. Melanocytes and sensory receptors develop from neural crest cells.
2. The skeletal system develops from mesoderm or neural crest cells.
3. Muscle develops from myoblasts, which migrate from somites.
4. The brain and spinal cord develop from the neural tube, and the peripheral nervous system develops from the neural tube and the neural crest cells.
5. The special senses develop mainly as neural tube or neural crest cell derivatives.
6. Many endocrine organs develop mainly as evaginations of the brain or digestive tract.
7. The heart develops as two tubes fuse into a single tube, which bends and develops septa to form four chambers.
8. The peripheral circulation develops from mesoderm as blood islands become hollow and fuse to form a network.

- The lungs form as evaginations of the digestive tract. These evaginations undergo repeated branching.
- The urinary system develops in three stages—pronephros, mesonephros, and metanephros—from the head to the tail of the embryo. The ducts join the allantois, part of which becomes the urinary bladder.
- The reproductive systems develop in conjunction with the urinary system. The presence or absence of certain hormones is very important to sexual development.

Growth of the Fetus

- The embryo becomes a fetus at 60 days.
- The fetal period, from day 60 to birth, is a time of rapid growth.

29.2 Parturition (p. 1098)

The total length of gestation is 280 days (clinical age).

Stages of Labor

Uterine contractions force the fetus out of the uterus during labor.

Hormonal Stimulation of Parturition

- Increased estrogen and decreased progesterone help initiate parturition.
- Fetal glucocorticoids act on the placenta to decrease progesterone synthesis and to increase estrogen and prostaglandin synthesis.
- Stretch of the uterus and decreased progesterone levels stimulate oxytocin secretion, which stimulates uterine contraction.

29.3 The Newborn (p. 1104)

Shortly after birth, the newborn baby experiences several dramatic changes when it is separated from the maternal circulation and transferred from a fluid to a gaseous environment.

Respiratory and Cardiovascular Changes

- The foramen ovale closes, separating the two atria.
- The ductus arteriosus closes, and blood no longer flows between the pulmonary trunk and the aorta.
- The umbilical vein and arteries degenerate.

Digestive Changes

- Meconium is a mixture of cells from the digestive tract, amniotic fluid, bile, and mucus excreted by the newborn.
- The stomach begins to secrete acid.
- The liver does not form adult bilirubin for the first 2 weeks.
- The neonate can digest lactose, but other foods must be gradually introduced.

Apgar Scores

- Apgar represents appearance, pulse, grimace, activity, and respiratory effort.
- Apgar and other methods are used to assess the physiological condition of the newborn.

Congenital Disorders

- Congenital disorders are abnormalities present at birth.
- Teratogens are environmental agents that cause some congenital disorders.

29.4 Lactation (p. 1107)

- Estrogen, progesterone, and other hormones stimulate the growth of the breasts during pregnancy.

- Suckling stimulates prolactin and oxytocin synthesis. Prolactin stimulates milk production, and oxytocin stimulates milk letdown.

29.5 First Year After Birth (p. 1108)

- The number of neuron connections and glial cells increases.
- Motor skills develop gradually, especially head, eye, and hand movements.

29.6 Aging and Death (p. 1109)

- Loss of cells that are not replaced contributes to aging.
 - A loss of neurons occurs.
 - Loss of muscle cells can affect skeletal and cardiac muscle function.
- Loss of tissue plasticity results from cross-link formation between collagen molecules. The lens of the eye loses the ability to accommodate. Other organs, such as the joints, kidneys, lungs, and heart, also have reduced efficiency with advancing age.
- The immune system loses the ability to act against foreign antigens and may attack self-antigens.
- Many aging changes are probably genetic.
- Death is the loss of brain functions.

29.7 Genetics (p. 1110)

- Genetics is the study of heredity, the characteristics children inherit from their parents.
- Genomic medicine uses an understanding of the biochemical relationship between genes and disease to diagnose and manage disease.

Mendelian Genetics

- The genes an organism has for a given trait is called the genotype. The expression of the genes is called the phenotype.
- Alleles are alternate forms of genes. A dominant allele masks the effects of a recessive allele for the same trait.
- An organism homozygous for a trait has two identical alleles for the trait, whereas an organism heterozygous for a trait has two different alleles for the trait.

Modern Concepts of Genetics

- Chromosomes
 - Somatic cells have a diploid number of chromosomes, whereas gametes have a haploid number. In humans, the diploid number is 46 and the haploid number is 23.
 - Humans have 22 pairs of autosomal chromosomes and 1 pair of sex chromosomes. Females have the sex chromosomes XX, and males have XY.
 - A karyotype is a display of the chromosomes of a somatic cell during metaphase of mitosis.
 - Chromosome pairs are called homologous chromosomes.
- The genome consists of all the genes found in the haploid number of chromosomes from one parent.
- Each gene occupies a specific locus, or location, on a chromosome.
- Alleles exist in many different forms, called multiple alleles.
- Gene dominance
 - In complete dominance, the dominant allele masks the effects of the recessive allele.
 - In codominance, two alleles at the same locus are expressed, so that separate, distinguishable phenotypes occur at the same time.
 - In incomplete dominance, the dominant allele does not completely mask the effects of the recessive allele.
- Polygenic traits result from the interaction of many genes.

7. Sex-linked traits
 - Sex-linked traits are traits affected by genes on the sex chromosomes.
 - X-linked traits are affected by genes on the X chromosome, and Y-linked traits are affected by genes on the Y chromosome.
 - X-linked traits are seen more frequently in males than in females because males have only one X chromosome.

Meiosis and the Transmission of Genes

1. Meiosis results in the production of gametes.
2. A Punnett square can determine the probability of particular alleles being transmitted to the next generation.

3. A carrier for a recessive trait is heterozygous for the trait, having one normal allele and one disorder-causing allele.

Genetic Disorders

1. A mutation is a change in the number or kinds of nucleotides in DNA.
2. Some genetic disorders result from an abnormal distribution of chromosomes during gamete formation.

REVIEW AND COMPREHENSION

1. The major development of organ systems takes place in
 - a. weeks 1 and 2 of development.
 - b. weeks 3–8 of development.
 - c. weeks 8–20 of development.
 - d. the last 30 weeks of development.
2. Given these structures:
(1) blastocyst (2) morula (3) zygote
Choose the arrangement that lists the structures in the order in which they form during development.
 - a. 1,2,3 c. 2,3,1 e. 3,2,1
 - b. 1,3,2 d. 3,1,2
3. The embryo proper develops from the
 - a. inner cell mass.
 - b. trophoblast.
 - c. blastocele.
 - d. yolk sac.
4. The placenta
 - a. develops from the trophoblast.
 - b. allows maternal blood to mix with embryonic blood.
 - c. invades the lacunae of the embryo.
 - d. All of these are correct.
5. The embryonic disk
 - a. forms between the amniotic cavity and the yolk sac.
 - b. contains the primitive streak.
 - c. becomes a three-layered structure.
 - d. All of these are correct.
6. The brain develops from
 - a. ectoderm.
 - b. endoderm.
 - c. mesoderm.
7. Most of the skeletal system develops from
 - a. ectoderm.
 - b. endoderm.
 - c. mesoderm.
8. The somites give rise to the
 - a. circulatory system. c. lungs. e. brain.
 - b. skeletal muscle. d. kidneys.
9. The pericardial cavity forms from
 - a. evagination of the early digestive tract.
 - b. the neural tube.
 - c. the coelom.
 - d. the branchial arches.
 - e. pharyngeal pouches.
10. The parts of the limbs develop
 - a. in a proximal-to-distal sequence.
 - b. in a distal-to-proximal sequence.
 - c. at approximately the same time.
 - d. before the primitive streak is formed.
11. Concerning development of the face,
 - a. the face develops by the fusion of five embryonic structures.
 - b. the maxillary processes normally meet at the midline to form the lip.
 - c. the primary palate forms the roof of the mouth.
 - d. clefts of the secondary palate normally occur to one side of the midline.
12. Concerning the development of the heart,
 - a. the heart develops from a single tube, which results from the fusion of two tubes.
 - b. the SA node develops in the wall of the sinus venosus.
 - c. the foramen ovale lets blood flow from the right atrium to the left atrium.
 - d. the bulbus cordis is absorbed into the ventricle.
 - e. All of these are correct.
13. Given these structures:
(1) mesonephros (2) metanephros (3) pronephros
Choose the arrangement that lists the structures in the order in which they form during development.
 - a. 1,2,3 d. 3,1,2
 - b. 1,3,2 e. 3,2,1
 - c. 2,3,1
14. A study of the early embryo indicates that the glans penis of the male develops from the same embryonic structure as which of these female structures?
 - a. labia majora c. clitoris e. urinary bladder
 - b. uterus d. vagina
15. Which hormones cause the differentiation of sex organs in the developing male fetus?
 - a. FSH and LH
 - b. LH and testosterone
 - c. testosterone and dihydrotestosterone
 - d. estrogen and progesterone
 - e. GnRH and FSH
16. The onset of labor may be a result of
 - a. increased estrogen secretion by the placenta.
 - b. increased glucocorticoid secretion by the fetus.
 - c. increased secretion of oxytocin.
 - d. stretch of the uterus.
 - e. All of these are correct.

17. Following birth,
- the ductus arteriosus closes.
 - the pH of the stomach increases.
 - the fossa ovalis becomes the foramen ovale.
 - blood flow through the pulmonary arteries decreases.
 - All of these events occur.
18. The hormone involved in milk production is
- oxytocin.
 - prolactin.
 - estrogen.
 - progesterone.
 - ACTH.
19. Which of these life stages is correctly matched with the time it occurs?
- neonate—birth to 1 month after birth
 - infant—1 month to 6 months
 - child—6 months to 5 years
 - puberty—10–12 years
 - middle age—20–40 years
20. Which of these occurs as we get older?
- Neurons replicate to replace lost neurons.
 - Skeletal muscle cells replicate to replace lost muscle cells.
 - Cross-links between collagen molecules increase.
 - The immune system becomes less sensitive to the body's own antigens.
 - Free radicals help prevent cancer.
21. A gene is
- the functional unit of heredity.
 - a certain portion of a DNA molecule.
 - a part of a chromosome.
 - All of these are correct.
22. Which of these terms is correctly matched with its definition?
- autosome—an X or a Y chromosome
 - phenotype—the genetic makeup of an individual
 - allele—variant form of a gene occupying locus on a homologous chromosome
 - heterozygous—having two identical genes for a trait
 - recessive—a trait expressed when the genes are heterozygous
23. Which of these genotypes is heterozygous?
- DD*
 - Dd*
 - dd*
 - Both a and c are correct.
24. The AB blood type in the ABO blood group is an example of
- dominant versus recessive alleles.
 - incomplete dominance.
 - codominance.
 - a polygenic trait.
 - sex-linked inheritance.
25. Assume that a trait is determined by an X-linked dominant gene. If the mother exhibits the trait but the father does not, then their
- sons are more likely than their daughters to exhibit the trait.
 - daughters are more likely than their sons to exhibit the trait.
 - sons and daughters are equally likely to exhibit the trait.

Answers in appendix E

CRITICAL THINKING

- Triploidy is the presence of three sets of chromosomes in a cell. Although rare, triploidy does occur in humans. What failures during fertilization can lead to triploidy?
- A physician tells a woman that she is pregnant and is 44 days past her LMP. Approximately how many days has the embryo been developing, and what developmental events are occurring?
- A high fever can prevent neural tube closure. If a woman had a high fever approximately 35–45 days after her LMP, what kinds of congenital disorders might be seen in the developing embryo?
- A woman goes into labor during the thirtieth week of her pregnancy. What are the effects of administering progesterone at this stage?
- Three minutes after birth, a newborn has an Apgar score of 5 as follows: A, 0; P, 1; G, 1; A, 1; and R, 2. What are some possible causes for this low score? What should be done for this neonate?
- When a woman breastfeeds, milk letdown can occur in the breast that is not being suckled. Explain how this response happens.
- An 18-year-old woman consulted a physician because of her failure to initiate menses. She had experienced normal breast development at age 13, but no pubic or axillary hair had ever appeared. Her height was 5 feet 6 inches, weight 119 pounds, blood pressure 110/70, and pulse 60 beats/minute. Her physical examination confirmed the presence of well-developed breasts and the external genitalia of a normal female. However, the vagina ended in a blind pouch, and there was no evidence of a cervix, ovaries, or a uterus. Within the inguinal area, the examining physician could palpate a small, spherical mass on each side. Is this patient's genotype most likely XX, XO, or XY? Explain why the genotype you selected is consistent with the manifestations.
- Select the conditions that would be present in a genetic male fetus having a mutation that causes the synthesis of an ineffective müllerian-inhibiting hormone.
 - Male internal reproductive structures develop.
 - Male internal reproductive structures do not develop.
 - Female internal reproductive structures develop.
 - Female internal reproductive structures do not develop.
 - Male external genitalia develop.
 - Female external genitalia develop.
 - 2,4,6
 - 1,3,5
 - 1,2,6
 - 2,3,5
- The ability to roll the tongue to form a "tube" results from a dominant gene. Suppose that a woman and her son can roll their tongues but her husband cannot. Is it possible to determine if the husband is the father of her son?
- The ABO antigens are a group of molecules found on the surface of red blood cells. Can an individual who has blood type AB be a parent of a child with blood type O? Why or why not?

The 1–18 group designation has been recommended by the International Union of Pure and Applied Chemistry (IUPAC) but is not yet in wide use.

The modern periodic table of the elements lists the known elements in order of their atomic masses. Each element has a box that contains the name of the element and its chemical symbol, atomic number, and atomic mass. The boxes are organized into a grid of horizontal rows, called periods, and vertical columns, called groups. Within a period, the elements are listed in order of increasing atomic number from left to right. Elements in a period have different chemical properties, whereas elements in a group have similar chemical properties.

The atomic number is the number of protons in an element. Each element has a unique number

of protons and therefore a unique atomic number. There are 90 naturally occurring elements. Scientists have been able to create new elements by changing the number of protons in the nuclei of existing elements. Protons, neutrons, or electrons from one atom are accelerated to very high speeds and then smashed into the nucleus of another atom. The resulting changes in the nucleus produce a new element with a new atomic number. These artificially produced elements are usually unstable, and they quickly convert back to more stable elements. The synthetic elements are technetium (Tc, atomic number 43), promethium (Pm, atomic

number 61), and all the elements with an atomic number of 93 or higher. An element with an atomic number of 116 has the highest number officially recognized by the International Union of Pure and Applied Chemistry (IUPAC), but elements with higher atomic numbers have reportedly been made. In addition, the IUPAC gives standard atomic weights to only four significant figures, atomic weights now give a range of values when previously there was just one given, and atomic weights are no longer given for compounds without naturally occurring isotopes.

Appendix B

Selected Abbreviations

α alpha	GCP glomerular capillary pressure	NaHCO₃ sodium bicarbonate
ACE angiotensin-converting enzyme	GDP guanosine diphosphate	NaOH sodium hydroxide
acetyl-CoA acetyl coenzyme A	GFR glomerular filtration rate	NFP net filtration pressure
ACh acetylcholine	GH growth hormone	—NH₂ amine group
ADH antidiuretic hormone	GHIH growth hormone-inhibiting hormone	NH₃ ammonia
ADP adenosine diphosphate	GHRH growth hormone-releasing hormone	NH₄⁺ ammonium ion
ANH atrial natriuretic hormone	GnRH gonadotropin-releasing hormone	NK cells natural killer cells
ANS autonomic nervous system	GTP guanosine triphosphate	NO nitric oxide
apo E apolipoprotein E	H⁺ hydrogen ion	O₂ oxygen
ATP adenosine triphosphate	H₂CO₃ carbonic acid	OH⁻ hydroxide ion
AV atrioventricular beta	H₂O water	PAH <i>para</i> -aminohippuric acid
BCOP blood colloid osmotic pressure	H₂O₂ hydrogen peroxide	P_{ALV} alveolar pressure
BMI body mass index	H₂PO₄⁻ dihydrogen phosphate ion	P_B barometric air pressure
BMR basal metabolic rate	HCG human chorionic gonadotropin	PGE prostaglandin E
BP blood pressure	HCl hydrochloric acid	PGF prostaglandin F
BPG 2,3-bisphosphoglycerate	HCO₃⁻ bicarbonate ion	P_i inorganic phosphate
bpm beats per minute	HDL high-density lipoprotein	PIF prolactin-inhibiting factor
BUN blood urea nitrogen	Hg mercury	PIH prolactin-inhibiting hormone
C₆H₁₂O₆ glucose	HIV human immunodeficiency virus	PIP₂ phosphoinositol
Ca₁₀(PO₄)₆(OH)₂ hydroxyapatite	HLA human leukocyte antigen	PMNs polymorphonuclear neutrophils
Ca²⁺ calcium ion	HPO₄²⁻ monohydrogen phosphate ion	PNS peripheral nervous system
cal calorie	HR heart rate	PO₄³⁻ phosphate ion
cAMP cyclic adenosine monophosphate	I⁻ iodide ion	P_{PL} pleural pressure
CBC complete blood count	ICSH interstitial cell-stimulating hormone	PR peripheral resistance
cGMP cyclic guanosine monophosphate	IFP interstitial fluid pressure	PRF prolactin-releasing factor
CH₃COOH acetic acid	Ig immunoglobulin	PRH prolactin-releasing hormone
Cl⁻ chloride ion	IP₃ inositol triphosphate	PTH parathyroid hormone
CNS central nervous system	IPSP inhibitory postsynaptic potential	RANKL receptor for activation of nuclear factor kappa B ligand
CO cardiac output	IU international units	RAS reticular activating system
CO carbon monoxide	K⁺ potassium ion	RBC red blood count
CO₂ carbon dioxide	kcal kilocalorie	RDA recommended daily allowances
—COOH carboxyl group	kg kilogram	RDI reference daily intake
COX-1 cyclooxygenase-1	L liter	RhoGAM Rh ₀ (D) immune globulin
CP capsule pressure	LDL low-density lipoprotein	RMP resting membrane potential
CRH corticotrophin-releasing hormone	LH luteinizing hormone	RNA ribonucleic acid
CSF cerebrospinal fluid	LHRH luteinizing hormone-releasing hormone	SA sinoatrial
DAG diacylglycerol	MAC membrane attack complex	SV stroke volume
DNA deoxyribonucleic acid	MALT mucosa-associated lymphoid tissue	T₃ triiodothyronine
ECG or EKG electrocardiogram	MAO monoamine oxidase	T₄ tetraiodothyronine
EEG electroencephalogram	MAP mean arterial pressure	TF tissue factor
EGF epidermal growth factor	mEq milliequivalent	TGF-β transforming growth factor beta
ENS enteric nervous system	Mg²⁺ magnesium ion	TMJ temporomandibular joint
EPSP excitatory postsynaptic potential	MHC major histocompatibility complex	TNF tumor necrosis factor
FAD flavin adenine dinucleotide	mOsm milliosmole	TRH thyroid-releasing hormone
FADH₂ reduced flavin adenine diphosphate	mRNA messenger ribonucleic acid	TRH thyroid-stimulating hormone
Fe²⁺ iron ion	mV millivolt	V_A alveolar ventilation
FEV₁ forced expiratory volume in one second	Na⁺ sodium ion	VLDL very low-density lipoprotein
FGF fibroblast growth factor	NaCl sodium chloride	vWF von Willebrand factor
FSH follicle-stimulating hormone gamma	NAD⁺ nicotinamide adenine dinucleotide	WBC white blood count
g gram	NADH reduced nicotinamide adenine dinucleotide	
GABA gamma-aminobutyric acid		

Prefixes, Suffixes, and Combining Forms

The ability to break down medical terms into separate components or to recognize a complete word depends on mastery of the combining forms (roots or stems) and the prefixes and suffixes that alter or modify their meanings. Common prefixes, suffixes, and combining forms are listed below in boldface type, followed by the meaning of each form and an example illustrating its use.

a-, an- without, lack of: *aphasia* (lack of speech), *anaerobic* (without oxygen)
ab- away from: *abductor* (leading away from)
-able capable: *viable* (capable of living)
acou- hearing: *acoustics* (science of sound)
acr- extremity: *acromegaly* (large extremities)
ad- to, toward, near to: *adrenal* (near the kidney)
adeno- gland: *adenoma* (glandular tumor)
-al expressing relationship: *neural* (referring to nerves)
-algia pain: *gastralgia* (stomach pain)
angio- vessel: *angiography* (radiography of blood vessels)
ante- before, forward: *antecubital* (before elbow)
anti- against, reversed: *antiperistalsis* (reversed peristalsis)
arthr- joint: *arthritis* (inflammation of a joint)
-ary associated with: *urinary* (associated with urine)
-asis condition, state of: *homeostasis* (state of staying the same)
auto- self: *autolysis* (self breakdown)
bi- twice, double: *bicuspid* (two cusps)
bio- live: *biology* (study of living)
-blast bud, germ: *fibroblast* (fiber-producing cell)
brady- slow: *bradycardia* (slow heart rate)
-c expressing relationship: *cardiac* (referring to heart)
carcin- cancer: *carcinogenic* (causing cancer)
cardio- heart: *cardiopathy* (heart disease)
cata- down, according to: *catabolism* (breaking down)
cephal- head: *cephalic* (toward the head)
-cele hollow: *blastocoele* (hollow cavity inside a blastocyst)
cerebro- brain: *cerebrospinal* (referring to brain and spinal cord)
chol- bile: *acholic* (without bile)
cholecyst- gallbladder: *cholecystokinin* (hormone causing the gallbladder to contract)
chondr- cartilage: *chondrocyte* (cartilage cell)
-cide kill: *bactericide* (agent that kills bacteria)
circum- around, about: *circumduction* (circular movement)
-clast smash, break: *osteoclast* (cell that breaks down bone)
co-, com-, con- with, together: *coenzyme* (molecule that functions with an enzyme), *commisure* (coming together), *convergence* (to incline together)
contra- against, opposite: *contralateral* (opposite side)

crypto- hidden: *cryptorchidism* (undescended or hidden testes)
cysto- bladder, sac: *cystocele* (hernia of a bladder)
-cyte-, cyto- cell: *erythrocyte* (red blood cell), *cytoskeleton* (supportive fibers inside a cell)
de- away from: *dehydrate* (remove water)
derm- skin: *dermatology* (study of the skin)
di- two: *diploid* (two sets of chromosomes)
dia- through, apart, across: *diapedesis* (ooze through)
dis- reversal, apart from: *dissect* (cut apart)
-duct- leading, drawing: *abduct* (lead away from)
-dynia pain: *mastodynia* (breast pain)
dys- difficult, bad: *dysmentia* (bad mind)
e- out, away from: *eviscerate* (take out viscera)
ec- out from: *ectopic* (out of place)
ecto- on outer side: *ectoderm* (outer skin)
-ectomy cut out: *appendectomy* (cut out the appendix)
-edem- swell: *myoedema* (swelling of a muscle)
em-, en- in: *empyema* (pus in), *encephalon* (in the brain)
-emia blood: *anemia* (deficiency of blood)
endo- within: *endometrium* (within the uterus)
entero- intestine: *enteritis* (inflammation of the intestine)
epi- upon, on: *epidermis* (on the skin)
erythro- red: *erythrocyte* (red blood cell)
eu- well, good: *euphoria* (well-being)
ex- out, away from: *exhalation* (breathe out)
exo- outside, on outer side: *exogenous* (originating outside)
extra- outside: *extracellular* (outside the cell)
-ferent carry: *afferent* (carrying to the central nervous system)
-form expressing resemblance: *fusi form* (resembling a fusion)
gastro- stomach: *gastrodynia* (stomach ache)
-genesis produce, origin: *pathogenesis* (origin of disease)
gloss- tongue: *hypoglossal* (under the tongue)
glyco- sugar, sweet: *glycolysis* (breakdown of sugar)
-gram a drawing: *myogram* (drawing of a muscle contraction)
-graph instrument that records: *myograph* (instrument for measuring muscle contraction)
hem- blood: *hemopoiesis* (formation of blood)
hemi- half: *hemiplegia* (paralysis of half of the body)

hepato- liver: *hepatitis* (inflammation of the liver)
hetero- different, other: *heterozygous* (different genes for a trait)
hist- tissue: *histology* (study of tissues)
homeo-, homo- same: *homeostasis* (state of staying the same), *homologous* (alike in structure or origin)
hydro- wet, water: *hydrocephalus* (fluid within the head)
hyper- over, above, excessive: *hypertrophy* (overgrowth)
hypo- under, below, deficient: *hypotension* (low blood pressure)
-ia, -id expressing condition: *neuralgia* (pain in nerve), *flaccid* (state of being weak)
-iatr- treat, cure: *pediatrics* (treatment of children)
-im not: *impermeable* (not permeable)
in- in, into: *injection* (forcing fluid into)
infra- below, beneath: *infraorbital* (below the eye)
inter- between: *intercostal* (between the ribs)
intra- within: *intraocular* (within the eye)
-ism condition, state of: *dimorphism* (condition of two forms)
iso- equal, the same: *isotonic* (same tension)
-itis inflammation: *gastritis* (inflammation of the stomach)
-ity expressing condition: *acidity* (condition of acid)
kerato- cornea or horny tissue: *keratinization* (formation of a hard tissue)
-kin- move: *kinesiology* (study of movement)
leuko- white: *leukocyte* (white blood cell)
-liga- bind: *ligament* (structure that binds bone to bone)
lip- fat: *lipolysis* (breakdown of fats)
-logy study: *histology* (study of tissue)
-lysis breaking up, dissolving: *glycolysis* (breakdown of sugar)
macro- large: *macrophage* (large phagocytic cell)
mal- bad: *malnutrition* (bad nutrition)
malaco- soft: *osteomalacia* (soft bone)
mast- breast: *mastectomy* (excision of the breast)
mega- great: *megacolon* (large colon)
melano- black: *melanocyte* (black pigment-producing skin cell)
meso- middle, mid: *mesoderm* (middle skin)
meta- beyond, after, change: *metastasis* (beyond original position)
micro- small: *microorganism* (small organism)

- mito-** thread, filament: *mitosis* (referring to threadlike chromosomes during cell division)
- mono-** one, single: *monosaccharide* (one sugar)
- morph-** form: *morphogenesis* (formation of tissues and organs)
- multi-** many, much: *multinucleated* (two or more nuclei)
- myelo-** marrow, spinal cord: *myeloid* (derived from bone marrow)
- myo-** muscle: *myocardium* (heart muscle)
- narco-** numbness: *narcotic* (drug producing stupor or weakness)
- neo-** new: *neonatal* (first four weeks of life)
- nephro-** kidney: *nephrectomy* (removal of the kidney)
- neuro-** nerve: *neuritis* (inflammation of a nerve)
- oculo-** eye: *oculomotor* (movement of the eye)
- odonto-** tooth or teeth: *odontomy* (cutting a tooth)
- oid** expressing resemblance: *epidermoid* (resembling epidermis)
- oligo-** few, scanty, little: *oliguria* (little urine)
- oma** tumor: *carcinoma* (cancerous tumor)
- op-** see, sight: *myopia* (nearsighted)
- ophthalm-** eye: *ophthalmology* (study of the eye)
- ortho-** straight, normal: *orthodontics* (discipline dealing with the straightening of teeth)
- ory** referring to: *olfactory* (relating to the sense of smell)
- ose** full of: *adipose* (full of fat)
- osis** a condition of: *osteoporosis* (porous condition of bone)
- osteo-** bone: *osteocyte* (bone cell)
- oto-** ear: *otolith* (ear stone)
- ous** expressing material: *serous* (composed of serum)
- para-** beside, beyond, near to: *paranasal* (near the nose)
- pathy** disease: *cardiopathy* (disease of the heart)
- penia** deficiency: *thrombocytopenia* (deficiency of thrombocytes)
- per-** through, excessive: *permeate* (pass through)
- peri-** around: *periosteum* (around bone)
- phag** eat: *dysphagia* (difficulty eating or swallowing)
- phas-** speak, utter: *aphasia* (unable to speak)
- phil-** like, love: *hydrophilic* (water-loving)
- phleb-** vein: *phlebotomy* (incision into a vein)
- phobia** fear: *hydrophobia* (fear of water)
- plas-** form, grow: *neoplasm* (new growth)
- plegia** paralyze: *paraplegia* (paralysis of lower limbs)
- pne-** breathe: *apnea* (lack of breathing)
- pneumo-** air, gas, or lungs: *pneumothorax* (air in the thorax)
- pod-** foot: *podiatry* (treatment of foot disorders)
- poie-** making, production: *hematopoiesis* (make blood cells)
- poly-** many, much: *polycythemia* (excess red blood cells)
- post-** after, behind: *postpartum* (after childbirth)
- pre-, pro-** before, in front of: *prenatal* (before birth), *prosect* (to cut before—for the purpose of demonstration)
- procto-** anus, rectum: *proctoscope* (instrument for examining the rectum)
- pseudo-** false: *pseudostratified* (falsely layered)
- psycho-** mind, soul: *psychosomatic* (effect of the mind on the body)
- pyo-** pus: *pyoderma* (pus in the skin)
- re-** back, again, contrary: *reflect* (bend back)
- retro-** backward, located behind: *retroperitoneal* (behind the peritoneum)
- rrhagia** burst forth, pour: *hemorrhage* (bleed)
- rrhea** flow, discharge: *rhinorrhea* (nasal discharge)
- sarco-** flesh or fleshy: *sarcoma* (connective tissue tumor)
- sclero-** hard: *arteriosclerosis* (hardening of the arteries)
- scope** examine: *endoscope* (instrument for examining the inside of a hollow organ)
- semi-** half: *semilunar* (shaped like a half moon)
- somato-** body: *somatotropin* (hormone causing body growth)
- stasis** stop, stand still: *hemostasis* (stop bleeding)
- steno-** narrow: *stenosis* (narrow canal)
- stomy** to make an artificial opening: *tracheostomy* (make an opening into the trachea)
- sub-** under: *subcutaneous* (under the skin)
- super-** above, upper, excessive: *supercilia* (upper brows)
- supra-** above, upon: *suprarenal* (above kidney)
- sym-, syn-** together, with: *symphysis* (growing together), *synopsis* (joining together)
- tachy-** fast, swift: *tachycardia* (rapid heart rate)
- therm-** heat: *thermometer* (device for measuring heat)
- tomy** cut, incise: *phlebotomy* (incision of a vein)
- tox-** poison: *antitoxin* (substance that counteracts a poison)
- trans-** across, through, beyond: *transection* (cut across)
- tri-** three: *triceps* (three-headed muscle)
- troph-** nourish: *hypertrophy* (enlargement or overnourishment)
- tropic** changing, influencing: *gonadotropic* (influencing the gonads)
- uria** urine: *polyuria* (excess urine)
- vas-** vessel: *vasoconstriction* (decreased diameter of blood vessel)
- vene-** vein: *venesection* (phlebotomy)
- viscer-** internal organ: *visceromotor* (movement of internal organs)
- zyg-** yoked, paired: *zygote* (diploid cell)

Appendix B-1

SCIENTIFIC NOTATION

Very large numbers with many zeros, such as 1,000,000,000,000,000, or very small numbers, such as 0.000000000000000001, are very cumbersome to work with. Consequently, the numbers are expressed in a kind of mathematical shorthand known as scientific notation. Scientific notation has the following form:

$$M \times 10^n$$

where n specifies how many times the number M is raised to the power of 10. The exponent n has two meanings, depending on its sign. If n is positive, M is multiplied by 10 n times. For example, if $n = 2$ and $M = 1.2$, then

$$1.2 \times 10^2 = 1.2 \times 10 \times 10 = 120$$

In other words, if n is positive, the decimal point of M is moved to the right n times. In this case

the decimal point of 1.2 is moved two places to the right.

$$1.20$$

If n is negative, M is divided by 10 n times.

$$1.2 \times 10^{-2} = \frac{1.2}{(10 \times 10)} = \frac{1.2}{(100)} = 0.012$$

In other words, if n is negative, the decimal point of M is moved to the left n times. In this case, the decimal point of 1.2 is moved two places to the left.

$$0.012$$

If M is the number 1.0, it often is not expressed in scientific notation. For example, 1.0×10^2 is the same thing as 10^2 , and 1.0×10^{-2} is the same thing as 10^{-2} .

Two common examples of the use of scientific notation in chemistry are Avogadro's number and pH. Avogadro's number, 6.023×10^{23} , is the number of atoms in 1 molar mass of an element. Thus

$$6.023 \times 10^{23} = 602,300,000,000,000,000,000,000$$

which is a very large number of atoms.

The pH scale is a measure of the concentration of hydrogen ions in a solution. A neutral solution has 10^{-7} moles of hydrogen ions per liter. In other words

$$10^{-7} = 0.0000001$$

which is a very small amount (1 ten-millionth of a gram) of hydrogen ions.

Appendix C

SOLUTION CONCENTRATIONS

Physiologists often express solution concentration in terms of percent, molarity, molality, and equivalents.

Percent

The weight-volume method of expressing **percent** concentrations states the weight of a solute in a given volume of solvent. For example, to prepare a 10% solution of sodium chloride, 10 g of sodium chloride is dissolved in a small amount of water (solvent) to form a salt solution. Then additional water is added to the salt solution to form 100 mL of salt solution. Note that the sodium chloride is dissolved in water and then diluted to the required volume. The sodium chloride is not dissolved directly in 100 mL of water.

Molarity

Molarity determines the number of moles of solute dissolved in a given volume of solvent. A 1 molar (1 M) solution is made by dissolving 1 mole (mol) of a substance in enough water to make 1 L of solution. For example, 1 mol of sodium chloride solution is made by dissolving 58.44 g of sodium chloride in enough water to make 1 L of solution. One mol of glucose solution is made by dissolving 180.2 g of glucose in enough water to make 1 L of solution. Both solutions have the same number (Avogadro's number) of formula units (NaCl) and molecules (glucose) in solution.

Osmoles, Osmolality, and Osmosis

An **osmole** is the measure of the number of particles in a solution. One osmole is the molecular mass, in grams, of a solute times the number of ions or

particles into which it dissociates in solution. A milliosmole (mOsm) is 1/1000 of an osmole. The osmolality of a solution is the number of osmoles in a kilogram of solution. Water moves by osmosis from a solution with a lower osmolality to a solution with a higher osmolality. Thus, water moves by osmosis from a solution of 100 mOsm/kg toward a solution of 300 mOsm/kg.

Molality

Although 1 M solutions have the same number of solute molecules, they do not have the same number of solvent (water) molecules. Because 58.5 g of sodium chloride occupies less volume than 180 g of glucose, the sodium chloride solution has more water molecules. **Molality** is a method of calculating concentrations that takes into account the number of solute and solvent molecules. A 1 molal solution (1 *m*) is 1 mol of a substance dissolved in 1 kg of water. Thus, all 1 molal solutions have the same number of solvent molecules.

When sodium chloride, which is an ionic compound, is dissolved in water, it dissociates to form two ions, a sodium cation (Na^+) and a chloride anion (Cl^-). Glucose does not dissociate when dissolved in water, however, because it is a molecule. Thus, the sodium chloride solution contains twice as many particles as the glucose solution (one Na^+ and one Cl^- for each glucose molecule). To report the concentration of these substances in a way that reflects the number of particles in a given mass of solvent, the concept of **osmolality** is used. The osmolality of a solution is the molality of the solution times the number of particles into which the solute dissociates in 1 kg of solvent. Thus, 1 mol of sodium chloride in 1 kg of water is a 2 osmolal (osm)

solution because sodium chloride dissociates to form two ions.

The osmolality of a solution is a reflection of the number, not the type, of particles in a solution. Thus, a 1 osm solution contains 1 osm of particles per kilogram of solvent, but the particles may be all one type or a complex mixture of different types.

The concentration of particles in body fluids is so low that the measurement milliosmole (mOsm), 1/1000 of an osmole, is used. Most body fluids have an osmotic concentration of approximately 300 mOsm and consist of many different ions and molecules. The osmotic concentration of body fluids is important because it influences the movement of water into or out of cells (see chapter 3).

Equivalents

Equivalents are a measure of the concentrations of ionized substances. One equivalent (Eq) is 1 mol of an ionized substance multiplied by the absolute value of its charge. For example, 1 mol of NaCl dissociates into 1 mol of Na^+ and 1 mol of Cl^- . Thus, there is 1 Eq of Na^+ (1 mol \times 1) and 1 Eq of Cl^- (1 mol \times 1). One mole of CaCl_2 dissociates into 1 mol of Ca^{2+} and 2 mol of Cl^- . Thus, there are 2 Eq of Ca^{2+} (1 mol \times 2) and 2 Eq of Cl^- (2 mol \times 1). In an electrically neutral solution, the equivalent concentration of positively charged ions is equal to the equivalent concentration of the negatively charged ions. One milliequivalent (mEq) is 1/1000 of an equivalent.

Appendix D

pH

Pure water weakly dissociates to form small numbers of hydrogen and hydroxide ions:

At 25°C, the concentration of both hydrogen ions and hydroxide ions is 10^{-7} mol/L. Any solution that has equal concentrations of hydrogen and hydroxide ions is considered **neutral**. A solution is an **acid** if it has a higher concentration of hydrogen ions than hydroxide ions, and a solution is a **base** if it has a lower concentration of hydrogen ions than hydroxide ions. In any aqueous solution (at 25°C), the hydrogen ion concentration $[\text{H}^+]$ times the hydroxide ion concentration $[\text{OH}^-]$ is a constant that is equal to 10^{-14} .

$$[\text{H}^+] \times [\text{OH}^-] = 10^{-14}$$

Consequently, as the hydrogen ion concentration decreases, the hydroxide ion concentration increases, and vice versa—for example,

	$[\text{H}^+]$	$[\text{OH}^-]$
Acidic solution	10^{-3}	10^{-11}
Neutral solution	10^{-7}	10^{-7}
Basic solution	10^{-12}	10^{-2}

Although the acidity or basicity of a solution could be expressed in terms of either hydrogen or hydroxide ion concentration, it is customary to use hydrogen ion concentration. The pH of a solution is defined as

$$\text{pH} = -\log_{10}(\text{H}^+)$$

Thus, a neutral solution with 10^{-7} mol of hydrogen ions per liter has a pH of 7.

$$\begin{aligned}\text{pH} &= -\log_{10}(\text{H}^+) \\ &= -\log_{10}(10^{-7}) \\ &= -(-7) \\ &= 7\end{aligned}$$

In simple terms, to convert the hydrogen ion concentration to the pH scale, the exponent of the concentration (e.g., -7) is used, and it is changed from a negative to a positive number. Thus, an acidic solution with 10^{-3} mol of hydrogen ions/L has a pH of 3, whereas a basic solution with 10^{-12} hydrogen ions/L has a pH of 12.

Appendix F

ANSWERS TO CRITICAL THINKING QUESTIONS

Chapter 1

1. Student B is correct. Body temperature begins to rise as a result of exposure to the hot environment. Sweating eliminates heat from the body and lowers body temperature. Body temperature returning to its ideal normal value is an example of negative feedback. Student A probably thought it was positive feedback because sweating continued to increase. However, sweating is the response. The variable being regulated by sweating is body temperature.
2. Answer *e* is correct. Positive-feedback mechanisms continuously stimulate a response until the initial stimulus is removed. They are sometimes harmful. The continually decreasing blood pressure is an example of a harmful positive feedback mechanism. Negative-feedback mechanisms result in a return to homeostasis. The elevated heart rate is a negative-feedback mechanism that attempts to return blood pressure to a normal value. In this case, the negative-feedback mechanism is inadequate to restore homeostasis, and medical intervention (a transfusion) is necessary.
3. When a boy is standing on his head, his nose is superior to his mouth. Directional terms refer to a person's body in the anatomical position, not to the body's current position.
4. The uterus is located in the pelvic cavity. The pelvic cavity, however, is surrounded by the bones of the pelvis and does not increase in size during pregnancy. Instead, as the fetus grows, the expanding uterus must move into the abdominal cavity, thereby crowding the abdominal organs and dramatically increasing the size of the abdominal cavity.
5. After the pole passes through the abdominal wall, it pierces the parietal peritoneum. In passing through the stomach, it penetrates the visceral peritoneum, the stomach itself, and the visceral peritoneum on the other side of the stomach. Because the diaphragm is lined inferiorly by parietal peritoneum and superiorly by parietal pleura, these are the next two membranes pierced. The pole then passes through the pleural space and visceral pleura to enter the lung.

Chapter 2

1. An atom of iron has 26 protons (the atomic number), 30 neutrons (the mass number minus the atomic number), and 26 electrons (because the number of electrons is equal to the number of protons). If an atom of iron loses 3 electrons, it has 3 more protons (positive charges) than electrons (negative charges). Therefore, the iron ion has an overall charge of +3, which is represented symbolically as Fe^{3+} .
2. The formation of free fatty acids and glycerol from a triglyceride is a decomposition reaction because a larger molecule breaks down into smaller molecules. All of the decomposition reactions in the body are collectively referred to as catabolism. This reaction can also be classified as a hydrolysis reaction because, as part of the reaction, a water molecule is split into hydrogen, which becomes part of the glycerol molecule, and hydroxide, which becomes part of a fatty acid molecule. Yes, the reverse anabolic reaction generates water.
3. The slight amount of heat functions as activation energy and starts a chemical reaction. The reaction releases a large amount of heat, causing the solution to become hot.
4. Heating (boiling) has destroyed the ability of the molecules in one or both of the solutions to function in the chemical reaction. This is called denaturation. There are two possibilities as to what is denatured: the reactants themselves or an enzyme that catalyzes the reaction.
5. Muscle contains proteins. To increase muscle mass, proteins must be synthesized from amino acids. The synthesis of molecules in living organisms requires the input of energy. That energy comes from the potential energy stored in the chemical bonds of food molecules, which is released during the decomposition of food molecules.
6. pH is a measure of H^+ concentration. If equal amounts of solutions A and B are mixed, the resulting H^+ concentration is the average value of the two solutions—that is, the pH is $(8 + 2) / 2 = 5$. A pH of 5 is acidic. This question illustrates an important point:

The pH of a solution can be changed by adding a more acidic or more basic solution to it.

7. Rapid respiration before diving into the water causes blood levels of carbon dioxide to decrease. As a result, there is a slight increase in blood pH. Recall that carbon dioxide molecules react with water to produce carbonic acid, and some of the carbonic acid molecules dissociate to form hydrogen ions and bicarbonate ions. These reactions are reversible. As Ned hyperventilates, the blood carbon dioxide levels decrease, which causes some hydrogen ions to react with bicarbonate ions to produce carbonic acid. The carbonic acid then dissociates to form water and carbon dioxide, so there is a net loss of protons. While holding his breath under water, carbon dioxide levels increased in Ned's blood. The carbon dioxide molecules react with water to form carbonic acid, which then dissociates to form hydrogen ions and bicarbonate ions. As a result, there is a slight decrease in blood pH. However, the pH of the blood does not change dramatically, in part because of buffers in the blood.
8. As A and B are added to the solution, the enzyme E catalyzes the formation of C. However, when C binds to the active site of E, the ability of E to catalyze the formation of C is blocked. As more and more C is produced, the rate of formation of C is slowed. Because the reaction of C with E is reversible, there will always be some E that has a functional (not blocked) active site, and some A will therefore always combine with B.
9. Heating the substances might help because proteins can be denatured and can coagulate (as in frying an egg). Another possibility is to try dissolving the substances in water. Most lipids are insoluble in water, whereas many proteins either are soluble in water or form colloids with water.

Chapter 3

1. The cells within the wound swell with water and lyse when a hypotonic solution is introduced. This kills potentially metastatic cells that may still be present in the wound.

- Water moves by osmosis from solution B into solution A. Because solution A is hyperosmotic to solution B, solution A has more solutes and less water than does solution B. Water therefore moves from solution B (with more water) to solution A (with less water).
- Answer *b* is correct. At point A on the graph, the extracellular concentration is equal to the intracellular concentration. If movement were by simple diffusion or by facilitated diffusion, at this point the rate of movement would be zero. Because it is not zero, it is reasonable to conclude that the mechanism involved is active transport.
- Answer *b* is correct. Because the solution is isotonic, no exchange of water occurs. Because the solution contains the same concentration of all substances except that it has no urea, only a net movement of urea occurs across the membrane.
- It is obvious that the heart and leg muscles of people who are jogging require the formation of ATP as a source of energy. As the heart and leg muscles increase in size, more ATP is produced by a greater number of mitochondria. Mitochondria are the critical membrane-bound organelles that increased in number by dividing. The genetic information for some of the proteins in mitochondria comes from the DNA of the mitochondria, and the genetic information for other proteins comes from DNA from the nuclei of the muscle cells.
- Because the drug inhibits mRNA synthesis, protein synthesis is stopped. If the cell releases proteins as they are synthesized, the rate of protein secretion dramatically decreases following the administration of the drug. On the other hand, if the cell releases stored proteins, the rate of secretion at first is normal and then gradually declines.

Chapter 4

- The tissue is epithelial tissue because it is lining a free surface, and the epithelium is stratified because it consists of more than one layer. The types of stratified epithelium are stratified squamous, stratified cuboidal, stratified columnar, and transitional epithelium. The structure of the cells in the surface layers determines the tissue type. Flat cells in the surface layer indicate stratified squamous epithelium. Cuboidal cells in the surface layer indicate stratified cuboidal epithelium, and columnar cells in the surface layer point to stratified columnar epithelium. The surface cells of transitional epithelium are roughly cuboidal with cubelike or columnar cells beneath them. When transitional epithelium is stretched, the surface cells are still

roughly cuboidal, but underlying layers can be somewhat flattened.

- In general, epithelial cells undergo cell division (mitosis) in response to injury, and the newly produced cells replace the damaged cells. However, if the basement membrane is destroyed, nothing is present to provide scaffolding for the newly formed epithelial cells. Without the basement membrane, there is no effective way for the newly formed epithelial cells to repair a structure, such as a kidney tubule. Since the basement membranes appear mostly intact, the person is likely to survive, and the kidney will regain most of its ability to function.
- Pseudostratified squamous epithelium has goblet cells that secrete mucus. The cilia move the mucus over the surface of the epithelium toward the upper portion of the trachea. Stratified squamous epithelium does not secrete abundant mucus, and it does not have cilia. Consequently, mucus secreted by the area of the trachea that is still lined by pseudostratified columnar epithelium is not moved over the portion of the trachea lined by stratified squamous epithelium. The mucus accumulates below the area of the trachea lined by stratified squamous epithelium, causing Willie's frequent cough.
- Glands producing merocrine secretions do so with no loss of actual cellular material, whereas glands producing holocrine secretions shed entire cells. The cells rupture and die, and the entire cell becomes part of the secretion. You can chemically analyze the secretions for the types of molecules found in cellular organelles. For example, if phospholipids and proteins normally found in membranes are in the secretion, the secretion is a holocrine secretion. If the secretion is watery or contains products that are not found in membranes or organelles, it is a merocrine secretion.
- The tissue described is dense, regularly arranged, collagenic connective tissue. Injury to this type of tissue affects structures made up of this type of connective tissue, which includes tendons. Damage to neck vertebrae can be ruled out because they are connected by ligaments containing abundant dense, regularly arranged elastic connective tissue. A ruptured intervertebral disk is not indicated because it would consist of dense, irregularly arranged collagenic connective tissue.
- Histamine is one of the mediators of inflammation released in response to tissue damage. However, several other chemical mediators are also released. Antihistamines might reduce the inflammatory response somewhat, but they are not likely to have a major effect because of the other chemical

mediators released at the same time. In certain types of inflammatory responses, such as allergic responses, histamines are released in large amounts. Under these conditions, antihistamines do reduce the inflammatory response.

Chapter 5

- The stratum corneum, the outermost layer of the skin, consists of many rows of flat, dead epithelial cells. The many rows of cells, which are continuously shed and replaced, are responsible for the protective function of the integument. In infants, there are fewer rows of cells, resulting in skin that is more easily damaged than that of adults.
- Melanocytes produce melanin, which protects underlying tissue from ultraviolet radiation. Therefore, we expect melanocytes to be present in the most superficial living tissue. Although the epidermis as a whole is the most superficial tissue of the body, not all regions of the epidermis are composed of living cells. Therefore, melanocytes are located in the most superficial living tissue layer, the stratum basale of the epidermis.
- Alcohol is a solvent that dissolves lipids (see chapter 2). It removes the lipids from the skin, especially in the stratum corneum. The rate of water loss increases after soaking the hand in alcohol because of the removal of the lipids that normally prevent water loss.
- Carotene, a yellow pigment from ingested plants, accumulates in lipids. The stratum corneum of a callus has more layers of cells than other, noncallused parts of the skin, and the cells in each layer are surrounded by lipids. The carotene in the lipids makes the callus appear yellow.
- Yes, the skin (dermis) can be overstretched due to obesity or rapid growth.
- Eyelashes have a short growth stage (30 days) and are therefore short. Fingernails grow continuously but are short because they are cut, broken off, or worn down.
- The hair follicle, but not the hair, is surrounded with nerve endings that can detect movement and pulling of the hair. The hair is dead, keratinized epithelium, so cutting the hair is not painful.
- Probably not, because, following removal of the nail from the nail fold, it may grow back into the nail fold and the ingrown toenail may recur. One solution is to remove the small part of the nail responsible for the ingrown toenail. Prior to this drastic approach, sterile gauze can be placed between the nail and the nail fold to force the nail away from the nail fold. After the nail fold is healed, the gauze can be removed.

9. Rickets is a disease of children resulting from inadequate vitamin D intake. Inadequate vitamin D leads to insufficient absorption of calcium from the small intestine, resulting in soft bones. If adequate vitamin D is ingested, rickets is prevented, whether a person is dark- or fair-skinned. However, if dietary vitamin D is inadequate, when the skin is exposed to ultraviolet light, 7-dehydrocholesterol is converted into cholecalciferol, which can be converted to vitamin D. Dark-skinned children are more susceptible to rickets because the additional melanin in their skin screens out the ultraviolet light and they produce less vitamin D.
 10. Chemotherapeutic drugs decrease mitosis in the stratum basale and stratum spinosum of the epidermis. As a result, there is a decrease in the number of layers of epithelial cells in the other layers of the skin (the stratum granulosum, stratum lucidum, and stratum corneum) where the cells are apparent. The rate of mitosis in the nail matrix decreases, so the rate of nail growth and the rate of mitosis in the hair bulb also decrease. Hair growth can stop, and hairs already formed can fall out of the hair follicles. The number of melanocytes in the skin does not decrease substantially because they do not typically undergo mitosis. The rate of melanin synthesis may decrease. More importantly, though, the rate at which epithelial cells are formed decreases, and the number of layers of epithelial cells in the epidermis decreases, so the rate of pigmentation may decrease. Sebaceous glands depend on mitosis to provide the cells that contribute to the holocrine secretion they produce. The decreased rate of mitosis causes a reduced rate of sebum production.
4. Testosterone normally causes a growth spurt at puberty, followed by slower growth and closure of the epiphyseal plate. Without testosterone, growth is slower but proceeds longer, resulting in a taller than normal person.
 5. Blood vessels in central canals run parallel to the long axis of the bone, and perforating canals run at approximately a right angle to the central canals. Thus, perforating canals connect to central canals, which allows blood vessels in the perforating canals to connect with blood vessels in the central canals. After a fracture, blood flow through the central canals stops back to the point where the blood vessels in the central canals connect to the blood vessels in the perforating canals. The regions of bone on both sides of the fracture associated with this lack of blood delivery die.
 6. Hyperparathyroidism stimulates increased bone breakdown and can cause osteitis fibrosa cystica, a condition in which the bone is eaten away as Ca^{2+} is released from the bone. The result can be a deformed bone that is likely to fracture. Vitamin D therapy could help because vitamin D promotes an increase in blood Ca^{2+} and therefore increased deposition of Ca^{2+} in bone.

Chapter 7

1. An infection in the nasal cavity could spread to adjacent cavities and fossae, including the paranasal sinuses: (1) frontal, (2) maxillary, (3) ethmoidal, and (4) sphenoidal; (5) the orbit (through the nasolacrimal duct); (6) the cranial cavity (through the cribriform plate); and (7) the throat (through the posterior opening of the nasal cavity).
2. Falling on the top of the head could drive the occipital condyles into the superior articulating processes of the atlas, causing a fracture. An uppercut to the jaw would slightly lift the occipital condyles away from the superior articulating processes of the atlas and usually does not result in a fractured atlas. However, such a blow to the jaw can fracture the temporal bone where it articulates with the mandible.
3. Forceful rotation of the vertebral column is most likely to damage the articular processes, especially in the lumbar region, where the articular processes tend to prevent excessive rotation (the superior articular processes face medially and the inferior articular processes face laterally).
4. If the ulna and radius become fused, the radius can no longer rotate relative to the

ulna. As a result, most of the rotation of the forearm and hand is lost.

5. The ischial tuberosity is the bony protuberance.
6. Women's hips are wider than men's. As the knees are positioned toward the midline, the slope of the femur from its proximal end toward its distal end is greater in women. As a result, more women than men tend to be knock-kneed.
7. The lateral malleolus extends farther distally than the medial malleolus does, thus making it more difficult to turn the foot laterally than to turn it medially. The styloid process of the radius extends farther distally than the styloid process of the ulna, thus making it more difficult to cock the wrist toward the thumb (laterally) than toward the little finger (medially).
8. Landing on the heels can fracture the calcaneus. A heavy object, such as a firefighter, landing on the dorsal surface of the foot could fracture the metatarsal bones or even the tarsal bones.

Chapter 8

1. If the sternocostal synchondrosis were to ossify, becoming a synostosis, there would no longer be any stretch through the costal cartilage, the thorax could not expand, and respiration would be severely hampered.
2.
 - a. suture, little or no movement
 - b. syndesmosis, some movement
 - c. complex synovial joints: the humeroulnoradial joint is a hinge joint and the radioulnar joint is a pivot joint; all have considerable movement
3.
 - a. flexion and supination
 - b. flexion of the hip and extension of the knee
 - c. abduction of the arm at the shoulder
 - d. flexion of the knee and plantar flexion of the foot
4. The descriptions of Donnie's symptoms and the diagnosis of AS provide us with important information to answer these questions. First, Donnie's lower back is the site of pain and the discomfort is spreading up his vertebral column, but not to his legs. Also, we are told that AS causes fibrosis, ossification, and fusion of joints due to chronic inflammation of the joints, specifically at insertion points for ligaments, tendons, and the joint capsule. Because Donnie's pain and stiffness are in his back and affect his joints, we know from chapter 7 that Donnie's discomfort is specifically associated with the vertebrae and the sacrum. We learned in chapter 8 that the joints between vertebrae, or intervertebral joints, are cartilaginous. We can therefore conclude that AS primarily affects cartilaginous joints. The second part of the question asks us to

Chapter 8

1. Normally, bone matrix and bone trabeculae are organized to be strongest along lines of stress. Random organization of the collagen fibers of bone matrix results in weaker bones. In addition, the reduced amount of trabecular bone makes the bone weaker. Fractures can occur when the weakened bone is subjected to stress.
2. Osteoporosis is depletion of bone matrix that results when more bone is destroyed than is formed. Because mechanical stress stimulates bone formation (osteoblast activity), running helps prevent osteoporosis in the bones being stressed. This includes the bones of the lower limbs and the spine.
3. The loss of bone density results because the bones are not bearing weight in the weightless environment. Therefore, osteoblasts are not sufficiently stimulated and

explain why chronic inflammation of the joints would lead to their fusion. Inflammation of the joints occurs at insertion sites for ligaments, tendons, and the joint capsule, all of which are near the ends of the articulating bones. Similar to the inflammation associated with bone repair described in chapter 6, chronic inflammation of the joints leads to collagen synthesis by fibroblasts. The collagen becomes organized into a fibrous scar similar to the granulation tissue that forms during bone repair. Since the inflammation is chronic, this fibrous scar continues to increase in size to the point that it covers the entire joint. The fibrous scar is later ossified, causing the bones of the joint to fuse.

Chapter 9

1. Botulism poisoning results from ingesting botulism toxin produced by the bacterium *Clostridium botulinum*. The toxin binds to presynaptic nerve terminals and prevents the release of acetylcholine. Thus, action potentials in nerves cannot produce action potentials in skeletal muscles, and skeletal muscles become paralyzed, which explains the difficulty in breathing and swallowing. Other reasonable explanations are that the toxin binds to and blocks the receptors for acetylcholine, that the toxin blocks the entry of Ca^{2+} into the presynaptic terminal and thus prevents acetylcholine release, and that the toxin specifically prevents the entry of ions through Na^+ channels of skeletal muscle fibers.
2. Muscular dystrophy results from gradual atrophy of skeletal muscle fibers and their replacement with connective tissue. Myasthenia gravis results from the degeneration of the receptors for acetylcholine on the postsynaptic membranes of skeletal muscle fibers. If an inhibitor of acetylcholinesterase is administered, the result should be an increase in the concentration of acetylcholine in the nerve muscle synapse. Thus, more acetylcholine is available to bind to acetylcholine receptors. In people suffering from myasthenia gravis, the increased concentration of acetylcholine in the synapse allows acetylcholine to bind a greater percentage of the acetylcholine receptors present and causes the muscle contractions to increase in strength. In people who have muscular dystrophy, the muscle contractions do not increase in strength because muscle atrophy is the cause of the weakness. The additional acetylcholine in the neuromuscular junction has no effect on the weakened muscle fibers.
3. Start with a subthreshold stimulus and increase the stimulus strength by very small increments. Apply the stimulus to the nerve of muscle A and muscle B. If the number of motor units is the same for both preparations, each time the stimulus strength is increased, the degree of tension produced by the muscles will also increase to the same degree in each muscle. If one muscle has more motor units than the other, the muscle with the greater number of motor units will exhibit a greater number of separate increases in tension, and the magnitude of the increases in tension will be smaller than those seen in the muscle with fewer motor units.
4. While the weight is being held steady, the cross-bridges are pulling the Z disks closer together, but the external load (the weight) is pulling the sarcomeres apart with equal force. Because the internal and external forces are equal, the cross-bridges are producing enough force to hold the weight steady, but not enough to shorten the muscle, so the sarcomeres remain the same length. When the person lowers the weight, the cross-bridges are producing less force than the weight. Thus, each time a cross-bridge detaches from actin, the thin filaments “slip” and the sarcomeres lengthen. When the person raises the weight, the cross-bridges are producing more force than the external load. Thus, the cross-bridges collectively are able to produce enough force to pull the Z disks closer together, and the sarcomeres get shorter.
5. The shape of an active tension curve for skeletal muscle can be seen in figure 9.22. In contrast, an active tension curve is much flatter for smooth muscle. That is, for each increase in the length of a muscle fiber, there is little change in the active tension produced by the smooth muscle fiber. Smooth muscle has the ability to increase in length without much increase in tension.
6. Both the 100-meter dash and weight lifting involve rapid and intense contractions of skeletal muscles that are completed quickly. These contractions depend on anaerobic respiration for a significant amount of the ATP produced. In contrast, the 10,000-meter run involves sustained muscular contractions that are not as rapid, but the slower contractions are repeated many times during the run. Aerobic respiration produces the majority of the ATP for the 10,000-meter run. Anaerobic respiration is associated with a decrease in creatine phosphate, an increase in creatine, an increase in lactic acid, and a decrease in glycogen, and the enzymes responsible for anaerobic respiration function more rapidly. Aerobic respiration is associated with increased enzyme activity in the mitochondria and an increase in carbon dioxide production. Oxygen is used more rapidly during aerobic respiration.
7. During the 100-meter race, Shorty depended on ATP produced by anaerobic respiration. That produced an oxygen deficit at the end of the run, which resulted in an elevated rate of respiration for a time. During the longer and slower run, most of the ATP for muscle contractions was produced by aerobic respiration, and very little oxygen deficit developed. Prolonged aerobic respiration is required to “pay back” the oxygen deficit. Therefore, Shorty’s rate of respiration was prolonged after the 100-meter race but not after the longer but slower run.
8. High blood K^+ concentration also results in depolarization of smooth muscle plasma membranes. Depolarization of the smooth muscle plasma membrane results in increased muscle contractions and increased permeability of the plasma membrane to both Na^+ and Ca^{2+} , which causes further depolarization and an increase in the intracellular concentration of Ca^{2+} . These changes result in the production of action potentials and muscle contractions.
9. The muscles would contract. ATP would be available to bind to the myosin heads, thus allowing myosin molecules to be released from actin molecules. The cross-bridges would immediately re-form, and complete cross-bridge cycling would result in contraction of the muscle fibers. As long as Ca^{2+} were present at high concentrations in the sarcoplasm, contraction of the muscles would occur. If the sarcoplasmic reticulum were intact, ATP would be available to drive the active transport of Ca^{2+} into the sarcoplasmic reticulum. As the Ca^{2+} decreased in the sarcoplasm, relaxation would result. If the sarcoplasmic reticulum were not intact, however, and could not transport Ca^{2+} into the sarcoplasmic reticulum as fast as they leaked out, the muscle would remain contracted until it fatigued.
10. Hormones can bind to ligand-gated Ca^{2+} channels, and the channels, in response, open. Calcium ions diffuse into the cell and cause contraction. Only a small amount of depolarization results as Ca^{2+} diffuses into the cell; since Na^+ channels do not open, a large change in the resting membrane potential does not occur.
11. In experiment A, the students used anaerobic respiration as they started to run in place, but aerobic respiration also increased to meet most of their energy needs. When they stopped, their respiration rate was increased over resting levels because of the repayment of the oxygen deficit due to anaerobic respiration. In experiment B,

almost all of the students' respiration came from anaerobic respiration because the students held their breath while running in place. Consequently, the students had a much larger oxygen deficit. The students' respiratory rate and depth would be greater than in experiment A, or their respiration rates would be elevated for a longer period of time than in experiment A.

- The color of the meat depends on the number of capillaries (blood is red) within the muscle and is based on its myoglobin content (myoglobin is also red). After cooking, the tissues look darker, not red, because the blood and myoglobin have been broken down by the heat. Thus, the dark meat is darker because it contains more capillaries and more myoglobin. This is consistent with slow-twitch muscle fibers, which are used for maintaining posture and for performing slow movements, such as walking. The white muscle, with fewer capillaries and lower myoglobin content, is consistent with fast-twitch muscle fibers, which are used for quick movements, such as running or flying.

Chapter 10

- | 1. Muscle | Action | Synergist | Antagonist |
|-------------------|--------------------------|--|--|
| Longus capitis | Flexes neck | Rectus capitis anterior, longus colli | Most of the posterior neck muscles |
| Erector spinae | Extends vertebral column | Interspinales, multifidus, semispinalis thoracis | Most of the anterior abdominal muscles |
| Coraco-brachialis | Adducts arm | Latissimus dorsi, pectoralis major, teres major, teres minor | Deltoid, supra-spinatus |
| | Flexes arm | Deltoid (anterior), pectoralis major, biceps, brachii | Deltoid (posterior), latissimus dorsi, teres major, teres minor, infra-spinatus, sub-scapularis, triceps brachii |
- The brachioradialis originates on the humerus and inserts onto the distal end of the radius. The fulcrum of this lever system is the elbow joint. With a weight held in the hand, the pull, applied between the weight and the fulcrum, is a class III lever system.

With the weight on the forearm, the weight is between the pull and the fulcrum and is a class II lever system. A greater weight can be lifted if placed on the forearm rather than in the hand, but weights placed on the forearm cannot be lifted as far.

- The muscles that flex the head also oppose extension of the neck. In an accident causing hyperextension of the neck, these muscles can be stretched and torn. The muscles involved can include the sternocleidomastoid, longus capitis, rectus capitis anterior, and longus colli. Automobile headrests are designed so that, if adjusted correctly, the back of the head hits the headrest during a rear-end accident, thereby preventing hyperextension of the neck.
- The only muscle that elevates the lower eyelid is the orbicularis oculi, which "closes the eye." With this muscle not functioning, the lower eyelid droops. The levator anguli oris, which elevates the angle of the mouth, was also affected, allowing the corner of the mouth to droop. The zygomaticus major may also have been affected, as it inserts onto the corner of the mouth (see figure 10.7).
- The genioglossus muscle protrudes the tongue. If it becomes relaxed, or paralyzed, the tongue may fall back and obstruct the airway. This can be prevented or reversed by pulling forward and down on the mandible, thus opening the mouth. The genioglossus originates on the genu of the mandible. As the mandible is pulled down and forward, the genioglossus is pulled forward with the mandible, thus pulling the tongue forward also.
- The rotator cuff muscles are the primary muscles holding the head of the humerus in the glenoid fossa, especially the supraspinatus. In fact, a torn rotator cuff, which usually involves a tear of the supraspinatus muscle, often results in dislocation of the shoulder.
- Speedy has ruptured the calcaneal tendon, and the gastrocnemius and soleus muscles have retracted, causing the abnormal bulging of the calf muscles. Because the major plantar flexors are no longer connected to the calcaneus, the runner cannot plantar flex the foot, and the foot is abnormally dorsiflexed because the antagonists have been disconnected.
- If you are sitting on a chair with the book open on the desk in front of you, very few muscles are required to turn the page. First the arm is extended slightly to push the forearm and hand along the edge of the book. This can be accomplished with the anterior portion of the deltoid muscle. The hand is then slightly supinated by means of the supinator muscle. The thumb and index finger are then flexed to grasp the page to be turned. This movement involves the

flexor pollicis brevis and flexor digitorum superficialis to the index finger (the flexor digitorum profundus may also be involved). The page is then turned by extending the fingers (extensor digitorum), pronating the hand (pronator quadratus and pronator teres), and medially rotating the arm (pectoralis major, teres major, latissimus dorsi).

Chapter 11

- Because the plasma membrane is much less permeable to Na^+ than to K^+ , changes in the extracellular concentration of Na^+ affect the resting membrane potential less than do changes in the extracellular concentration of K^+ . Therefore, increases in extracellular Na^+ have a minimal effect on the resting membrane potential. Because the membrane is much more permeable to Na^+ during the action potential, the elevated concentration of Na^+ in the extracellular fluid allows Na^+ to diffuse into the cell at a more rapid rate during the action potential, resulting in a greater degree of depolarization during the depolarization phase of the action potential.
- Smooth muscle cells contract spontaneously in response to spontaneous depolarizations that produce action potentials. One way action potentials can be produced spontaneously is if membrane permeability to Na^+ spontaneously increases. As a result, some Na^+ enters the smooth muscle cells and causes a small depolarizing graded potential. The small depolarization can cause voltage-gated Na^+ channels to open, which results in further depolarization, thereby stimulating additional Na^+ voltage-gated ion channels to open. This positive-feedback cycle can continue until the plasma membrane is depolarized to its threshold level and an action potential is produced.
- Action potential conduction along a myelinated nerve fiber is more energy-efficient because the action potential is propagated by saltatory conduction, which produces action potentials at the nodes of Ranvier. Compared with an unmyelinated nerve fiber, only a small portion of the myelinated neuron's membrane has action potentials. Thus, less Na^+ flows into the neuron (depolarization) and less K^+ flows out of the neuron (repolarization). Consequently, the sodium-potassium pump has to move fewer ions in order to restore ion concentrations. Because the sodium-potassium pump requires ATP, myelinated axons use less ATP than unmyelinated axons.
- The inhibitory neuromodulator causes the postsynaptic neuron to become less sensitive to excitatory stimuli, probably by causing

hyperpolarization of the postsynaptic neuron. As a result, the excitatory neurotransmitter released from the excitatory neuron is less likely to produce postsynaptic action potentials.

5. With aging, the amount of myelin surrounding axons decreases, which decreases the speed of action potential propagation. Also, at synapses, action potentials in the presynaptic terminal take longer to cause the production of action potentials in the postsynaptic membrane. It is believed this results from a reduced release of neurotransmitter by the presynaptic terminal and a reduced number of receptors in the postsynaptic membrane.
6. Organophosphates inhibit acetylcholinesterase, thereby causing an increase in acetylcholine in the synaptic cleft, which leads to overproduction of action potentials, tetanus of muscles, and possible death from respiratory failure (see chapter 9). Curare is the best antidote because it blocks the effect of acetylcholine and counteracts the organophosphate. Too much curare, however, can cause flaccid paralysis of the respiratory muscles. Injecting acetylcholine would make the effect of the organophosphate worse. Potassium chloride causes depolarization of muscle fiber membranes, thereby making them more sensitive to acetylcholine.
7. If the motor neurons supplying skeletal muscle are innervated by both excitatory and inhibitory neurons, blocking the activity of the inhibitory neurons with strychnine results in overstimulation of the motor neurons by the excitatory neurons.
8. GABA binds to a ligand-gated receptor and opens Cl^- channels, causing hyperpolarization of the postsynaptic membrane. Alcohol enhances binding of GABA to its receptors. Therefore, alcohol enhances the hyperpolarization effect of GABA on postsynaptic membranes for synapses in which GABA is a neurotransmitter. Finally, since chronic alcohol consumption makes the GABA receptors less sensitive to both alcohol and GABA, the postsynaptic membranes of people who consume alcohol chronically are hyperpolarized less by a given amount of GABA than are those of other people. Therefore, the membrane is less hyperpolarized in the absence of alcohol, and this triggers withdrawal symptoms. Benzodiazepine enhances the effect of GABA on its receptors, thus also enhancing the hyperpolarizing effect of GABA in synapses in which GABA is a neurotransmitter.
9. When the neurotoxin binds to ligand-gated Na^+ channels in the postsynaptic membrane of a skeletal muscle fiber, they open, and Na^+ enters the cell, producing graded potentials.

When the graded potentials reach threshold, an action potential is produced, stimulating the muscle fiber to contract. However, the neurotoxin tends to remain bound to the ligand-gated Na^+ channels, which prevents ACh from binding. Thus, the nervous system's ability to stimulate the muscle fiber decreases as more and more neurotoxin binds to ligand-gated Na^+ channels. Because the ligand-gated Na^+ channels with bound neurotoxin remain open, Na^+ continues to enter the muscle fiber, causing its resting membrane potential to depolarize. Eventually, the membrane becomes so depolarized that it is unresponsive to stimulation. Death from a cobra bite usually occurs because of paralysis of respiratory muscles.

10. A Na^+ channelopathy, in which Na^+ channels open more readily than normal or stay open longer than normal, could cause an increased production of action potentials. A Ca^{2+} channelopathy, in which more Ca^{2+} than normal enters the presynaptic terminal, could result in increased release of neurotransmitter from the presynaptic terminal and thus an increased production of action potentials.

Chapter 12

1. If the neuron with its cell body in the cerebrum is an inhibitory neuron and if it synapses with the motor neuron of a reflex arc, stimulation of the cerebral neuron can inhibit the reflex.
2. The phrenic nerve is cut in the thorax while the lung is being removed.
3. Pulling on the upper limb when it is raised over the head can damage the lower brachial plexus—in this case, the origin of the ulnar nerve. The ulnar nerve innervates muscles that abduct/adduct the fingers and flex the wrist.
4. The sciatic nerve has rootlets from L4 to S3. Depending on the rootlet compressed, pain can be felt in different locations.
5.
 - a. obturator nerve
 - b. femoral nerve
 - c. sciatic (tibial) nerve
 - d. obturator nerve
 - e. obturator nerve, some from femoral nerve
6. The plaster cast is pressing against the common fibular (peroneal) nerve at the neck of the fibula. Tingling is expected along the lateral and anterior leg and the dorsum of the foot.
7. Lack of sensation in the lower limbs and inability to move them are consequences of complete transection (transverse cut) of the spinal cord. Because Cecil could still breathe on his own, the phrenic nerves,

which innervate the diaphragm, must still be intact. The phrenic nerves originate from C3, C4, and C5, so the transection must have occurred below C5. Also, Cecil was able to move his upper limbs, and the upper arms are controlled by nerve fibers that originate from C3, C4, and C5. However, the hands and fingers (whose movement was somewhat impaired) are primarily controlled by nerve fibers that originate from C6, C7, C8, and T1. Thus, the transection is probably between C5 and C6 or between C6 and C7.

Chapter 13

1. If CSF does not drain properly, the fluid accumulates and exerts pressure on the brain (hydrocephalus). In the developing fetus, the ventricles enlarge because of the excess fluid pressure. The head also enlarges because the skull bones have not fused. However, the expansion of the head is not sufficient to relieve all the pressure exerted on the developing brain by the expanding ventricles. As a result, the cerebral cortex becomes proportionately thinner as it is compressed between the ventricles and the skull. In many cases, fewer gyri form in the cerebral cortex. Brain damage may or may not result, depending on the amount of excess CSF, the ventricular pressure generated, and the areas of the brain damaged by the pressure.
2. Enlargement of the lateral and third ventricles, without enlargement of the fourth ventricle, suggests a blockage between the third and fourth ventricles in the cerebral aqueduct. This defect, called aqueductal stenosis, is a common congenital problem.
3. Blood in the CSF taken through a spinal tap indicates the presence of blood in the subarachnoid space and suggests that the patient has a damaged blood vessel in the subarachnoid space.
4. I: Test vision; II: Have the person describe the smell of something placed under the nose; III: Test eye movement; IV: Test the ability to move the eye down and out; V: Test the sense of feeling in the face; VI: Test the ability to move the eye to the side; VII: Test the ability to taste an item on the front of the tongue and check for facial expression; VIII: Test the ability to hear; IX: Test the ability to swallow; X: Test the ability to swallow and check the uvula when the mouth is opened (the uvula will “point” away from the side where X is not working); XI: Test the ability to turn the head; XII: Have the person protrude his or her tongue (if XII is not functioning on one side, the tongue will “point” toward the damaged side).

5. The cerebellum, which is in charge of controlling coordinated muscle movement and maintaining muscle tone, was damaged in this patient.
6. The olfactory nerves (CN I) travel through the olfactory foramina within the cribriform plate of the ethmoid bone as they pass from the nasal epithelium to the olfactory bulbs (see table 13.5). In this case, the cribriform plate of the ethmoid bone was probably fractured, severing the connections of the olfactory nerves to the olfactory bulb and resulting in a loss of the sense of smell.
7. The abducens nerves supply the lateral rectus muscles, which are responsible for moving the eyes laterally (abducting the eyes). Damage to the abducens nerve on the left side reduced or eliminated Stanley's ability to abduct his left eye. The inability to move the left eye in concert with the right eye results in double vision.
8. Based on the source of pain, it appears that the maxillary branch of the trigeminal nerve on the right side is affected. This condition, known as trigeminal neuralgia, results in sharp bursts of pain that are often initiated by stimulation of a particular trigger area. Loss of tactile sensations from the affected area is likely to result. Because the main muscles of mastication are innervated by the mandibular branch of the trigeminal nerve, chewing is not greatly affected, and the maxillary branch of the trigeminal does not innervate the muscles of the pharynx and tongue that are critical for the swallowing process. Since Andy experiences no pain in the area of the nose or superior to the eyes, the ophthalmic branch of the trigeminal nerve does not appear to be involved.
9. It is likely that Afton experienced facial palsy (Bell palsy), which can be temporary. This condition may result from a stroke or a tumor, or it can be triggered by inflammation of the parotid gland, anesthesia, or exposure of the superficial branches of the nerve to cold (which is probably the cause in Afton's case). The loss of motor tone in the face is due to decreased innervation of the muscles of facial expression. Also, some muscles of the pharynx are affected, but these are not related to drooping of the face.

Chapter 14

1. The first sensations the woman perceives when she picks up an apple and bites into it are visual (special), tactile (general), and proprioceptive (general). The woman holds the apple in her hand and looks at it. The tactile sensations from mechanoreceptors in the hand tell her the apple is firm and smooth. The proprioceptive sensations originating in the joints of the hand tell her the size and shape of the apple. Visual input also tells her the size and color of the apple and that it has a smooth surface. As the woman bites into the apple and begins to chew, proprioceptive sensations from the teeth and jaws provide information on how widely she must open her mouth to accommodate the apple and how hard to bite down. Tactile sensations originating in the tongue and cheeks tell her the location of the bite of apple and its texture as it is moved about in the mouth. In chapter 15 you will learn that taste sensations (special, chemoreceptor) from the tongue indicate that the apple has both sweet and sour characteristics. Olfactory sensations (special) provide more specific information that the "fruity taste" is that of an apple.
2.
 - a. The most likely explanation is that the olfactory neurons have adapted and no longer respond to the odor stimulus.
 - b. The fact that people can hear the sound when they make a conscious effort indicates that the hair cells in the spiral organ have not adapted and are still able to detect the sound stimulus. Many action potentials arriving in the brain are prevented from causing conscious perception until we consciously "pay attention" to the stimulus. For example, you may not be paying attention to general conversations in a crowded room or hall until someone says your name. The sound of your name leaps out of the surrounding babble, and you are suddenly interested.
3. It is possible that the dorsal-column/medial-lemniscal system within the right side of the spinal cord was damaged. However, it is also possible that this system was damaged within the medulla oblongata, where neurons synapse and cross over to the left side of the brain, or within the tracts on the left side that ascend from the medulla oblongata to the thalamus. Another possibility is damage to the cerebral cortex on the left side. Additional information is needed to determine exactly where the injury is located.
4. The fibers of the lateral spinothalamic tract carry impulses for pain and temperature. A lesion in the area where these fibers decussate results in the bilateral loss of pain and temperature sensations only at the level of the lesion, but no loss of sensation below the lesion. This occurs because fibers decussating above or below the lesion, as well as tracts that pass lateral to the lesion, are unaffected. This disorder, called syringomyelia, is often caused by a spinal cord tumor.
5. The damaged tracts are the lateral corticospinal tract, controlling motor functions on the right side of the body, and the lateral spinothalamic tract for pain and temperature sensations from the left side of the body. Damage to these tracts in the right side of the spinal cord produces the observed symptoms because within the cord the lateral spinothalamic tract crosses over at the level of entry and is therefore located on the opposite side of the cord from its peripheral nerve endings, whereas the corticospinal tract lies on the same side of the cord as its target muscles.
6. Complete unilateral transection of the right side of the spinal cord would result in loss of motor function (lateral corticospinal tract), proprioception, and two-point discrimination (dorsal-column/medial-lemniscal system) on the same side of the body as the lesion, below the level of the lesion. Pain and temperature sensations (lateral spinothalamic tract) would be lost on the opposite side of the body from below the level of the lesion. These symptoms describe the Brown-Séquard syndrome. Light touch would not be greatly affected on either side because of the large number of collateral branches in the anterior spinothalamic tract.
7. Damage to the cerebellum can result in decreased muscle tone, balance impairment, a tendency to overshoot when reaching for or touching something, and an intention tremor. These symptoms are opposite those seen with basal ganglia dysfunction. Cerebellar dysfunction exhibits symptoms very similar to those seen in an inebriated person, and the same tests can be applied, such as having the person touch his or her nose or walk a straight line.
8. Memory for the 10 minutes prior to the accident was stored in short-term memory and was disrupted before it could be transferred to long-term memory. Anytime a person suffers a concussion, there is a possibility that postconcussion syndrome will develop later. Symptoms include muscle tension or migraine headaches, reduced alcohol tolerance, difficulty learning new things, reduction in creativity and motivation, fatigue, and personality changes. The syndrome may last a month to a year. Postconcussion syndrome may be the result of a slowly occurring subdural hematoma, which may be missed in an early examination.
9. The subdural hematoma is likely to be over the medial portion of the left side of the cerebral hemisphere in the area of the premotor cortex and expanding to the area of the primary motor cortex. The premotor area must be intact for a person to carry out complex, skilled, or learned movements, especially

those requiring manual dexterity. If blood is removed from the hematoma and if no more bleeding occurs, it is likely that Perry's motor movements will improve rapidly.

Chapter 15

1. The lens of the eye is biconvex and causes light rays to converge. If the lens is removed, the replacement lens should also cause light rays to converge. A biconvex lens or a lens with a single convex surface should work. Bifocals or trifocals can also be recommended to compensate for because of the loss of accommodation.
2. Carrots contain vitamin A (retinoic acid), which can be used to form retinal. Retinal and opsin combine to form rhodopsin, which is found in rods. Rhodopsin is necessary for rods to respond to low levels of light. Lack of vitamin A can result in lack of rhodopsin and night blindness.
3. This phenomenon is called a negative afterimage. While the man is staring at the clock, the darkest portion of the image (the black clock) causes dark adaptation in part of the retina—that is, part of the retina becomes more sensitive to light. At the same time, the lightest part of the image (the white wall) causes light adaptation in the rest of the retina, and that part of the retina becomes less sensitive to light. When the man looks at a white wall, the dark-adapted portion of the retina, which is more sensitive to light, produces more action potentials than does the light-adapted part of the retina. Consequently, he perceives a light clock against a darker background.
4. A lesion of the optic chiasm results in visual loss in both the right and left temporal fields, a condition called bitemporal hemianopsia, or tunnel vision. Tunnel vision can cause problems for normal functions, such as driving a car, because the peripheral vision is severely limited. This condition can also suggest a much more serious problem, such as a pituitary tumor just posterior to the optic chiasm.
5. Eyestrain, or eye fatigue, occurs primarily in the ciliary muscles. It occurs because close vision requires accommodation. Accommodation occurs as the ciliary muscles contract, releasing the tension of the suspensory ligaments and allowing the lens to become more rounded. Continued close vision requires the maintenance of accommodation, which requires that the ciliary muscles remain contracted for a long time, resulting in their fatigue.
6. The most likely area damaged is the spiral organ, where waves result in the production of action potentials. The action is much like

ocean waves breaking on the shore during a violent storm, compared with those breaking in from a calm ocean. Specifically, damage likely occurs in the part of the spiral organ near the oval window because this part of the basilar membrane vibrates the most in response to high-frequency sounds.

7. Normally, as pressure changes, the auditory tubes open to allow equalization of pressure between the middle ear and the external environment. If this does not occur, the built-up pressure in the middle ear can rupture the tympanic membrane, or the pressure can be transmitted to the inner ear and cause sensorineural damage.
8. Normally, airborne sounds cause the tympanic membrane to vibrate, resulting in the movement of the middle ear ossicles and the production of waves in the perilymph of the scala vestibuli. Vibration of the skull bones can also cause vibration of the perilymph in the scala vestibuli.

Chapter 16

1. The sympathetic division of the ANS is responsible for dilation of the pupil. Preganglionic fibers from the upper thoracic region of the spinal cord pass through spinal nerves (T1 and T2), into the white rami communicantes, and into the sympathetic chain ganglia. The preganglionic fibers ascend the sympathetic chain and synapse with postganglionic neurons in the superior cervical sympathetic chain ganglia. The axons of the postganglionic neurons leave the sympathetic chain ganglia as small nerves that project to the iris of the eye.
2. Reduced salivary and lacrimal gland secretions can indicate damage to the facial nerves, which innervate the submandibular, sublingual, and lacrimal glands. The glossopharyngeal nerves innervate the parotid glands, but not the lacrimal glands.
3.
 - a. pelvic splanchnic nerves
 - b. outflow of gray ramus
 - c. vagus nerve
 - d. oculomotor nerve
 - e. pelvic splanchnic nerve
4. Inactivation of acetylcholinesterase results in a buildup of acetylcholine in synapses and an overstimulation of muscarinic receptors. One would expect mostly parasympathetic effects because the effects of acetylcholine are enhanced: blurred vision as a result of contraction of ciliary muscles, excess tear formation because of overstimulation of the lacrimal glands, and frequent or involuntary urination because of overstimulation of the urinary bladder. Pallor resulting from vasoconstriction in the skin is a sympathetic effect that would not be

expected because skin blood vessels respond to norepinephrine. Muscle twitching or cramps of skeletal muscles might occur because they normally respond to acetylcholine. Atropine, a muscarinic blocking agent, can be used to treat exposure to malathion.

5. Epinephrine causes vasoconstriction and confines the drug to the site of administration. This increases the drug's duration of action locally and decreases its systemic effects. Vasoconstriction also reduces bleeding if a dry field (an area clear of blood on its surface) is required.
6. Because normal action potentials are produced, the drug does not act at the synapse between the preganglionic and postganglionic neurons. Because injected norepinephrine works, sympathetic receptors in the heart are functioning and are not affected by the drug. Therefore, the drug must somehow affect the postganglionic neurons. Possibly it inhibits neurotransmitter production or release from the postganglionic neurons.
7. Because cutting the white rami of T1–T4 does not affect the drug's action, sympathetic preganglionic neurons in the spinal cord and sympathetic centers in the brain can be ruled out as a site of action. Because cutting the vagus nerves eliminates the drug's effect, the drug cannot be acting at the synapse between the preganglionic neurons and the postganglionic neurons, or between the synapse of the postganglionic neuron and the effector of either division of the ANS. The drug must therefore excite parasympathetic centers in the brainstem, resulting in decreased heart rate.
8.
 - a. Responses in a person who is extremely angry are primarily controlled by the sympathetic division of the ANS. These responses include increased heart rate and blood pressure, decreased blood flow to the internal organs, increased blood flow to skeletal muscles, decreased contractions of the intestinal smooth muscle, flushed skin in the face and neck region, and dilation of the pupils of the eyes.
 - b. For a person who has just finished eating and is relaxing, parasympathetic reflexes are more important than sympathetic reflexes. The blood pressure and heart rate are at normal resting levels, the blood flow to the internal organs is greater, contractions of smooth muscle in the intestines are greater, and secretions that achieve digestion are more active. If the urinary bladder or the colon becomes distended, autonomic reflexes that result in urination or defecation can result. Blood flow to the skeletal muscles is reduced.

Chapter 17

1. Liver disease and kidney disease would increase the concentration of this hormone in the blood, and the concentration would remain high for a longer time. The liver modifies the hormone to cause it to be excreted by the kidneys more rapidly. In the case of liver disease, the hormone is not modified and excreted rapidly. Therefore, the concentration becomes higher than normal, and the high concentration remains for longer than normal. A similar result is seen if the kidneys are diseased and the hormone cannot be excreted rapidly.
2. Secretion of hormones is usually controlled by negative feedback. If a hormone controls the concentration of a substance in the circulatory system, the hormone is secreted in smaller amounts if the substance increases in the circulatory system. If a tumor begins to secrete the substance in large amounts, the presence of the substance has a negative-feedback effect on the secretion of the hormone, and the concentration of the hormone in the circulatory system is very low.
3. Usually, intracellular mediator mechanisms respond quickly, and the hormone's effect is brief. Nuclear receptor mechanisms usually take a long time (several hours) to respond, and their effects last much longer. If the hormone is large and water-soluble, it is probably functioning through an intracellular mediator mechanism; if the hormone is lipid-soluble, it is probably a nuclear receptor mechanism. If you have the ability to monitor the concentration of a suspected intracellular mediator and it increases in response to the hormone, or if you can inhibit the synthesis of an intracellular mediator and it prevents the target cells' response to the hormone, it is an intracellular mediator mechanism. If you can inhibit the synthesis of mRNA and this inhibits the action of the hormone, or if you can measure an increase in mRNA synthesis in response to the hormone, then the mechanism is a nuclear receptor mechanism.
4. When the hormone binds to its receptor, the α subunit of the G protein is released. However, GTP must bind to the α subunit before it can have its normal effect. If the α subunit cannot bind to GTP, the hormone has no effect on the target tissue.
5. Phosphodiesterase causes the conversion of cAMP to AMP, thus reducing the concentration of cAMP. Therefore, a drug that inhibits phosphodiesterase increases the amount of cAMP in cells where cAMP is produced. Thus, an inhibitor of phosphodiesterase increases a tissue's response to a hormone that has cAMP as an intracellular mediator.

6. Epinephrine's shorter half-life allows it to produce a short-lived response. The response to a potentially harmful situation is terminated shortly after the situation passes. If epinephrine had a longer half-life, the heart rate and the blood glucose level would be elevated for a long time, even if the harmful situation were very brief.
7. Because thyroid hormones are important in regulating the basal metabolic rate, their long half-life is an advantage. Thyroid hormones are secreted and have a prolonged effect without large fluctuations in the basal metabolic rate. If thyroid hormones had a short half-life, the basal metabolic rate could fluctuate with changes in the rate of secretion of thyroid hormones. Certainly, the rate of secretion of thyroid hormones would have to be controlled within narrow limits if it did have a short half-life.
8. Elevated GnRH levels in the blood as a result of the GnRH-secreting tumor would cause the down-regulation of GnRH receptors in the anterior pituitary. This would decrease the ability of GnRH to stimulate the anterior pituitary, and the rate of LH and FSH secretion by the anterior pituitary would decrease and remain decreased as long as the GnRH levels were chronically elevated. Therefore, the functions of the reproductive system controlled by LH and FSH would decrease.
9. Insulin levels normally change in order to maintain normal blood sugar levels, despite periodic fluctuations in sugar intake. A constant supply of insulin from a skin patch might result in insulin levels that are too low when blood sugar levels are high (after a meal) and might be too high when blood sugar levels are low (between meals). In addition, insulin is a protein hormone that would not readily diffuse through the lipid barrier of the skin (see chapter 5).

Chapter 18

1. The hypothalamohypophysial portal system allows neurohormones that function as releasing and inhibiting hormones, which are secreted by neurons in the hypothalamus, to be carried directly from the hypothalamus to the anterior pituitary gland. Consequently, the releasing and inhibiting hormones are not diluted or destroyed by the enzymes, which are abundant in the kidneys, liver, lungs, and general circulation, before they reach the anterior pituitary. Also, the time it takes for releasing and inhibiting hormones to reach the anterior pituitary is less than if they were secreted into the general circulation.

2. Polydipsia and polyuria are consistent with both diabetes mellitus and diabetes insipidus. Diabetes mellitus, however, is consistent with an increased urine osmolality because of the large amount of glucose lost in the urine. Diabetes insipidus is consistent with urine with a low specific gravity because little water is reabsorbed by the kidneys. Thus, urine has an osmolality close to that of the body fluids, and the rapid loss of dilute urine results in a decrease in blood pressure. Therefore, polyuria with a low specific gravity is consistent with diabetes insipidus but not with diabetes mellitus. The administration of ADH would reverse the symptoms of diabetes insipidus. Neither polydipsia nor polyuria results from a lack of glucagon or aldosterone.
3. The symptoms are consistent with acromegaly, which is a consequence of elevated GH secretion after the epiphyses have closed. Increased GH causes enlarged finger bones, the growth of bony ridges over the eyes, and increased growth of the jaw. The anterior pituitary tumor increases pressure at the base of the brain near the optic nerves as it enlarges. The pituitary rests in the sella turcica of the sphenoid bone; as it enlarges, pressure increases because the pituitary is nearly surrounded by rigid bone, and the brain is located just superior to the pituitary. As the anterior pituitary enlarges because of a tumor, it pushes superiorly, and pressure is applied to the ventral portion of the brain. In addition, the GH causes bone deposition on the inner surface of skull bones, which also increases the pressure inside the skull.
4. If hyperthyroidism results from a pituitary abnormality, laboratory tests should show elevated TSH levels in the circulatory system in addition to elevated T_3 and T_4 levels. If hyperthyroidism results from the production of a nonpituitary thyroid-stimulating substance, laboratory tests should also show elevated T_3 and T_4 levels, but TSH levels will be low because of the negative-feedback effects of T_3 and T_4 on the hypothalamus and pituitary gland.
5. It is likely that Julie's elevated ACTH levels are causing elevated blood levels of cortisol, which in turn are causing the observed symptoms. The elevated ACTH levels are probably due to a hormone-secreting tumor (adenoma) in the anterior pituitary gland. According to National Institutes of Health sources, pituitary adenomas cause 70% of Cushing syndrome cases, excluding those caused by glucocorticoid use. Most people with the disorder have a single adenoma. Cushing syndrome affects women five times

more often than men. The most widely used treatment is surgical removal of the tumor, known as transsphenoidal adenectomy. Using a special microscope and fine instruments, the surgeon approaches the pituitary gland through a nostril or an opening made below the upper lip. Because this procedure is extremely delicate, patients are often referred to centers specializing in this type of surgery. The success rate of this procedure is more than 80% when performed by a surgeon with extensive experience. If surgery fails or produces only a temporary cure, the surgery can be repeated, often with good results. Radiation of the pituitary gland is another possible treatment.

6. The second student is correct. Low levels of vitamin D reduce calcium uptake in the digestive tract, which results in a decreased blood level of calcium ions. As blood calcium levels decrease, the rate of PTH secretion increases. Parathyroid hormone increases bone breakdown, which maintains blood calcium levels, even if vitamin D deficiency exists for a prolonged time. Osteomalacia results because of the increased bone reabsorption necessary to maintain normal blood calcium levels.
7. Because the person is diabetic and probably taking insulin, insulin shock is more likely than diabetic coma. To confirm the condition, however, a blood sample should be taken. If the condition is due to diabetic coma, the blood glucose levels will be elevated. If the condition is due to insulin shock, the blood glucose levels will be below normal. In the case of insulin shock, glucose can be administered intravenously. In the case of diabetic coma, insulin should be administered. An isotonic solution containing insulin can be administered to reduce the osmolality of the extracellular fluid.
8. Elevated epinephrine from the adrenal medulla promotes elevated blood pressure and increases the workload on the heart, increases the rate of metabolism, and results in increased sweating and nervousness. The risks for heart attack and stroke are increased. Elevated cortisol causes hyperglycemia and can lead to diabetes mellitus, a depressed immune system with increased susceptibility to infections, and the destruction of proteins, leading to tissue wasting.
9. We learn that Katie has androgen insensitivity syndrome. The name suggests that her tissues are not sensitive to androgens (malelike hormones). We learned that a tissue responds to hormones on the presence of specific receptors. With androgen

insensitivity syndrome, the endocrine malfunction is not the production of the hormone, as in insulin-dependent (type I) diabetes mellitus, but the presence of the receptor in the target cells. Even though her cells produce plenty of the hormone testosterone, the target cells do not respond because the testosterone receptor has malfunctioned and does not recognize testosterone. Katie's feminine appearance is a direct result of the lack of a normal male body because her tissues were resistant to testosterone, which is responsible for growth of the male genitalia and other sex characteristics (see table 18.12 and chapter 19). Therefore, externally Katie looked female when she was born. Without testosterone working in her body or her brain and without normal social cues to associate with other males, she had always identified herself as female and was devastated to learn she could not have children. Her doctor and mother decided to wait until she was older to explain the entire condition to her.

Chapter 19

1. Because of the rapid destruction of the red blood cells, we would expect erythropoiesis to increase in an attempt to replace the lost red blood cells. The reticulocyte count would therefore be above normal. Jaundice is a symptom of hereditary hemolytic anemia because the destroyed red blood cells release hemoglobin, which is converted into bilirubin. Removal of the spleen cures the disease because the spleen is the major site of red blood cell destruction.
2. Blood doping increases the number of red blood cells in the blood, thereby increasing its oxygen-carrying capacity. The increased number of red blood cells also makes it more difficult for the blood to flow through the blood vessels, increasing the heart's workload.
3. The correct answer is *c*. Ben's red blood cells are of normal size. However, his reticulocyte level is low, which indicates a reduced rate of red blood cell synthesis. The low red blood cell count is also consistent with a reduced rate of red blood cell synthesis. Hemoglobin concentration and hematocrit are low, both of which are consistent with the reduced red blood cell count. The prothrombin time is longer than normal, the prothrombin count is low, and the platelet count is low. All these observations are consistent with aplastic anemia, in which the stem cells that produce blood cells in the red marrow are damaged. Chemicals such as benzene and chloramphenicol can also destroy red marrow cells and cause aplastic anemia.

4. Hypoventilation results in decreased blood oxygen levels, which stimulate erythropoiesis. Therefore, the number of red blood cells increases and produces secondary polycythemia.
5. Vitamin B₁₂ and folic acid are necessary for blood cell division. Lack of these vitamins results in pernicious anemia. Iron is necessary for the production of hemoglobin. Lack of iron results in iron-deficiency anemia. Vitamin K is necessary for the production of many blood clotting factors. Lack of vitamin K can greatly increase blood clotting time, resulting in excessive bleeding.
6. Grace has hemolytic anemia. The RBC is lower than normal because the red blood cells are being destroyed faster than they are being replaced. With fewer red blood cells, hemoglobin and hematocrit are lower than normal. Bilirubin levels are above normal because of the breakdown of the hemoglobin released from the ruptured red blood cells.
7. The correct answer is *c*. As Pam went from a lower to a higher elevation, the barometric pressure decreased; therefore, the availability of oxygen in the air also decreased. Consequently, as Pam moved from sea level to a higher elevation, her kidneys secreted greater amounts of erythropoietin, and red blood cell synthesis increased. After about 4 days in Jackson Hole, Pam's blood should have increased numbers of reticulocytes and red blood cells. By day 6, Pam's red blood cell count had increased significantly and was still rising. Changes in oxygen levels should not affect platelet count.

Chapter 20

1. The walls of the ventricles are thicker than the walls of the atria because the ventricles must produce a greater pressure to pump blood into the arteries. Only a small pressure is required to pump blood from the atria into the ventricles during diastole. The wall of the left ventricle is thicker than the wall of the right ventricle because the left ventricle produces a much greater pressure to force blood through the aorta than the right ventricle produces to move blood through the pulmonary trunk and pulmonary arteries.
2. During systole, the cardiac muscle in the right and left ventricles contracts, which compresses the coronary arteries. During diastole, the cardiac muscle of the ventricles relaxes, and blood flow through the coronary arteries increases. The diastolic pressure is sufficient to cause blood to flow through the coronary arteries during diastole.
3. Contraction of the ventricles, beginning at the apex and moving toward the base of the

- heart, forces blood out of the ventricles and toward their outflow vessels—the aorta and pulmonary trunks. The aorta and pulmonary trunks are located at the base of the heart.
4. Ectopic foci cause various regions of the heart to contract at different times. Ectopic action potentials in the ventricles cause the areas in which the action potentials develop to contract independently of all other areas of the ventricles. As a result, the coordinated contraction of ventricular cardiac muscle is interrupted, and pumping effectiveness is reduced. The normal filling and emptying of the ventricles during the cardiac cycle is also interrupted.
 5. A drug that prolongs the plateau of cardiac muscle cell action potentials prolongs the time each action potential exists and increases the refractory period. Therefore, the drug slows the heart. A drug that shortens the plateau shortens the length of time each action potential exists and shortens the refractory period. Therefore, the drug can allow the heart rate to increase further.
 6. Endurance-trained athletes have a decreased resting heart rate because their cardiac muscle undergoes hypertrophy in response to exercise. The hypertrophied cardiac muscle causes the stroke volume to increase substantially. The increased stroke volume is sufficient to maintain an adequate cardiac output and blood pressure even though the heart rate is slower.
 7. The two heartbeats occurring closely together can be heard through the stethoscope because the heart valves open and close normally during each of the heartbeats even if they are close together. The second heartbeat, however, produces a greatly reduced stroke volume because there is not enough time for the ventricles to fill with blood between the first and second contractions. Thus, the preload is reduced. Because the preload is reduced, the second heartbeat has a greatly reduced stroke volume, which fails to produce a normal pulse. The pulse deficit results from the reduced stroke volume of the second of the two beats that are very close together.
 8. Atrial contractions complete ventricular filling, but they are not primarily responsible for ventricular filling. Therefore, even if the atria are fibrillating, blood can still flow into the ventricles, and ventricular contractions can occur. As long as the ventricles contract rhythmically, the heart can pump an adequate amount of blood, even though the atria are not effective pumps. However, if the ventricles fail to contract forcefully and rhythmically, they cannot function as pumps. Thus, the stroke volume will become too low to maintain adequate blood flow to tissues. Therefore, atria transplants are not essential but ventricle transplants are.
 9. An ECG measures the electrical activity of the heart and would not indicate a slight heart murmur. Heart murmurs are detected by listening to the heart sounds. The boy may have a heart murmur, but the mother does not understand the basis for making such a diagnosis.
 10. When both common carotid arteries are clamped, the blood pressure within the internal carotid arteries drops dramatically. The decreased blood pressure is detected, and the baroreceptor reflex increases heart rate and stroke volume. The resulting increase in cardiac output causes the increase in blood pressure.
 11. Venous return declines markedly in hemorrhagic shock because of the loss of blood volume. With decreased venous return, stroke volume decreases (Starling law of the heart). The decreased stroke volume results in a decreased cardiac output, which produces decreased blood pressure. In response to the decreased blood pressure, the baroreceptor reflex causes an increase in heart rate in an attempt to restore normal blood pressure. However, with inadequate venous return, the increased heart rate is not able to restore normal blood pressure.
- ## Chapter 21
1.
 - a. aorta, left coronary artery, circumflex artery, posterior interventricular artery or aorta, right coronary artery, posterior interventricular artery
 - b. aorta, brachiocephalic artery, right common carotid artery, right internal carotid artery or aorta, left common carotid artery, left internal carotid artery
 - c. aorta, brachiocephalic artery, right subclavian artery, right vertebral artery, basilar artery or aorta, left subclavian artery, left vertebral artery, basilar artery
 - d. aorta, left or right common carotid artery, left or right external carotid artery
 - e. aorta, left subclavian artery, axillary artery, brachial artery, radial or ulnar artery, deep or superficial palmar arch, digital artery (on the right: the brachiocephalic artery would be included)
 - f. aorta, common iliac artery, external iliac artery, femoral artery, popliteal artery, anterior tibial artery
 - g. aorta, celiac artery, common hepatic artery
 - h. aorta, superior mesenteric artery, intestinal branches
 - i. aorta, left or right internal iliac artery
 2.
 - a. great cardiac vein, coronary sinus or anterior cardiac vein
 - b. transverse sinus, sigmoid sinus, internal jugular vein, brachiocephalic vein, superior vena cava
 - c. retromandibular vein, external jugular vein, subclavian vein, brachiocephalic vein, superior vena cava
 - d. *deep*: vein of hand, radial or ulnar vein, brachial vein, axillary vein, subclavian vein, brachiocephalic vein, superior vena cava
superficial: vein of hand, radial or ulnar vein, cephalic or basilic vein, axillary vein, subclavian vein, brachiocephalic vein, superior vena cava
 - e. *deep*: vein of foot, dorsalis veins of foot, anterior tibial vein, popliteal vein, femoral vein, external iliac vein, common iliac vein, inferior vena cava
superficial: vein of foot, great saphenous vein, external iliac vein, common iliac vein, inferior vena cava; or vein of foot, small saphenous vein, popliteal vein, femoral vein, external iliac vein, common iliac vein, inferior vena cava
 - f. gastric vein or gastroepiploic vein, hepatic portal vein, hepatic sinusoids, hepatic vein, inferior vena cava
 - g. renal vein, inferior vena cava
 - h. hemiazygous vein or accessory hemiazygous vein, azygous vein, superior vena cava
 3. A superficial vessel is easiest, such as the right cephalic or basilic vein. The catheter is passed through the cephalic (or brachial) vein and the superior vena cava to the right atrium. Because the pulmonary veins are not readily accessible, dye is not normally placed directly into them. Instead, the dye is placed in the right atrium using the procedure just described. The dye passes from the right atrium into the right ventricle, the pulmonary arteries, the lungs, the pulmonary veins, and the left atrium. If the catheter has to be placed into the left atrium, it can be inserted through an artery, such as the femoral artery, and passed via the aorta to the left ventricle and then into the left atrium.
 4. The resistance to blood flow is less in the venae cavae for two reasons: First, the diameter of one vena cava is greater than the diameter of the aorta; second, an increased diameter of a blood vessel reduces resistance to flow (Poiseuille's law). In addition, there are two venae cavae, the superior vena cava and the inferior vena cava, but only one aorta. The blood flow through the aorta and the venae cavae is about equal, but the velocity of blood flow is much higher in the aorta than it is in the venae cavae.
 5. According to Laplace's law, as the diameter of a blood vessel increases, the force

applied to the vessel wall increases, even if the pressure remains constant. The increased connective tissue in the walls of the large blood vessels makes the wall of those vessels stronger and more capable of resisting the force applied to the wall.

6. The nursing student's diagnosis is incorrect. Blood pressure measurements are normally made in either the right or the left arm, both of which are close to the level of the heart. Blood pressure taken in the leg is influenced by pressure created by the pumping action of the heart, but the effect of gravity on the blood, as it flows into the leg, also influences the blood pressure in a substantial way. In this case, gravity increases blood pressure from about 120 mm Hg systolic to 200 mm Hg.
7. Decreased liver function includes a decrease in the synthesis of plasma proteins. Consequently, the concentration of plasma proteins decreases, and the colloid osmotic pressure of the blood decreases. Less water moves by osmosis into the capillaries at the venous ends, and edemas result.
8. Chemoreceptors in the medulla oblongata detect carbon dioxide and the pH of the blood. The normal blood levels of CO₂ and pH stimulate these chemoreceptors, which in turn stimulate the vasomotor center. The vasomotor center keeps blood vessels partially constricted under resting conditions. This basal level of activity is called vasomotor tone. Blowing off CO₂ reduces the blood levels of carbon dioxide and increases the pH of the body fluids. These changes reduce vasomotor tone and result in vasodilation. If a person hyperventilates and blows off CO₂, the stimulus to the vasomotor center decreases, which results in a decrease in vasomotor tone. The decrease in vasomotor tone results in a decrease in systemic blood pressure. If the blood pressure decreases enough, the blood flow to the brain decreases and can cause a sensation of dizziness or even loss of consciousness.
9. Epinephrine is secreted from the adrenal medulla in response to stressful stimuli. The responses it stimulates are consistent with increased physical activity. Vasoconstriction of the blood vessels in the skin shunts blood away from the skin to skeletal muscles. Vasodilation occurs in blood vessels of exercising skeletal muscles. Blood flow through the exercising skeletal muscles increases. Because epinephrine causes vasodilation of the blood vessels of cardiac muscle, blood flow through the cardiac muscle increases. This response is consistent with the increased work performed by the heart under conditions of increased physical activity.

10. Answer *b* is correct. Shortly after Dick was wounded, the loss of blood caused his blood pressure to decrease. Rapidly, the baroreceptor and adrenal medullary mechanisms were activated. His heart rate increased, and peripheral vasoconstriction increased as a result. There is no indication that the CNS ischemic response was activated, because it requires a severe decrease in blood flow to the brain. The renin-angiotensin-aldosterone mechanism is activated as the systemic blood pressure decreases. Angiotensin II is a potent vasoconstrictor that helps the baroreceptor mechanism increase peripheral resistance. The increase in aldosterone secretion increases Na⁺ and, consequently, water reabsorption in the kidneys, but it requires approximately 24 hours to be active. The fluid shift mechanism operates, but it takes several hours to function. The ADH mechanism is activated in response to a substantial decrease in blood pressure; it helps maintain blood volume by reducing the amount of urine produced.
11. The answer is *e*. It is possible that Mr. Wilson had a stroke, which activated the CNS ischemic response. The fact that he was unconscious is consistent with a stroke, and his rapid heart rate and high blood pressure are consistent with activation of the CNS ischemic response. A heart attack would not necessarily cause Mr. Wilson to be unconscious and would be associated with decreased blood pressure rather than increased blood pressure, especially if it caused unconsciousness. Shock would also be associated with a decrease in blood pressure.

Chapter 22

1. Elevating the limb reduces blood pressure in the limb, resulting in less fluid movement from the blood into the tissues (see chapter 21). Thus, the edema is reduced as fluid moves out of the tissues faster than it enters them. Massage moves lymph through the lymphatic vessels in the same fashion as the contraction of skeletal muscle does. The periodic application of pressure to lymphatic vessels forces lymph to flow toward the trunk of the body, but valves prevent flow in the reverse direction. The removal of lymph from the tissue helps relieve edema.
2. Normally, T cells are processed in the thymus and then migrate to other lymphatic tissues. Without the thymus, this processing is prevented. Because there are normally five T cells for every one B cell, the number of lymphocytes is greatly reduced. The loss of T cells results in an increased susceptibility to infections and an inability to reject grafts because of the loss of cell-mediated immunity.

In addition, since helper T cells are involved with the activation of B cells, antibody-mediated immunity is also depressed.

3. That there is no immediate effect indicates a reservoir of T cells exists in the lymphatic tissue. As the reservoir is depleted over time, the number of lymphocytes decreases and cell-mediated immunity is depressed, the animal becomes more susceptible to infections, and the ability to reject grafts decreases. The ability to produce antibodies decreases because of the loss of helper T cells that are normally involved with the activation of B cells.
4. Injection B results in the greater amount of antibody production. At first, the antigen causes a primary response. A few weeks later, the slowly released antigen causes a secondary response, resulting in greatly increased production of antibodies. Injection A does not cause a secondary response because all of the antigen is eliminated by the primary response.
5. If the patient has already been vaccinated, the booster shot stimulates a memory (secondary) response and rapid production of antibodies against the toxin. If the patient has never been vaccinated, vaccinating now is not effective because there is not enough time for the patient to develop his or her own primary response. Therefore, antiserum is given to provide immediate, but temporary, protection. Sometimes both are given: The antiserum provides short-term protection, and the tetanus vaccine stimulates the patient's immune system to provide long-term protection. If the shots are given at the same location in the body, the antiserum (antibodies against the tetanus toxin) can cancel the effects of the tetanus vaccine (tetanus toxin is altered to be nonharmful).
6. The infant's antibody-mediated immunity is not functioning properly, whereas his cell-mediated immunity is working properly. This explains his susceptibility to extracellular bacterial infections and his resistance to intracellular viral infections. It took so long to become apparent because IgG from the mother crossed the placenta and provided the infant with protection. The infant began to get sick after these antibodies degraded.
7. (a) At the first location, an antibody-mediated response resulted in an immediate hypersensitivity reaction, which produced inflammation. Most likely, the response resulted from IgE antibodies. (b) At the second location, a cell-mediated response resulted in a delayed hypersensitivity reaction, which produced inflammation. This probably involved the release of cytokines and the lysis of cells. (c) At the

other locations, neither an antibody-mediated nor a cell-mediated response occurred.

8. The ointment was a good idea for the poison ivy, which causes a delayed hypersensitivity reaction—for example, too much inflammation. For the scrape, it was a bad idea because a normal amount of inflammation is beneficial and helps fight infection.
9. The correct answer is *b*. The immune response that occurred in the next several hours was primarily the innate immune response. Tissue was damaged, and mediators of inflammation were released. As a consequence, there were increases in capillary permeability, coagulation of blood, and chemotaxis of neutrophils; all are components of inflammation and the innate immune response. Increased mitosis of memory B cells is likely, but more than a few hours would be required, and it is most likely to occur in response to antigens. Bacteria and other antigens may enter the wound, and an adaptive immune response may result, but this, too, would take more than several hours to occur.
10. The correct answer is *a*. Upon first exposure to a type of antigen, the unprocessed antigens are ingested by macrophages, and the ingested antigens are broken down to fragments as they are processed. The processed antigen fragments are combined with MCH II molecules and transported to the cells' surfaces. A specific helper T cell recognizes the processed antigens bound to the MCH II molecules (the MHC II complex) at the macrophages' surfaces and binds to the MHC II complexes. Costimulation occurs, and interleukin-1 is released from the macrophages, while interleukin-2 is released from the T lymphocytes. As a result, the helper T cells undergo mitosis (see figure 22.17).

Chapter 23

1. We expect vital capacity to be greatest when standing because the abdominal organs move inferiorly, thereby allowing greater depression of the diaphragm and a greater inspiratory reserve volume.
2. The hose increases dead space and therefore decreases alveolar ventilation. Ima Diver has to compensate by increasing respiratory rate or tidal volume. If the hose is too long, she will not be able to compensate. Furthermore, with a long hose, air is simply moved back and forth in the hose, so that little exchange of air between the atmosphere and the lungs takes place. Another consideration is the effect of water pressure on the thorax, which decreases compliance and increases the work of ventilation. In fact, a few feet under

water, there is enough pressure on the thorax to prevent the intake of air, even through a short hose connected to the atmosphere.

3. The increase in atmospheric pressure increases the partial pressure of oxygen. According to Henry's law, as the partial pressure of oxygen increases, the amount of oxygen dissolved in the body fluids increases. The increase in dissolved oxygen is detrimental to the gangrene bacteria. Because hemoglobin is already saturated with oxygen, the HBO treatment does not increase hemoglobin's ability to pick up oxygen in the lungs.
4. The patient's lungs expand because of the pressure generated by the rescuer's muscles of expiration. This fills the lungs with air that has a greater pressure than atmospheric pressure. Air flows out of the patient's lungs as a result of this pressure difference and because of the recoil of the thorax and lungs. Although the partial pressure of oxygen of the rescuer's expired air is less than atmospheric pressure, enough oxygen can be provided to sustain the patient. The lower partial pressure of oxygen can also activate the chemoreceptor reflex and stimulate the patient to breathe. In addition, the rescuer's partial pressure of carbon dioxide is higher than atmospheric pressure, and this can activate the chemosensitive area in the medulla.
5. The left side of the diaphragm moves superiorly. During inspiration, thoracic volume increases as the right side of the diaphragm moves inferiorly and the intercostal muscles move the ribs outward. Increased thoracic volume causes a decrease in pressure in the thoracic cavity. As a result, the pressure on the superior surface of the diaphragm is less than on the inferior surface. The paralyzed left side of the diaphragm moves superiorly because of this pressure difference.
6. At the end of expiration, the thoracic wall is not moving. Therefore, the forces causing the thoracic wall to move inward and outward must be equal. At the end of expiration, the lungs are adhering to the thoracic wall through the pleurae, and recoil of the lungs is pulling the thoracic wall inward. As a result of the pneumothorax, air enters the pleural cavity and the visceral and parietal pleurae separate from each other. The recoil of the lungs causes them to collapse. Without the inward force produced by lung recoil, the thoracic wall expands outward.
7. All else being equal (i.e., the thickness of the respiratory membrane, the diffusion coefficient of the gas, and the surface area of the respiratory membrane), diffusion is a function of the partial pressure difference of the gas across the respiratory membrane. The greater the difference in partial pressure, the greater the rate of diffusion. The greatest rate of oxygen diffusion should therefore occur at the end of inspiration, when the partial pressure of oxygen in the alveoli is at its highest. The greatest rate of carbon dioxide diffusion should occur at the end of inspiration, when the partial pressure of carbon dioxide in the alveoli is at its lowest.
8. EPO increases the number of red blood cells and consequently the blood viscosity. Thus, even though the blood has a higher oxygen-carrying capacity, it increases the workload on the heart and can cause a heart attack or stroke.
9. (a) Cutting the vagus nerves would eliminate the Hering-Breuer reflex and result in greater than normal inspiration. This would increase tidal volume. (b) Cutting the phrenic nerves would eliminate contraction of the diaphragm. Tidal volume would decrease drastically, and death would probably result. Cutting the intercostal nerves would eliminate raising of the ribs and sternum and decreased tidal volume, unless the diaphragm compensated.
10. While hyperventilating and making ready to leave your instructor behind, you might make the following arguments:
 - I would argue that hyperventilation increases the oxygen content of the air in the lungs; therefore, you would have more oxygen to use when holding your breath.
 - It is hemoglobin that is saturated. Hyperventilation increases the amount of oxygen dissolved in the blood plasma.
 - Hyperventilation decreases the amount of carbon dioxide in the blood. This makes it possible to hold your breath longer because of a decreased urge to take a breath.
 - Hyperventilation activates alveoli not in use because increasing alveolar oxygen and decreasing alveolar carbon dioxide cause lung arterioles to relax, thereby increasing blood flow through the lungs.
11. When Ima is hyperventilating, the stimulus for the hyperventilation is anxiety, which is more important than the carbon dioxide in controlling respiratory movements. As the blood levels of carbon dioxide decrease during hyperventilation, vasodilation occurs in the periphery. As a result, the systemic blood pressure decreases. The systemic blood pressure can decrease enough that blood flow to the brain decreases. Decreased blood flow to the brain results in a reduced oxygen level in the brain tissue, causing dizziness. Breathing into a paper bag raised Ima's

blood levels of carbon dioxide toward normal. Because the carbon dioxide did not rise above normal, it did not increase the urge to breathe. The more normal level of carbon dioxide prevented peripheral vasodilation. As Ima breathed into the paper bag, her anxiety likely subsided, allowing the normal regulation of respiration to resume.

Chapter 24

1. With the loss of the swallowing reflex, the vocal folds no longer occlude the glottis. Consequently, vomit can enter the larynx and block the respiratory tract.
2. Without adequate amounts of hydrochloric acid, the pH in the stomach is not low enough for the activation of pepsin. This loss of pepsin function would result in inadequate protein digestion. However, if the food is well chewed, proteolytic enzymes in the small intestine (e.g., trypsin, chymotrypsin) can still digest the protein. If the stomach secretion of intrinsic factor decreases, the absorption of vitamin B₁₂ is hindered. Inadequate amounts of vitamin B₁₂ can result in decreased red blood cell production (pernicious anemia).
3. Even though ulcers are usually caused by bacteria, overproduction of hydrochloric acid due to stress is a possible contributing factor. Reducing hydrochloric acid production is recommended. In addition to antibiotic therapy, commonly recommended treatments include relaxation, drugs that reduce stomach acid secretion, and antacids to neutralize the hydrochloric acid. Smaller meals are also advised because distension of the stomach stimulates acid production. In addition, proper diet is important, and patients are advised to avoid alcohol, caffeine, and large amounts of protein because they stimulate acid production. Stress also stimulates the sympathetic nervous system, which inhibits duodenal gland secretion. As a result, the duodenum has less mucous coating, making it more susceptible to gastric acid and enzymes. Relaxing after a meal helps decrease sympathetic activities and increase parasympathetic activities.
4. Blockage of the common bile duct can result in jaundice (due to an accumulation of bile pigments in the blood) and clay-colored stools (due to lack of bile pigments in the feces). Other symptoms include abdominal pain, nausea, and vomiting. In addition, fat absorption is impaired because of the absence of bile salts in the duodenum, and a loose, bulky stool results. Lack of fat absorption reduces the absorption of fat-soluble vitamins, such as vitamin K, impairing normal clotting function.

5. The patient is still able to defecate. Following a meal, the gastrocolic and duodenocolic reflexes initiate mass movement of the feces into the rectum. In the rectum, local reflexes and the defecation reflex (integrated in the sacral level of the cord and not requiring connections to high brain centers) cause defecation. However, the patient loses awareness of the need to defecate (due to loss of sensory input to the brain) and the ability to prevent defecation voluntarily via the external anal sphincter.
6. Cholera toxin irreversibly activates a G protein that causes persistent activation of the chloride channel. The activated channel allows excessive movements of chloride from the cells into the digestive tract. Water follows the osmotic gradient generated by the chloride, which leads to diarrhea. Conversely, mutations in the channel reduce the movement of chloride into the digestive tract. A thick mucus builds up on the surface of the epithelial cells, leading to some symptoms of cystic fibrosis.
7. Oral rehydration therapy relies on the principle of osmosis. Water follows solutes as they are absorbed across the intestinal epithelium. The combination of sodium and glucose is optimal, since the two molecules are cotransported by a symporter that is driven by a sodium gradient established by the Na⁺-K⁺ pump. Hence, the presence of sodium aids glucose absorption. Fructose is absorbed by a facilitated diffusion transporter that is not coupled to a sodium gradient.
8. Dietary changes are beneficial but alone would not likely be sufficient for FH patients. Only about 15% of the cholesterol in the body comes from diet; the remainder is synthesized, primarily in the liver. A diet reduced in total fat and cholesterol, along with exercise, would help lower serum LDL cholesterol levels. However, since FH patients no longer have the normal LDL receptor-mediated feedback loop, increased cellular synthesis of cholesterol would continue. Often statin drug therapy is necessary to restore cholesterol levels to normal.

Chapter 25

1. In figure 25.2, the Daily Value for saturated fat is listed as less than 20 g for a 2000 kcal/day diet. The % Daily Values appearing on food labels are based on a 2000 kcal/day diet. Therefore, the % Daily Value for saturated fat for one serving of this food would be 10% ($2/20 = 0.10$, or 10%).
2. According to the Daily Value guidelines, total fats should be no more than 30% of total kilocaloric intake. For a person

consuming 3000 kcal/day, this is 900 kcal ($3000 \text{ kcal} \times 0.30$). There are 9 kcal in a gram of fat. Therefore, the maximum amount (weight) of fats the active teenage boy should consume is 100 g ($900/9$).

3. The % Daily Value is the amount of the nutrient in one serving divided by its Daily Value. Therefore, the % Daily Value is 10% ($10/100 = 0.10$, or 10%).
4. The protein in meat contains all the essential amino acids and is a complete protein food. Although plants contain proteins, a variety of plants must be consumed to ensure that all the essential amino acids are included in adequate amounts. Also, plants contain less protein per unit weight than meat, so a larger quantity of plants must be consumed to get the same amount of protein.
5. Copper is necessary for the proper functioning of the electron-transport chain. Inadequate copper in the diet results in reduced ATP production—that is, not enough energy.
6. A person loses weight when kilocalories used per day exceed kilocalories ingested per day. About 60% of the kilocalories used per day is due to basal metabolic rate. A person with a high basal metabolic rate loses weight faster than a person with a low basal metabolic rate, all else being equal. Another factor to consider is physical activity, which accounts for about 30% of kilocalories used per day. An active person loses more weight than a sedentary person does.
7. This approach will not work because he is not losing stored energy from adipose tissue. In the sauna, he gains heat, primarily by convection from the hot air and by radiation from the hot walls. The evaporating sweat is removing heat gained from the sauna. The loss of water will make him thirsty, and he will regain the lost weight from fluids he drinks and food he eats.
8. As ATP breakdown increased, more ATP would be produced to replace that used. Over an extended time, the ATP must be produced through aerobic respiration. Therefore, oxygen consumption and basal metabolic rate increase. The production of ATP requires the metabolism of carbohydrates, lipids, or proteins. As these molecules are used at a faster than normal rate, body weight decreases. Increased appetite and increased food consumption resist the loss in body weight. As ATP is produced and used, heat is released as a by-product. The heat raises body temperature, which is resisted by the dilation of blood vessels in the skin and by sweating.

9. During a fever, the body produces heat by shivering. The body also conserves heat by the constriction of blood vessels in the skin (producing pale skin) and by reduction in sweat loss (producing dry skin). When the fever breaks—that is, “the crisis is over”—heat is lost from the body to lower body temperature to normal. This is accomplished by the dilation of blood vessels in the skin (producing flushed skin) and increased sweat loss (producing wet skin).

Chapter 26

- The beer consumed composes a large volume of hyposmotic fluid, which increases blood volume and causes blood osmolality to decrease. The increased blood volume is detected by baroreceptors, and the decreased blood osmolality is detected by osmoreceptors in the hypothalamus. The response to these stimuli is inhibition of ADH secretion. The alcohol in the beer also inhibits ADH secretion. The increased volume inhibits the renin-angiotensin-aldosterone hormone mechanism, which in turn inhibits aldosterone secretion. The changes in aldosterone, however, take much longer to influence kidney function than changes in ADH. As a result of these changes, a large volume of dilute urine is produced until the blood osmolality and blood volume return to normal.
- The loss of sweat results in a loss of water and electrolytes. Replacing just the water restores blood volume and decreases blood osmolality. At first, the decreased osmolality inhibits ADH secretion, and dilute urine is produced. However, as blood volume decreases as a result of urine production, ADH secretion and the renin-angiotensin-aldosterone mechanisms are stimulated. Consequently, urine concentration increases, and only a small amount of urine is produced.
- As aldosterone levels decrease, sodium reabsorption in the nephron decreases; consequently, plasma sodium levels decrease. The sodium is lost in the urine, and water follows the sodium by osmosis. Thus, a large amount of urine having a high concentration of sodium is produced. The loss of water reduces blood volume, which causes the low blood pressure. As aldosterone levels decrease, potassium secretion into the nephron also decreases, resulting in increased plasma potassium levels. The increased extracellular potassium causes the depolarization of nerve and muscle membranes, leading to tremors of skeletal muscles and cardiac arrhythmias, including fibrillation.
- There are several ways to decrease the glomerular filtration rate:

- Decrease hydrostatic pressure in the glomerulus.
 - Decrease systemic arterial blood pressure.
 - Decrease extracellular fluid volume.
 - Decrease peripheral resistance.
 - Decrease cardiac output.
 - Constrict or occlude the afferent arteriole.
 - Relax the efferent arteriole.
 - Increase glomerular capsule pressure.
 - Increase the colloid osmotic pressure of the plasma.
 - Decrease the permeability of the filtration barrier.
 - Decrease the total area of the glomeruli available for filtration.
- Assume that the ascending limb of the loop of Henle and the distal convoluted tubules are impermeable to sodium and other ions but actively pump out water. Other characteristics of the kidney are assumed to be unchanged. As the urine moves up the ascending limb, it becomes hyperosmotic, because sodium remains behind as water is pumped out. Assuming that the collecting ducts are impermeable to sodium, on reaching the collecting ducts the presence or absence of ADH determines the final concentration of the urine. If ADH is absent, little or no water is exchanged as the urine passes down the collecting ducts and a hyperosmotic urine is produced. On the other hand, if ADH is present, water moves from the interstitial fluid into the collecting ducts, thus diluting the urine and producing a hyposmotic urine.
 - Urea is partially responsible for the high osmolality of the interstitial fluid in the medulla of the kidney. Since a high osmolality of the interstitial fluid must exist for the kidney to produce a concentrated urine, a small amount of urea in the kidney results in the production of dilute urine.
 - A low-salt diet tends to reduce the osmolality of the blood. Consequently, ADH secretion is inhibited, producing dilute urine and thus eliminating water. This in turn reduces blood volume and blood pressure.
 - As the loops of Henle become longer, the mechanisms that increase the concentration of the interstitial fluid of the medulla become more efficient, thus raising the concentration of the interstitial fluid. The higher the concentration of interstitial fluid in the medulla of the kidney, the greater the concentration of the urine the kidney is able to produce.
 - Answer *d* is correct. For at least 2 hours before help arrived, Marvin suffered from hemorrhagic shock, which was responsible for hypoxic injury to his kidneys. Hypoxic

injury is the consequence of ischemia due to prolonged shock, and it results in cells sloughing off and blocking the lumen of the nephron, so that the filtrate cannot flow through it. Marvin's urine volume decreased because cells of the nephron sloughed off and blocked the lumen of the nephron. The reabsorption of wastes was increased because the flow rate of the filtrate slowed and the wastes were able to pass through the wall of the nephron and reenter the circulatory system, rather than becoming part of the filtrate. This explains the increased blood volume and the distended neck veins. The high blood H^+ is due to decreased H^+ secretion; and the high blood K^+ is due to decreased K^+ secretion. There is no increase in blood HCO_3^- because the rate of HCO_3^- reabsorption is not increased. There is a decrease in erythropoietin secretion by the damaged kidney, which explains the reduced red blood cell count.

- Answer *a* is correct. The respiratory system responds to below-normal pH by increasing the rate of respiration. However, Marvin's kidneys were not able to respond to the low pH because of the hypoxic injury. The hypoxic injury is responsible for the metabolic acidosis (lower-than-normal blood pH), and the damaged nephrons could not adequately increase HCO_3^- reabsorption or H^+ secretion.
- High blood renin levels would result in increased blood aldosterone levels (see figure 26.17). The aldosterone increases the number of sodium potassium transport proteins in the basal membranes of cells in the distal convoluted tubules and collecting ducts. More Na^+ would be reabsorbed, and more K^+ would be excreted into the urine. Consequently, blood K^+ levels would be lower than normal. The low blood K^+ levels result in the hyperpolarization of membrane potentials. As a result, stimuli of a greater strength than normal are required to produce action potentials in nerve and muscle tissue.
- Water that moves into the collecting duct cells would diffuse into the interstitial fluid at a reduced rate because of the reduced number of aquaporins. Urine volume would increase because of water retention in the distal convoluted tubule and collecting ducts. Urine concentration would decrease because of dilution by the water. ADH can cause an increase in the number of aquaporin-2 water channel proteins in the apical membrane of the distal convoluted tubules and collecting ducts, but not in aquaporin-3 or aquaporin-4 channels in the basal membranes. These channels determine the permeability of the basal

membranes to water. Therefore, ADH would not be an effective treatment. The net effect would be polyuria, which is similar to nephrogenic diabetes insipidus caused by an abnormal aquaporin-2 water channel protein.

Chapter 27

1. When excess glucose is not reabsorbed, it osmotically obligates water to remain in the nephron. This results in the production of a large amount of urine, called polyuria, with a consequent loss of water, salts, and glucose. The loss of water can be compensated for by increasing fluid intake. The intense thirst that stimulates increased fluid intake is called polydipsia. The loss of salts can be compensated for by increasing the salt intake. The high glucose levels in the blood increase the blood osmolality, thus stimulating the secretion of ADH. This increases the permeability of the distal convoluted tubule and collecting duct to water. Normally, this allows reabsorption of water from the collecting ducts and thus conserves water. However, if glucose levels in the urine are high enough, water loss increases even with high levels of ADH.
2. When ADH levels first increase, the reabsorption of water increases, and urinary output is reduced. This also causes an increase in blood volume and therefore an increase in blood pressure. The increased blood pressure increases the glomerular filtration rate, which increases urinary output to normal levels. In addition, the increased blood volume inhibits the renin-angiotensin-aldosterone mechanism, inhibits aldosterone secretion, and stimulates natriuretic hormone secretion. These responses also increase urinary output.
3. Blocking H^+ secretion produces acidosis. Because H^+ is exchanged for Na^+ , the Na^+ remains in the urine as sodium bicarbonate. This effectively prevents the reabsorption of HCO_3^- and produces an alkaline urine. The blood pH is reduced because H^+ is not being secreted as rapidly by the nephron. The respiratory rate increases because of the stimulatory effect of decreased blood pH on the respiratory center.
4. Breathing through the glass tube increases the dead air space and decreases the efficiency of gas exchange. Consequently, blood carbon dioxide levels increase and produce a decrease in blood pH. Compensatory responses include an increased respiratory rate and the production of acidic urine.
5. Answer *e* is correct. The rate of stomach secretion increased prior to the time Harry vomited. Gastric secretions include a high

concentration of HCl. As the stomach secretes HCl, it secretes H^+ into the stomach and absorbs HCO_3^- into the blood. Also, after Harry took the antacid, which is mostly $NaHCO_3$, the HCO_3^- was absorbed and entered the circulatory system. A significant amount of HCO_3^- entering the circulatory system causes an increase in the blood pH. The increased pH affects the regulatory centers of the respiratory system and causes respiration to slow. Although the kidney's response is slower, by 24 hours later, the rate of H^+ secretion by the kidney slows, and HCO_3^- absorption slows in response to an increase in the blood pH. The slower rates of respiration, H^+ secretion, and HCO_3^- absorption by the kidneys help keep the blood pH from becoming higher than normal.

Chapter 28

1. Removing the testes would eliminate the major source of testosterone. Blood levels of testosterone would therefore decrease. Because testosterone has a negative-feedback effect on the hypothalamus and pituitary gland, GnRH, FSH, and LH secretion would increase, and the blood levels of these hormones would increase. An adult male's primary and secondary sex characteristics are already developed; however, removal of the testes would eliminate sperm production. Also, the lack of testosterone would cause a decrease in sex drive and muscular strength.
2. Prior to puberty, the levels of GnRH are very low because the hypothalamus is very sensitive to the inhibitory effects of testosterone. Since GnRH levels are low, so are FSH and LH levels. Loss of the testes and testosterone production would result in an increase in GnRH, FSH, and LH levels. Because little testosterone is produced, the boy would not develop sexually and would have no sex drive. Small amounts of androgens would be produced because the adrenal cortex produces some androgens. As an adult, he would be taller than normal, with thin bones and weak musculature. His voice would not deepen, and the normal masculine distribution of hair would not develop.
3. Ideally, the pill would inhibit spermatogenesis. Using the same approach as the birth control pill in females, the inhibition of FSH and LH secretion should work. Chronic administration of GnRH suppresses FSH and LH levels enough to cause infertility through down-regulation. However, lack of LH can also result in reduced testosterone levels and loss of sex drive. Some evidence indicates that administering testosterone in the proper amounts reduces FSH and LH secretion, thus leading to less sperm cell production while still maintaining normal sex drive. For a large percentage of males the technique results in a sperm concentration in the semen that is too low to allow fertilization. However, the technique is not sufficiently precise to be used as a standard birth control technique.
4. In a postmenopausal woman, the ovaries have stopped producing estrogen and progesterone. Without the negative-feedback effect of these hormones, the levels of GnRH, FSH, and LH increase. Removal of the nonfunctioning ovaries in a postmenopausal woman would not change the level of any of these hormones or produce any symptoms not already occurring due to the lack of ovarian function.
5. The removal of the ovaries from a 20-year-old woman eliminates the major site of estrogen and progesterone production, thereby causing an increase in GnRH, FSH, and LH levels due to lack of negative feedback. We would expect to see the symptoms of menopause, such as cessation of menstruation and reduction in the size of the uterus, vagina, and breasts. A temporary reduction in sex drive may also occur.
6. It is clear that estrogen and progesterone administration resulted in a large decrease in the amount of LH in the plasma the day of ovulation. The differences in plasma LH levels between the groups at other times are very small. The incidence of pregnancies suggests that the reduced plasma LH levels may result in no ovulation.
7. The progesterone inhibits GnRH in the hypothalamus. Consequently, the anterior pituitary is not stimulated to produce LH and FSH. Lack of LH prevents ovulation, and lack of FSH prevents development of the follicles. LH is also required for the maturation of follicles prior to ovulation. Without follicle development, inadequate estrogen is produced, which causes the hot flashes.
8. GnRH administered either before or after the normal time of ovulation does not result in ovulation because the anterior pituitary is less sensitive to the effect of GnRH during those times. Also, follicles in the ovary are not adequately developed. The concentration of GnRH must be carefully controlled because too little results in inadequate release of FSH and LH from the anterior pituitary. Too little FSH and LH fails to cause ovulation. Too much GnRH given at the proper time results in the maturation of more than one follicle and the release of an oocyte from more than one of the follicles. If the oocytes are fertilized, multiple embryos can result.
9. Because of their enlarged prostates, the patients are likely to have difficulty

urinating. An enlarged prostate gland compresses the prostatic urethra, slowing the emptying of the urinary bladder and enhancing the urgency to urinate. Dr. Procter conducted a digital exam by palpating the men's prostate glands through their rectums. The patient with the enlarged but smooth prostate is likely to have benign prostatic hypertrophy and low blood levels of PSA. Benign prostatic hypertrophy is general enlargement of the prostate without specific tumors. The patient with the enlarged but asymmetrical prostate gland is more likely to have elevated blood levels of PSA and prostate cancer. Lack of symmetry and a rough surface can be caused by tumors within the prostate gland.

10. The correct answer is *d*. If a testis fails to descend into the scrotal sac, the higher body temperature causes the spermatogonia to degenerate. Consequently, that testis produces no sperm cells. Sustentacular cells remain in the seminiferous tubules, and interstitial cells remain in the testis. Both testosterone secretion by the interstitial cells and LH secretion from the anterior pituitary gland remain normal.
11. The correct answer is *d*. Decreased blood flow to the anterior pituitary gland would result in decreased LH secretion, not increased LH secretion. The decreased secretion of LH from the anterior pituitary causes a decrease in the blood level of testosterone. Because it takes approximately 74 days to produce a sperm cell, the sperm count is likely to remain normal during the week when the blood LH and FSH levels are reduced.

Chapter 29

1. Triploidy can occur as a result of polyspermy, the fertilization of one oocyte with two sperm cells. Polyspermy is usually prevented by the fast and slow blocks to polyspermy, both of which depend on the depolarization of the oocyte membrane. If this depolarization does not occur, the zona pellucida does not degenerate, and other sperm cells can attach to the oocyte membrane, leading to polyspermy.
2. The approximate length of time the embryo has been developing, called the postovulatory age, is 14 days less than the time since the last menstrual period (LMP). In this case, the postovulatory age is 30 days (44–14). By this time, the neural tube has closed, the somites have formed, the digestive tract is developing, the limb buds have appeared, a tubular beating heart is present, and the lungs are developing. Because reproductive structures are still just forming, male and female embryos are indistinguishable at this age.
3. The fever occurred on days 21–31 of development, during the time of neural tube closure (days 18–25). If the fever prevented neural tube closure, the child could be born with anencephalus or spina bifida.
4. Progesterone reduces the release of oxytocin, the hormone that stimulates uterine contractions. Also, progesterone reduces the number of oxytocin receptors in the uterus. These effects reduce labor contractions and can prevent preterm delivery.
5. The Apgar score of 5 indicates appearance (A, 0) white or blue; pulse (P, 1) low; grimace (G, 1) slight; activity (A, 1) little movement and poor muscle tone; and respiration (R, 2) normal. The white or blue appearance (A, 0) is consistent with a poor circulation, as also indicated by reduced pulse (P, 1). The reduced heart rate, resulting in the low pulse, may indicate a circulatory system problem. The reduced reflexes and motor activity (G, 1; A, 1) can result from lack of oxygen in the muscles due to poor circulation. Because the infant has poor circulation despite normal respiration, clearing the airway (if obstructed) and administering oxygen are in order. This Apgar score can have several causes, and additional information would be necessary to determine the specific cause.
6. Suckling the breast stimulates the release of oxytocin from the neurohypophysis (posterior pituitary). Once the oxytocin

is in the blood, it travels to both breasts and causes milk letdown.

7. The woman most likely has an XY genotype. The spherical structures in the inguinal area are testes, but a genetic abnormality caused the androgen receptors to be defective or absent. Consequently, reproductive structures could not respond to androgens secreted by the testes. The embryonic testes secreted müllerian-inhibiting hormone, and therefore the müllerian duct system degenerated. This explains the lack of a uterus and a cervix. Female external genitalia developed because of the absence of androgen receptors. Normal breast development occurred because of the small amount of estrogen produced by the adrenal glands and because some testosterone is converted to estrogen in peripheral tissues.
8. Answer *b* is correct. Müllerian-inhibiting hormone causes the duct system that gives rise to female internal reproductive structures to degenerate in male fetuses. If the hormone is not effective, female internal reproductive structures, such as oviducts and a uterus, develop, at least to some degree, along with internal male reproductive structures. Because the developing testes produce testosterone, male external reproductive structures develop.
9. It is not possible from this information alone. If tongue rolling is designated *T* and the inability to roll the tongue is designated *t*, then a *Tt* woman and a *tt* man have a 50% probability of having a *Tt* child and a 50% probability of having a *tt* child. Therefore, a man who cannot roll his tongue and a woman who can roll her tongue can have a child who can roll his or her tongue. This connection alone, however, is not sufficient to establish paternity.
10. A person with blood type AB has the genotype $I^A I^B$ but no *i* allele. A person with blood type O has a genotype of *ii*. Because the AB parent has no *i* allele, an AB individual cannot be the parent of a child with blood type O.

Appendix G

ANSWERS TO PREDICT QUESTIONS

Chapter 1

2. Although you may not know the specific mechanisms of antibiotics, you learned that bacteria in our body have been found to be very important for our overall health. Any disruption in our body's microbial population could disturb homeostasis. In addition, you learned that the gut microbial population is particularly important. Therefore, ingestion of an antibiotic could disturb the gut's microbiome. You also learned in chapter 1 that sometimes a negative feedback mechanism may be insufficient to restore homeostasis and medical intervention is necessary. In this case, as you will learn more about in chapter 24, transplanting microbes from one person to another may restore the gut's microbiota and homeostasis.

3. This question is about the hierarchical levels of organization in the body. The question tells us that an organ, the pancreas, is the source of the health disorder. Next, the question explains that particular groups of cells (tissue) in this organ are responsible for the normal functioning of the body. Finally, the question tells us that the individual cells release the chemical insulin, which, in this case, is not being produced, as it should. It is the lack of this chemical that is disrupting the health of the individual. Considering the hierarchy of organization, chemical → cell → tissue → organ, an adjustment at any of these levels could theoretically solve the issue.

Currently, the chemical level is where diabetes is most commonly corrected. Purified insulin is injected into the blood at certain times. However, there are also drugs that stimulate the pancreatic cells to increase insulin production or to make other cells more responsive to insulin. Next, the tissue level is an important area of research to determine whether groups of insulin-producing pancreatic cells (pancreatic islets; see chapter 18 opening photo and caption) can be isolated and implanted into the patient. Finally, the next higher level, the organ level, could

be a level of correction by transplanting a new pancreas into a diabetes patient.

4. To answer this question, we must first recognize the components of the feedback systems that maintain homeostasis in the body: receptor, control center, and effector. Recall that any disruption in normal function (such as fainting) is a disruption in homeostasis.

a. Normally, homeostasis of blood pressure is maintained in this kind of situation when receptors near the heart are stimulated by lower blood pressure upon standing (blood falls away from the brain due to gravity). These receptors send a signal to the brain control center, which stimulates the effector, the heart, to beat faster. The increased heart rate causes blood pressure to go back to normal, thus maintaining homeostasis.

b. Because Molly's blood pressure dropped when she stood, the feedback system described in (a) was initiated and her heart rate increased. However, the elevated heart rate was not sufficient to prevent Molly from fainting. Too little blood was delivered to her brain, and she lost consciousness.

c. When Molly fell to the floor, she returned to a lying-down position. This eliminated the pooling effect of the blood in the veins below the heart because of gravity. Therefore, blood return to the heart increased, blood pressure increased, blood flow to the brain increased, homeostasis of brain tissue was restored, and she regained consciousness.

5. Initially, we might think that Ashley's increased respiratory rate is indicative of positive feedback. However, we must first look at the underlying reason for her elevated breathing rate. If you have ever run a race, you know that, eventually, your breathing rate goes back to normal once you stop running. However, during the race your body needs more oxygen to be able to keep

running. Because running requires oxygen, oxygen levels in the blood go down. The lowered oxygen level is detected by receptors, which communicate with the control center. The control center stimulates the effector, the diaphragm, to increase breathing rate. Once oxygen levels are returned to the set point, the breathing rate returns to normal. This is the essence of negative feedback: The response is stopped when the variable returns to the normal range.

6. The use of the anatomical directional terms can be compared to using the cartographic directions terms N, S, E, and W. As long as we know the reference points, and the corresponding terms, we can reference any part of the body. However, there are some terms for four-legged animals that are different from those for upright, two-legged humans, yet others are the same in both species. For example, in both humans and cats, *cephalic* means toward the head. But because the head of the cat points in the direction the cat walks, *anterior* also refers to the head, whereas in humans, *anterior* refers to the front of the body (e.g., face, stomach). In both humans and cats, *dorsal* means toward the back. But in cats, *superior* also means toward the back, whereas in humans, *superior* refers to the head. In humans, *posterior* is the other term for the rear (e.g. back of head, back).

Organism	Head	Back	Front of body
Cat	Cephalic/ anterior	Dorsal/ superior	Ventral/ inferior
Human	Cephalic/ superior	Dorsal/ posterior	Ventral/ anterior

7. In order to recognize which term to use here, we must first realize that directional terms are relative to the body. Therefore, it does not matter what position our body is in compared with the earth; body parts always have the same relationship to each other. Thus, the kneecap is always both proximal (closer to point of attachment to the body) and superior (closer to head) to the heel. It is also anterior to the heel because

it is on the anterior side of the lower limb, whereas the heel is on the posterior side.

- The first step is to define the abdominopelvic and peritoneal cavities. The abdominopelvic cavity is located inferiorly to the diaphragm and superiorly to the symphysis pubis. The peritoneal cavity is located between the visceral peritoneum, which covers organs in the abdominopelvic cavity, and the parietal peritoneum, which lines the wall of the abdominopelvic cavity. Thus, notice the bright white area in figure 1.16c. This is the peritoneal cavity containing only peritoneal fluid. Although the peritoneal cavity is around these organs, they are not within the peritoneal cavity. Second, looking at the right side of figure 1.16c again, notice there are organs behind the parietal peritoneum, but inside the abdominopelvic cavity. These organs are also not within the peritoneal cavity and are considered retroperitoneal (e.g., the kidneys).

Chapter 2

- The question asks us to differentiate between mass and weight. First, consider the definitions. Weight, in particular, is dependent on the force of gravity. Therefore, if an astronaut is in outer space, where the force of gravity from earth is nearly nonexistent, the astronaut is “weightless.” However, the definition of mass is the amount of matter present in the object itself. Thus, no matter the location of an object, the mass remains constant.
- The question asks us to predict the atomic structure of potassium. By definition, the atomic number (19) is the number of protons. Therefore, there are 19 protons in potassium. Since the number of electrons in an atom is the same as the number of protons, there are 19 electrons. To find the number of neutrons of any element, subtract the atomic number (19) from the mass number (39): $39 - 19 = 20$. Thus, there are 20 neutrons.
- To answer this question, we must recall the relationship among CO_2 , H_2O and H^+ in solution. Carbon dioxide readily combines with water resulting in the production of free H^+ . Therefore, as the amount of CO_2 decreases, the reversible reaction will shift in the other direction to form CO_2 . Similar to the trough of water example, if CO_2 levels decrease, it is like raising the right side of the trough, causing water to flow to the left. The reaction “flows” to the left: $\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}^+ + \text{HCO}_3^-$. In order for this to happen, free H^+ combines with HCO_3^- , decreasing its level in the blood. Section 2.3 explains that this decrease in H^+ levels changes the pH of the blood so that it becomes more basic.
- To answer this question, it may be helpful to write out the formulas of the reactants and the products. Hydrogen gas is represented by H_2 , whereas O_2 represents oxygen gas; the product, water, is represented by H_2O . The oxygen atom is more electronegative than hydrogen, and each hydrogen forms a polar covalent bond with the oxygen. Recall that a polar covalent bond occurs when the more electronegative atom can pull the electrons more strongly and the electrons associate with the oxygen more than they do the hydrogens. In a way, the oxygen has gained some negativity and its charge has been lowered. Thus, we say that the oxygen is reduced. On the other hand, the hydrogen atoms have partially lost their units of negativity, their electrons, and are more positive than they were before. In this case, we say the hydrogens are oxidized. The term *oxidized* is used because oxygen is an effective electron acceptor. A useful mnemonic device to remember these terms is OIL RIG (oxidation is loss [of electrons]; reduction is gain [of electrons]).
- During exercise, our body is doing work by muscular contractions. Work involves converting one form of energy into another, and as we read in the previous section, this conversion is not 100% efficient. As a result, heat energy is released. When contracting our muscles, potential energy is converted to kinetic energy and heat energy. Thus, more heat is produced when exercising than when at rest, and our body temperature increases.
- Recall that the definition of an acid is a proton donor. Thus, by losing an H^+ , dihydrogen phosphate ion (H_2PO_4^-), it is functioning as the conjugate acid. When the H^+ is lost, monohydrogen phosphate ion (HPO_4^-) is formed and is the conjugate base. The definition of a base is a proton acceptor. Thus, if H^+ is added to the solution, it combines with HPO_4^- and forms H_2PO_4^- . In this way, the conjugate base, HPO_4^- , helps resist an increase in free H^+ by acting as an H^+ “sponge.” If OH^- is added to the solution, it combines with any free H^+ to form water. Now, H_2PO_4^- (the conjugate acid) can dissociate into H^+ and HPO_4^- , thus serving as a reservoir of H^+ , and a decrease in H^+ is prevented, again resisting a change in pH. This is the essence of a buffer system: alternating between binding excess H^+ and donating H^+ when needed.

Chapter 3

- Recall that a substance that binds to a protein receptor must be specific to the binding site. The drug is able to bind to the receptor as well, presumably, because it is structural similar to the normal ligand. Similar to transport proteins, substances with similar structures compete for binding sites on the membrane. We can conclude that the lower dosage (250 mg) was not high enough to overwhelm the binding of the normal ligand. Increasing the dosage (750 mg) allowed the drug to out compete and bind more often to the receptor, thereby blocking the normal activity.
- First, we need to consider the normal process and identify the intracellular and extracellular areas involved. We are told that urea diffuses from liver cells, which is the intracellular region, to the blood, which is the extracellular region. Recall that diffusion is the net movement of molecules down their concentration gradient, so in this case from the area of higher urea concentration inside the cells to the area of lower urea concentration in the blood. The kidneys remove the urea from the blood; therefore, if the kidneys stopped functioning, the concentration of urea in the blood would increase. Eventually, this would eliminate the urea concentration gradient or even reverse it. Urea would remain in the cells and increase to toxic levels, which could damage or even kill the cells.
- If the membrane is freely permeable, there is no barrier to the movement of solutes or water. The solutes and water would each move down their concentration gradients. Since the solute concentration is higher in the tube, the solutes diffuse from the tube to the beaker until equal amounts of solutes exist inside the tube and beaker (i.e., equilibrium). In a similar fashion, water, which is at a higher concentration in the beaker compared with the tube, will diffuse into the tube until equal amounts of water are inside the tube and beaker. As a result of the diffusion of the water and solutes, the solution concentrations inside the tube and beaker will be the same because they both contain the same amounts of solutes and water.
- Remember that diffusion, whether simple or facilitated, is the movement of a substance down its concentration gradient. That means that the glucose concentration gradient between the extracellular fluid and the cytoplasm depends on the amount of glucose molecules only and is not affected by other molecules, even if they are similar. If glucose is converted to other molecules inside the cell, the concentration gradient is maintained, and the cell can continue to take up more glucose passively by facilitated diffusion.

6. To answer this question, we must first consider the functions involved in each cell described and identify the organelles that carry out these functions. Referring to table 3.1 would help quickly identify the organelles and functions. (a) Cells that synthesize and secrete proteins would require organelles involved in the manufacturing, packaging, and releasing of proteins from the cell. The rough endoplasmic reticulum, with the attached ribosomes, carries out the synthesis of proteins that will be released from the cell. The Golgi apparatus is also involved in the packaging of cellular materials that are secreted by packaging the proteins into secretory vesicles that move to the plasma membrane. (b) Active transport requires ATP to move materials across the plasma membrane, so we would expect the cell to have many mitochondria to produce ample ATP. (c) Recall that the organelle involved in the synthesis of lipids is the smooth endoplasmic reticulum. (d) Cells that ingest foreign substances by endocytosis would require the enzymes needed to break down those substances. We learned that lysosomes are vesicles of digestive enzymes that breakdown materials that have been brought into the cell.
7. The first piece of relevant information is that viruses aren't cells. Antibiotics are drugs that attack features of cells. Bacteria are cells—independent, free-living organisms with their own, specific molecules and cellular mechanisms. Bacteria can synthesize their own proteins and reproduce on their own. Conversely, viruses occupy human cells and use human molecules for survival. In order to medically attack a virus, attack of human cells and human-specific molecules is often necessary. In general, antibiotics attack bacteria-specific molecules and processes.
8. The first step in answering this question is to review the pairing relationship between nucleotides of DNA and RNA. In DNA, the base pairing associations are A aligns with T, G aligns with C, C aligns with G, and T aligns with A. However, since T is not found in RNA, the base pairing is slightly different in that A aligns with U instead of T, but all other base pairing patterns are the same. The first question asks for the sequence of the mRNA that is transcribed from the given DNA sequence. The answer is GCAUGC GGCUCUGCAGUUG. The second question asks for the sequence of the complementary strand of DNA. The answer is GCATGCGCTCTGCAGTTG. Notice that the only difference in the first and second answer is that the Us have been replaced with Ts.

Chapter 4

2. a. The question asks about the relationship between form and function of tissues. First, consider the name of the tissue type: nonkeratinized, stratified epithelium. The term *stratified* means more than one layer of cells, whereas the term *simple* means a single layer of cells. In the digestive tract, a principle function is absorption, a process that would be hindered by the many layers of stratified epithelium. Stratified epithelium is more suited to areas where the layers would protect underlying tissues from abrasion. Cuboidal cells are specialized for secretion and absorption. These cells contain a large number of organelles that produce the secretions and transporters needed to support absorption.
- b. In this scenario, both tissue types are stratified, but one type lacks keratin. The protein keratin provides a tough layer that retards water movement. If keratin were absent from the epidermis, the body could not retain water effectively and would be more prone to damage from abrasion.
- c. In the mouth, because whole foods are sometimes very coarse, the tissue needs to be thick and tough like stratified squamous. If the mouth were lined with simple columnar, it would be severely damaged during chewing.
3. First, define a tight junction: an intercellular junction that forms a permeability barrier. The tight junctions impede simple diffusion in the space between cells. As a result, tight junctions force ions and water to move through the epithelial cells in order to move from one side of the epithelium to the other. The most likely type of epithelial tissue would be simple cuboidal or simple columnar, which can readily absorb or secrete materials. The NaCl may be moved via active transport or facilitated diffusion across the cell membrane. Once NaCl reaches a higher concentration on one side of the epithelial cell membrane, water will follow the NaCl via osmosis.
4. The question asks how the structure of a tissue's components contributes to its function. When the vertebrae flex, elastic ligaments attached to the vertebrae help them return to their normal, upright position. When a muscle contracts, the pull it exerts is transmitted along the length of its tendons. The tendons need to be very strong in that direction but not as strong in others. The collagen fibers, which are like microscopic ropes, are therefore all arranged in the same direction to maximize their strength. If tendons were

- elastic, muscle contraction tension would not move the bone effectively. Imagine trying to connect train cars end to end with rubber bands, rather than steel couplings. Movement of the train would be ineffective, as the engine would be able to move quite a distance before the next car would move, and so on.
5. The question tells us that (1) vitamin C is required for collagen formation, (2) scars are formed from collagen, and (3) there is a lack of vitamin C (scurvy). Therefore, if there is a lack of vitamin C, the density of collagen fibers in a scar may be reduced and the scar may not be as durable as a normal scar. Overall, there is slow and poor wound healing in a patient with scurvy.
6. First, consider the characteristics of hyaline cartilage that make it an effective tissue for ease of joint mobility. Hyaline cartilage provides a smooth surface, so that bones in joints can move easily. In contrast, dense irregular collagenous connective tissue is a fibrous meshwork that is noted for its strength and ability to withstand stretching—for example, in the dermis layer of the skin. When the smooth surface provided by hyaline cartilage is replaced by fibrous connective tissue, the smooth surface is replaced by a less smooth surface, and the movement of bones in joints is much more difficult. The increased friction helps increase the inflammation and pain that occur in the joints of people who have rheumatoid arthritis.
7. First, define inflammation. Inflammation produces five main symptoms: redness, heat, swelling, pain, and disturbance of function. These symptoms occur because of an increased blood flow to the area. Consequently, if the area is so badly damaged that blood vessels are destroyed, then without blood vessels, no inflammation occurs in the damaged site. However, blood vessels are still intact in the tissues surrounding the severely damaged area. Thus, the signs of inflammation appear around the periphery of the damaged tissues.

Chapter 5

2. In the description of the epidermis, the superficial layer of the skin, we learned that the keratinized cells are coated with lipids to prevent fluid loss. Recall from chapter 3 that substances that are lipid-soluble easily diffuse through lipid layers but water-soluble substances do not. By applying the same principles of diffusion across cell membranes to diffusion across the skin, we can predict that lipid-soluble substances diffuse easily but water-soluble substances do not.
3. a. Previously, we learned that bacteria are ubiquitous and are able to survive in environments thought to be uninhabitable

by any organism. We also learned that each bacterial species is unique. It is probable that *P. acnes* are resistant to the anti-bacterial properties of sebum. In fact, you learned that *P. acnes* require sebum to survive. The bacteria consume components of sebum.

- b. Since *P. acnes* are dependent on sebum for their survival, reducing the total amount of sebum produced starves *P. acnes* of essential nutrients. The skin without enough sebum to feed *P. acnes* becomes a very unwelcoming environment for these pesky bacteria.
4. From the description of the injury, we know that the hammer struck Bob's nail bed. It is apparent that the hit was hard enough to rupture small blood vessels deep to the nail matrix. Blood accumulated between the nail and the nail bed, causing the dark area. In chapter 4 we learned that inflammation is the response that occurs when tissues are damaged and a normal inflammatory event is edema, or swelling at the injury site. The accumulation of blood and edema increased the pressure deep to the nail body, which stimulated pain receptors. When a hole was drilled through the nail, the accumulated bloody fluid drained, reducing the pressure and, consequently, the pain. Since the nail matrix, which is proximal to the injury site, was not injured, the nail continued to grow over the next 2 months, until the injured area was pushed distally to the free edge of the nail.
 5. a. In this chapter we learned that body temperature is affected by blood flow in the skin. When body temperature decreases, blood flow through the skin also decreases to reduce heat loss. Billy's ears and nose turned pale because of decreased blood flow. Constriction of blood vessels in Billy's skin reduced heat loss and helped maintain his body temperature.
 - b. Recall that the redness of skin is due to increased blood flow through the skin, so Billy's ears and nose turned red because of increased blood flow. As skin temperature decreases and blood vessels constrict, tissue can be damaged by the lack of blood flow and ice crystal formation. Cold-induced vasodilation periodically increases blood flow and prevents or slows the rate of ice crystal formation. This strategy for maintaining tissue homeostasis is beneficial as long as body temperature can be maintained. Also, we learned that blood flow determines the distribution of heat to different regions of the body. The red appearance of the nose and ears indicates increased blood flow in these areas, and we can

assume that this leads to warming of this tissue that is probably very cold due to the weather.

- c. The white color indicates the complete lack of blood flow through the skin of his ears and nose. The tissue will most likely be damaged due to the absence of blood flow in these areas.
 - d. Remember that one of the major functions of the skin is to prevent microorganisms from entering the body. If frostbite destroys skin cells, this function can be compromised, resulting in infection.
6. We learned that one of the functions of the skin is to reduce water loss. Sam's burns resulted in severe damage to his skin, which most likely led to increased water loss at the injury site, causing dehydration and reduced urine production. We learned that Sam was administered large volumes of fluid to counteract his increased fluid loss. But how much fluid should be given? The amount of fluid given should match the amount that is lost, plus enough to keep the kidneys functioning properly. An adult receiving intravenous fluids should produce 30 to 50 mL of urine per hour, and children should produce 1 mL/kg of body weight per hour. By monitoring Sam's urine output, the nurse can determine if he is getting enough fluids. If his urine output is too low, more fluids can be given.

Chapter 6

2. First, let's consider the structure of cartilage. The book tells us that the perichondrium, which surrounds the cartilage, contains blood vessels, but the blood vessels do not enter the cartilage. The book also states that nutrients must diffuse through the matrix before reaching the chondrocytes. Logically, cells that aid in tissue repair would also enter cartilage more slowly than if blood vessels penetrated the cartilage. The question next asks whether the lack of perichondrium, blood vessels, and nerves would be advantageous for articular cartilage. When considering the function of articular cartilage, the absence of such structures makes sense. Articular cartilage provides a smooth, low-friction surface for two bones to move past each other easily. If there were solid structures within the joint, the effect of smooth movement would be lost. Imagine trying to ice skate on a rink whose ice had garden hoses frozen just under and along the surface. We would spend more time trying to get back to our feet than skating.
3. The first concept you're presented with in this question is that proton pumps can be artificially "turned off" by medications.

As you've learned in previous chapters, certain chemicals, such as medicines, may affect transport proteins anywhere in the body. So, PPIs taken for stomach acid inhibition could also inhibit proton pumps in osteoclasts. Presumably, if osteoclasts were unable to create an acidic environment to dissolve bone, blood Ca^{2+} levels could decrease too much. In addition, lowering stomach acid production may lead to poor Ca^{2+} absorption and consequently, osteoporosis. This would be especially true if the patient took a high dose of a PPI for an extended time. In fact, the U.S. Food and Drug Administration has previously issued warnings about this very topic. However, there has not been overwhelming evidence either way, although there has been enough convincing evidence to warrant continued research and caution on the part of physicians. If a patient has other risk factors for osteoporosis, a PPI may not be the best course of treatment.

4. This question requires knowledge of cartilage histology, bone formation, and bone histology. Recall that, to acquire O_2 and nutrients, cartilage relies on diffusion through the matrix. As osteoclasts migrate into the developing bone structure and start to remove the cartilage, the cartilage becomes calcified, no more diffusion is possible, and the chondrocytes die. However, when we examine bone histology, we see that adjacent osteocytes are connected via cell processes. As the matrix is laid down, the area where the cell processes meet does not become covered in ossified matrix, forming canaliculi. Therefore, osteocytes continue receiving oxygen and nutrients through the canaliculi or from one osteocyte to another through cell processes.
5. To begin, define interstitial growth (from section 6.2): growth of cartilage through division of chondrocytes within the existing matrix. Because cartilage matrix is pliable, expansion of the existing matrix occurs as new matrix is added by the new chondrocytes. Remember that new bone growth is added to existing bone by appositional growth only. The definition of appositional growth is the addition of new osteoblasts and bone matrix on the surface of existing bone or cartilage. Next, consider the composition of bone matrix. It contains an inorganic component, calcium phosphate, which is not pliable. Therefore, if an existing osteocyte were to divide within its lacuna, the existing matrix would physically impede deposition of more matrix.
6. It is likely that Jill is still growing. Consequently, the epiphyseal plates in her long bones have not yet been converted

to epiphyseal lines. If a break occurs in an epiphyseal plate, it can slow bone growth and interfere with bone elongation. As a result, the femur, and therefore her left leg, will be shorter than her right leg. Recovery is difficult because cartilage repairs slowly due to the fact that cartilage is much less vascular than bone.

7. To answer this question, first describe the physical difference between cartilage and bone: cartilage matrix is semisolid (pliable) when compared with bone matrix, which is solid (rigid). Next address what the advantage is of having cartilage covering articular surfaces. The advantage of covering articulations (joints) with cartilage is that it provides a flexible, smooth surface for bone movement. A major impetus for many joint replacement surgeries is degeneration of the articular cartilage, as movement of a joint without articular cartilage is quite painful (see chapter 8 Clinical Impact, “Joint Replacement”).
8. The question tells us that Nellie’s blood levels of estrogen are much higher than normal for a 12-year-old girl. The text explained that important growth stimulators are reproductive hormones, which usually promote a burst of growth at puberty (approximately 12 years for girls). Because Nellie’s estrogen levels are higher than normal, she will most likely grow at a faster rate than she normally would have over the next 6 months. However, if the estrogen levels are not lowered back to normal, Nellie will probably be shorter at 18 than expected. Recall that, in addition, to stimulating a burst of growth at puberty, estrogen causes a closure of the epiphyseal plate and growth in bone length stops. Also, estrogen is more effective at this than testosterone, so Nellie may stop growing years before she would have with normal estrogen levels.
9. Because the presence of the osteomyelitis-causing bacteria throws the RANK, RANKL, and OPG system into disarray, any osteoporosis medication that inhibits osteoclast formation could potentially slow the rate of bone loss. In addition, since osteoblasts increase inflammation in the site of infection, anti-inflammatory medication would perhaps slow bone loss that is due to excessive immune system function. However, there is still much work to be done to develop reliable treatments for bone loss prevention during osteomyelitis.
10. Hopefully, Betty will discourage her granddaughter from smoking, as it reduces estrogen levels. Lowered estrogen levels, as we learned while reading the background information, are a major contributor to

osteoporosis. Additionally, Betty should encourage her granddaughter to get adequate calcium and vitamin D in her diet and to get some sunscreen-free sun exposure for vitamin D production (no more than 20 minutes a day). Betty and her granddaughter might consider taking a yoga class together as well. Exercise is an important source of increased bone density because it causes the muscles to put stress on the bones, which thickens the bones. Because the greater the density of bone before the onset of osteoporosis, the more tolerant it is to bone loss, most people (especially women in their 20s and 30s) need to make sure to get adequate calcium and exercise.

11. a. Henry’s bone density is less than normal for a man his age. Less dense bone is more likely to break.
- b. Henry’s eating habits have resulted in insufficient dietary intake of Ca^{2+} and vitamin D. Therefore, the absorption of Ca^{2+} from his intestine into his blood has been inadequate.
- c. We might expect Henry’s blood Ca^{2+} to be low because of his diet. However, low blood Ca^{2+} levels stimulate increased PTH secretion. An increase in PTH maintains normal blood Ca^{2+} by increasing the number of osteoclasts, which break down bone and release Ca^{2+} into the blood. Thus, Henry’s blood Ca^{2+} levels are maintained at the expense of his bones, which become less dense as more matrix than usual is broken down. Increased PTH levels also promote more Ca^{2+} reabsorption from the urine.
- d. Normally, exposure to sunlight activates a precursor molecule in the skin that eventually becomes activated vitamin D in the kidneys (see chapter 5). Henry produces few, if any, precursor molecules because of his nocturnal lifestyle. Therefore, Henry has low vitamin D levels and, so, has reduced absorption of Ca^{2+} from his small intestine.
- e. Exercise is a major source of mechanical stress on bones, which increases osteoblast activity. Because Henry does not exercise, his osteoblasts have not been as active as they might have otherwise been, which has allowed the osteoclasts to dissolve his bone to a greater degree than normal. The overactivity of the osteoclasts partially accounts for Henry’s lower bone density.

Chapter 7

2. After reading section 7.2, you probably realize that common structures, such as the “arm,” the “hand,” and the “nose,” are

actually a combination of multiple bones. Therefore, a “broken nose” could involve the nasal bones, the ethmoid bones, the vomer bone, the maxillae bones, or the inferior nasal conchae.

3. To answer this question, consider the function of the vertebrae and bones in general. The question asks why cervical vertebrae (in the neck) are smaller than lumbar vertebrae (in the lower back). Most bones are protective and weight bearing. The larger and thicker the bone, the more protection and weight-bearing functions it can provide. Because the lumbar vertebrae are much more inferior than the cervical, they bear more weight. Once again, we see “form follows function.” Second, the question asks what the differences in vertebrae structure would be between an actively exercising person and a more sedentary person. Recall from chapter 6 (see section 6.7, “Bone Remodeling”) that mechanical stress, such as that from exercise, applied to a bone stimulates osteoblasts to lay down new matrix. Thus, a person who regularly exercises will have a greater bone density in all the vertebrae than someone who never exercises.
4. In this scenario, Dr. Smart is able to diagnose a broken clavicle without x-rays. To determine how this is possible, we first need to know the normal position of the arm and the clavicle’s role in attaining this. The text explains that the clavicle’s job is to hold the upper limb away from the body. In addition, if we look at figure 7.22, it shows that the clavicle supports the scapula anteriorly. Therefore, when Sarah arrived at the emergency room, Dr. Smart probably saw that her shoulder was more inferior and anterior than normal and that her arm was resting against the side of her body and not being held away from the body, as it normally is.
5. In a dried skeleton, the joints between bones are now visible and all the long bones of the hand are obvious. In a live hand, the “knuckles” are actually where the phalanges arise. With the soft tissue intact, it appears that the metacarpals extend from the most proximal phalanx to the carpals. But if we look at figure 7.27, we see that the proximal phalanx is not tremendously shorter than the metacarpal bones, especially the third metacarpal and proximal phalanx. It is a common misconception that the metacarpals of the palm are part of the fingers.
6. The top of modern ski boots is placed high up the leg to make the weakest point of the fibula less susceptible to great strain during a fall. Modern ski boots are also designed to reduce ankle mobility, which increases comfort and performance.

- To answer this question, we must first recognize the areas of the skeleton that do not have a thick layer of muscle or fat overlying them. Additionally, we must think about the regions of the body where pressure would occur in a bedridden individual: anywhere on the skull, the zygomatic bones, the acromion process, the scapula, the olecranon process, the coccyx, the greater trochanter, the lateral epicondyle of the femur, the patella, the lateral malleolus, the sacrum, and the anterior iliac spine.
- The question addresses the form and function of the femur, especially in older people. Recall from chapter 6 that as people age bone density declines because the reproductive hormones decline. We learned that estrogen in women and testosterone in men help bones grow and stay dense. However, because older women's estrogen levels tend to be lower than older men's testosterone levels, their bones are even more fragile than men's. Additionally, the femoral neck is commonly injured in elderly people because it is the smallest portion of the femur, which supports the weight of the body. It also forms an angle between the pelvis and the shaft of the femur, so the downward force of gravity on the body places enormous pressure on this part of the femur. That pressure is usually resisted in younger people with strong bones, but not as much in the elderly.

Chapter 8

- First, we must define a suture and its location. A suture is a seam between two skull bones. Second, we need to define a synostosis: an ossified joint, such that two bones have become one solid bone. Next, the question asks about the effect of skull bones fusing prematurely on a child's brain development. To address this, recall that, in a normal newborn, the sutures are more extensive than in an adult skull and are called fontanels (soft spots). The fontanels allow for expansion of the skull to accommodate brain growth. If a newborn's skull were completely solid, the brain's growth would be impeded, and developmental problems would arise in the child.
- The first step is to determine the function of the articular cartilage. Look at figure 8.7 to find its location. There we can see the articular cartilage covers the ends of the bones, which meet at the joint. Depending on the specific joint, there may be significant force causing the bones to move toward each other; thus, the articular cartilage protects the ends of the bones and may endure significant mechanical stress. Next, describe the structure of the synovial membrane: It is a "thin, delicate membrane." It is a logical conclusion, then, that the synovial membrane would suffer damage if it covered the articular cartilage.
- To begin, it is required to know what anatomical position is. Recall that, when a person is standing, the face is forward, the arms are to the sides, and the palms of the hands are facing forward. Next, it is necessary to know the different terms used to describe movements of limbs and body parts relative to others. Now, picture yourself in anatomical position: Your right arm would move laterally out to the side (abduction) and then your hand would move closer to your head, bending at the elbow (flexion). Flexion at the shoulder and elbow also works.
- The first step is to locate the AC joint on figure 8.21. However, simply consider the name of the joint: acromio (acromion process) clavicular (clavicle) joint. Tearing the AC ligament disrupts a portion of the only bony attachment of the upper limb to the body. Looking at figure 8.21 we can see that a separated shoulder may also include tearing of the coracoclavicular ligament, further destabilizing the shoulder. If the connection of the scapula to the clavicle is broken, the scapula and humerus tend to be displaced inferiorly, and the proximal pivot point for the upper limb is disrupted, not allowing smooth rotation of the humerus in the glenoid cavity.
- This question requires you to apply your knowledge of the knee ligaments to a clinical situation involving two tests of ligament integrity (anterior and posterior drawer tests). For Mr. Dent, the normal anterior drawer test result indicates that the anterior cruciate ligament was not injured. However, the increased movement in the posterior direction indicates that his posterior cruciate ligament (PCL) was torn. The PCL connects the femur to the tibia at the back of the knee to limit the backward or posterior motion of the tibia. A PCL tear occurs most commonly when there is a strong direct blow to the front of the knee. The sudden force backwards can tear the PCL, especially if the knee is flexed (bent) close to a 90 degree angle. Common incidents that cause PCL damage are car accidents when the knee hits the dashboard and contact sports such as when a football player is tackled from the front below the knee.

Chapter 9

- The first step to answering this question is to define the resting membrane potential and the distribution of ions across the cell membrane in a resting, electrically excitable cell. At rest, the concentration of K^+ is higher inside the cell than outside the cell. This means that a concentration gradient exists for K^+ from inside the plasma membrane to outside the plasma membrane. Therefore, if K^+ ion channels were opened, regardless of the stimulus that caused them to open, K^+ would diffuse out of the cell. Because K^+ is a positively charged ion and other, negatively charged particles, such as proteins, remain in the cell, the resting membrane potential would decrease or would become more negative.
- The important concept here is the role of acetylcholine in skeletal muscle contraction. Acetylcholine is the neurotransmitter that first stimulates ligand-gated Na^+ channels to open, thus depolarizing (exciting) the muscle fiber. Recall that a muscle fiber is also an electrically excitable cell and that, in order for it to generate its response (a contraction), it must fire an action potential. If insufficient acetylcholine were released from the presynaptic terminal of an axon to depolarize the skeletal muscle fiber membrane to threshold, an action potential would not be produced in the muscle fiber and the muscle could not contract. However, a single neuron may not release enough acetylcholine on its own; rather, it may release only enough to generate a subthreshold local potential. In that case a muscle contraction would require the release of acetylcholine from several neurons, and, if the local potentials were produced over a short period of time, they could summate (see chapter 11) and reach threshold, and an action potential would be produced.
- To answer this question, we first need to understand what a motor unit is and how it works. In chapter 9 we learned that a motor unit is a motor neuron and all the muscle fibers it innervates. The pattern is that motor units with few muscle fibers perform more precise, delicate tasks (e.g., the motor units in our fingers), whereas motor units with a greater number of muscle fibers perform more gross movement tasks (e.g., the motor units in the gastrocnemius [calf] muscle). Therefore, upon recovery from poliomyelitis, muscle control decreases when reinnervation of muscle fibers occurs because the number of motor units in the muscle is decreased. The greater the number of motor

units in a muscle, the greater the potential for fine gradations of muscle contraction as motor units are recruited. A smaller number of motor units means that gradations of muscle contraction are not as fine.

5. a. Before we can answer these questions, it is necessary to know what the function of acetylcholinesterase is. We can actually tell just by the name. Enzymes, which react with a certain chemical, are named by the chemical's name and the suffix *-ase*. Thus, acetyl cholinesterase reacts with acetylcholine by degrading it. If this enzyme cannot work, then acetylcholine is not broken down in the synaptic cleft. Instead, it accumulates there and continuously stimulates the muscle fiber. As a result, the muscle remains contracted until it fatigues. Death is caused by the victim's inability to breathe. Either the respiratory muscles are in spastic paralysis or they are so depleted of ATP that they cannot contract at all.
- b. Since the main interruption of organophosphate poison is disruption of acetylcholine break down and then continuous muscle stimulation, the primary goal is to either get rid of acetylcholine or prevent it from doing its job. One such drug for treating organophosphate poisoning is called curare. Curare binds to acetylcholine receptors and thus prevents acetylcholine from binding to them. Because curare does not activate the receptors, the muscles do not respond to nervous stimulation. In the event of too much curare the person suffers from flaccid paralysis and dies from suffocation because the respiratory muscles are not able to contract.
6. As a weight is lifted, the muscle contractions are concentric contractions. When a weight lifter lifts a heavy weight above the head, most of the muscle groups contract with a force while the muscle is shortening. Concentric contractions are a category of isotonic contractions in which tension in the muscle increases or remains about the same while the muscle shortens. While the weight is held above the head, the contractions are isometric contractions, because the length of the muscles does not change. While the weight is lowered, unless the weight lifter simply drops the weight, the length of the muscles increases as the weight is lowered for most of the muscle groups. Eccentric contractions are contractions in which tension is maintained in a muscle while the muscle increases in length. The major muscle groups are therefore contracting eccentrically while the weight is lowered.

So Mary explained to the two students that they were each correct, since the weight lifter used all three types of contractions.

7. The first step to answer this question is to define glycogen and its role in exercise in the nondisease state. Glycogen is the stored form of glucose. Free, immediately usable glucose is in limited supply, and the body quickly relies on glycogen for sustained exercise. Without the ability to break down glycogen to glucose molecules, muscle depends on the uptake of glucose from outside the cells (e.g., from the blood) or from the metabolism of fatty acids. Consequently, a person's ability to carry out vigorous exercise, including anaerobic exercise, is reduced. Fatigue and lower exercise tolerance are characteristic of the condition, but exercise can be maintained at a slow pace.
8. This question is really asking about oxygen deficit and recovery oxygen consumption—in other words, how long a person needs to breathe heavily after exercise to return the body functions to baseline. The increase in breathing after running up the stairs is recovery oxygen consumption and is partially due to the oxygen deficit that occurs at the beginning of exercise. Because the duration and intensity of the exercise were similar in both boys, the only explanation for the difference in recovery oxygen consumption is their general physical fitness. Because of conditioning, Eric's muscles accumulated more mitochondria, were more vascular, and received more oxygen from his more efficient respiratory system. Thus, Eric's muscles produced more of his ATP aerobically. On the other hand, John was very out of shape, and so his muscles had fewer mitochondria and less blood supply and his respiratory system was not efficient. Therefore, John's muscles relied more on anaerobic respiration to produce ATP. Anaerobic respiration is far less efficient than aerobic respiration and produces only 2 ATP per glucose molecule and lactic acid. When someone like John primarily depends on anaerobic respiration, there is a larger accumulated oxygen deficit during exercise and a larger recovery oxygen consumption after exercise. Therefore, after the exercise, John's metabolism switched to aerobic respiration to restore homeostasis. John's respiration rate was elevated longer than Eric's because John's homeostasis was disrupted more than Eric's, in part to metabolize the lactic acid produced during anaerobic metabolism.
9. Susan was unable to keep pace during the finishing sprint because her muscles were not trained for quick movements, such

as sprinting. She had trained them only for aerobic, steady-state activity like that occurring during most of the race. As her coach, you should advise Susan to incorporate high-intensity sprinting activities into her training. Such activities will cause her fast-twitch muscle fibers to increase their performance capacity, which will increase her ability to sprint at the end of the race.

10. To answer this question, the first step is to refer to figure 9.26. We learned that a ligand is a chemical that, upon binding to its receptor, will stimulate a response. In figure 9.26, a smooth muscle cell is depicted, which shows that the ligand receptors are G protein-linked receptors. Binding of the ligand results in the opening of Ca^{2+} channels. Calcium ions diffuse into the cell and bind to calmodulin, which activates the enzyme myosin kinase to phosphorylate myosin heads and start the cross-bridge cycle. As long as intracellular Ca^{2+} levels are elevated, the cross-bridge cycle will take place. Because the cross-bridges release slowly, the contraction is sustained: Once a myosin head has been phosphorylated, it can form cross-bridges, move the actin, detach, and re-form cross-bridges again and again without breaking down new ATP molecules for each cycle.
11. DMD affects the muscles of respiration and causes deformity of the thoracic cavity. The reduced capacity of muscle tissue to contract is one factor that reduces the ability to breathe deeply or cough effectively. In addition, the thoracic cavity can become severely deformed because of the replacement of skeletal muscle with connective tissue. The deformity can reduce the ability to breathe deeply. DMD can also affect the muscle of the heart and cause heart failure. The boy with advanced DMD would have muscles that contained fewer muscle fibers and more fibrous connective tissue and fat. His posture would be much worse due to abnormal curvature of the spinal column (such as kyphoscoliosis) and more deformity of the thoracic cage. In general, his physical condition would be worse because of weakened heart muscle and difficulty breathing due to thoracic cage and vertebral column deformities. He would be much more likely to be wheelchair-bound due to severe weakness of his skeletal muscles.

Chapter 10

2. The question is asking about which muscles of the tongue allow people to "stick their tongue out," or protrude it. Refer to table 10.6, where the actions of tongue muscles are described. There, we

- find it is the extrinsic muscle the genioglossus that works to protrude the tongue. Further, the question tells us that Rachel's left mandible was broken and nerves were damaged. Recall from chapter 9 that skeletal muscles require a nerve impulse in order to contract. Therefore, we can conclude that the left genioglossus is unable to contract and the right is able to contract. So, when Rachel protrudes her tongue, it will only go to the left because it is only getting pushed out on the right side.
- This question asks about the function of the eye muscles. Refer to table 10.8, where the actions of the lateral and medial rectus muscles of the eye are described. Notice that the lateral rectus "pulls" the eye laterally and the medial rectus "pulls" the eye medially. So, if the lateral rectus is weak and does not pull the eye laterally, the medial rectus will predominate, and the eye will deviate medially.
 - The first step is to remember that we learned in chapter 8 that the definition of abduction is movement away from the body's midline. Next, it is necessary to know the location of the supraspinatus muscle to answer the question. The supraspinatus rests in the supraspinous fossa of the scapula. Then refer to table 10.14, where the function of the supraspinatus is summarized. Also refer to figure 10.23, which focuses on the rotator cuff muscles, of which the supraspinatus is a member. There, you see that in extreme abduction the supraspinatus would be compressed against the acromion process of the scapula.
 - When doing chin-ups the elbow flexes as you pull your body up toward the bar and extends as you lower your body back down. Refer to table 10.16 for the muscles involved in flexing and extending the elbow. Notice that the biceps brachii both flexes the elbow and supinates the forearm; however, the brachialis only flexes the elbow. When the forearm is pronated, the biceps brachii cannot contract as forcefully when flexing the elbow because the distal end of the biceps brachii is partially medially rotated. Thus, chin-ups with the arm pronated are more difficult. Bodybuilders who want to build up the brachialis muscles do pronated chin-ups. When the forearm is supinated (palms toward you), both muscles can work optimally, making these the easier chin-ups.

Chapter 11

- First, consider the basic function of the axon. At this point in the reading, we know that axons are a cellular projection from the neuron, sometimes called nerve fibers. We also know that the cell body is the site of protein synthesis for the entire cell. Therefore, if the distal portion of an axon is severed from the rest of the cell, it will die. There is no way for the distal axon to replenish the enzymes and other proteins essential for survival. On the other hand, any remaining portion of axon still attached to the cell body survives and, in many cases, grows to replace the severed portion.
- Although this question seems to ask about the cause of death, it is really asking about what cellular changes nervous tissue would exhibit in the event of trauma. First recall the types of glial cells found in central nervous tissue, in particular any cells involved in tissue repair or protection. The primary cell type of the neuroglia with these functions is the microglia. They are defined as "cells that become mobile and phagocytic in response to inflammation" and are described as cells that "migrate to areas damaged by infection, trauma, or stroke." Second, the question tells us that the pathologist found evidence of a prior stroke. The pathologist recognized the prior stroke because of the large number of microglia in the brain tissue surrounding the blocked blood vessels. In addition, the pathologist knew at least one damaged area was several weeks old because it takes time for microglia to migrate to a damaged area. However, the second damaged area of the brain showed evidence of a reduced blood supply, but far fewer microglia. Recall from chapter 4 that cardinal signs of inflammation include redness and edema, both of which were evident in the area of the brain injured by the fall. Therefore, the pathologist could conclude that either the second stroke killed the man, and caused him to fall, or it caused him to fall and the trauma to the brain incurred during the fall caused his death.
- The first step to answer this question is to define the basis for the resting membrane potential. Recall that the inside of the plasma membrane is more negative than the outside of the plasma membrane due to a higher concentration of negatively charged proteins inside the cell. The K^+ is also in higher concentration inside the cell and tends to "offset" the negative charge of the proteins. However, the K^+ leak channels allow K^+ to diffuse out of the cell, down the concentration gradient. Removal of K^+ removes positive charge inside the cell, and the membrane potential becomes more negative. Therefore, because Tissue A has more K^+ leak channels, more K^+ can leak out of Tissue A cells than in Tissue B cells, and the inside of Tissue A cells becomes more negative. The resting membrane potential is larger for Tissue A than for Tissue B; it is further from threshold.
- First, consider the role Ca^{2+} plays in establishing the resting membrane potential. We learned that Ca^{2+} ions are important for keeping voltage-gated Na^+ channels closed. When voltage-gated Na^+ channels open, the cell depolarizes, or becomes more positively charged on the inside of the plasma membrane. Thus, if Ca^{2+} levels drop, the voltage-gated Na^+ channels open, Na^+ diffuses into the cell, making it more positive, and the resting membrane potential increases.
- To answer this question, let us first describe the Na^+ concentration and its role in a normal excitable cell. We learned that, in a normal cell, the concentration of Na^+ is much higher outside the cell than inside the cell. As a result, when Na^+ channels open, Na^+ diffuses into the cell quickly, causing the changes in the membrane potential that result in an action potential. The movement of Na^+ into the cell is the result of its steep concentration gradient. Remember, also, that enough Na^+ must enter a cell for the membrane potential to reach threshold, opening the voltage-regulated Na^+ channels and causing an action potential. If the extracellular concentration of Na^+ were reduced, then the concentration gradient would also be reduced. The effect would be that, if the cell were stimulated, less Na^+ would enter the cell. The cell would not reach threshold, and an action potential would not occur.
- To answer this question, we must first define threshold. Threshold is the membrane potential at which voltage-gated Na^+ channels first begin to open. A prolonged threshold stimulus will result in a single action potential at the end of each relative refractory period. However, a prolonged, stronger-than-threshold stimulus will produce a greater number of action potentials than a threshold stimulus of the same duration due to a higher Na^+ permeability in the axon. The stronger-than-threshold stimulus will even produce action potentials during the relative refractory period. Therefore, a neuron receiving a stronger stimulus will send a greater frequency of action potentials. Because of the all-or-none properties of neurons, one action potential has the same magnitude as another. Thus, in order for a neuron to communicate stimulus strength (e.g., warm water vs. scalding water), the neuron receiving the stronger stimulus sends a higher frequency of action potentials.

8. First, what is the absolute refractory period? Recall that it is the time during which a neuron cannot fire an action potential no matter how strong the stimulus. This is due to all the voltage-gated Na^+ channels already being open. Thus, if the axon is nonresponsive for 1 ms, action potentials can be generated no faster than every millisecond. Because there are 1000 ms in 1 second, the maximal frequency is 1000 action potentials/second.
9. The question asks us to compare signal transmission rates of electrical and chemical synapses. The first thing we need to do is consider the mechanism for each type of synapse. Electrical synapses require only ion flow from one neuron to the next. Chemical synapses rely on diffusion of the neurotransmitter across the synaptic cleft, binding to the receptor and then triggering a signal transduction pathway. Thus, electrical synapses take no more time to be transmitted than an individual action potential takes traveling from node to node in a myelinated axon, or down the axon in an unmyelinated axon. On the other hand, the chemical synapse is more complex and reliant on molecular conformation change, enzyme activity, and so on, all of which are slower processes.
10. The key piece of information in the question is the fact that neuron B releases both a neurotransmitter and a neuromodulator, which is excitatory (produces EPSPs). EPSPs depolarize neuron C and bring it closer to threshold than it is when stimulated by only neuron A. Neuron C does not require as much time for temporal summation to reach threshold to fire an action potential when stimulated by neuron B vs. neuron A. Therefore, neuron C fires more action potentials with stimulation by neuron B alone than with temporal summation of neuron A alone. In other words, the neurotransmitter from neuron B is more effective when released with the neuromodulator from neuron B than it is when released alone from neuron A.

Chapter 12

2. In chapter 11, we learned that a ganglion is a cluster of neuron cell bodies. Similarly, in this chapter we learned that the dorsal root ganglia are clusters of sensory cell bodies and the dorsal roots are bundles of sensory axons. The ganglia are larger in diameter than the roots because of the size difference between the cell bodies and axons. To answer the second question, refer to figure 12.4 to see the direction of action potential propagation in sensory axons and motor axons. Sensory axons carry action potentials from

peripheral tissues to the central nervous system (CNS), which includes the brain and spinal cord. Motor axons carry action potentials from the CNS to peripheral tissues. Now, identify the types of axons in each structure listed. Recall that spinal nerves have both sensory and motor axons, so action potentials are propagated both to the spinal cord and away from the spinal cord. Dorsal roots contain only sensory axons, so action potentials are conducted to the spinal cord only. Finally, ventral roots contain only motor axons, so action potentials are conducted away from the spinal cord.

3. The body areas in figure 12.14 is color-coded and labeled for the nerve innervation. To answer this question, look at the left arm, forearm, and hand to see which nerves are indicated. In the figure, it is apparent that nerves C5–T1 are damaged. C5 and T1 innervate the left arm, C6 and T1 innervate the forearm, and C7 and C8 innervate the hand.
4. Recall that the phrenic nerve innervates the diaphragm, allowing for the contraction necessary for breathing. If the right phrenic nerve were damaged, then we would expect lack of muscle contraction in the right half of the diaphragm, affecting breathing. To answer the second part of the question, we need to consider the location of spinal cord injury to predict the effect it would have on the diaphragm. Remember that the phrenic nerve is part of the cervical plexus, which includes spinal nerves C1–C4. If the spinal cord were severed at the level of C2, the phrenic nerve would be damaged, and the contractions of the diaphragm would not occur, eliminating the person's ability to breathe. Death would likely occur if medical assistance were not administered quickly. On the other hand, if the spinal cord were completely severed at the level of C6, the phrenic nerve would not be damaged, and the diaphragm would not be affected.
5.
 - a. Looking at figure 12.14, we can see that nerves C7, C8, and T1 innervate the skin of the hand. Also after reviewing the description of the brachial plexus and viewing figures 12.19, 12.21, and 12.22, we can conclude that the radial, ulnar, and median nerves innervate the skin of the hand.
 - b. Figures 12.19 and 12.21 indicate that the symptoms of pain, tingling, and numbness in the ring finger and little finger of the right hand that radiated down the posteromedial portion of the forearm and hand most likely involve damage to the ulnar nerve, although this does not explain the radiation of symptoms into the forearm and elbow.
 - c. When the physician carried out a careful examination of Sarah's right upper limb to

map the extent of the pain and numbness, he most likely was trying to develop a differential diagnosis between the ulnar nerve damage and damage to the C8–T1 brachial plexus root. Cervical ribs compress the roots of the brachial plexus, which might be the cause of Sarah's symptoms. An x-ray of the neck can indicate the presence of extra rib, which most commonly affects the roots C8–T1.

- d. Based on our answers for parts a and b, we can assume that the ulnar nerve is most likely affected, so the muscles innervated by the ulnar nerve may be affected. These muscles are listed in figure 12.21. However, the radial and median nerves are also associated with the C8–T1 root and may be affected; therefore, the muscles innervated by these might also be affected. These muscles are listed in figures 12.19 and 12.22.
6. Figure 12.25 indicates that the femoral nerve innervates several muscles involved in hip flexion and knee extension, both activities that were difficult for Carl. This indicates that the femoral nerve is involved. The sources of nerve fibers in the femoral nerve are L2, L3, and L4; therefore, the intervertebral disk involved compresses L2, L3, or L4 on the left side of the vertebral column. Recall that figure 12.14 includes a dermatomal map. We can see from the map that L3 innervates the dermatome of the medial thigh and is the most likely spinal nerve involved. Carl's motor movements were affected because the reduced control of action potentials from the femoral nerve to the muscles of the thigh caused muscle weakness. The referred pain results from compression of the spinal nerve that innervates the medial thigh and the knee. The compression stimulates action potentials in the nerves, and the pain is referred to the site of the sensory receptors for that nerve.

Chapter 13

2. We learned in this chapter that reflexes that maintain blood pressure are integrated by the medulla oblongata. In response to blood loss, the reflexes increase the heart rate. Similarly, the reflexes cause the constriction of blood vessels in the skin and viscera to increase blood volume and therefore blood pressure. The lack of blood flow through the skin results in pallor. Recall that respiratory reflexes are integrated in the medulla oblongata and the pons.
3.
 - a. The Clinical Impact, "Traumatic Brain Injuries and Hematomas," explains that, often, when one part of the head suffers a heavy blow, the brain moves within

the cranial cavity and hits the opposite side of the cranial cavity. In this case, the blow to the back of the head forced the brain anteriorly, and the frontal lobes struck the frontal bones with enough force to tear blood vessels between the brain and the dura. Subsequent bleeding from these vessels into the subdural space created the subdural hematoma. This type of injury is a countercoup brain injury because it occurs on the side of the brain opposite the point of traumatic impact.

- b. We can assume that the herniation of the medulla into the vertebral canal compressed the tissue of the medulla and therefore disrupted its function. Recall from its description that the medulla oblongata contains the centers for controlling respiration and heart rate. Damage to these areas of the brain interrupted the woman's ability to regulate her breathing rate and heart rate, which was most likely a major factor contributing to her death.
4. To answer this question, let us first review the functions of the oculomotor, trochlear, and abducens nerves, listed in table 13.5. Besides innervating the levator palpebrae superioris muscle, the oculomotor nerve innervates the four eye muscles that move the eyeball so that the gaze is directed superiorly, inferiorly, medially, or superolaterally. If the patient can move the eyes in these directions, the oculomotor nerve is not damaged. Similarly, the abducens nerve directs the gaze laterally, and the trochlear nerve directs the gaze inferolaterally. If the patient can move the eyes in these directions, the associated nerves are intact.
5. To answer this question we must first determine the function of the sternocleidomastoid muscle. The description in table 10.1 states that, when one sternocleidomastoid muscle contracts, it rotates the head and neck to the opposite side. If the innervation to one sternocleidomastoid muscle is eliminated due to accessory nerve injury, the opposite muscle is unopposed and turns the face toward the side of the injury. A person with wry neck whose head is turned to the left most likely has an injured left accessory nerve.

Chapter 14

2. First, let us review the sensory information carried by the spinothalamic tract. From table 14.3 we can see that these include pain, temperature, light touch, pressure, tickle, and itch. Next, we can also see from table 14.3 and figure 14.8 that crossover of axons of the spinothalamic tract occurs in the spinal cord. From this we can conclude that a lesion on one side of the spinal cord that interrupts the spinothalamic tract would eliminate the specific sensations carried by that tract below the level of the lesion, but on the opposite side of the body. Not all sensations associated with the spinothalamic tract will be eliminated. Pain and temperature sensation from the opposite side of the body below the lesion would be eliminated. There would be few, if any, clinical changes in detecting light touch because other tracts still carry this information.
3. To answer this question, we need to first identify the sensory pathway involved. Reviewing table 14.3, we can see that the dorsal-column/medial-lemniscal system carries the sensations of proprioception, fine touch (two-point discrimination), and vibration. We can also specifically identify the fasciculus gracilis tract, since Bill and Mary lost the sensations in the lower half of the body. The next step is to determine why Bill and Mary have similar symptoms but different injuries. Recall that the secondary neuron axons cross over along the sensory pathway, so that stimuli from one side of the body are conveyed to the primary sensory cortex on the opposite side. We can see that the crossover of axons for the fasciculus gracilis tract occurs in the medulla, which is part of the brainstem. Bill experienced a spinal cord injury that interrupted the fasciculus gracilis. Since the axons have not crossed over in the spinal cord, we can assume that the spinal cord injury was on the left side, the same side as the sensory receptors. Mary, on the other hand, experienced a brainstem injury. If the injury occurred below the medulla, the site of axon crossover, we would expect it to be on the left side, similar to what was seen in Bill's spinal cord injury. However, if the injury occurred above the medulla, we would assume that it affected the right side, since the secondary neuron axons cross over in the nucleus gracilis of the medulla.
4. Before answering this question, consider the activities carried out by the two sets of limbs. We use the lower limbs primarily for standing and walking, both of which are activities we do not focus our attention. We use our upper limbs for all kinds of activities, including writing, texting on our cellphones, or even playing video games. These activities require much more conscious effort compared with the activities of the lower limbs.
5. To answer the first part of the question, we must recall the types of pain and the types of structures associated with each type of pain. Constipation is causing pain associated with the colon, a deep structure. Remember that the deeper structures lack tactile receptors, so the type of pain experienced is diffuse. We also learned after reading about referred pain that the pain associated with deeper structures is usually felt in more superficial structures. Using figure 14A, we can predict that the man feels the pain around his navel, the common area for referred pain associated with the colon.
6. Recall that stimulating the reticular activating system (RAS) promotes consciousness. Also, remember that acoustic stimuli, such as a dripping faucet, stimulate the RAS. Luke could not sleep because his RAS was stimulated, promoting consciousness and preventing sleep.
7. The vagus nerve supplies the muscles of the larynx that aid in voice production; therefore, minor injury to this nerve in the neck can lead to hoarseness or changes in the voice. In our reading of "Motor Output and Reflexes Projecting Through the Brainstem," we also learned that the vagus nerve controls muscles of the pharynx, larynx, and soft palate associated with swallowing and speech. Damage to the vagus nerve could therefore affect these two activities.
8. After carefully reviewing Vern's symptoms, we can see that the stroke primarily affected muscle activities of his face, head, and neck on the right side. We can therefore conclude that the stroke occurred on the left side of his brain. After reviewing figure 14.13 we can predict the stroke specifically affected the lateral portion of the precentral gyrus of the cerebrum, where motor control of the lips, jaw, face, tongue, and pharynx are represented. After reading Clinical Impact, "Aphasia," we can conclude that Vern does not have expressive aphasia since he is able to understand language and can achieve proper speech that makes sense with words in proper sequence. In this case, the Wernicke area and the association areas around it appear to be unaffected. However, Vern does exhibit characteristics of expressive aphasia in that his speech is hesitant and distorted. This is usually the result of a lesion in the motor speech area, the Broca area.
9. a. We learned in chapter 11 that myelination speeds up action potential propagation along axons; therefore, demyelination would slow the speed of action potential propagation. We can assume that demyelination of the optic nerve slows the speed of action potential propagation of visual input to the cerebral cortex,

affecting visual perception. In this case, demyelination resulted in blurred vision.

- b. It is possible that other neurons besides those of the optic nerve are affected by the demyelination. Demyelination of motor neurons in descending motor pathways would affect muscle activity and result in muscle weakness. Demyelination of sensory neurons in ascending sensory pathways would affect perception of stimuli and may cause the tingling sensations.
- The first clue to answering this is to understand that these microbial metabolites are chemicals in the same way that the body's signal molecules are also chemicals. Therefore, as you learned in chapter 11, neurotransmitters are chemical signals, produced by neurons that bind to receptors on their targets. Once the neurotransmitters have bound to the receptor, many different types of cell processes can be initiated. In addition, you learned in chapter 3 that other chemical signals also bind to receptors in the cell membrane. In the same way, if gut bacterial metabolites function in our body as chemical signals, upon arriving at their target, these bacterial metabolites could also bind to receptors in neuron cell membranes and stimulate cellular mechanisms to begin. Recall that lipid-soluble molecules can easily cross plasma membranes and because the short-chain fatty acids are lipid-based, they also easily cross the blood brain barrier (see chapter 13). You will learn in the next chapter that our sense of smell and taste function in a similar fashion. Chemicals from the air or our food bind to receptors in neuron cell membranes in our nose and our taste buds. Thus, it is not out of the realm of possibilities that our body could utilize bacterial chemicals to regulate internal processes. In fact, this is a hallmark of a symbiotic relationship, such as what we have with our gut microbiota.
 - Recall that the right side of the body is monitored and controlled by the left side of the brain. The crossing over of axons from one side of the brainstem or spinal cord to the other side of the brainstem or spinal cord results in this pattern of regulation. Since Scott exhibited loss of skeletal muscle movement and sensations on his right side, we can conclude that the left side of the brainstem was more severely affected by the stroke. But why did Scott experience pain and temperature sensations on the left side of his face? At the level of the upper medulla oblongata, neither the motor nor the sensory pathways to the limbs have

yet crossed over to the left side of the CNS. Most of the motor fibers cross at the inferior end of the medulla oblongata, whereas sensory pain and temperature axons cross over at the level where they enter the CNS. Loss of pain and temperature on the left side of the face indicates that the lesion occurred at the level where the sensory axons from the face had entered the CNS but had not yet crossed.

Chapter 15

- Ernie's sensory neuropathy is the loss of taste sensation in the posterior one-third of the right half of his tongue. In reviewing "Neuronal Pathways for Taste" we learn that the glossopharyngeal nerves carry taste sensations from the posterior one-third of the tongue. Considering that only the right side of Ernie's tongue is affected, we can conclude that it is the right glossopharyngeal nerve that is damaged.
- After reviewing the section "Lacrimal Apparatus" we learn that tears from the surface of the eyeball drain through the lacrimal caniculi into the lacrimal sac, which empties into the nasal cavity through the nasolacrimal duct. Our sense of smell is due to the presence of olfactory receptors in the nasal cavity. If medications are placed into the eyes, some may drain into the nasal cavity, which may stimulate the olfactory receptors of the olfactory organ. Our sense of taste is due to the presence of taste receptors in the mouth and pharynx. The ability to "taste" the medication is due to the fluid draining from the nasal cavity into the pharynx, stimulating taste receptors. Similarly, a person's nose "runs" when he or she cries because the excess tear production leads to more fluid drainage into the nasal cavity and therefore a "runny nose."
- In this question, Max and his grandfather were looking at an object that was far away (the glacier) and an object that was close (the piece of ice). To answer this question, we need to consider three important factors for each scenario: accommodation, pupil constriction, and convergence. While Max and his grandfather were looking at the distant glacier, the ciliary muscles of their eyes were relaxed, and the suspensory ligaments of their ciliary bodies maintained elastic pressure on the lenses of the eyes, keeping the lenses relatively flat and allowing for distant vision. When they looked at the piece of ice that was close to them, accommodation occurred. The ciliary muscles contracted, pulling the choroids toward the lenses and reducing the tension on the suspensory ligaments. This allowed the lenses to assume a more spherical form because of their own elastic nature. More spherical lenses have more convex surfaces, causing greater refraction of light. Also, pupil constriction occurred when they were looking at the piece of ice. As the pupils constrict during close vision, the depth of focus is greater, and more light is required on the observed object. Convergence also occurs during close vision. As an object moves closer to the eye, the eyes must rotate medially so that the object is kept in focus on corresponding areas of each retina; otherwise, the object becomes blurry. The reason Max's grandfather had to reach for his glasses to view the piece of ice is because he suffers from presbyopia, which occurs because the lenses become sclerotic and less flexible as people age. Presbyopia is corrected by wearing reading glasses for close work and removing them when the person wants to see at a distance. Either bifocals or progressive lenses can also be used if a person also has myopia, or problems seeing distant objects clearly.
- Recall that rod photoreceptors, which are distributed over most of the retina, are involved in both peripheral vision (out of the corner of the eye) and vision under conditions of very dim light. Stimulation of rods would explain why a person notices movements at night out of the corner of the eye. However, cone photoreceptors, which are concentrated in the fovea centralis, are involved in focusing directly on an object, and they do not function well in dim light. Thus, when the person tries to focus on the movement, the low light level is not enough to stimulate the cones, and the person cannot see what caused the movement.
- Before answering this question, let us review figure 15.23 to see the normal visual fields. We can see that each visual field is divided into temporal and nasal portions. The visual pathway is then color-coded to correlate with each portion for the right and left side. In the case of lesion A, we can see that the temporal part of the left visual field (light green) and the nasal part of the right visual field (dark blue) are affected. The black areas correlate with the same areas in the visual field. Using the same strategy, we can see that lesion B would affect both the temporal part (light blue) and the nasal part (dark blue) of the right visual field, so the entire right visual field would be affected, and an oval representing it would be black. The left visual field would be normal, with the temporal (light green) and nasal (dark green) parts

indicated. Following is an illustration of the right and left visual fields.

7. First, let us define *perfect pitch* and *tone deaf*. Perfect pitch is the ability to reproduce a pitch precisely just by being told its name or reading it on a sheet of music, with no other musical support, such as piano accompaniment. Tone deafness is the complete inability to recognize or reproduce musical pitches. Both of these characteristics can be due to variation in the structure of the basilar membrane, the inhibitory reflex from the superior olivary nucleus to the spiral organ, and the auditory cortex. Recall that the basilar membrane is structurally different from the base to the apex, allowing different segments to be sensitive to different frequencies (see figure 15.34). In individuals with perfect pitch, the structure of the basilar membrane may be such that tones are adequately spaced along the cochlear duct to facilitate clear separation of tones, whereas in tone-deaf individuals the spacing is inadequate to clearly separate tones.

We also learned that the superior olivary nucleus of the medulla oblongata has an inhibitory effect that only allows action potentials from regions of the basilar membrane with maximum vibration to be conducted to the auditory cortex. This allows an individual to distinguish specific sound frequencies. For people with perfect pitch, the reflex from the superior olivary nucleus to the spiral organ may have a very narrow “window of function,” whereas for individuals that are tone deaf, the reflex may not function well enough.

Finally, at the auditory cortex, action potentials that originate in the spiral organ are translated to perceived sounds. Variation in translation accuracy would explain the difference between individuals with perfect pitch and those with tone deafness.

8. Recall that the sound wave amplitude determines the volume of a sound, whereas wave frequency determines the pitch of the sound. Loud sounds have sound waves with greater amplitude. This greater amplitude causes the basilar membrane to vibrate more violently over a wider range. The spreading of the wave in the basilar membrane to some extent counteracts the reflex from the superior olivary nucleus that is responsible for enabling a person to hear subtle tone differences.

9. We learned that the brain compares sensory input from the semicircular canals, eyes, and proprioceptors in the back and lower limbs and that conflicting information can cause motion sickness. If you close your eyes, one of these sources of information is eliminated and the brain has less conflicting input to compare, reducing the probability of motion sickness. We can perceive more motion in close objects than in distant objects, so looking at the horizon would also reduce the visual input of perceived motion to the brain and reduce the probability of motion sickness.

Chapter 16

2. This question is referring to the different types of cholinergic receptors: nicotinic receptors and muscarinic receptors. Remember that, even though these are cholinergic receptors to which acetylcholine normally binds, they were classified based on laboratory findings that nicotine binds to one type of cholinergic receptor and muscarine binds to the other type of cholinergic receptor. Also recall that all preganglionic neurons of the sympathetic and parasympathetic divisions and all postganglionic neurons of the parasympathetic division release acetylcholine. Also, the postganglionic neurons of the sympathetic division that innervate sweat glands also release acetylcholine. Figure 16.7 allows us to determine which of these synapses would be affected by nicotine and which of these synapses would be affected by muscarine. Nicotinic receptors are located within the autonomic ganglia in the membranes of postganglionic neurons of both the sympathetic and parasympathetic divisions. Consumption of nicotine would result in stimulation of the postganglionic neurons, and consequently, the stimulation of the effectors of both the sympathetic and parasympathetic divisions. Again, figure 16.7 illustrates that muscarinic receptors are located on the effectors of the parasympathetic division. After the consumption of muscarine, only the effectors that respond to acetylcholine would be affected. This includes all the effectors innervated by the parasympathetic division and the sweat glands, which are innervated by the sympathetic division.
3. Muscarinic receptors are associated with all effectors innervated by the parasympathetic division as well as the sweat glands. We can assume that bethanechol chloride binding to muscarinic receptors results in effects similar to those of parasympathetic stimulation of organs. Contraction of the urinary bladder is a normal response to

the parasympathetic division, so we would expect the same result when bethanechol chloride is administered. Side effects of bethanechol chloride can be produced by the stimulation of muscarinic receptors elsewhere in the body. The stimulation of smooth muscle in the digestive tract can produce abdominal cramps, and stimulation of the air passageways can cause an asthmatic attack. Decreased tear production and salivation as well as dilation of the pupils are not expected side effects because parasympathetic stimulation causes increased tear production and salivation as well as constriction of the pupils. Recall that, even though the sympathetic division innervates sweat glands, these glands have muscarinic receptors, so we would expect increased sweating as a side effect of bethanechol chloride.

4. a. Dilation of the pupil is caused by the contraction of the dilator pupillae, which are the radial muscles of the iris.
- b. Recall from the discussion of the iris that the sympathetic division innervates and therefore controls the radial muscles (dilator pupillae). The parasympathetic division innervates and therefore controls the circular muscles (sphincter pupillae).
- c. A drug that mimics sympathetic stimulation, such as an adrenergic drug, could activate $\alpha 1$ receptor on the radial muscles of the iris and cause Sally’s pupils to dilate. On the other hand, a drug that blocks parasympathetic stimulation, such as a muscarinic blocking agent, would prevent constriction of the pupil and therefore cause dilation.
- d. Remember from chapter 15 that the ciliary muscles constrict, changing the shape of the lenses when viewing close objects. Blurred vision indicates the eyedrops are inhibiting ciliary muscle contraction. From table 16.3 we can see that ciliary muscle contraction is a parasympathetic effect, so we would predict that the eyedrops contain a muscarinic blocking agent, one that would affect parasympathetic effectors.
- e. Notice that this scenario is essentially the opposite as that described in part c. Based on our answer for part c, we would expect that an adrenergic blocking agent that binds to $\alpha 1$ receptors and prevents sympathetic stimulation would cause the pupils to constrict. Similarly, a muscarinic agent could stimulate the circular muscles of the iris, causing the pupils to constrict.
- f. Recall that sympathetic stimulation of blood vessels normally keeps them in a

state of partial contraction. An adrenergic blocking agent that inhibits sympathetic stimulation allows the blood vessels in the conjunctiva of the eye to dilate, causing the appearance of blood-shot eyes.

5. Sweat glands are innervated by the sympathetic division of the autonomic nervous system, the effects of which are greater during times of physical activity. Prior to and during the first part of the race, there was little stimulation of Brad's sweat glands by the sympathetic division. However, Brad's body temperature began to rise because of the increased metabolism of his exercising skeletal muscles. The higher body temperature resulted in increased sympathetic stimulation of his sweat glands. The increased sweat production allowed for evaporative cooling, resulting in more and more heat loss from the body. Therefore, Brad's body temperature did not increase much during the race. After the race, the evaporation of sweat continued to cool Brad's skin quickly, and his body temperature began to fall. The slight decrease in body temperature caused the sympathetic stimulation of his sweat glands to decrease, so that the rate of sweating decreased. As the rate of sweating decreased, the rate at which heat was lost from his body also decreased. Consequently, Brad's body temperature changed only a small amount, and homeostasis was maintained both while he was exercising and after he stopped exercising.
6. Recall that the primary function of the autonomic nervous system is to maintain homeostasis. In both of the scenarios Sarah's blood pressure changes. In chapter 1 we learned that most homeostasis control mechanisms are negative-feedback mechanisms that reverse the change. Also, notice that both questions address sympathetic reflexes controlling blood vessels. Remember that blood vessels are only innervated by the sympathetic nervous system. When Sarah does a headstand, blood drains toward her head, and the blood pressure in the arteries of her chest and head increases. Sensory receptors detect the increase in blood pressure, so the frequency of action potentials in sensory neurons increases. The brain, in turn, activates sympathetic stimulation of the blood vessels, which causes them to dilate. Consequently, the blood pressure in the arteries of the neck and head does not increase dramatically. When Sarah stands quickly after crouching for a short time, blood tends to drain away from her head, and the blood pressure in the arteries of

her chest and head decreases. Sensory receptors detect the decrease in blood pressure, so the frequency of action potentials in sensory neurons decreases. The brain, in turn, activates sympathetic reflexes that cause blood vessels to constrict. Consequently, the blood pressure in her neck and head does not fall dramatically.

Chapter 17

2. a. The major clue we are given is that Josie has low thyroid hormone levels, yet her TSH levels (the hormone that stimulates thyroid hormone release) are very high. Normally, thyroid hormone would negatively feedback at the anterior pituitary to inhibit TSH secretion once thyroid hormone levels had reached their set point. But since Josie's thyroid is unable to produce thyroid hormone, there has been a loss of negative feedback, and TSH never receives the signal to shut off, so the TSH levels rise above normal.
 - b. Usually, tumors create more cells than normal that contribute to the higher hormone levels. Therefore, if Josie had more thyroid hormone-secreting cells than normal, as with cancer, her thyroid hormone levels would be much higher than normal, not lower than normal as the tests indicated.
 - c. The thyroid gland requires iodine to produce thyroid hormones because iodine is an integral part of the hormone molecule. Thus, lack of iodine prevented the synthesis of thyroid hormones and the lack of negative feedback on the anterior pituitary gland. Thus, TSH levels increased, overstimulated the thyroid gland, and caused it to grow larger than normal.
 - d. By providing the thyroid gland with iodine, it was able to resume normal production of thyroid hormone. Once thyroid hormone levels reached their set point, they would negatively feedback at the anterior pituitary to inhibit TSH release, and its levels would return to normal.
 - e. Josie will probably need to continue taking thyroid hormone supplements for sometime. After a large portion of the thyroid gland was destroyed by 131I, its ability to secrete T3 and T4 would fall below their normal range of values unless Josie took supplemental thyroid hormone. Theoretically, her doctor could slowly reduce her supplement, which could cause her thyroid to grow to compensate for the reduced intake levels.
3. The question gives us two very important pieces of information: (1) Estrogen stimulates an increase in progesterone receptor number in the uterus and (2) progesterone action (binding to its receptors) is required for pregnancy. Thus, if too little estrogen is secreted, the up-regulation of receptors in the uterus for progesterone cannot occur. As a result, progesterone cannot prepare the uterus for the embryo to attach to its wall following ovulation, and pregnancy cannot occur. Because of the lack of up-regulation of progesterone receptors, the uterus cannot respond adequately to progesterone. If fewer than normal progesterone receptors are present, then a much larger than normal amount of progesterone is needed to produce its normal response.
4. The first piece of information we need to answer this question is given to us: The hormones that prevent asthma attacks work through cAMP mechanisms. The question then asks us to describe various cAMP-based mechanisms of hormone action. A drug can increase the cAMP concentration in a cell by stimulating its synthesis or by inhibiting its breakdown. A drug that binds to a receptor that increases adenylate cyclase activity increases cAMP synthesis. Because phosphodiesterase normally causes the breakdown of cAMP, an inhibitor of phosphodiesterase decreases the rate of cAMP breakdown and causes cAMP to increase in the smooth muscle cells of the airway, producing relaxation.
5. This question highlights the idea of form follows function. Each class of hormones is best suited for a particular type of response. Nuclear receptor mechanisms result in the synthesis of new proteins that exist within the cell for a considerable amount of time. Thus, nuclear receptors are better adapted for mediating responses that last a relatively long time (i.e., for many minutes, hours, or longer). On the other hand, membrane-bound receptors that increase the synthesis of intracellular mediators, such as cAMP, normally activate enzymes already in the cytoplasm of the cell for shorter periods. The synthesis of cAMP occurs quickly, but the duration is short because cAMP is broken down quickly, and the activated enzymes are then deactivated. Therefore, membrane-bound receptor mechanisms are better adapted to short-term and rapid responses. In short, nuclear receptor mechanisms usually result in new proteins, whereas membrane-bound receptors usually activate already existing proteins.

Chapter 18

2. Secretions from the posterior pituitary are sometimes called neurohormones because the posterior pituitary is continuous with the brain and an extension of the nervous system. The neurons that secrete these hormones have their cell bodies in the hypothalamus of the brain, and their axons extend into the posterior pituitary. If the posterior pituitary is removed, the distal ends of the axons of the neurons that have their cell bodies in the hypothalamus are removed. The neurons survive, and after a few days, the proximal ends of the axons become capable of secreting the neuropeptides that the neurons normally secrete. Cells located entirely within the gland secrete the hormones of the anterior pituitary. They are released in response to neurohormones that travel through the hypothalamohypophysial portal system from the hypothalamus to the anterior pituitary. Removal of the anterior pituitary removes the cells that synthesize and secrete anterior pituitary hormones. Consequently, there is a permanent decrease in anterior pituitary hormones.
3. The beer Luke drank contained a substantial amount of water, as well as some alcohol. The water in the beer increased Luke's blood volume and reduced his blood osmolality, which caused ADH secretion from the posterior pituitary gland to decrease. In addition, the alcohol in the beer caused the rate of ADH secretion to decrease even further. The decreased ADH secretion caused the kidneys to increase the volume of dilute urine, which resulted in reduced blood volume with an increased osmolality. By morning, he was somewhat dehydrated, and that caused him to be thirsty.
4. Recall that growth hormone (GH) targets cartilage in the epiphyseal plate of long bones and stimulates cell division of the chondrocytes. Administering GH to young people before the growth of their long bones is complete causes their long bones to grow. While Mr. Hoops's son is actively growing, GH administration would cause him to grow taller. To accomplish this, GH has to be administered over a considerable length of time. However, there could also be unwanted changes consistent with acromegaly (oversecretion of GH). Other side effects, such as abnormal joint formation and diabetes mellitus, are also possible. In addition to undesirable changes in the skeleton, nerves frequently are compressed as a result of the proliferation of connective tissue. Because GH spares glucose usage, chronic hyperglycemia results, frequently

- leading to diabetes mellitus and severe atherosclerosis. Thus, Mr. Hoops's doctor would not prescribe GH.
5. Remember that hormones of the hypothalamus and anterior pituitary regulate thyroid hormones. TRH from the hypothalamus stimulates the secretion of TSH from the anterior pituitary. TSH travels to the thyroid to promote secretion of thyroid hormones. In response to the large amount of the abnormal TSH-like immunoglobulin (a protein), thyroid hormones are oversecreted by the thyroid gland (hyperthyroidism). Thus, Becky has a type of hyperthyroidism called Graves disease. Because production of the protein cannot be inhibited by thyroid hormones as TSH is, oversecretion of the thyroid gland is prolonged, and the symptoms associated with hyperthyroidism become obvious: her increased appetite and weight loss, as well as her other symptoms. Because TSH stimulates gland growth as well as hormone secretion, the thyroid gland enlarges. In addition, the increased thyroid hormones have a negative-feedback effect on the hypothalamus and pituitary gland. TRH secretion from the hypothalamus and TSH secretion from the anterior pituitary gland are inhibited.
 6. Removal of the thyroid gland means that the tissue responsible for thyroid hormone (T_3 and T_4) secretion from thyroid follicles, and calcitonin secretion from parafollicular cells is gone. However, blood levels of Ca^{2+} remain within their normal range. Thyroid hormone does not affect Ca^{2+} levels and calcitonin is not essential for the maintenance of normal blood Ca^{2+} levels. However, recall that the four parathyroid glands are embedded in thyroid tissue on the posterior side of the thyroid gland. Although thyroid removal surgery is generally very safe, there is some risk of removing or damaging the parathyroid glands, especially in young children. Removal of the parathyroid gland eliminates PTH secretion. Without PTH, blood levels of Ca^{2+} fall. Recall from chapter 9 that, when the blood levels of Ca^{2+} fall below normal, the permeability of nerve and muscle cells to Na^+ increases. As a consequence, spontaneous action potentials are produced, causing tetanus of muscles. Death can result from tetany of respiratory muscles.
 7. To answer this question, you must first realize that, because cortisone mimics the normal adrenal cortex hormone, cortisol, it will also act by negative feedback at the anterior pituitary. Cortisone inhibits ACTH secretion from the anterior pituitary. Second,

it is important to understand that ACTH is required to prevent atrophy of the adrenal cortex. In the absence of ACTH, the adrenal cortex shrinks and may never recover to produce its normal secretions, even if ACTH secretion increases again.

8. a. Ethan's symptoms are consistent with those commonly found in people suffering from Cushing syndrome. Elevated blood glucose levels and reduced blood K^+ levels are also consistent with Cushing syndrome. Cortisol increases gluconeogenesis and decreases the use of glucose in metabolism. Therefore, blood glucose levels increase. Increased blood glucose levels stimulate insulin secretion, and insulin causes glucose to be taken up by adipose cells, where they convert glucose to fat. The decrease in muscle mass occurs because cortisol decreases protein synthesis and increases protein breakdown. Reduced blood levels of K^+ result from an increased rate of K^+ transport by the renal tubules and their elimination in the urine.
- b. Ethan's blood cortisol levels were very high, and his blood ACTH levels were very low. Blood CRH levels are not normally measured. ACTH from the anterior pituitary normally stimulates cortisol secretion from the adrenal glands. Because cortisol has a negative-feedback effect on the rate of ACTH secretion, and because the blood ACTH levels were low, the high blood levels of cortisol could not be due to elevated ACTH secretion from the anterior pituitary. A possible cause of increased cortisol secretion is an adrenal gland tumor, which was confirmed by imaging techniques.
- c. After the surgical removal of Ethan's left adrenal gland, the blood levels of cortisol decreased because the tumor was the source. As the blood cortisol levels decreased to normal, the rate of ACTH secretion from the anterior pituitary gland increased. Blood cortisol levels can be within the normal range of values if production of cortisol by the right adrenal gland compensates for the missing left adrenal gland. If cortisol production by the remaining adrenal gland is not adequate, additional cortisol will have to be administered.
- d. If Ethan's high blood cortisol had been due to a hormone-secreting tumor of the anterior pituitary gland, blood levels of both ACTH and cortisol would have been elevated. There was no evidence that cancer was involved but, if cancer

tissue was the source of ACTH, blood ACTH and cortisol levels would have increased.

9. Recall from chapter 16 that the parasympathetic nervous system is the “rest-and-digest” portion of the autonomic nervous system. Therefore, an increase in insulin secretion in response to parasympathetic stimulation and gastrointestinal hormones is consistent with the maintenance of homeostasis because parasympathetic stimulation and increased gastrointestinal hormones result from conditions such as eating a meal. Insulin levels therefore increase just before large amounts of glucose and amino acids enter the blood. The elevated insulin levels prevent a large increase in blood glucose and the loss of glucose in the urine.
10. It is important to understand that a large meal, high in carbohydrates, will increase blood glucose as the nutrients are transported from the small intestine into the blood. The body cells need to take up the glucose across their plasmal membranes either to utilize it immediately or to store it for later use. Cells take up glucose only in the presence of insulin. Glucose serves as the stimulus for insulin secretion and the inhibitor of glucagon secretion. Thus, after eating, insulin levels increase and glucagon levels decrease. Long before 12 hours has passed after a meal, blood glucose levels drop. Again, it is glucose that serves as the signal for hormone secretion. Now the reduction in blood glucose stimulates glucagon secretion and inhibits insulin secretion. Glucagon then promotes release of stored glucose into the blood to be utilized by cells until the next meal. In response to a meal high in protein but low in carbohydrates, insulin secretion is only slightly elevated, but glucagon secretion is increased. Insulin secretion is stimulated by the parasympathetic system and an increase in blood amino acid levels. Glucagon is stimulated by low blood glucose levels and by some amino acids. The lower insulin secretion causes some increase in the rate of glucose uptake and amino acid uptake, but the rate of uptake is not great enough to cause blood glucose levels to fall below normal values. Glucagon also causes glucose to be released from the liver. During exercise, sympathetic stimulation inhibits insulin secretion. As blood glucose levels decline, enhanced glucagon secretion occurs. The lower rate of insulin secretion reduces the rate at which tissues, such as skeletal muscle, take up glucose. Thus, during exercise, muscle depends on intracellular glycogen and fatty acids for energy, and blood glucose levels are maintained within

the normal range of values. The actions of glucagon prevent glucose levels from dropping too much.

11. Recall from chapter 16 that the sympathetic nervous system is activated during intense exercise and inhibits insulin secretion. Blood glucose levels are not high because skeletal muscle tissue continues to take up some glucose and metabolize it. In chapter 9, we learned that skeletal muscles store glucose as glycogen, and muscle contraction depends on glucose and fatty acid metabolism. During a long run, muscle glycogen levels are depleted as the cells metabolize more and more glucose. The “kick” at the end of a race results from increased energy produced by anaerobic respiration, which uses glucose or glycogen as an energy source. However, because blood glucose levels and glycogen levels are low at the end of a long-distance race, the runners’ source of energy is insufficient for the greatly increased muscle activity a sprint to the finish would require.
12. In this “Microbes in your Body”, you learned that obese people tend to have more of the *Firmicutes* bacteria in their gut than would lean people. You also learned that shifts in gut microbiota populations are correlated with changes in the production of microbial products, including anti-hunger hormones. Finally, in this chapter, you learned that nutrient intake and blood glucose levels are related to particular hormone levels. These hormones include cortisol and GH. Cortisol and GH levels both increase when glucose levels decline. Each of these two hormones induces lipolysis (lipid break down). This decreases overall adipose tissue stores. GH then promotes lean muscle mass, presumably because the body utilizes the lipid break down products as energy sources or precursor molecules. Thus, in an obese person, anti-hunger signals are low, which could encourage ingestion of more food throughout the day. In other words, people with more *Firmicutes* bacteria in their gut would be hungrier than normal. If this were the case, blood glucose levels would remain higher than normal. With elevated blood glucose levels, neither cortisol nor GH levels increase and adipose tissue stores remain the same or even become greater. To summarize, obese people may eat more because they don’t have the appropriate signals to stop eating. In addition, they have lower levels of GH and cortisol, both of which break down adipose tissue. The combination of being hungrier and having lower levels of GH and cortisol promotes the storage of even more adipose tissue resulting in continued or increased obesity.

13. Removal of part of the thyroid gland reduces the amount of thyroid hormone secreted by the gland. Usually, enough thyroid tissue can be removed to reduce secretion of thyroid hormone to within the normal range. In addition, the remaining thyroid tissue normally does not enlarge enough to produce more thyroid hormone, although there are exceptions. The removal of the thyroid tissue does not remove the influence of the abnormal antibodies on the tissues behind the eyes. Thus, in many cases the condition’s effect on the eyes is not improved.

Chapter 19

2. The fetus relies solely on the maternal blood supply for oxygen. Fetal hemoglobin must be more effective at binding oxygen than adult hemoglobin in the maternal blood, so that the fetal circulation can draw the needed oxygen away from the maternal circulation. If the hemoglobin of the maternal blood had an equal or higher oxygen affinity, the hemoglobin of fetal blood would not be able to draw away the required oxygen, and the fetus would die.
3. We learned in this chapter that reticulocytes are immature red blood cells released from the red bone marrow into the circulation. Consider that, by donating a unit of blood, Juan’s red blood cell count dropped below normal, so we would expect his body to respond by producing more red blood cells. Erythropoietin secretion from the kidneys stimulates erythropoiesis, red blood cell production, in the red bone marrow to increase. As a result, we would expect Juan’s reticulocyte count to increase during the week after he donated blood. This process continues at the increased rate until Juan’s normal red blood cell count is reestablished.
4. To answer this question, we first need to determine the effect carbon monoxide has on red blood cells. Recall that carbon monoxide binds very readily to hemoglobin and does not tend to unbind. Therefore, carbon monoxide-bound hemoglobin in red blood cells can no longer transport oxygen. This essentially leads to a decrease in blood oxygen levels. We also learned that low blood oxygen levels stimulate red blood cell production by causing the release of erythropoietin, primarily by the kidneys. Erythropoietin stimulates red blood cell production in the red bone marrow. Thus, we can predict that the number of red blood cells in the person’s blood would increase.
5. Referring to table 19.2 will help identify each of the white blood cells. It is also

- helpful to compare the size of each cell with red blood cells as well. In each figure, red blood cells are visible for easy comparison. (a) The cell in this figure is slightly larger than red blood cells and has a large, round nucleus with a small amount of cytoplasm. This cell is a lymphocyte. (b) The cell in this figure is larger than a red blood cell and has many bluish-purple granules. This cell is a basophil. (c) The cell in this figure is very large and has a kidney-shaped nucleus. It is a monocyte. (d) The cell in this figure has a three-lobed nucleus. It is most likely a neutrophil. (e) The cell in this figure has a bi-lobed nucleus and many bright red-stained granules. It is an eosinophil.
6. Platelets are normally inactive; however, they become activated at sites of tissue injury. These are the areas where clot formation is needed to stop bleeding.
 7. Before answering this question, consider that Cedric had two different drugs in his system that affect blood clotting. Both the aspirin and t-PA contributed to his rapid improvement. We learned in this chapter that aspirin inhibits thromboxane synthesis and consequently slows down the rate at which clotting occurs. Since Cedric had taken aspirin that morning, we can assume that his condition could have been worse if he had not done so. The t-PA increases the conversion of plasminogen to plasmin, which breaks down the clot. The t-PA acted quickly to remove the cardiac thrombosis before major damage to his heart occurred.
 8.
 - a. We learned that HDN is caused by an Rh incompatibility between a pregnant mother with Rh-negative blood and her Rh-positive child. If the mother is sensitized to the Rh antigen, she can produce anti-Rh antibodies that cross the placenta and cause agglutination and hemolysis of fetal red blood cells. A transfusion would replace the red blood cells lost by agglutination and hemolysis.
 - b. Remember that an exchange transfusion is different than just a transfusion. In a transfusion, donor blood is introduced to the recipient, but in an exchange transfusion, the recipient's blood is replaced, meaning that as the donor blood is introduced into the system the recipient's blood is removed. An exchange transfusion not only increases the number of red blood cells but also decreases bilirubin and anti-Rh antibody levels by removing them in the withdrawn blood. The presence of fewer anti-Rh antibodies decreases the agglutination and lysis of red blood cells.
 - c. Remember that erythropoietin stimulates red blood cell production. Even though new red blood cells were introduced during the exchange transfusion, administering erythropoietin will also increase Billy's red blood cell count.
 - d. Erythropoietin levels increase as a result of low blood oxygen levels. This is directly related to the red blood cell count. Considering that Billy's red blood cell count was extremely low as a result of HDN, we would predict that his erythropoietin level would be higher than a fetus without HDN.
 - e. A major physiological change that occurred after birth was that Billy was able to breathe on his own. The ability to oxygenate the blood using the lungs is greater than the ability to oxygenate the blood across the placenta. Billy's blood oxygen levels increased and his erythropoietin levels decreased. Thus, his production of red blood cells decreased and his anemia got worse.
 - f. To treat HDN with an exchange transfusion, the donor's blood should be Rh-negative, even though the newborn is Rh-positive. Rh-negative red blood cells do not have Rh antigens. Therefore, any anti-Rh antibodies in the newborn's blood do not react with the transfused Rh-negative red blood cells. Eventually, all of the Rh-negative red blood cells die, and only Rh-positive red blood cells are produced by the newborn.
 - g. Remember that blood types are genetically determined. Giving an Rh-positive newborn a transfusion of Rh-negative blood would not change the newborn's blood type. Even though Rh-negative blood is introduced to the body, over time all of the Rh-negative red blood cells die. The new red blood cells are produced from the bone marrow stem cells, which are genetically Rh-positive. Thus, only Rh-positive red blood cells are produced by the newborn.
 9. After reading the question, we know to focus on blood tests that are associated with identification of bacterial infections. White blood cells defend the body against pathogens. A white blood differential cell count would be useful and would show an abnormally high neutrophil percentage because they increase during bacterial infections.
- pericardium. In Tony's case, the pericarditis is a result of a viral infection. Pericarditis can lead to fluid accumulation in the pericardial sac. Tony's pain results from inflammation and distention of the pericardial membranes. His pulse was weak because the fluid in the pericardial sac compressed both the heart and the veins delivering blood to the heart; consequently, the heart could not fill with as much blood as normal. With less blood entering the heart, Tony's stroke volume, or volume of blood pumped from the heart, also decreased, causing a weak pulse and lower blood pressure. Recall from chapter 16 that increased sympathetic stimulation of the heart occurs when blood pressure begins to decrease, resulting in tachycardia. The increased heart rate helps maintain blood pressure. The jugular veins, which carry blood toward the heart, are distended because the accumulated fluid in the pericardial sac compresses the heart, preventing complete filling of the heart and reducing the flow of blood from the jugular veins toward the heart. Tony's physician used a needle to remove excess fluid from the pericardial space. Reviewing figure 20.2, we can see that the needle is most likely inserted in the fifth or sixth intercostal space near the sternum and penetrates the following body layers: the skin, the subcutaneous tissue, the intercostal muscles, the fibrous pericardium, and the parietal pericardium.
3. The SA node is the pacemaker of the heart. Action potentials develop at a normal rate in the SA node and are conducted to the AV node and stimulate atrial contraction. In the AV node, the action potentials are delayed. The action potentials are rapidly conducted through the ventricular muscle and cause the ventricles to contract. If the delay is too long, action potentials are produced in the SA node again before action potential conduction through the AV node is complete. If more than one action potential at a time is produced in the SA node before conduction of action potentials through the ventricles is complete, the atria contract at a greater frequency than the ventricles. The atria may contract two or three times for each time the ventricles contract.
 4. Before answering the question, we need to define tetanic contraction. Recall from chapter 9 that a tetanic contraction is a sustained contraction in which the frequency of stimulation of the muscle is so rapid that no relaxation occurs. The purpose of cardiac muscle contractions is to pump blood through the circulation by contracting and relaxing in a repeated cycle. Tetanic contractions in cardiac muscle would

Chapter 20

2. The Clinical Impact, "Pericarditis and Cardiac Tamponade," explains that pericarditis is an inflammation of the serous

interrupt the pumping action produced by the cycle of contraction and relaxation, and the blood flow would cease. Tetanic skeletal muscle contractions are important to maintain posture or to hold a limb in a specific position.

5. The key piece of information to answer this question is that cardiac muscle cells are interconnected via specialized gap junctions, or intercalated disks. The intercalated disks allow cytoplasm, and thus depolarization-inducing positive ions to flow from cell to cell. Disrupting these connections interrupts the ion flow and prevents contraction. However, in skeletal muscle, adjacent muscle fibers do not share cytoplasm; rather, each fiber is stimulated separately by its own motor neuron or motor neuron branch. Therefore, while microlesions in a particular skeletal muscle fiber may prevent its contraction, adjacent cells would not be affected.
6. In section 20.3, “Anatomy of the Heart,” we learn that the left ventricle has the thicker wall. The pressure produced by the left ventricle is much higher than the pressure produced by the right ventricle. It is important for each ventricle to pump the same amount of blood because, with two connected circulation loops (pulmonary circuit and systemic circuit), the volume of blood flowing into one must equal the volume of blood flowing into the other, so that one does not become overfilled at the expense of the other. For example, if the right ventricle pumps less blood than the left ventricle, blood accumulates in the systemic blood vessels. If the left ventricle pumps less blood than the right ventricle, blood accumulates in the pulmonary blood vessels.
7. The pumping action of the heart depends on coordinated cycles of contraction and relaxation of the chambers of the heart, allowing them to fill and empty in the proper sequence. Fibrillation destroys the coordinated contractions, and the cardiac muscle loses its function as a pump. Recall that the ventricles are the primary pumping chambers of the heart and the atria function more as blood reservoirs. The pumping action of the ventricles is necessary to maintain normal blood flow to the tissues of the body at all times. Ventricular fibrillation results in death because of the heart’s inability to pump blood. The pumping action of the atria is most important during exercise; therefore, atrial fibrillation does not destroy the ventricles’ ability to pump blood.
8. Figure 20.19 will be very useful in answering this question. From the figure we can see that ventricular diastole occurs between the second heart sound of one cardiac cycle and the first heart sound of the next cardiac cycle. The second heart sound is produced as the aortic semilunar valve closes. The aortic pressure decreases from 95 mm Hg to approximately 80 mm Hg when the left ventricle contracts again. This causes the bicuspid valve to close, producing the first heart sound of the next cardiac cycle. Now, let us consider the pressure changes in the left atrium and ventricle. When the aortic semilunar valve closes (second heart sound), the pressure in the left ventricle decreases rapidly to nearly 0 mm Hg. As soon as the pressure decreases below the pressure in the left atrium, the bicuspid valve opens, and blood flows into the left ventricle. Pressure remains low in the left atrium and the left ventricle, with pressure in the left atrium slightly greater than in the left ventricle. Finally, pressure increases a few mm Hg when the left atrium contracts, causing additional blood to flow from the left atrium into the left ventricle. When the left ventricle begins to contract, the pressure in the left ventricle increases but, as soon as the pressure is greater in the left ventricle than in the left atrium, the bicuspid valve closes, causing the first heart sound of the next cardiac cycle.
9. We learned in chapter 16 that sympathetic stimulation increases heart rate. If venous return remains constant, stroke volume decreases as the number of beats per minute increases. An increased heart rate and stroke volume means the heart is doing more work, which means the cardiac tissue requires more oxygen for cellular respiration. Dilation of the cardiac blood vessels is important because it allows for a greater blood supply to carry more oxygen to the cardiac tissue.
10. a. In the Clinical Impact, “Abnormal Heart Sounds,” we learned that a stenosed valve has an abnormally narrow opening. The stenosed valve makes it more difficult for contractions of the left ventricle to force blood into the aorta. The stroke volume decreases because the left ventricle is unable to overcome the increased resistance to blood flow through the narrowed valve.
 - b. Because of the increased resistance caused by the stenosed aortic semilunar valve, the left ventricle had to generate a greater force to cause blood to flow into the aorta. Just as skeletal muscle hypertrophies in response to the resistance of moving heavy weights, cardiac muscle hypertrophies in response to the greater resistance to blood flow through the stenosed valve.
11. c. The mean arterial pressure is equal to cardiac output \times peripheral resistance. Recall that cardiac output is equal to stroke volume \times heart rate. We described earlier how a stenosed valve causes a decrease in stroke volume, which in turn causes a decrease in mean arterial pressure, unless there is a compensating increase in heart rate or peripheral resistance.
 - d. When Norma rises to a standing position, gravity affects blood in the arteries and veins, and the blood tends to settle in the blood vessels below the heart. Consequently, there is decreased venous return to the heart, which results in decreased cardiac output (the Starling law of the heart). Decreased cardiac output results in decreased blood pressure, and therefore decreased blood flow to the brain, causing dizziness.
 - e. The baroreceptor reflexes detect changes in blood pressure and lead to changes in heart rate and the force of contraction to maintain homeostatic blood pressure levels. We have already predicted that Norma’s blood pressure decreases when she stands. This activates the baroreceptor reflexes. From figure 20.23, we see that her heart rate would increase. Although Norma has a normal baroreceptor reflex, the heart is not able to pump enough blood past the stenosed valve to increase stroke volume and maintain blood pressure.
 - f. After reviewing Clinical Impact, “Angina, Infarctions, and the Treatment of Blocked Coronary Arteries,” we know that angina pectoris results from inadequate blood delivery to heart muscle through the coronary circulation. Norma’s stenosed valve has reduced blood pressure in the aorta, which reduces blood delivery to the body and to the coronary blood vessels. At rest, sufficient blood is delivered to the cardiac muscle, and there is no pain; however, when Norma starts exercising, the cardiac muscle requires more oxygen, which the blood cannot deliver through the stenosed valve. This results in an increase in anaerobic respiration and a decrease in pH, which is responsible for the pain of angina pectoris.

11. Rupture of the left ventricle can occur several days after a myocardial infarction. As the necrotic tissues are being removed by macrophages, the wall of the ventricle becomes thinner and may bulge during systole. If the wall of the ventricle becomes very thin before new connective tissue is

deposited, it can rupture. If the left ventricle ruptures, blood flows from the left ventricle into the pericardial sac, resulting in cardiac tamponade. As blood fills the pericardial sac, it compresses the ventricle from the outside. As a consequence, the ventricle is not able to fill with blood, and its pumping ability is rapidly eliminated. Rupture of the left ventricular wall, therefore, quickly results in death.

Chapter 21

2. As stated in the question, atherosclerosis of vessels occurs when lipid deposits block the vessels, which results in reduced blood flow through the vessel. The tissues to which the blocked vessels supply blood will therefore have reduced oxygen and nutrients. Since the carotid artery supplies blood to the brain, we would expect atherosclerosis of these vessels to lead to reduced brain function, which may include confusion and loss of memory.
3.
 - a. We learned in the section “Blood Flow and Poiseuille’s Law” that a small change in the diameter of a vessel dramatically changes the resistance to flow and therefore the amount of blood that flows through it. Vasoconstriction of blood vessels in the skin in response to cold exposure causes a reduction in blood flow through the skin because the blood vessel diameter decreases and the resistance to blood flow increases. The skin will appear pale due to the lower blood flow.
 - b. Just like the answer to part a, this question focuses on the relationship between blood vessel diameter and blood flow (Poiseuille’s law). Vasodilation of blood vessels in the skin in response to elevated body temperature would cause an increase in blood flow through the skin because the blood vessel diameter increases and the resistance to blood flow decreases. The skin will appear flushed due to the higher blood flow.
 - c. Poiseuille’s law also states that the viscosity of blood determines resistance to blood flow. As viscosity of blood increases, blood flow decreases. Erythrocytosis results in an increase in red blood cell numbers, which also increases the viscosity of blood. We would therefore expect that erythrocytosis decreases blood flow.
4. Vasoconstriction of Richard’s cutaneous blood vessels would cause a substantial increase in his systemic blood pressure. From Laplace’s law, we learned that, as the diameter of a vessel increases, the force applied to the vessel wall increases. An aneurysm is a bulge that forms in an arterial wall that has weakened. The increase in Richard’s blood pressure due to the sudden vasoconstriction of his cutaneous blood vessels would apply more force on the aneurysm. Because this is a weakened area of the artery wall, the increase in force applied to the aneurysm is more likely to rupture the wall. The rupture of an arterial wall is life threatening.
5. Arterial blood pressure can increase substantially without resulting in edema. Recall that the precapillary sphincters constrict to match blood flow into capillary beds with the metabolic needs of tissues. Thus, the capillary blood pressure does not change substantially, even if blood pressure increases to high levels. Blood pressure must increase above approximately 175 mm Hg before edema results. In contrast, a small increase in venous pressure leads to edema because there is not a sphincter muscle that protects the capillary from an increase in pressure due to resistance of blood flow out of the capillary bed. If venous pressure increases, the blood pressure in the capillaries must increase also to overcome the resistance to blood flow and maintain the normal movement of blood. The increase in capillary pressure changes the net filtration pressure, increasing the amount of fluid that flows from the capillary into the tissues and reducing the amount of interstitial fluid that enters the circulation, therefore resulting in edema.
6.
 - a. The blocked vein in Harry’s right leg caused edema and led to tissue ischemia. Edema developed inferior to the blocked vein. Blockage of the vein increased the capillary hydrostatic pressure in the capillary beds drained by the blocked vein. The increased capillary hydrostatic pressure increased the amount of fluid that flowed from the capillaries into the tissue spaces and reduced the amount of fluid that returned to the capillaries. Consequently, fluid accumulated in the tissue spaces and caused edema (see figure 21.36). The ischemia resulted in pain, much the way ischemia of the heart causes pain during myocardial infarctions (see chapter 20).
 - b. Emboli that originated in the posterior tibial vein would pass through the following parts of the circulatory system before lodging in the pulmonary arteries of the lungs: posterior tibial vein, popliteal vein, femoral vein, external iliac vein, common iliac vein, inferior vena cava, right atrium, right ventricle, pulmonary trunk, right or left pulmonary artery. Emboli lodge in branches of the pulmonary arteries and are most likely to lodge in the lungs because the pulmonary arteries branch many times before delivering blood to the pulmonary capillaries, and as they branch their diameters decrease. Even small emboli eventually lodge in the smaller branches of the pulmonary arteries. The other parts of the circulatory system through which the emboli pass have much larger diameters, so emboli can pass readily through them.
 - c. When emboli are large enough or numerous enough to block blood flow through a significant part of the lungs, resistance to blood flow through the lungs increases. The increased resistance increases the pulmonary venous pressure, which increases the afterload for the right ventricle. If the right ventricle is unable to overcome the increased afterload, failure of the right side of the heart can occur, and blood flow through the lungs is reduced.
 - d. First let us address the effect of pulmonary emboli on blood oxygen levels. Pulmonary emboli large enough to significantly reduce blood flow through the lungs reduce the lungs’ ability to carry out gas exchange with blood, and blood oxygen levels decrease. Next, let us address the affect of pulmonary emboli on the left ventricle’s ability to pump blood. Pulmonary emboli block normal blood flow through the lungs, thereby reducing the blood volume returning to the left ventricle. This would also cause a reduction in cardiac output. Recall that cardiac output also affects blood pressure, so we would expect hypotension, or a reduction in blood pressure, to occur. As blood pressure falls, the homeostatic mechanisms described in figure 21.40 are activated to increase blood pressure to normal levels. Manifestations of hypotension, such as increased heart rate, weak pulse, and pallor, would be present.
 - e. Heparin and coumadin are anticoagulants, discussed in chapter 19. They are prescribed to slow down the rate of blood clot formation. Heparin must be administered intravenously, but coumadin can be taken orally, which makes home use possible. Harry’s prothrombin time will be checked periodically to ensure that enough anticoagulant is administered to prevent enlargement of the thrombus in the deep vein of his leg and to prevent additional emboli from forming.

Remember that enzymes naturally found in our blood break down coagulated blood. In Harry's case the clots are removed because the slower rate of coagulation allows the clots to be broken down faster than they can form.

7. In chapter 16, we learned that, during times of rest, sympathetic stimulation decreases. We can predict that, while this athlete is relaxing, the sympathetic stimulation of the arteries in her skeletal muscles, the arteries in her digestive system, and the large veins decreases. As a result, vasoconstriction increases in the arteries of her muscles, and vasodilation occurs in the blood vessels of her digestive system and in the large veins. Blood flow decreases to her skeletal muscles, which are less active and require less oxygen and nutrients. Blood flow increases in her digestive system, which is more active during times of rest and relaxation and therefore has a higher oxygen and nutrient demand. In addition, blood accumulates in the large veins as they undergo vasodilation. Consequently, venous return to the heart decreases, which is consistent with the reduced cardiac output.
8. During a headstand, gravity acts on the blood, causing it to settle in the vessels of the head and chest. Blood pressure in the area of the aortic arch and carotid sinus baroreceptors increases. Figure 21.40 illustrates how the baroreceptor reflexes regulate changes in blood pressure. The increased blood pressure activates the baroreceptor reflexes, increasing parasympathetic stimulation of the heart and decreasing sympathetic stimulation. Thus, the heart rate decreases. As blood from the periphery runs down to the heart, venous return increases, causing stroke volume to increase (Starling law of the heart). The activated baroreceptor reflexes also decrease vasomotor tone, and some peripheral vasodilation can occur.
9. The rapid loss of a large volume of blood activates the mechanisms responsible for maintaining blood pressure. Recall that blood pressure regulatory mechanisms include the baroreceptor reflexes, chemoreceptor reflexes, and hormonal mechanisms. In response to a dramatic drop in blood pressure due to the rapid loss of a large volume of blood, the baroreceptor mechanism, adrenal medullary mechanism, and chemoreceptor mechanism increase the heart rate and result in vasoconstriction of blood vessels, especially in the skin and viscera. Angiotensin II is produced quickly, and it causes vasoconstriction and stimulates aldosterone secretion. Aldosterone, which requires up to 24 hours

to become maximally active, increases water reabsorption from the kidneys and reduces the loss of water in the form of urine. Blood volume is therefore increased. All of these mechanisms increase blood pressure back to its normal value.

If blood is lost over several hours, the decrease in blood pressure is not as dramatic as when blood loss occurs quickly. Consequently, mechanisms that respond to a rapid and large decrease in blood pressure are stimulated to a lesser degree. These include the chemoreceptor reflex, the vasopressin mechanism, and the adrenal medullary mechanism. The baroreceptor reflexes are most sensitive to sudden decreases in blood pressure, but the baroreceptor reflexes are still sensitive to decreases in blood pressure that occur over a period of several hours. The baroreceptor reflexes that trigger vasoconstriction in response to the blood loss are substantial. The kidneys detect even small decreases in blood volume. Consequently, the renin-angiotensin-aldosterone mechanism is activated and remains active until the blood pressure is returned to its normal range of values. Aldosterone secretion increases and, though it requires several hours to become maximally active, it continues to stimulate water reabsorption by the kidneys, increasing blood volume until the blood pressure returns to its normal range of values.

Chapter 22

2. a. Cancer cells can break free from a tumor and spread, or metastasize, to other parts of the body by entering lymphatic or blood capillaries (see chapter 3). If the cancer cells enter the lymphatic capillaries, they are carried to the lymph nodes, which filter lymph. The first lymph nodes in which cancer cells are likely to become trapped are the sentinel lymph nodes.
 - b. Test results showed that all of the sentinel lymph nodes contained cancer cells, indicating that cancer cells had spread into her lymphatic system. Cindy's cancerous tumor is in her left breast, and the axillary lymph nodes drain the superficial thorax and upper limb. Removal of these lymph nodes minimizes the risk of further metastasis.
 - c. Recall from chapter 21 approximately one-tenth of the fluid entering tissues is normally removed by the lymphatic system. Removal of the lymph nodes and their attached lymphatic vessels disrupts the normal removal of fluid from tissues, resulting in lymphedema, the accumulation of fluid in the tissues.
 - d. Remember that contraction of skeletal muscle and the thoracic pressure changes associated with breathing are both mechanisms for moving lymph through lymphatic vessels. Exercise increases skeletal muscle contractions and breathing. Consequently, more fluid can enter lymphatic capillaries, reducing edema.
 - e. The external force applied to tissues by a compression bandage or garment reduces the movement of fluid from the circulation into tissues (see chapter 21) thereby reducing lymphedema.
 - f. Recall that contraction of lymphatic vessels and the presence of valves along these vessels ensure that lymph moves through lymphatic vessels in one direction, from the peripheral tissues toward the venous system of the thorax. A compression pump mimics the normal contraction and relaxation of the lymphatic vessels, moving the lymph in a distal-to-proximal direction.
3. Because we learned that gut microbiota are critical to normal immune system function, it is possible that the malnourished twin will suffer from an immune deficiency throughout life. There is also the possibility of this twin having many more allergies than their sibling. Feeding undernourished children special probiotics that promote growth of "good" microbes, providing banked breast milk from other mothers, and as a last resort, transplanting fecal material from the thriving sibling, are all solutions that could restore their gut microbiota to normal.
 4. Remember that the combination of a MHC class I molecule and an antigen is necessary to activate T cells. MHC molecules are genetically determined. Thus, unless mouse B is essentially genetically identical to mouse A, the T cells from mouse A that are introduced to mouse B will not respond to the antigen. The T cells are MHC-restricted, meaning they must interact with the MHC proteins of mouse A as well as the antigen from virus X, to be activated and respond.
 5. We learned that a B cell phagocytizes and processes antigens that combine with MHC molecules on the surface of cells. Helper T cells interact with the MHC-antigen complex to stimulate the B cell to divide. The daughter cells then produce antibodies. If the antigens are eliminated, the stimulus for B-cell proliferation and antibody production is then removed.
 6. The first exposure to the disease-causing agent (antigen) evokes a primary immune response, which destroys the existing pathogens but also produces memory cells

that can respond to future infections. As time passes, the antibodies produced during the primary immune response will degrade, and memory cells will die. If, before all of the memory cells are eliminated, a second exposure to the antigen occurs, a secondary response results, increasing the number of antibodies and memory cells again. The newly produced memory cells can provide immunity until the next exposure to the antigen.

7. We learned in this chapter that helper T cells are necessary for the effective activation of cytotoxic T cells. With the depression of helper T cell activity, cytotoxic T cell activity is also reduced.
8. First, recall that vaccines are a form of artificial active immunity caused by deliberately introducing an antigen into the body, stimulating a primary response by the immune system. The immune system responds to the vaccine by increasing the number of specific memory cells and antibodies for the particular disease. This provides long-lasting immunity without disease symptoms. The booster shot stimulates a memory (secondary) response, resulting in the formation of even more memory cells and antibodies. A booster shot improves the effectiveness of the immune system's ability to fight the types of infections for which a person is vaccinated.
9. After reading the Systems Pathology, we learned that SLE is an autoimmune disorder in which self-antigens activate immune responses. Often, this results in the formation of immune complexes and inflammation. Sometimes antibodies bind to antigens on plasma membranes, resulting in the rupture of the plasma membranes. Purpura results from bleeding into the skin. One cause of purpura is thrombocytopenia, a condition in which the number of platelets is greatly reduced, resulting in decreased platelet plug formation and blood clotting (see chapter 19). Considering that SLE is an autoimmune disorder, we can predict that the purpura is the result of the production of antibodies that destroy platelets, causing thrombocytopenia.

Chapter 23

2. It could be that Jake was fibbing when he claimed to be unafraid, trying to impress his girlfriend. But whether he was frightened or not, in order for his body to produce such a sound, certain muscles need to contract. The muscles of expiration cause airflow from the lungs to the exterior through the larynx. As air rushes past the vocal cords, they vibrate. If air is explosively pushed past the vocal cords, they vibrate to a greater degree than when air is pushed past them to a lesser degree, and they produce a louder sound. As for the high pitch of the scream, it is the position of the vocal cords that is important. More tension results in a higher frequency of vibration of the vocal cords, producing a higher-pitched sound. How does the tension increase? The arytenoid cartilages are rotated medially, which moves the vocal cords medially and posteriorly. Finally, the epiglottis-controlling muscles cause it to tip anteriorly so that air can flow past and out of the mouth. For Jake, the result was a high-pitched scream that either endeared him to his girlfriend or left him single.
3. We learned that the cartilage rings of the trachea are incomplete, C-shaped rings and that the esophagus lies in the groove of those rings along the posterior side of the trachea. When a large mouthful of food is swallowed, it stretches the esophagus. Because of the groove along the trachea, movement of food is encouraged because the esophagus can expand. In addition, the trachea can remain open, so that breathing can resume immediately upon swallowing.
4. To answer this question, knowledge you gained from chapter 22 about artificial active immunity is critical. Recall that a vaccination consists of isolated epitopes from the surface of a pathogen that are then injected into a person. In doing so, the vaccine serves to introduce the pathogen to the immune system. This exposure to the pathogen's isolated epitopes allows the immune system to activate specific cytotoxic T cells and B cells for that pathogen. The adaptive immune system will then create antibodies and memory cells for the pathogen, a central role of the immune system. By identifying and purifying the *B. pertussis* virulence factors that allow the bacterium to avoid the complement system, the vaccine would allow the immune system to create antibodies against both the virulence factors and *B. pertussis*'s epitopes. Binding of the antibodies to the complement avoidance virulence factors would neutralize these factors thereby enabling complement to quickly attack and kill the bacteria. In addition, because complement and adaptive immunity work cooperatively, antibody production would occur more quickly. This provides protection against future exposures to *B. pertussis*.
5. In order to calculate alveolar ventilation, you need to use the following formula: $VA = f(VT - VD)$ [f = respiratory rate; VT = tidal volume; VD = dead space].
 $VA = 12(500 - 150) = 4200 \text{ mL/min.}$
 If the tidal volume, dead space, and respiratory rate all increase during exercise, the new alveolar ventilation would be $VA = 24(4000 - 300) = 88,800 \text{ mL/min.}$
 This means that, during exercise, the person gets 84,600 mL/min more air exchange, ultimately increasing the amount of O_2 acquired during exercise when the O_2 demand is higher.
6. The air the diver is breathing has a greater total pressure than atmospheric pressure at sea level. Consequently, the partial pressure of each gas in the air increases. According to Henry's law, as the partial pressure of a gas increases, the amount (concentration) of gas dissolved in the liquid (e.g., body fluids) with which the gas is in contact increases. When the diver suddenly ascends, the partial pressure of gases in the body returns toward sea level barometric pressure. As a result, the amount (concentration) of gas that can be dissolved in body fluids suddenly decreases. When the fluids can no longer hold all the gas, gas bubbles form.
7. At high altitudes, the atmospheric PO_2 decreases because of lower atmospheric pressure. The decreased atmospheric PO_2 results in a decrease in alveolar PO_2 and less oxygen diffusion into lung tissue. If the person's arterioles are especially sensitive to the lower oxygen levels, constriction of the arterioles reduces blood flow through the lungs, and the ability to oxygenate blood decreases.
8. Remember that the oxygen-hemoglobin dissociation curve normally shifts to the right in tissues. The shift of the curve to the left caused by CO reduces hemoglobin's ability to release oxygen to tissues, which contributes to the detrimental effects of CO poisoning. In the lungs, the shift to the left may slightly increase the hemoglobin's ability to pick up oxygen, but this effect is offset by its decreased ability to release oxygen to tissues.
9. A person who cannot synthesize BPG has mild erythrocytosis because his or her hemoglobin releases less oxygen to tissues. Consequently, increased erythropoietin will probably be released from the kidneys, and increased red blood cell production will occur in red bone marrow.
10. When CO_2 moves from fetal blood into maternal blood, it increases CO_2 levels inside maternal red blood cells. As a result, pH inside maternal red blood cells decreases, the affinity of maternal hemoglobin for oxygen decreases, and more oxygen is released. In other words, the maternal

oxygen-hemoglobin curve shifts to the right. Simultaneously, the movement of CO₂ from fetal blood into maternal blood decreases CO₂ levels inside fetal red blood cells and increases pH inside fetal red blood cells. This means that the affinity of fetal hemoglobin for oxygen increases, and more oxygen will bind to fetal hemoglobin. In other words, the fetal oxygen-hemoglobin dissociation curve shifts to the left. This shifting of the maternal and fetal oxygen-hemoglobin curves is called the double Bohr effect. The double Bohr effect increases the delivery of oxygen from maternal blood to fetal blood because maternal hemoglobin releases more oxygen and fetal hemoglobin is more effective at picking up that oxygen.

11. First, we know that hyperventilation is rapid, shallow breathing. Thus, as less air is inhaled with each breath and the rate of breathing goes up, blood levels of CO₂ decline, which increases blood pH. Recall that, as CO₂ is lost, H⁺ and HCO₃⁻ combine to form H₂CO₃, which in turn dissociates to form CO₂ and H₂O. The lowered H⁺ levels cause an increase in blood pH. Remember that the pH scale is an inverse scale where low H⁺ concentration results in high pH. In addition, because CO₂ levels provide the urge to breathe, a person could theoretically hold his or her breath longer after hyperventilating. Holding one's breath increases blood CO₂ levels and decreases blood pH. On the other hand, holding your breath results in a decrease in pH because CO₂ accumulates in the blood. The CO₂ combines with H₂O to form H₂CO₃, which dissociates to form H⁺ and HCO₃⁻. The elevation in H⁺ levels causes a decrease in blood pH (high H⁺ concentration results in low pH).
12. To answer this question, we need to consider what types of stimuli affect the respiratory center. Look at figure 23.21. Notice that receptors for temperature (e.g., cold water), pain (e.g., very cold water), and touch (e.g., swatting on the buttocks) all stimulate the respiratory center. That is why we gasp when we jump into a cold swimming pool—it is involuntary—and babies were swatted on the buttocks—to stimulate their first breath of air.
13. Resistance to airflow is caused by a buildup of mucus and increased inflammatory damage to the air passageways. It becomes difficult to expel air, so FEV₁ decreases. As air is trapped in the alveoli, residual volume gradually increases. Because air exchange in the alveoli is less than normal, physiological dead space increases.

Chapter 24

2. Four. Recall that the greater omentum is a localized mesentery, which consists of serous membranes. Each single layer of the mesentery has two layers of simple squamous epithelium. Since the greater omentum is folded back on itself, that results in four layers of simple squamous epithelium.
3. First, realize that moving the soft palate can close the opening between the nasopharynx and the oropharynx. Normally, during swallowing, the soft palate is elevated, closing off the nasopharynx so that liquids and food bypass the nasal cavity, pass through the oropharynx, and enter the esophagus. If a person laughs suddenly while drinking a liquid, the liquid may be explosively expelled from the mouth and even the nose because the soft palate relaxes during laughing. If a person tries to swallow and speak at the same time, choking is most likely to occur. Speaking requires that the epiglottis be elevated, so that air can pass out of the larynx. When the epiglottis is raised, food or liquid can pass into the larynx and choke the person.
4. Alice's physician concluded that the inflammation of her larynx was due to the reflux of gastric fluid into her esophagus while she was sleeping. In general, reflux is more likely after eating a meal and while lying down. Gastric acid secretion increases after a meal mainly because of the cephalic and gastric phases of gastric secretion, and gravity normally helps keep gastric fluid in the stomach. During the night, the gastric fluid moved through the esophagus and entered her larynx. An antacid was prescribed to neutralize the low pH of the gastric secretions. Two classes of drugs decrease H⁺ secretion. Both histamine receptor antagonists and proton pump inhibitors reduce the movement of H⁺ into the lumen of the stomach, thereby increasing the pH of the gastric fluid secreted by the stomach mucosa. The histamine receptor antagonist binds to histamine receptors and blocks the action of histamine, and the proton pump inhibitor reduces the H⁺-K⁺ exchange pump. Either type could have been prescribed for Alice. The smaller volume of gastric acid secreted by the stomach mucosa and the higher pH of the stomach secretions reduce the acid reflux that cause inflammation of her larynx.
5. In order to completely understand why Amos's doctor prescribed an antibiotic, read the Clinical Impact, "Peptic Ulcer," in this chapter. There, you will find that about 80% of peptic ulcers are due to a specific bacterial infection. Thus, based on the physician's recommendations, the cause of Amos's condition is a bacterial infection (*Helicobacter pylori*). The effect of the antacid is to increase the pH of the chyme that enters the small intestine from the stomach, which reduces the inflammation and pain. Amos cannot control the condition with antacids alone because the antacids do not eliminate the bacterial infection. Prolonged inflammation can cause perforation of the duodenum. The ulceration penetrates the mucosa, submucosa, muscularis, and serosa, allowing the intestinal contents to exit the duodenum. This condition can result in peritonitis and hemorrhage.
6. First, let us consider that acidic chyme in the small intestine is the stimulus. Stimuli are detected by receptors, and then control centers send a signal to initiate a response that will regulate homeostasis. In this case, the control center is the pancreas. In response to the acidic chyme, pancreatic secretin stimulates bicarbonate ion secretion from the pancreas (the effector), which neutralizes the acidic chyme. Thus, secretin prevents the acid levels in the chyme from becoming too high and keeps them in the normal range. The neutralization of the acidic chyme removes the stimulus for more secretin release, and bicarbonate ion is no longer secreted. Because the response was inhibited, this is an example of a negative-feedback system.
7. The first concept to address is how normal microbiota could rid a patient of a *C. diff* infection. You learned in chapter 1 "Microbes in your Body" that our normal microbiota population is essential to our health. Our normal microbiota usually far outnumber *C. diff* in our gut. However, after treatments with antibiotics, our normal gut microbiota have been severely reduced in number along with the pathogenic bacteria. Because *C. diff* flourishes after antibiotic treatment, we can conclude that they are a normal member of our microbiota population, but are usually kept in check by our "good" bacteria. However, when the "good" bacteria population decreases, there's no competition for the *C. diff* and the population increases. Thus, an effective treatment is to increase the normal microbiota to outcompete the *C. diff*. As you've learned, this is why fecal transplants are effective for *C. diff* infections. A swallowed pill could be an effective method to repopulate the intestinal microbiota, but only if the capsule containing the dried bacteria could stay intact as it passes through the stomach. Intestinal microbiota could not survive the low pH of the stomach. Once the dried

- bacteria reach the intestine, they could then begin dividing. Eventually, these normal bacteria would outnumber the *C. diff* and cause the *C. diff* population to decline to nonpathogenic, typical levels. Even if such a pill does not become widely available, in the meantime, fecal transplants continue to be very effective.
- An enema is the introduction of fluid into the rectum, which causes it to distend. Recall that the defecation reflex is initiated by the movement of feces into the rectum and the subsequent stretch of the rectal wall. Therefore, because an enema stretches the rectal wall, it initiates the defecation reflex.
 - Recall that diarrhea is either increased stool frequency or increased volume, which can result in the abnormal loss of fluid and ions from the colon. This fluid loss from the colon affects the cardiovascular system in the same way that blood loss does. In either case, the result is hypovolemia, which causes a drop in blood pressure in a positive-feedback cycle. Eventually, heart failure results from insufficient blood flow to the heart itself.

Chapter 25

- Most of the vitamins, with the exception of A, D, and niacin, are essential vitamins, meaning they cannot be produced by the body but must be obtained from the diet. Recall that, after a vitamin is destroyed, its function is lost. If the vitamins were broken down by digestion before being absorbed, they would not be functional, and vitamin deficiencies would occur.
- To answer this question we need to first identify the Daily Value for carbohydrates, which is 300 g/day. The % Daily Value is then determined by dividing the amount in the serving of food (30 g) by the Daily Value (300 g). The % Daily Value for carbohydrates from one serving of this food product is 10% ($30/300 = 0.10$, or 10%).
- The last step in the electron-transport chain is when the electrons are passed to oxygen to form water. If this step is blocked, the citric acid and electron-transport chain cannot function, so ATP will not be produced aerobically. Lactic acid fermentation alone cannot produce sufficient levels of ATP to maintain normal cellular activity, and death will occur.
- We can see from table 25.1 that one cola or beer has about 145 kcal/serving. To determine the time it takes to burn these kcal, we divide the kcal/serving by the number of kcal used per hour. Watching TV uses 95 kcal/h, so $145/95$ is equal to about 1.5 hours, or 1 hour and 30 minutes.
- Jogging at a pace of 6 mph uses 580 kcal/h, so $145/580$ is equal to 0.25 h, or 15 minutes.
- Recall that catabolism of food releases energy that can be used by the body for normal biological work, such as muscle contraction. However, about 40% of the total energy released is actually used for biological work. The remaining energy is lost as heat. Exercise increases the amount of biological work and therefore requires more energy in the form of ATP. As more ATP is produced to fuel the exercise, more heat is also generated as lost energy, thereby increasing body temperature. Shivering consists of small, rapid muscle contractions that produce heat in an effort to prevent a decrease in body temperature in the cold.

Chapter 26

- Even though hemoglobin is a smaller molecule than albumin, it does not normally enter the filtrate because hemoglobin is contained within red blood cells, and these cells cannot pass through the filtration membrane. However, if red blood cells rupture, by a process called hemolysis, the hemoglobin is released into the plasma, and large amounts of hemoglobin enter the filtrate. Conditions that cause red blood cells to rupture in the circulatory system allow large amounts of hemoglobin to enter the urine.
- In this chapter we learned that the reabsorption of water from the nephron is based on osmosis. If Na^+ and Cl^- are not actively transported out of the nephron, the concentration of ions inside the nephron stays elevated. The normal osmotic gradient that moves water out of the nephron is greatly reduced and the water stays in the nephron, which increases urine volume.
- Inhibition of ADH secretion is one of alcohol's numerous effects on the body. Lack of ADH causes the distal convoluted tubules and the collecting ducts to be relatively impermeable to water. Therefore, the water cannot move by osmosis from the distal nephrons and collecting ducts but remains in the nephrons to become urine. In addition, because other fluids are normally consumed with the alcohol, the increased water intake also results in an increase in dilute urine.
- Decreased water reabsorption in the distal convoluted tubules and collecting ducts results in increased water loss in urine and a large urine volume. Additionally, because the infants' kidneys were unable to reabsorb water from the filtrate, the infants' blood osmolality increased.
 - The infants' plasma levels of ADH increased during the water deprivation test. The hallmark of NDI is normal secretion of ADH from the pituitary followed by an abnormal response in the kidneys.
 - Normally, following exposure to ADH, the cells of the distal convoluted tubules and collecting ducts insert aquaporin-2 water channels into the apical membranes, which increases their permeability to water. However, in autosomal recessive and autosomal dominant NDI, the aquaporin-2 is dysfunctional, and water stays in the collecting duct to exit the body as part of urine.
 - Plasma levels of ADH will range from abnormally low to nondetectable because central diabetes insipidus results from a deficiency in ADH secretion.
 - Although it seems counterintuitive to treat a patient already suffering from polyuria with a drug that increases urine output, treatment with a Na^+ reabsorption inhibitor in conjunction with a low-sodium diet ultimately promotes homeostatic water balance in patients' cell fluids. By preventing plasma levels of sodium from becoming abnormally elevated, water is not prone to move by osmosis out of cells' cytoplasm into the extracellular fluid toward the blood plasma.
- During the race, Amanda's blood volume decreased because of increased water loss through breathing and sweating. Because of Amanda's severe dehydration, her body immediately initiated the mechanism that maintains blood pressure. The vasoconstriction and reduced blood volume explain her pallor. Increased sympathetic stimulation caused the more rapid heart rate. The renal arteries also became vasoconstricted. Subsequently, the GFR decreased, and urine production was reduced. In addition, Amanda's ADH levels increased, which increased water reabsorption from the distal convoluted tubules and collecting ducts.
- The question asks what is the relevance of urea clearance. Low urea clearance indicates that the amount of blood cleared of urea, a metabolic waste product, per minute is lower than normal. It is consistent with the reduced number of functional nephrons characteristic of advanced cases of renal failure. In addition, low urea clearance indicates that the GFR is reduced and blood levels of urea are increasing. A low blood Na^+ level is consistent with the reduced ability of the smaller number of functional nephrons to reabsorb Na^+ at the normal

rate. The high blood K^+ level is consistent with the reduced ability of the smaller number of functional nephrons to secrete K^+ at the normal rate.

8. Recall that the female urethra is much shorter than the male urethra and is more accessible to bacteria from the external environment. For this reason, females are more susceptible to bladder infections than males.
9. The first piece of information you need to make this prediction is that the micturition reflex is initiated by stretch receptors in the bladder wall. However, when the volume of fluid in the bladder is below 300 ml, the urge to urinate can be repressed by centers in the pons and cerebrum. You also learned that a bacterial infection or another source of irritation could stimulate the urge to urinate, even if there is not much urine in the bladder. Purposeful infection of the bladder wall with tuberculosis bacteria during the BCG treatment causes irritation of the bladder wall and would stimulate an increased frequency of action potentials along the sensory neurons. The higher frequency of action potentials is interpreted as a greater urge to urinate. This is true for all bacterial infections in the bladder.
10. After 9 days Roger's kidneys began to produce a large volume of urine with larger-than-normal Na^+ and K^+ concentrations. As a result, Roger became dehydrated by day 9. Dehydration results in reduced blood volume and blood pressure. His hematocrit was increased because the volume of his blood was decreased, but there was no decrease in the number of red blood cells. The percentage of the blood made of red blood cells therefore increased. The pale skin was the result of vasoconstriction, which was triggered by the reduced blood pressure. Dizziness resulted from reduced blood flow to the brain when Roger tried to stand and walk. He was lethargic in part because of reduced blood volume, but also because of low blood levels of K^+ and Na^+ , caused by the loss of these ions in the urine. Low blood levels of Na^+ and K^+ alter the electrical activity of nerve and muscle cells and result in muscular weakness. The arrhythmia of his heart was due to low blood levels of K^+ and increased sympathetic stimulation, which was also triggered by low blood pressure.

Chapter 27

2. The first step is to define hemorrhagic shock. Recall from the chapter 21 Clinical Impact, "Shock," that hemorrhagic shock is

due to excessive internal or external bleeding, which lowers blood volume. During hemorrhagic shock, blood pressure decreases and visceral blood vessels constrict. As a consequence, blood flow to the kidneys and the blood pressure in the glomeruli decrease dramatically. The total filtration pressure decreases, as does the amount of filtrate formed each minute. The rate at which Na^+ enters the nephron therefore decreases. In addition, the kidneys secrete large amounts of renin, which causes the formation of angiotensin I from angiotensinogen. Angiotensin I is converted to angiotensin II, which stimulates aldosterone secretion. Aldosterone increases the rate at which Na^+ is reabsorbed from the filtrate in the distal convoluted tubules and collecting ducts.

3. Remember that acidic (low) pH is due to an elevated concentration of H^+ . Hydrogen ions in the blood are derived from the combination of CO_2 and water. When hyperventilating, the faster breathing rate results in a greater than normal rate of CO_2 loss from the circulatory system. Because CO_2 levels decrease, fewer H^+ are formed and the pH becomes more basic. Breathing into a paper bag corrects for the effects of hyperventilation because the person re-breathes air that has a higher concentration of CO_2 . Carbon dioxide levels increase in the body, more H^+ is formed, and pH levels drop back into the normal range.
4. Aldosterone hyosecretion results in acidosis. Aldosterone increases the rate at which Na^+ is reabsorbed from nephrons, but it also increases the rate at which K^+ and H^+ are secreted. Hyosecretion of aldosterone decreases the rate at which H^+ is secreted by the nephrons and therefore can result in acidosis.
5.
 - a. Each time Dan vomited, he lost a substantial amount of fluid. Because he was very nauseated, he did not consume any food or liquid. Water crosses the wall of the stomach by osmosis. Secretion of acid by the gastric glands of Dan's stomach produced the acidic gastric fluid, and vomiting eliminated the fluid from the stomach. As a result of the lost fluid volume, Dan's body weight decreased. His body weight before he became nauseated was not known. The 71 kg body weight at 12 hours is probably less than his normal body weight. By 36 hours, Dan had lost an additional 3 kg. Because of the decrease in the plasma volume, Dan's blood pressure began to fall. The mechanisms that regulate blood pressure and blood volume were activated (see figure 27.4). The decrease in blood pressure and the increase in heart rate at 36 hours were a result of the continued fluid loss as vomiting continued. Because of the baroreceptors reflex (see figure 21.40), there is increased sympathetic stimulation of the heart and peripheral blood vessels. As a result, heart rate and pallor increase due to vasoconstriction of the blood vessels of the skin. It is likely that his heart rate was increased somewhat by 12 hours, but it was clearly increased by 36 hours. Although not reported, the ADH mechanism caused his urine volume to decrease dramatically. Thirst would have increased if Dan had not been so nauseated. At 12 hours, the mechanisms that control blood pressure were adequate to maintain blood pressure within its normal range. By 36 hours, Dan's blood pressure had decreased in spite of the homeostatic mechanisms.
 - b. The gastric glands of the stomach secrete H^+ (See Chapter 24). The rate of H^+ secretion had to increase in response to nausea and vomiting because Dan expelled a significant volume of acidic gastric fluid each time he vomited. The increased H^+ secretion caused metabolic acidosis (see Section 27.5). At the same time H^+ was secreted, HCO_3^- was absorbed into the circulatory system. Therefore, the plasma HCO_3^- levels and plasma pH were increased at both 12 and 36 hours. The secretion of H^+ into the stomach and the absorption of HCO_3^- into the blood caused the plasma pH to increase. The mechanisms that control blood pH were activated (see figure 27.13). However, they were not adequate to keep the plasma pH within its normal range. The plasma pH had increased at 12 hours and increased further at 36 hours.
 - c. The plasma PCO_2 levels were increased at both 12 and 36 hours. As the pH of the body fluids rose, stimulation of the respiratory centers decreased (see figure 23.22). Consequently, CO_2 elimination slowed, and plasma CO_2 levels increased.
 - d. After Dan stopped vomiting, the rate of fluid loss decreased. The rate of H^+ loss and HCO_3^- absorption slowed dramatically. He was also able to consume liquids. These changes and the mechanisms that regulate body fluid volume and plasma pH continued to function until homeostasis was reestablished.

Chapter 28

2. a. In chapter 3, we learned that cancer cells result from several mutations that accumulate over many generations of cell division. This may require several years to develop. Cells that had accumulated some mutations leading to cancer might have existed in Vern's prostate at the time of the first biopsy, but actual cancer cells might not have been present. Also, a biopsy removes a small sample of cells from the tissue. If only a few cancer cells were present, it is very likely that they were missed in the first biopsy.
 - b. Similar to the answer for part a, cancer cells result from the accumulation of mutations over generations of cell division. Pathologists examine biopsies and make conclusions based on their observations of the microscopic anatomy of the cells in a tissue sample. Cells that may become cancerous in the future may not possess the anatomical features the pathologist would use to classify them as cancerous. This was likely the case in the examination of the first biopsy. After 8 years had passed, some of these cells had accumulated mutations that altered their appearance, and the pathologist examining the second biopsy identified these cells.
 - c. We can assume that the six biopsy samples were of different regions of Vern's prostate gland. It appears that the cancerous tumor is small and the needle biopsy only passed through the tumor two of the six times.
 - d. It is likely that mutations that cause cells to secrete increased amounts of PSA accumulated in some cells of the prostate, but all of the mutations that cause cells to become cancerous may not have been present. In this case, elevated PSA levels indicate the increased risk of tumor formation.
3. Sperm cells are deposited into the female reproductive system and need to move quite a distance to come in contact with the oocyte (see figure 28.21). Coagulation may help keep the sperm cells together within the female reproductive tract, thereby increasing the likelihood of fertilization.
 4. Erection is the result of neural stimulation of arteries that supply the erectile tissue. Erectile dysfunction (ED) is caused by either defective stimulation of the erectile tissue by nerve fibers or reduced response of the blood vessels to neural stimulation. Recall from Clinical Impact, "Erectile Dysfunction," that sildenafil does not stimulate erection, but instead increases the effectiveness of stimulation by enhancing the response of blood vessels to action potentials by slowly breaking down cGMP. As cGMP accumulates in the smooth muscle cells of the blood vessels, they relax, allowing blood to flow into the erectile tissue. Mr. Grover is sometimes able to achieve erections, especially after treatment, so it is reasonable to assume that he is unable to achieve erections at other times because of dysfunction in neural stimulation. There could be fewer action potentials reaching the erectile tissue due to nerve damage or decreased ability of the central nervous system to increase action potentials in the nerves. Another possibility is that Mr. Grover is unable to achieve minimal sexual excitement, which would decrease action potentials in the appropriate nerves.
 5. To make this prediction, recall from chapter 3 that some forms of endocytosis are receptor-mediated. Also recall that viruses must enter their host cells to take over DNA replication and protein synthesis machinery. If the mechanism by which the virus is taken up by the host cell is understood, this mechanism could be manipulated to prevent cancer from developing. It is well known that some human viruses induce the host cells to endocytose them by binding to certain cell surface receptors. By administering a blocker molecule (called an antagonist) that would bind to the cell surface receptor to prevent the virus from binding, endocytosis of the virus could not occur. Without endocytosis of the virus, it cannot replicate nor build new viruses. By administering both a blocker and a vaccine, a person would be doubly protected.
 6. The question addresses the time period in the menstrual cycle just before the LH surge, which promotes ovulation. Referring to figure 28.18, it is evident that estrogen and progesterone are normally at their lowest levels before the LH surge. In contrast, progesterone is at its highest level after ovulation and prevents further development of follicles. Therefore, administration of a large amount of progesterone and estrogen just before the preovulatory LH surge inhibits the release of GnRH, LH, and FSH. Consequently, ovulation does not occur. However, progesterone is the more potent hormone when it comes to inhibiting ovulation. Injections of a small amount of estrogen just before ovulation could stimulate GnRH, LH, and FSH secretion with little negative effect on ovulation. Continual administration of high concentrations of GnRH causes the anterior pituitary

cells to become insensitive to GnRH. Thus, LH and FSH levels remain low and the ovarian cycle stops.

7. Recall that progesterone has an inhibitory effect on the hypothalamus and anterior pituitary (see figure 28.19). High progesterone levels after menses would therefore inhibit GnRH secretion from the hypothalamus and consequently FSH and LH secretion from the anterior pituitary. Without FSH and LH, the events of the ovarian cycle, including estrogen production, are inhibited. Remember that the proliferation of the endometrium is stimulated by estrogen. If estrogen levels do not increase following menses, the endometrium does not thicken. In addition, estrogen normally increases the synthesis of uterine progesterone receptors, so without estrogen the secretory response of the endometrium to the elevated progesterone would be inhibited.
8. Molly's mother could have had leiomyomas also, although, without direct data of medical examinations, one cannot be certain. If that was the cause of her irregular menstruations, they may have become less frequent as Molly's mother experienced menopause. During menopause, the uterus gradually becomes smaller, and eventually the cyclical changes in the endometrial lining cease. If the condition was relatively mild, the onset of menopause could explain the gradual disappearance of the irregular and prolonged menstruations. (Note: If the tumors are large, constant, and severe, menstruations are likely even if regular menstrual cycles stop due to menopause.)

Chapter 29

2. The primitive streak essentially forms the central axis of an embryo. If two primitive streaks formed in one embryonic disk, we would expect two different embryos, or essentially twins, to develop. If the two primitive streaks were touching each other, conjoined twins would develop. The degree to which the two primitive streaks were touching would determine the severity of the attachment.
3. Recall that the function of müllerian-inhibiting hormone is to prevent the development of the paramesonephric duct system, which gives rise to the female internal reproductive system. The lack of müllerian-inhibiting hormone would therefore allow the paramesonephric duct system to develop, particularly the uterus and uterine tubes. Assuming that testosterone secretion is normal, the internal male reproductive system would also develop.

In the presence of dihydrotestosterone, derived from testosterone, the external male genitalia would also develop.

4. Recall that clinical age is dependent on LMP (last menstrual period) of the mother and that developmental age begins at fertilization, which is assumed to occur on day 14 after LMP. Most of the times reported in the text are developmental age. To determine the clinical age, add 14 to the developmental age. The one exception is parturition, which is reported as clinical age. To determine the developmental age, subtract 14 from the clinical age. We can easily construct a table to compare the ages:

	Clinical Age	Developmental Age
Fertilization	14 days	0 days
Implantation	21 days	7 days
Beginning of fetal period	70 days	56 days
Parturition	280 days	266 days

5. The doctor would not do as the woman requested because elevated calcium levels could lead to tetanic uterine muscle contractions. Tetanic contractions might compress blood vessels and cut the blood supply to the fetus. Recall from chapter 27 that hypercalcemia can also result in heart arrhythmias and skeletal muscle weakness. Instead of calcium, the doctor may administer oxytocin, which strengthens uterine contractions and is less likely to produce tetany.
6. Suckling causes a reflex release of oxytocin from the mother's posterior pituitary. Oxytocin causes expulsion of milk from the breast, but it also causes contraction of the uterus. Contraction of the uterus is responsible for the sensation of cramps in her abdomen.
7. Genotypes are the alleles a person has for a given trait, and the phenotype is the

person's appearance. In the case of polydactyly, there are three possible genotypes: *DD* (homozygous dominant), *Dd* (heterozygous), and *dd* (homozygous recessive). Since polydactyly is a dominant trait, we would expect the individuals with genotype *DD* or *Dd* to exhibit polydactyly and the individuals with the genotype *dd* not to exhibit polydactyly.

8. When fertilization occurs, the two haploid gametes combine to form a new diploid zygote. If the gametes had the same number of chromosomes as somatic cells, the chromosome number would double with each generation.
9. To answer this question we must determine Paula's and Marvin's genotypes. Paula has PKU, which we know is an autosomal recessive trait. That means that she is homozygous recessive (*pp*). Marvin does not have PKU, so his genotype is either homozygous dominant (*PP*) or heterozygous (*Pp*). Since no PKU has appeared in Marvin's family for several generations, it is more likely that he is homozygous dominant. If Paula has two PKU alleles (*pp*) and Marvin has two normal alleles (*PP*), each of their children will receive one of the alleles from each parent. Therefore, all of their children will have one allele for PKU and one normal allele (*Pp*). Because PKU is a recessive disease, none of the children will have the disorder.
10. Duchenne muscular dystrophy is an X-linked condition. Remember that a male child receives an X chromosome from his mother and a Y chromosome from his father. We can therefore assume that Wilma is a "carrier" for Duchenne muscular dystrophy, meaning she is heterozygous for the condition. As a male, Wally has only one X chromosome in his cells, and his X chromosome must have the normal allele

because Wally does not have Duchenne muscular dystrophy. Because each of their children will receive an X chromosome from Wilma, they may receive either an X chromosome with the normal allele or an X chromosome with the Duchenne muscular dystrophy allele. Males who receives a chromosome with a normal allele from Wilma and a Y chromosome from Wally will be normal. Males who receive an X chromosome with the muscular dystrophy allele from Wilma and the Y chromosome from Wally will have Duchenne muscular dystrophy. Therefore, the probability that their next child will have the condition is 0 if the child is female and 0.5 (or 1/2) if the child is male. However, the probability that each female child will be a carrier for the condition is 0.5 (or 1/2).

11. Down syndrome (trisomy 21) is an aneuploidy condition where the individual has three copies of chromosome 21. At fertilization, instead of the child receiving two chromosomes 21, one from each parent, the child has three chromosomes 21, two from one parent and one from the other. We learned in this chapter that this type of disorder is the result of nondisjunction, or the failure of chromosomes to segregate correctly during meiosis. One possible explanation for this condition is that nondisjunction occurred during oogenesis, producing an oocyte with two chromosomes 21. If this oocyte were fertilized by a sperm cell that had one chromosome 21, the resulting zygote would have three copies of chromosome 21. Nondisjunction during spermatogenesis and subsequent fertilization of a normal oocyte would also result in a zygote with three copies of chromosome 21. The probability of nondisjunction occurring during oogenesis increases in women after approximately age 35.

Glossary

Many of the words in this glossary and the text are followed by a simplified phonetic spelling showing pronunciation. The pronunciation key reflects standard clinical usage as presented in *Stedman's Medical Dictionary* (28th edition), a leading reference volume in the health sciences.

The phonetic system used is a basic one and has only a few conventions:

- Two diacritical marks are used; the macron (—) for long vowels; and the breve (˘) for short vowels.
- Principal stressed syllables are followed by a prime ('); monosyllables do not have a stress mark.
- Other syllables are separated by hyphens.

The following pronunciation key provides examples and consonant sounds encountered in the phonetic system. No attempt has been made to accommodate the slurred sounds common in speech or regional variations in speech sounds. Note that a vowel with a breve (˘) is used for the indefinite vowel sound of the schwa (ə). Native pronunciation of foreign words is approximated as closely as possible.

Pronunciation Key

Vowels

ā	day, care, gauge	ě	taken, genesis
a	mat, damage	e	term, learn
ǎ	about, para	ī	pie

ī	pit, sieve, build	ū	unit, curable
ō	note, for so,	ÿ	cut
o	not, oncology, ought	ah	father
oo	food	aw	fall, cause, raw
ow	cow, out	ē	be, equal, ear
oy	troy, void		

Consonants

b	bad	n	no
ch	child	ng	ring
d	dog	p	pan
dh	this, smooth	r	rot
f	fit	s	so, miss
g	got	sh	should
h	hit	t	ten
j	jade	th	thin, with
k	kept	v	very
ks	tax	w	we
kw	quit	y	yes
l	law	z	zero
m	me	zh	azure, measure

In some words the initial sound is not that of the initial letter(s), or the initial letter(s) is not sounded or has a different sound, as in the following examples:

aerobe (ar'ob)	phthalein (thal'e-in)
eimuria (ime're-a)	pneumonia
	(nu-mo'ne-a)
gnathic (nath'ik)	psychology (si-kol'o-je)
knuckle (nuk-l)	ptosis (to'sis)
oedipism (ed'i-pizm)	xanthoma (zan-tho'ma)

A

A band Length of the myosin myofilament in a sarcomere.

abdomen (ab-dō'men, ab'dō-men) Belly, between the thorax and the pelvis.

abduction (ab-dük'shün) [L., *abductio*, take away] Movement away from the midline.

absolute refractory period (ab'sō-loot rē-frac'tōr-ē) Portion of the action potential during which the membrane is insensitive to all stimuli, regardless of their strength.

absorptive cell (ab-sōrp'tiv) Cell on the surface of villi of the small intestines and the luminal surface of the large intestine that is characterized by having microvilli; secretes digestive enzymes and absorbs digested materials on its free surface.

absorptive state Immediately after a meal when nutrients are being absorbed from the intestine into the circulatory system.

accommodation (ă-kom'ō-dā'shün) [L., *ac* + *commodo*, to adapt] Ability of electrically excitable tissues, such as nerve or muscle cells, to adjust to a constant stimulus so that the magnitude of the local potential decreases through time; also called adaptation.

acetabulum (as-ě-tab'ū-lüm) [L., shallow vinegar vessel or cup] Cup-shaped depression on the external surface of the coxa.

acetylcholine (ACH) (as-e-til-kō'lēn) Neurotransmitter substance released from motor neurons, all preganglionic neurons of the parasympathetic and sympathetic divisions, all postganglionic neurons of the parasympathetic division, some postganglionic neurons of the sympathetic division, and some central nervous system neurons.

acetylcholinesterase (as'ē-til-kō-lin-es'ter-ās) Enzyme found in the synaptic cleft that causes the

breakdown of acetylcholine to acetic acid and choline, thus limiting the stimulatory effect of acetylcholine.

Achilles tendon See calcaneal tendon.

acid (as'id) Molecule that is a proton donor; any substance that releases hydrogen ions (H⁺).

acidic Solution containing more than 10⁻²⁷ mol of hydrogen ions per liter; has a pH less than 7.

acinus; pl. **acini** (as'i-nūs, as'ī-nī) [L., berry, grape] Grape-shaped secretory portion of a gland. The terms *acinus* and *alveolus* are sometimes used interchangeably. Some authorities differentiate the terms: Acini have a constricted opening into the excretory duct, whereas alveoli have an enlarged opening.

acromion (ă-krō'mē-on) [Gr., *akron*, extremity + *omos*, shoulder] Bone comprising the tip of the shoulder.

acrosome (ak'rō-sōm) [Gr., *akron*, extremity + *soma*, body] Cap on the head of the spermatozoon, with hydrolytic enzymes that help the spermatozoon penetrate the ovum.

actin filament (ak'tin) Thin myofilament within the sarcomere; composed of two F actin molecules, tropomyosin, and troponin molecules.

action potential [L., *potentia*, power, potency] Change in membrane potential in an excitable tissue that acts as an electric signal and is propagated in an all-or-none fashion.

activation energy (ak-ti-vā'shün) Energy that must be added to molecules to initiate a reaction.

active site Portion of an enzyme in which reactants are brought into close proximity and that plays a role in reducing activation energy of the reaction.

active tension Tension produced by the contraction of a muscle.

active transport Carrier-mediated process that requires ATP and can move substances against a concentration gradient.

adaptive immunity Immune status in which there is an ability to recognize, remember, and destroy a specific antigen.

adenohypophysis (ad'ě-nō-hī-pof'ī-sis) Portion of the hypophysis derived from the oral ectoderm; also called anterior pituitary.

adenosine diphosphate (ADP) (ă-den'ō-sēn) Adenosine, an organic base, with two phosphate groups attached to it. Adenosine diphosphate combines with a phosphate group to form adenosine triphosphate.

adenosine triphosphate (ATP) Adenosine, an organic base, with three phosphate groups attached to it. Energy stored in ATP is used in nearly all of the endergonic reactions in cells.

- adenylate cyclase** (ad'e-nil-āte sīklās) An enzyme acting on ATP to form 3',5'-cyclic AMP plus pyrophosphate (two phosphate groups). A crucial step in the regulation and formation of the intracellular chemical signal 3',5'-cyclic AMP.
- adipocyte** (ad'i-pō-sīt) Fat cell.
- adipose** (ad'i-pōs) [L., *adeps*, fat] Fat.
- adrenal gland** (ā-drē'nāl) [L., *ad*, to + *ren*, kidney] Located near the superior pole of each kidney, it is composed of a cortex and a medulla. The adrenal medulla is a highly modified sympathetic ganglion that secretes the hormones epinephrine and norepinephrine; the cortex secretes aldosterone and cortisol as its major secretory products. Also called suprarenal gland.
- adrenergic neuron** (ad-rē-ner'jik) Nerve fiber that secretes norepinephrine (or epinephrine) as a neurotransmitter substance.
- adrenergic receptor** (ad-rē-ner'jik) Receptor molecule that binds to adrenergic agents, such as epinephrine and norepinephrine.
- adrenocorticotrophic hormone (ACTH)** (ā-drē'nō-kōr'ti-kō-trō'pik) Hormone of the adenohypophysis that governs the nutrition and growth of the adrenal cortex, stimulates it to functional activity, and causes it to secrete cortisol.
- adventitia** (ad-ven-tish'ā) [L., *adventicius*, coming from abroad, foreign] Outermost covering of any organ or structure that is properly derived from outside the organ and does not form an integral part of the organ.
- aerobic respiration** (ār-ō'bik) Breakdown of glucose in the presence of oxygen to produce carbon dioxide, water, and approximately 38 ATPs; includes glycolysis, the citric acid cycle, and the electron-transport chain.
- afferent arteriole** (af'er-ent) Branch of an interlobular artery of the kidney that conveys blood to the glomerulus.
- afferent division** Nerve fibers that send impulses from the periphery to the central nervous system.
- agglutination** (ā-gloo-ti-nā-shūn) [L., *ad*, to + *gluten*, glue] Process by which blood cells, bacteria, or other particles are caused to adhere to one another and form clumps.
- agglutinin** (ā-gloo'ti-nin) Antibody that binds to an antigen and causes agglutination.
- agglutिनogen** (ā-gloo-tin'ō-jen) Antigen on surface of red blood cells that can stimulate the production of antibodies (agglutinins) that combine with the antigen and cause agglutination.
- agranulocyte** (ā-gran'ū-lō-sīt) Nongranular leukocyte (monocyte or lymphocyte).
- ala**; pl. **alae** (ā'lā, ā'lē) [L., a wing] Wing-shaped structure.
- aldosterone** (al-dos'ter-ōn) Steroid hormone produced by the zona glomerulosa of the adrenal cortex that facilitates potassium exchange for sodium in the distal renal tubule, causing sodium reabsorption and potassium and hydrogen secretion.
- alkaline** (al'kā-līn) Solution containing less than 10^{-7} mol of hydrogen ions per liter; has a pH greater than 7.0.
- alkalosis** (al-kā-lō'sis) Condition characterized by blood pH of 7.45 or above.
- allantois** (ā-lan'tō-is) Tube extending from the embryonic hindgut into the umbilical cord; forms the urinary bladder.
- allele** (ā-lēl') [Gr., *allelon*, reciprocally] Any one of a series of two or more different genes that may occupy the same position or locus on a specific chromosome.
- all-or-none principle** When a stimulus is applied to a cell, an action potential is either produced or not. In muscle cells, the cell either contracts to the maximum extent possible (for a given condition) or does not contract.
- alternative pathway** Part of the nonspecific immune system for activation of complement.
- alveolar duct** (al-vē'ō-lār) Part of the respiratory passages beyond a respiratory bronchiole; from it arise alveolar sacs and alveoli.
- alveolar gland** Gland in which the secretory unit has a saclike form and an obvious lumen.
- alveolar sac** Two or more alveoli that share an opening.
- alveolus**; pl. **alveoli** (al-vē'ō-lūs, al-vē'ō-lī) Cavity. Examples include the sockets into which teeth fit, the endings of the respiratory system, and the terminal endings of secretory glands.
- amino acid** (ā-mē'nō) Class of organic acids that constitute the building blocks for proteins.
- amplitude-modulated signal** (am'pli-tood) Signal that varies in magnitude or intensity, such as with large versus small concentrations of hormones.
- ampulla** (am-pul'lā, am-pul'lē) [L., two-handled bottle] Saclike dilatation of a semicircular canal; contains the crista ampullaris. Wide portion of the uterine tube between the infundibulum and the isthmus.
- amygdala** (a-mig'da-la, -lē) [L. fr. Gr., *amygdale*, almond] Nucleus in the temporal lobe of the brain, amygdaloid nucleus; also called amygdaloid nuclear complex.
- amylase** (am'il-ās) One of a group of starch-splitting enzymes that cleave starch, glycogen, and related polysaccharides.
- anabolism** (ā-nab'ō-lizm) [Gr., *anabole*, a raising up] All of the synthesis reactions that occur within the body; requires energy.
- anaerobic respiration** (an-ār-ō'bik) Breakdown of glucose in the absence of oxygen to produce lactic acid and two ATPs; consists of glycolysis and the reduction of pyruvic acid to lactic acid.
- anal canal** Terminal portion of the digestive tract.
- anal triangle** Posterior portion of the perineal region through which the anal canal opens.
- analgesic** (an-al-jē'zik) Compound capable of producing analgesia, without producing anesthesia or loss of consciousness, characterized by reduced response to painful stimuli.
- anaphase** (an'ā-fāz) Time during cell division when chromatids divide (or, in the case of first meiosis, when the chromosome pairs divide).
- anastomoses** (ā-nas'tō-mō'sez) Natural communication, direct or indirect, between two blood vessels or other tubular structures. An opening created by surgery, trauma, or disease between two or more normally separate spaces or organs.
- anatomical dead air space** Volume of the conducting airways from the external environment down to the terminal bronchioles.
- androstenedione** (an-drō-stēn-dī'ōn) Androgenic steroid of weaker potency than testosterone; secreted by the testis, ovary, and adrenal cortex.
- anencephaly** (an'en-sef'ā-lē) [Gr., *an* + *enkephalos*, no brain] Defective development of the brain and absence of the bones of the cranium. Only a rudimentary brainstem and a trace of basal ganglia are present.
- aneurysm** (an'ū-rizm) [Gr., *eurys*, wide] Dilated portion of an artery.
- angiotensin I** (an-jē-ō-ten'sin) Peptide derived when renin acts on angiotensinogen.
- angiotensin II** Peptide derived from angiotensin I; stimulates vasoconstriction and aldosterone secretion; also called active angiotensin.
- anion** (an'ī-on) Ion carrying a negative charge.
- antagonist** (an-tag'ō-nist) Muscle that works in opposition to another muscle.
- anterior chamber** Chamber of the eye between the cornea and the iris.
- anterior interventricular sulcus** Groove on the anterior surface of the heart, marking the location of the septum between the two ventricles.
- anterior pituitary gland** See adenohypophysis.
- antibody** (an'tē-bod-ē) Protein found in the plasma that is responsible for humoral immunity; binds specifically to antigen.
- antibody-mediated immunity** Immunity due to B cells and the production of antibodies.
- anticoagulant** (an'tē-kō-ag'ū-lant) Agent that prevents coagulation.
- antidiuretic hormone (ADH)** (an'tē-dī-ū-ret'ik) Hormone secreted from the neurohypophysis that acts on the kidney to reduce the output of urine; also called vasopressin because it causes vasoconstriction.
- antigen** (an'ti-jen) [anti(body) + Gr., *gen*, producing] Substance that induces a state of sensitivity or resistance to infection or toxic substances after a latent period; substance that stimulates the specific immune system; also called epitope.
- antigenic determinant** (an-ti-jen'ik) Specific part of an antigen that stimulates an immune system response by binding to receptors on the surface of lymphocytes; also called epitope.
- antithrombin** (an-tē-throm'bin) Substance that inhibits or prevents the effects of thrombin so that blood does not coagulate.
- antrum** (an'trūm) [Gr., *antron*, a cave] Cavity of an ovarian follicle filled with fluid containing estrogen.
- anulus fibrosus** (an'ū-lūs fī-brō'sus) [L., fibrous ring] Fibrous material forming the outer portion of an intervertebral disk.
- anus** (ā'nūs) Lower opening of the digestive tract through which fecal matter is extruded.
- aorta** (ā-ōr'tā) [Gr., *aorte* from *aeiro*, to lift up] Large, elastic artery that is the main trunk of the systemic arterial system; carries blood from the left ventricle of the heart and passes through the thorax and abdomen.
- aortic arch** [L., bow] Curve between the ascending and descending portions of the aorta.
- aortic body** One of the smallest bilateral structures, similar to the carotid bodies, attached to a small branch of the aorta near its arch; contains chemoreceptors that respond primarily to decreases in blood oxygen; less sensitive to decreases in blood pH or increases in carbon dioxide.
- apex** (ā'peks) [L., summit or tip] Extremity of a conical or pyramidal structure. The apex of the heart is the rounded tip directed anteriorly and slightly inferiorly.
- Apgar score** Named for U.S. anesthesiologist Virginia Apgar (1909–1974). Evaluation of a newborn infant's physical status by assigning numerical values to each of five criteria: appearance (skin color), pulse (heart rate), grimace (response to stimulation), activity (muscle tone),

- and respiratory effort; a score of 10 indicates the best possible condition.
- apical ectodermal ridge** Layer of surface ectodermal cells at the lateral margin of the embryonic limb bud; stimulates growth of the limb.
- apical foramen** [L., aperture] Opening at the apex of the root of a tooth, gives passage to the nerve and blood vessels.
- apocrine sweat gland** (ap'ō-krin) [Gr., *apo*, away from + *krino*, to separate] Gland whose cells contribute cytoplasm to its secretion (e.g., mammary glands). Sweat glands that produce organic secretions traditionally are called apocrine. These sweat glands, however, are actually merocrine glands.
- appendicular skeleton** (ap'en-dik'ū-lār) The portion of the skeleton consisting of the upper limbs and the lower limbs and their girdles.
- appositional growth** (ap-ō-zish'ūn-al) [L., *ap* + *pono*, to put or place] To place one layer of bone, cartilage, or other connective tissue against an existing layer.
- aqueous humor** (ak'wē-ūs, ā'kwē-ūs) Watery, clear solution that fills the anterior and posterior chambers of the eye.
- arachnoid** (ā-rak'noyd) [Gr., *arachne*, spider, cobweb] Thin, cobweb-appearing meningeal layer surrounding the brain; the middle of the three layers.
- arcuate artery** (ar'kū-āt) Artery that originates from the interlobar arteries of the kidney and forms an arch between the cortex and medulla of the kidney.
- areola** (ā-rē'ō-lā, -lē) [L., *area*] Circular, pigmented area surrounding the nipple; its surface is dotted with little projections caused by the presence of the areolar glands beneath.
- areolar gland** (ā-rē'ō-lār) Gland forming small, rounded projections from the surface of the areola of the mamma.
- arrectores pilorum**; pl. **arrector pili** (ā-rek-tō'rez pī-lōr'um, ā-rek'tōr pī'lī) [L., that which raises; hair] Smooth muscle attached to the hair follicle and dermis that raises the hair when it contracts.
- arterial capillary** (ar-tē're-āl) Capillary opening from an arteriole or a metarteriole.
- arteriole** (ar-tēr'ē-ōl) Minute artery with all three tunics that transports blood to a capillary.
- arteriosclerosis** (ar-tēr'ē-ō-skler-ō'sis) [L., *arterio* + Gr., *sklerosis*, hardness] Hardening of the arteries.
- arteriovenous anastomosis** (ar-tēr'ē-ō-vē'nūs ā-nas'tō-mō'sis) Vessel through which blood is shunted from an arteriole to a venule without passing through the capillaries.
- artery** (ar'ter-ē) Blood vessel that carries blood away from the heart.
- articular cartilage** (ar-tik'ū-lār kar'ti-lij) Hyaline cartilage covering the ends of bones within a synovial joint.
- articulation** (ar-tik-ū-lā'shūn) Place where two bones come together; also called joint.
- arytenoid cartilages** (ar-i-tē'noyd) Small, pyramidal laryngeal cartilages that articulate with the cricoid cartilage.
- ascending aorta** Part of the aorta from which the coronary arteries arise.
- ascending colon** (kō'lon) Portion of the colon between the small intestine and the right colic flexure.
- asthma** (az'mă) Condition of the lungs in which widespread narrowing of airways occurs, caused by contraction of smooth muscle, edema of the mucosa, and mucus in the lumen of the bronchi and bronchioles.
- astrocyte** (as'trō-sīt) [Gr., *astron*, star + *kytos*, a hollow, a cell] Star-shaped neuroglia cell involved with forming the blood-brain barrier.
- atherosclerosis** (ath'er-ō-skler-ō'sis) Arteriosclerosis characterized by irregularly distributed lipid deposits in the intima of large and medium-sized arteries.
- atomic number** (ā-tom'ik) Number of protons in each type of atom.
- atrial diastole** (ā'trē-āl dī-as'tō-lē) Dilation of the heart's atria.
- atrial natriuretic hormone (ANH)** (ā'trē-āl nā'trē-ū-ret'ik) Peptide released from the atria when atrial blood pressure is increased; lowers blood pressure by increasing the rate of urinary production, thus reducing blood volume.
- atrial systole** (ā'trē-āl sis'tō-lē) Contraction of the atria.
- atrioventricular (AV) bundle** (ā'trē-ō-ven-trik'ū-lar) Bundle of modified cardiac muscle fibers that projects from the AV node through the interventricular septum.
- atrioventricular (AV) node** Small node of specialized cardiac muscle fibers that gives rise to the atrioventricular bundle of the conduction system of the heart.
- atrioventricular valve** One of two valves closing the openings between the atria and ventricles.
- atrium**; pl. **atria** (ā'trē-ūm, ā'trē-ā) [L., entrance hall] One of two chambers of the heart into which veins carry blood.
- auditory cortex** (aw'di-tōr-ē kōr'teks) Portion of the cerebral cortex that is responsible for the conscious sensation of sound; in the dorsal portion of the temporal lobe within the lateral fissure and on the superolateral surface of the temporal lobe.
- auditory ossicle** (os'i-kl) Bone of the middle ear; includes the malleus, incus, and stapes.
- auditory tube** Auditory canal; extends from the middle ear to the nasopharynx.
- auricle** (aw'ri-kl) [L., *auris*, ear] Part of the external ear that protrudes from the side of the head; also called pinna. Small pouch projecting from the superior, anterior portion of each atrium of the heart.
- auscultatory** (aws-kūltā-tō-rē) Relating to auscultation, listening to the sounds made by the various body structures as a diagnostic method.
- autoimmune disease** (aw-tō-i-mūn' di-zēz') Disease resulting from a specific immune system reaction against self-antigens.
- autonomic ganglia** (aw-tō-nom'ik gang'glē-ā) Ganglia containing the nerve cell bodies of the autoimmune division of the nervous system.
- autonomic nervous system (ANS)** Nervous system composed of nerve fibers that send impulses from the central nervous system to smooth muscle, cardiac muscle, and glands.
- autophagia** (aw-tō-fā'jē-ā) [Gr., *auto*, self + *phagein*, to eat] Segregation and disposal of organelles within a cell.
- autoregulation** (aw'tō-reg-ū-lā'shūn) Maintenance of a relatively constant blood flow through a tissue despite relatively large changes in blood pressure; maintenance of a relatively constant glomerular filtration rate despite relatively large changes in blood pressure.
- autorhythmic** Spontaneous and periodic—for example, in smooth muscle, spontaneous (without nervous or hormonal stimulation) and periodic contractions.
- autosome** (aw'tō-sōm) [Gr., *auto*, self + *soma*, body] Any chromosome other than a sex chromosome; normally exist in pairs in somatic cells and singly in gametes.
- axial skeleton** (ak'sē-āl) Skull, vertebral column, and rib cage.
- axillary** (ak'sil-ār-ē) Relating to the axilla; the space below the shoulder joint, bounded by the pectoralis major anteriorly, the latissimus dorsi posteriorly, the serratus anterior medially, and the humerus laterally.
- axolemma** (ak'sō-lem'ā) [Gr., *axo* + *lemma*, husk] Plasma membrane of the axon.
- axon** (ak'son) [Gr., *axis*] Main central process of a neuron that normally conducts action potentials away from the neuron cell body.
- axon hillock** Area of origin of the axon from the nerve cell body.
- axoplasm** (ak'sō-plazm) Neuroplasm or cytoplasm of the axon.

B

- baroreceptor** (bar'ō-rē-sep'ter, bar'ō-rē-sep'tōr) Sensory nerve ending in the walls of the atria of the heart, venae cavae, aortic arch, and carotid sinuses; sensitive to stretching of the wall caused by increased blood pressure; also called pressoreceptor.
- baroreceptor reflex** Detects changes in blood pressure and produces changes in heart rate, heart force of contraction, and blood vessel diameter that return blood pressure to homeostatic levels.
- basal ganglia** (bā'sāl gang'glē-ā) Nuclei at the base of the cerebrum involved in controlling motor functions.
- base** (bās) Molecule that is a proton acceptor; any substance that binds to hydrogen ions. Lower part or bottom of a structure; the base of the heart is the flat portion directed posteriorly and superiorly; veins and arteries project into and out of the base, respectively.
- basement membrane** (bās'ment mem'brān) Specialized extracellular material located at the base of epithelial cells and separating them from the underlying connective tissues.
- basilar membrane** (bas'i-lār mem'brān) Wall of the membranous labyrinth bordering the scala tympani; supports the organ of Corti.
- basophil** (bā'sō-fil) [Gr., *basis*, baso + *phileo*, to love] White blood cell with granules that stain specifically with basic dyes; promotes inflammation.
- B cell** Type of lymphocyte responsible for antibody-mediated immunity.
- belly** (bel'ē) Largest portion of muscle between the origin and insertion.
- beta-oxidation** (bā'tā ok-si-dā'shūn) Metabolism of fatty acids by removing a series of two-carbon units to form acetyl-CoA.
- bicarbonate ion** (bī-kar'bon-āt) Anion (HCO₃⁻) remaining after the dissociation of carbonic acid.
- bicuspid valve** (bī-kūs'pid) Valve closing the orifice between left atrium and left ventricle of the heart; also called mitral valve.
- bile** (bīl) Fluid secreted from the liver into the duodenum; consists of bile salts, bile pigments, bicarbonate ions, cholesterol, fats, fat-soluble hormones, and lecithin.

- bile canaliculus** (bīl kan'ă-lik'ū-lūs) One of the intercellular channels approximately 1 μm or less in diameter that occurs between liver cells into which bile is secreted; empties into the hepatic ducts.
- bile salt** Organic salt secreted by the liver that functions as an emulsifying agent.
- bilirubin** (bil-i-roo'bin) [L., *bili* + *ruber*, red] Bile pigment derived from hemoglobin during the destruction of red blood cells.
- biliverdin** (bil-i-ver'din) Green bile pigment formed from the oxidation of bilirubin.
- binocular vision** (bin-ok'ū-lăr) [L., *bini*, paired + *oculus*, eye] Vision using two eyes at the same time; responsible for depth perception when the visual fields of the eyes overlap.
- bipolar neuron** (bī-pō'ler) One of the three categories of neurons consisting of a neuron with two processes—one dendrite and one axon—arising from opposite poles of the cell body.
- blastocle** (blas'tō-sēl) [Gr., *blastos*, germ + *koilos*, hollow] Cavity in the blastocyst.
- blastocyst** (blas'tō-sist) [Gr., *blastos*, germ + *kystis*, bladder] Stage of mammalian embryos that consists of the inner cell mass and a thin trophoblast layer enclosing the blastocle.
- bleaching** In response to light, retinal separates from opsin.
- blind spot** (blīnd) Point in the retina where the optic nerve penetrates the fibrous tunic; contains no rods or cones and therefore does not respond to light.
- blood clot** Coagulated phase of blood.
- blood colloid osmotic pressure (BCOP)** Osmotic pressure due to the concentration difference of proteins across a membrane that does not allow passage of the proteins.
- blood groups** Classification of blood based on the type of antigen found on the surface of red blood cells.
- blood island** Aggregation of mesodermal cells in the embryonic yolk sac that forms vascular endothelium and primitive blood cells.
- blood pressure** [L., *pressus*, to press] Tension of the blood within the blood vessels; commonly expressed in units of millimeters of mercury (mm Hg).
- blood-brain barrier** Permeability barrier controlling the passage of most large-molecular compounds from the blood to the cerebrospinal fluid and brain tissue; consists of capillary endothelium and may include the astrocytes.
- blood-thymic barrier** Layer of reticular cells that separates capillaries from thymic tissue in the cortex of the thymus gland; prevents large molecules from leaving the blood and entering the cortex.
- Bohr effect** Named for Danish physiologist Christian Bohr (1855–1911). Shift of the oxygen-hemoglobin dissociation curve to the right or left because of changes in blood pH. The definition sometimes is extended to include shifts caused by changes in blood carbon dioxide levels.
- bony labyrinth** (lab'i-rinth) Part of the inner ear; contains the membranous labyrinth that forms the cochlea, vestibule, and semicircular canals.
- Boyle's law** The pressure of a gas is equal to the volume of a container times the constant, K, for a given temperature. Assuming a constant temperature, the pressure of a gas is inversely proportional to its volume.
- brachial** (bră'kē-āl) [L., *brachium*, arm] Relating to the arm.
- branchial arch** Typically, six arches in vertebrates; in the lower vertebrates, they bear gills, but they appear transiently in the higher vertebrates and give rise to structures in the head and neck.
- broad ligament** Peritoneal fold passing from the lateral margin of the uterus to the wall of the pelvis on each side.
- bronchiole** (brong'kē-ōl) One of the finer subdivisions of the bronchial tubes, less than 1 mm in diameter; has no cartilage in its wall but does have relatively more smooth muscle and elastic fibers.
- brush border** Epithelial surface consisting of microvilli.
- buffer** (būf'er) Mixture of an acid and a base that reduces any changes in pH that would otherwise occur in a solution when acid or base is added to the solution.
- bulb of the penis** Expanded posterior part of the corpus spongiosum of the penis.
- bulb of the vestibule** Mass of erectile tissue on each side of the vagina.
- bulbar conjunctiva** (būl'bar kon-jūnk-tī'vā) Conjunctiva that covers the surface of the eyeball.
- bulbourethral gland** (būl'bō-ū-rē'thrāl) One of two small compound glands that produce a mucoid secretion; it discharges through a small duct into the spongy urethra.
- bulbus cordis** (būl'būs) [L., plant bulb] End of the embryonic cardiac tube where blood leaves the heart; becomes part of the ventricle.
- bursa**; pl. **bursae** (ber'sā, ber'sē) [L., purse] Closed sac or pocket containing synovial fluid, usually found in areas where friction occurs.
- bursitis** (ber-sī'tis) [L., *purse* + Gr., *ites*, inflammation] Inflammation of a bursa.
- C**
- calcaneal tendon** (kal-kā'nē-al) Common tendon of the gastrocnemius, soleus, and plantaris muscle that attaches to the calcaneus; also called Achilles tendon.
- calcitonin** (kal-si-tō'nin) Hormone released from parafollicular cells that acts on tissues to cause a decrease in blood levels of calcium ions.
- calmodulin** (kal-mod'ū-lin) [*calcium* + *modulate*] Protein receptor for Ca²⁺ that plays a role in many Ca²⁺-regulated processes, such as smooth muscle contraction.
- calorie (cal)** (kal'ō-rē) [L., *calor*, heat] Unit of heat content or energy. The quantity of energy required to raise the temperature of 1 g of water 1°C.
- calpain** (kal'pān) Enzyme involved in changing the shape of dendrites; involved with long-term memory.
- calyx**; pl. **calyces** (kā'liks, kal'i-sēz) [Gr., cup of a flower] Flower-shaped or funnel-shaped structure; specifically, one of the branches or recesses of a renal pelvis into which the tips of the renal pyramids project.
- cancer** (kan'ser) Any of various types of malignant neoplasms, most of which invade surrounding tissues, may metastasize to several sites, and are likely to recur after attempted removal and to cause death of the patient unless adequately treated.
- canine** (kā'nīn) Referring to the cuspid tooth.
- cannula** (kan'ū-lā) [L., *canna*, reed] Tube; often inserted into an artery or a vein.
- capacitation** (kā-pas'i-tā'shūn) [L., *capax*, capable of] Process whereby spermatozoa acquire the ability to fertilize ova; occurs in the female genital tract.
- capitulum** (kā-pit'ū-lūm) [L., *caput*, head] Head-shaped structure.
- carbaminohemoglobin** (kar-bam'i-nō-hē-mō-glō'bin) Carbon dioxide bound to hemoglobin by means of a reactive amino group on the hemoglobin.
- carbohydrate** (kar-bō-hī'drāt) Monosaccharide (simple sugar) or the organic molecules composed of monosaccharides bound together by chemical bonds—for example, glycogen. For each carbon atom in the molecule, there are typically one oxygen molecule and two hydrogen molecules.
- carbonic acid/bicarbonate buffer system** One of the major buffer systems in the body; major components are carbonic acid and bicarbonate ions.
- carbonic anhydrase** Enzyme that catalyzes the reaction between carbon dioxide and water to form carbonic acid.
- carcinoma** (kar-si-nō'mā) Malignant neoplasm derived from epithelial tissue.
- cardiac** [Gr., *kardia*, heart] Related to the heart.
- cardiac cycle** [Gr., *kyklos*, circle] Complete round of cardiac systole and diastole.
- cardiac nerve** Nerve that extends from the sympathetic chain ganglia to the heart.
- cardiac output (CO)** Volume of blood pumped by the heart per minute; also called minute volume.
- cardiac part** Region of the stomach near the opening of the esophagus.
- cardiac reserve** [L., *re* + *servo*, to keep back, reserve] Work that the heart is able to perform beyond that required during ordinary circumstances of daily life.
- carotid body** (ka-rot'id) One of the small organs near the carotid sinuses; contains chemoreceptors that respond primarily to decreases in blood oxygen; less sensitive to decreases in blood pH or increases in carbon dioxide.
- carotid sinus** Enlargement of the internal carotid artery near the point where the internal carotid artery branches from the common carotid artery; contains baroreceptors.
- carpal** (kar'pāl) [Gr., *karpos*, wrist] Bone of the wrist.
- carrier** Person in apparent health whose chromosomes contain a pathologic mutant gene, which may be transmitted to his or her children.
- cartilage** (kar'ti-lij) [L., *cartilage*, gristle] Firm, smooth, resilient, nonvascular connective tissue.
- cartilaginous joint** (kar-ti-laj'i-nūs) Bones connected by cartilage; includes synchondroses and symphyses.
- catabolism** (kā-tab'ō-lizm) [Gr., *katabole*, a casting down] All of the decomposition reactions that occur in the body; releases energy.
- catalyst** (kat'ă-list) Substance that increases the rate at which a chemical reaction proceeds without being changed permanently.
- cataract** (kat'a-rakt) Complete or partial opacity of the lens of the eye.
- cation** (kat'ī-on) [Gr., *kation*, going down] Ion carrying a positive charge.

- caveola**; pl. **caveolae** (kav-ē-ō'lă, kav-ē-ō'lē) [L., small pocket] Shallow invagination in the membranes of smooth muscle cells that may perform a function similar to that of both the T tubules and sarcoplasmic reticulum of skeletal muscle.
- cecum** (sē'kūm, sē'kă) [L., *caecus*, blind] Cul-de-sac forming the first part of the large intestine.
- cell-mediated immunity** Immunity due to the actions of T cells and null cells.
- celom** (sē'lom, sē-lō'mă) [Gr., *koilo* + *amma*, a hollow] Principal cavities of the trunk—for example, the pericardial, pleural, and peritoneal cavities. Separate in the adult, they are continuous in the embryo.
- cementum** (se-men'tūm) [L., *caementum*, rough quarry stone] Layer of modified bone covering the dentin of the root and neck of a tooth; blends with the fibers of the periodontal membrane.
- central nervous system (CNS)** Major subdivision of the nervous system, consisting of the brain and spinal cord.
- central vein** Terminal branches of the hepatic veins that lie centrally in the hepatic lobules and receive blood from the liver sinusoids.
- centrosome** (sen'trō-sōm) Specialized zone of cytoplasm close to the nucleus and containing two centrioles.
- cerebellum** (ser-e-bel'ūm) [L., little brain] Separate portion of the brain attached to the brainstem at the pons; important in maintaining muscle tone, balance, and coordination of movement.
- cerebrospinal fluid (CSF)** (ser'ē-brō-spī-nāl) Fluid filling the ventricles and surrounding the brain and spinal cord.
- ceruminous glands** (sē-roo'mi-nūs) Modified sebaceous glands in the external acoustic meatus that produce cerumen (earwax).
- cervical canal** (ser'vī-kal) Canal extending from the isthmus of the uterus to the opening of the uterus into the vagina.
- cervix**; pl. **cervices** (ser'viks, ser-vī'sēz) [L., neck] Lower part of the uterus extending from the isthmus of the uterus into the vagina.
- chalazion** (ka-lă'zē-on) Chronic inflammation of a meibomian gland; also called meibomian cyst.
- cheek** (chēk) Side of the face forming the lateral wall of the mouth.
- chemical signal** Molecule that binds to a macromolecule, such as receptors or enzymes, and alters their function; also called ligand.
- chemoreceptor** (kē'mō-rē-sep'tor) Sensory cell that is stimulated by a change in the concentration of chemicals to produce action potentials. Examples include taste receptors, olfactory receptors, and carotid bodies.
- chemoreceptor reflex** Chemoreceptors detect a decrease in blood oxygen, an increase in carbon dioxide, or a decrease in pH and produce an increased rate and depth of respiration and, by means of the vasomotor center, vasoconstriction.
- chemosensitive area** (kem-ō-sen'si-tiv, kē-mō-sen'si-tiv) Chemosensitive neurons in the medulla oblongata detect changes in blood, carbon dioxide, and pH.
- chemotactic factor** (kē-mō-tak'tik) Part of a microorganism or chemical released by tissues and cells that act as chemical signals to attract leukocytes.
- chemotaxis** (kē-mo-tak'sis) [Gr., *chemo* + *taxis*, orderly arrangement] Attraction of living protoplasm (cells) to chemical stimuli.
- chief cell** Cell of the parathyroid gland that secretes parathyroid hormone. Cell of a gastric gland that secretes pepsinogen.
- chloride** (klōr'īd) Compound containing chlorine—for example, salts of hydrochloric acid.
- chloride shift** Diffusion of chloride ions into red blood cells as bicarbonate ions diffuse out; maintains electrical neutrality inside and outside the red blood cells.
- choana**; pl. **choanae** (kō'an-ă, kō-ă-nē) See internal nares.
- cholecystokinin** (kō'lē-sis-tō-kt'nin) Hormone liberated by the upper intestinal mucosa on contact with gastric contents; stimulates the contraction of the gallbladder and the secretion of pancreatic juice high in digestive enzymes.
- cholinergic neuron** (kol-in-er'jik) Nerve fiber that secretes acetylcholine as a neurotransmitter substance.
- chondroblast** (kon'drō-blast) [Gr., *chondros*, gristle, cartilage + *blastos*, germ] Cartilage-producing cell.
- chondrocyte** (kon'drō-sīt) [Gr., *chondros*, gristle, cartilage + *kytos*, a cell] Mature cartilage cell.
- chorda tympani**; pl. **chordae** (kōr'dă tim'pan-ē, kōr'dē) Branch of the facial nerve that conveys taste sensation from the front two-thirds of the tongue.
- chordae tendineae** (kōr'dă ten'di-nē-ē) [L., cord] Tendinous strands running from the papillary muscles to the atrioventricular valves.
- choroid** (kō'royd) Portion of the vascular tunic associated with the sclera of the eye.
- choroid plexus** [Gr., *chorioeides*, membranelike] Specialized plexus located within the ventricles of the brain that secretes cerebrospinal fluid.
- chromatid** (krō'mă-tid) One-half of a chromosome; separates from its partner during cell division.
- chromatin** (krō'ma-tin) Colored material; the genetic material in the nucleus.
- chromosome** (krō'mō-sōm) Colored body in the nucleus, composed of DNA and proteins and containing the primary genetic information of the cell; 23 pairs in humans.
- chronic pain** Prolonged pain.
- chylomicron** (kī-lō-mī'kron) [Gr., *chylos*, juice + *micros*, small] Microscopic particle of lipid surrounded by protein; in chyle and blood.
- chymotrypsin** (kī-mō-trip'sin) Proteolytic enzyme formed in the small intestine from the pancreatic precursor chymotrypsinogen.
- ciliary body** (sil'ē-ar-ē) Structure continuous with the choroid layer at its anterior margin that contains smooth muscle cells; functions in accommodation.
- ciliary gland** Modified sweat gland that opens into the follicle of an eyelash, keeping it lubricated.
- ciliary muscle** Smooth muscle in the ciliary body of the eye.
- ciliary process** Portion of the ciliary body of the eye that attaches by suspensory ligaments to the lens.
- ciliary ring** Portion of the ciliary body of the eye that contains smooth muscle cells.
- circumduction** (ser-kūm-dūk'shūn) [L., around + *ductus*, to draw] Movement in a circular motion.
- circumferential lamellae** (ser-kūm-fer-en'shē-al lă-mel'ē) Lamellae covering the surface of and extending around compact bone inside the periosteum.
- circumvallate papilla** (ser-kūm-val'ăt pă-pil'ă) Type of papilla on the surface of the tongue surrounded by a groove.
- cisterna**; pl. **cisternae** (sis-ter'nă, sis-ter'nē) Interior space of the endoplasmic reticulum.
- cisterna chyli** (kīl'ē) [L., tank + Gr., *chylos*, juice] Enlarged inferior end of the thoracic duct that receives chyle from the intestine.
- citric acid cycle** (sit'rik) Series of chemical reactions in which citric acid is converted into oxaloacetic acid, carbon dioxide is formed, and energy is released. The oxaloacetic acid can combine with acetyl-CoA to form citric acid and restart the cycle. The energy released is used to form NADH, FADH, and ATP.
- classical pathway** Part of the specific immune system for activation of complement.
- clavicle** (klav'i-kl) The collarbone, between the sternum and scapula.
- cleavage furrow** (klēv'ij) Inward pinching of the plasma membrane that divides a cell into two halves, which separate from each other to form two new cells.
- cleft palate** (kleft) Failure of the embryonic palate to fuse along the midline, resulting in an opening through the roof of the mouth.
- clinical age** (klin'i-kl) Age of the developing fetus from the time of the mother's last menstrual period before pregnancy.
- clinical perineum** (klin'i-kl per'i-nē'ūm) Portion of the perineum between the vaginal and anal openings.
- clitoris** (klit'ō-ris) Small, cylindrical, erectile body, rarely exceeding 2 cm in length, situated at the most anterior portion of the vulva and projecting beneath the prepuce.
- cloaca** (klō-ă-kă) [L., sewer] In early embryos, the endodermally lined chamber into which the hindgut and allantois empty.
- cloning** (klōn'ing) Growing a colony of genetically identical cells or organisms.
- clot retraction** Condensation of a clot into a denser, compact structure; caused by the elastic nature of fibrin.
- coagulation** (kō-ag-ū-lă'shūn) Process of changing from liquid to solid, especially of blood; formation of a blood clot.
- cochlear duct** (kok'lē-ăr) Interior of the membranous labyrinth of the cochlea; also called cochlear canal or scala media.
- cochlear nerve** Nerve that carries sensory impulses from the organ of Corti to the vestibulocochlear nerve.
- cochlear nucleus** Neurons from the cochlear nerve synapse within the dorsal or ventral cochlear nucleus in the superior medulla oblongata.
- codon** (kō'don) Sequence of three nucleotides in mRNA or DNA that codes for a specific amino acid in a protein.
- cofactor** (kō'fak'ter, kō-fak'tōr) Nonprotein component of an enzyme, such as coenzymes and inorganic ions essential for enzyme action.
- collagen fibers** (kol'lă-jen) [Gr., *koila*, glue + *gen*, producing] Ropelike protein of the extracellular matrix.
- collateral ganglia** (ko-lat'er-ăl gang'glē-ă) Sympathetic ganglia at the origin of large abdominal

- arteries; include the celiac, superior, and inferior mesenteric arteries; also called **prevertebral ganglia**.
- collecting duct** Straight tubule that extends from the cortex of the kidney to the tip of the renal pyramid. Filtrate from the distal convoluted tubes enters the collecting duct and is carried to the calyces.
- colloid** (kol'oyd) [Gr., *kolla*, glue + *eidōs*, appearance] Atoms or molecules dispersed in a gaseous, liquid, or solid medium that resist separation from the liquid, gas, or solid.
- colloidal solution** (ko-loyd'äl) Fine particles suspended in a liquid; resistant to sedimentation or filtration.
- colon** (kō'lon) Division of the large intestine that extends from the cecum to the rectum.
- colostrum** (kō-lost'rūm) Thin, white fluid; the first milk secreted by the breast at the termination of pregnancy; contains less fat and lactose than the milk secreted later.
- columnar** Shaped like a column.
- commissure** (kom'i-shūr) [L., *commissura*, a joining together] Connection of nerve fibers between the cerebral hemispheres or from one side of the spinal cord to the other.
- common bile duct** Duct formed by the union of the common hepatic and cystic ducts; it empties into the small intestine.
- common hepatic duct** Part of the biliary duct system formed by the joining of the right and left hepatic ducts.
- compact bone** Bone that is denser and has fewer spaces than cancellous bone.
- competition** Similar molecules binding to the same carrier molecule or receptor site.
- complement** (kom'plē-ment) Group of serum proteins that stimulates phagocytosis and inflammation.
- complement cascade** Series of reactions in which each component activates the next component, resulting in activation of complement proteins.
- compliance** (kom-plī'ans) Change in volume (e.g., in lungs or blood vessels) caused by a given change in pressure.
- compound** (kom'pownd) Substance composed of two or more different types of atoms that are chemically combined.
- concha; pl. conchae** (kon'kă, kon'kē) [L., shell] Structure comparable to a shell in shape—for example, the three bony ridges on the lateral wall of the nasal cavity.
- conduction** (kon-dūk'shūn) [L., *con* + *ductus*, to lead, conduct] Transfer of energy, such as heat, from one point to another without evident movement in the conducting body.
- cone** (kōn) Photoreceptor in the retina of the eye; responsible for color vision.
- congenital** (kon-jen'i-täl) [L., *congenitus*, born with] Occurring at birth; may be genetic or due to some influence (e.g., drugs) during development.
- conjunctiva** (kon-jūnk-tī'vă) [L., *conjungo*, to bind together] Mucous membrane covering the anterior surface of the eyeball and lining the lids.
- conjunctival fornix** (kon-jūnk-tī'väl fōr'niks) Area in which the palpebral and bulbar conjunctiva meet.
- constant region** Portion of an antibody that does not combine with an antigen and is the same in different antibodies.
- continuous capillary** [L., *capillaris*, relating to hair] Capillary in which pores are absent; is less permeable to large molecules than are other types of capillaries.
- contraction phase** (kon-trak'shūn) One of the three phases of muscle contraction; the time during which tension is produced by the contraction of muscle.
- convection** (kon-vek'shūn) [L., *con* + *vectus*, to carry or bring together] Transfer of heat in liquids or gases by movement of the heated particles.
- coracoid** (kōr'ă-koyd) [Gr., *korakodes*, crow's beak] Resembling a crow's beak—for example, a process on the scapula.
- Cori cycle** Named for Czech-U.S. biochemist and Nobel laureate Carl F. Cori (1896–1984). Lactic acid, produced by skeletal muscle, is carried in the blood to the liver, where it is aerobically converted into glucose. The glucose may return through the blood to skeletal muscle or may be stored as glycogen in the liver.
- cornea** (kōr'nē-ă) Transparent portion of the fibrous tunic that makes up the outer wall of the anterior portion of the eye.
- corniculate cartilages** (kōr-nik'ū-lăt) Conical nodules of elastic cartilage surmounting the apex of each arytenoid cartilage.
- corona radiata** Single layer of columnar cells derived from the cumulus mass, which anchor on the zona pellucida of the oocyte in a secondary follicle.
- coronary** (kōr'o-nār-ē) [L., *coronarius*, a crown] Resembling a crown; encircling.
- coronary artery** One of two arteries that arise from the base of the aorta and carry blood to the muscle of the heart.
- coronary ligament** Peritoneal reflection from the liver to the diaphragm at the margins of the bare area of the liver.
- coronary sinus** Short trunk that receives most of the veins of the heart and empties into the right atrium.
- coronoid** (kōr'ō-noyd) [Gr., *korone*, a crown] Shaped like a crow's beak—for example, a process on the mandible.
- corpus; pl. corpora** (kōr'pūs, -pōr-ă) [L., *body*] Any body or mass; the main part of an organ.
- corpus albicans** (al'bi-kanz) Atrophied corpus luteum, leaving a connective tissue scar in the ovary.
- corpus callosum** (käl-lō'sūm) [L., *body* + *callous*] Largest commissure of the brain, connecting the cerebral hemispheres.
- corpus cavernosum; pl. corpora cavernosa** One of two parallel columns of erectile tissue forming the dorsal part of the body of the penis or the body of the clitoris.
- corpus luteum** (lū'tē-ūm) Yellow endocrine body formed in the ovary in the site of a ruptured vesicular follicle immediately after ovulation; secretes progesterone and estrogen.
- corpus luteum of pregnancy** Large corpus luteum in the ovary of a pregnant female; secretes large amounts of progesterone and estrogen.
- corpus spongiosum** (spūn'jē-ō'sūm) Median column of erectile tissue located between and ventral to the two corpora cavernosa in the penis; posteriorly it forms the bulb of the penis, and anteriorly it terminates as the glans penis; it is traversed by the urethra. In the female, it forms the bulb of the vestibule.
- corpus striatum** (strī-ă'tūm) [L., *corpus*, body + *striatus*, striated or furrowed] Caudate nucleus, putamen, and globus pallidus; so-named because of the striations caused by intermixing of gray and white matter, which result from the number of tracts crossing the anterior portion of the corpus striatum.
- cortex; pl. cortices** (kōr'teks, kōr'ti-sēz) [L., bark] Outer portion of an organ (e.g., adrenal cortex or cortex of the kidney).
- corticotropin-releasing hormone (CRH)** (kōr'ti-kō-trō'pin) Hormone from the hypothalamus that stimulates the anterior pituitary gland to release adrenocorticotrophic hormone.
- cortisol** (kōr'ti-sol) Steroid hormone released by the zona fasciculata of the adrenal cortex; increases blood glucose and inhibits inflammation.
- covalent bond** (kō-väl'ent) Chemical bond characterized by the sharing of electrons.
- coxal bone** (kok'să) Hipbone.
- cranial nerve** (kră'nē-ăl) Nerve that originates from a nucleus within the brain; there are 12 pairs of cranial nerves.
- cranial vault** Eight skull bones that surround and protect the brain; braincase.
- craniosacral division** (kră'nē-ō-să'krăl) Parasympathetic division of the autonomic nervous system.
- cranium** (kră'nē-ūm) [Gr., *kranon*, skull] Skull; in a more limited sense, the braincase.
- cremaster muscle** (krē-mas'ter) Extension of abdominal muscles originating from the internal oblique muscles; in the male, raises the testicles; in the female, envelops the round ligament of the uterus.
- crenation** (krē-nă'shūn) [L., *crena*, notched] Denoting the outline of a shrunken cell.
- cricoid cartilage** (krī'koyd) Most inferior laryngeal cartilage.
- cricothyrotomy** (krī'kō-thī-rot'ō-mē) Incision through the skin and cricothyroid membrane for relief of respiratory obstruction.
- crista, cristae** (kris'tă, kris'tē) [L., crest] Shelflike infolding of the inner membrane of a mitochondrion.
- crista ampullaris** (kris'tă am-pul'ăr-īs) [L., crest] Elevation on the inner surface of the ampulla of each semicircular duct for dynamic or kinetic equilibrium.
- critical closing pressure** Pressure in a blood vessel below which the vessel collapses, occluding the lumen and preventing blood flow.
- crown** Part of a tooth that is covered with enamel.
- cruciate** (kroo'shē-ăt) [L., *cruciatius*, cross] Resembling or shaped like a cross.
- crus of the penis** (krūs) Posterior portion of the corpus cavernosum of the penis attached to the ischiopubic ramus.
- crypt** (kript) Pitlike depression or tubular recess.
- cryptorchidism** (krip-tōr'ki-dizm) Failure of the testis to descend.
- crystalline** (kris'tă-lēn) Protein that fills the epithelial cells of the lens in the eye.
- cuboidal** Resembling a cube.
- cumulus oophorus** (ō-of'ōr-ūs) [L., a heap] Mass of epithelial cells surrounding the oocyte; also called cumulus mass.
- cuneiform cartilages** (kū'nē-i-fōrm) Small rods of elastic cartilage above each corniculate cartilage in the larynx.

cupula; pl. cupulae (koo'poo-lă, kŭ'pŭ-lă, koo'poo-lĕ) [L., *cupa*, tub] Gelatinous mass that overlies the hair cells of the cristae ampullares of the semicircular ducts.

cuticle (kŭ'ti-kl) [L., *cutis*, skin] Outer, thin layer, usually horny—for example, the outer covering of hair or the growth of the stratum corneum onto the nail.

cystic duct (sis'tik) Duct leading from the gallbladder; joins the common hepatic duct to form the common bile duct.

cytokine (sī'tō-kĭn) Protein or peptide secreted by a cell that regulates the activity of neighboring cells.

cytokinesis (sī'tō-ki-nĕ'sis) [Gr., *cyto*, cell + *kinesis*, movement] Division of the cytoplasm during cell division.

cytology (sī-tol'ō-jĕ) [Gr., *kytos*, a hollow (cell) + *logos*, study] Study of anatomy, physiology, pathology, and chemistry of the cell.

cytoplasm (sī'tō-plazm) Protoplasm of the cell surrounding the nucleus.

cytoplasmic inclusion (sī-tō-plaz'mik) Any foreign or other substance contained in the cytoplasm of a cell.

cytotoxic reaction (sī'tō-tok'sik) [Gr., *cyto*, cell + L., *toxic*, poison] Antibodies (IgG or IgM) combine with cells and activate complement, and cell lysis occurs.

cytotrophoblast (sī'tō-trof'ō-blast) Inner layer of the trophoblast, composed of individual cells.

D

Daily Values Dietary reference values useful for planning a healthy diet. The Daily Values are taken from the Reference Daily Intakes (RDIs) and the Daily Reference Values.

Daily Reference Values (DRVs) Recommended amounts in the diet for total fat, saturated fat, cholesterol, total carbohydrate, dietary fiber, sodium, potassium, and protein. The values for total fat, saturated fat, cholesterol, and sodium are the uppermost limits considered desirable because of their link to certain diseases.

Dalton's law Named for English chemist John Dalton (1766–1844). In a mixture of gases, the portion of the total pressure resulting from each type of gas is determined by the percentage of the total volume represented by each gas type.

dartos muscle (dar'tōs) Layer of smooth muscle in the skin of the scrotum; contracts in response to lower temperature and relaxes in response to higher temperature; raises and lowers testes in the scrotum.

deciduous tooth (dĕ-sid'ū-ŭs) Tooth of the first set of teeth; also called primary tooth.

decussate (dĕ'kŭ-săt, dĕ-kŭs'ăt) [L., *decusso*, X-shaped, from *decussis*, ten (X)] To cross.

deep inguinal ring (ing'gwi-năl) Opening in the transverse fascia through which the spermatic cord (or round ligament in the female) enters the inguinal canal.

defecation (def-ĕ-kă'shŭn) [L., *defaeco*, to remove the dregs, purify] Discharge of feces from the rectum.

defecation reflex Combination of local and central nervous system reflexes initiated by distension of the rectum and resulting in the movement of feces out of the lower colon.

deglutition (dĕ-gloo-tish'ŭn) [L., *de* + *glutio*, to swallow] Act of swallowing.

dendrite (den'drĭt) [Gr., *dendrites*, tree] Branching processes of a neuron; receives stimuli and conducts potentials toward the cell body.

dendritic cell (den-drit'ik) Large cells with long, cytoplasmic extensions that are capable of taking up and concentrating antigens, leading to the activation of B or T lymphocytes.

dendritic spine Extension of nerve cell dendrites where axons form synapses with the dendrites; also called gemmule.

dental arch (den'täl) [L., *arcus*, bow] Curved maxillary or mandibular arch in which the teeth are located.

dentin (den'tin) Bony material forming the mass of the tooth.

deoxyhemoglobin (dĕ-oks'ĕ-hĕ-mō-glō'bĭn) Hemoglobin without oxygen bound to it.

deoxyribonuclease (dĕ-oks'ĕ-rĭ-bō-noo'klĕ-ās) Enzyme that splits DNA into its component nucleotides.

deoxyribonucleic acid (DNA) (dĕ-oks'ĕ-rĭ-bō-noo-klĕ'ic) Type of nucleic acid containing deoxyribose as the sugar component, found principally in the nuclei of cells; constitutes the genetic material of cells.

depolarization (dĕ-pō'lăr-i-ză'shŭn) **phase** Change in the electric charge difference across the plasma membrane that causes the difference to be smaller or closer to 0 mV; phase of the action potential in which the membrane potential moves toward zero, or becomes positive.

depression (dĕ-presh'ŭn) Movement of a structure in an inferior direction.

depth perception (per-sep'shun) Ability to distinguish between near and far objects and to judge their distance.

dermatome (der'mă-tōm) Area of skin supplied by a spinal nerve.

dermis (der'mis) [Gr., *derma*, skin] Dense irregular connective tissue that forms the deep layer of the skin.

descending aorta Part of the aorta, further divided into the thoracic aorta and abdominal aorta.

descending colon Part of the colon extending from the left colonic flexure to the sigmoid colon.

desmosome (dez'mō-sōm) [Gr., *desmos*, a band + *soma*, body] Point of adhesion between cells. Each contains a dense plate at the point of adhesion and a cementing extracellular material between the cells.

desquamate (des'kwă-măt) [L., *desquamo*, to scale off] Peeling or scaling off of the superficial cells of the stratum corneum.

diabetes insipidus (dĭ-ă-bĕ'tĕz in-sip'ĭ-dŭs) Chronic excretion of large amounts of urine of low specific gravity accompanied by extreme thirst; results from inadequate output of antidiuretic hormone.

diabetes mellitus (me-lĭ'tŭs) Metabolic disease in which carbohydrate use is reduced and that of lipid and protein enhanced; caused by a deficiency of insulin or an inability to respond to insulin and is characterized, in more severe cases, by hyperglycemia, glycosuria, water and electrolyte loss, ketoacidosis, and coma.

diapedesis (dĭ-ă-pĕ-dĕ'sis) [Gr., *dia*, through + *pedesis*, a leaping] Passage of blood or any of its formed elements through the intact walls of blood vessels.

diaphragm (dĭ-ă-fram) Musculomembranous partition between the abdominal and thoracic cavities.

diaphysis (dĭ-af'i-sis) [Gr., growing between] Shaft of a long bone.

diastole (dĭ-as'tō-lĕ) [Gr., *diastole*, dilation] Relaxation of the heart chambers, during which they fill with blood; usually refers to ventricular relaxation.

diencephalon (dĭ-en-sef'ă-lon) [Gr., *dia*, through + *enkephalos*, brain] Second portion of the embryonic brain; in the inferior core of the adult cerebrum.

diffuse lymphatic tissue Dispersed lymphocytes and other cells with no clear boundary; found beneath mucous membranes, around lymph nodules, and within lymph nodes and spleen.

diffusion (di-fŭ'zhŭn) [L., *diffundo*, to pour in different directions] Tendency for solute molecules to move from an area of high concentration to an area of low concentration in solution; the product of the constant random motion of all atoms, molecules, or ions in a solution.

diffusion coefficient Measure of how easily a gas diffuses through a liquid or tissue.

digestive tract (di-jes'tiv, dĭ-jes'tiv) Mouth, oropharynx, esophagus, stomach, small intestine, and large intestine.

digit (dij'it) Finger, thumb, or toe.

dilator pupillae (dĭ'lă-tĕr pŭ-pil'ĕ) Radial smooth muscle cells of the iris diaphragm that cause the pupil of the eye to dilate.

diploid (dip'loyd) Normal number of chromosomes (in humans, 46 chromosomes) in somatic cells.

disaccharide (dĭ-sak'ă-rĭd) Condensation product of two monosaccharides by the elimination of water.

dissociate (di-sō'sĕ-ăt) [L., *dis* + *socio*, to disjoin, separate] Ionization in which ions are dissolved in water and the cations and anions are surrounded by water molecules.

distal convoluted tubule Convoluted tubule of the nephron that extends from the ascending limb of the loop of Henle and ends in a collecting duct.

distributing artery Medium-sized artery with a tunica media composed principally of smooth muscle; regulates blood flow to different regions of the body.

dominant (dom'i-nant) [L., *dominus*, a master] Gene that is expressed phenotypically to the exclusion of a contrasting recessive gene.

dorsal root (dŏr'săl) Sensory (afferent) root of a spinal nerve.

dorsal root ganglion (gang'glĕ-on) Collection of sensory neuron cell bodies within the dorsal root of a spinal nerve; also called spinal ganglion.

ductus arteriosus (dŭk'tŭs ar-tĕr'ĕ-ō-sŭs) Fetal vessel connecting the left pulmonary artery with the descending aorta.

ductus deferens (def'er-enz) Duct of the testicle, running from the epididymis to the ejaculatory duct; also called vas deferens.

duodenal gland (doo'ō-dĕ'năl, doo-od'ĕ-năl) Small gland that opens into the base of intestinal glands; secretes a mucoid alkaline substance.

duodenocolic reflex (doo-ō-dĕ'nō-kŏ-lik) Local reflex resulting in a mass movement of the contents of the colon; produced by stimuli in the duodenum.

duodenum (doo-ō-dĕ'nŭm, doo-od'ĕ-nŭm) [L., *duodeni*] First division of the small intestine; connects to the stomach.

dura mater (doo'ră măt'er) [L., hard mother] Tough, fibrous membrane forming the outer covering of the brain and spinal cord.

E

- ear drum** (ēr'drūm) Cellular membrane that separates the external from the middle ear; vibrates in response to sound waves; also called tympanic membrane.
- ectoderm** (ek'tō-derm) Outermost of the three germ layers of an embryo.
- ectopic focus**; pl. **foci** (ek-top'ik fōkūs, fō'sī) Any pacemaker other than the sinus node of the heart; abnormal pacemaker; an ectopic pacemaker.
- edema** (e-dē'mā) [Gr., *oidema*, a swelling] Excessive accumulation of fluid within or around cells, usually causing swelling.
- effector T cell** (ē-fek'tōr, ē-fek'tōr) Subset of T lymphocytes that is responsible for cell-mediated immunity.
- effluent arteriole** (ef'er-ent ar-tēr'ē-ōl) Vessel that carries blood from the glomerulus to the peritubular capillaries.
- effluent division** Nerve fibers that send impulses from the central nervous system to the periphery.
- effluent ductule** (ef'er-ent dūk'tool) [L., *ductus*, duct] One of a number of small ducts leading from the testis to the head of the epididymis.
- ejaculation** (ē-jak-ū-lā'shūn) Reflexive expulsion of semen from the penis.
- ejaculatory duct** (ē-jak'ū-lā-tōr-ē) Duct formed by the union of the ductus deferens and the excretory duct of the seminal vesicle; opens into the prostatic urethra.
- ejection period** (ē-jek'shūn) Time in the cardiac cycle when the semilunar valves are open and blood is being ejected from the ventricles into the arterial system.
- elastin** (ē-las'tin) Yellow, elastic, fibrous mucoprotein that is the major connective tissue protein of elastic structures (e.g., large blood vessels and elastic ligaments).
- electrocardiogram (ECG, EKG)** (ē-lek-trō-kar'dē-ō-gram) [Gr., *elektron*, amber + *kardia*, heart + *gramma*, a drawing] Graphic record of the heart's electric currents obtained with an electrocardiograph.
- electrolyte** (ē-lek'trō-līt) [Gr., *electro* + *lytos*, soluble] Cation or anion in solution that conducts an electric current.
- electron** (ē-lek'tron) Negatively charged subatomic particle in an atom.
- electron-transport chain** Series of electron carriers in the inner mitochondrial membrane; they receive electrons from NADH and FADH₂, using the electrons in the formation of ATP and water.
- element** (el'ē-ment) [L., *elementum*, rudiment, beginning] Substance composed of atoms of only one kind.
- elevation** (el-ē-vā'shūn) Movement of a structure in a superior direction.
- embolism** (em'bō-lizm) [Gr., *embolisma*, a piece of patch, literally something thrust in] Obstruction or occlusion of a vessel by a transported clot, a mass of bacteria, or other foreign material.
- embolus**; pl. **emboli** (em'bō-lūs, em'bō-lī) [Gr., *embolos*, plug, wedge, or stopper] Plug, composed of a detached clot, a mass of bacteria, or another foreign body, occluding a blood vessel.
- embryo** (em'brē-ō) Developing human from the first to the eighth week of development.
- embryonic disk** (em-brē-on'ik) Point in the inner cell mass at which the embryo begins to be formed.
- embryonic period** From approximately the second to the eighth week of development, during which the major organ systems are organized.
- emission** (ē-mish'ūn) [L., *emissio*, to send out] Discharge; accumulation of semen in the urethra prior to ejaculation. A nocturnal emission is a discharge of semen while asleep.
- emmetropia** (em-ē-trō'pē-ā) [Gr., *emmetros*, according to measure + *ops*, eye] In the eye, the state of refraction in which parallel rays are focused exactly on the retina; no accommodation is necessary.
- emulsify** (ē-mūl'si-fi) To form an emulsion.
- enamel** (ē-nam'ēl) Hard substance covering the exposed portion of the tooth.
- endocardium**; pl. **endocardia** (en-dō-kar'dē-ūm, en-dō-kar'dē-ā) Innermost layer of the heart, including endothelium and connective tissue.
- endocrine gland** (en'dō-krin) [Gr., *endon*, inside + *krino*, to separate] Ductless gland that secretes a hormone internally, usually into the circulation.
- endocytosis** (en'dō-si-tō'sis) Bulk uptake of material through the cell membrane.
- endoderm** (en'dō-derm) Innermost of the three germ layers of an embryo.
- endolymph** (en'dō-limf) [Gr., *endo* + L., *lymphā*, clear fluid] Fluid found within the membranous labyrinth of the inner ear.
- endometrium**; pl. **endometria** (en'dō-mē'trē-ūm, en'dō-mē'trē-ā) Mucous membrane composing the inner layer of the uterine wall; consists of a simple columnar epithelium and a lamina propria that contains simple tubular uterine glands.
- endomysium** (en'dō-miz'ē-ūm, en'dō-mis'ē-ūm) [Gr., *endo*, within + *mys*, muscle] Fine connective tissue sheath surrounding a muscle fiber.
- endoneurium** (en-dō-noo'rē-ūm) [Gr., *endo*, within + *neuron*, nerve] Delicate connective tissue surrounding individual nerve fibers within a peripheral nerve.
- endoplasmic reticulum**; pl. **reticula** (en'dō-plas'mik re-tik'ū-lūm, re-tik'ū-lā) Double-walled membranous network inside the cytoplasm; rough has ribosomes attached to the surface; smooth does not have ribosomes attached.
- endorphin** (en-dōr'fin) Opiate-like polypeptide found in the brain and other parts of the body; binds in the brain to the same receptors that bind exogenous opiates.
- endosteum** (en-dos'tē-ūm) [Gr., *endo*, within + *osteon*, bone] Membranous lining of the medullary cavity and the cavities of spongy bone.
- endothelium**; pl. **endothelia** (en-dō-thē'lē-ūm, en-dō-thē'lē-ā) [Gr., *endo*, within + *thele*, nipple] Layer of flat cells lining blood and lymphatic vessels and the chambers of the heart.
- enkephalin** (en-kef'ā-lin) Pentapeptide found in the brain; binds to specific receptor sites, some of which may be pain-related opiate receptors.
- enteric nervous system (ENS)** Complex network of neuron cell bodies and axons within the wall of the digestive tract; capable of controlling the digestive tract independently of the central nervous system through local reflexes.
- enterokinase** (en'tēr-ō-kī'nās) Intestinal proteolytic enzyme that converts trypsinogen into trypsin.
- enzyme** (en'zīm) [Gr., *en*, in + *zyme*, leaven] Protein that acts as a catalyst.
- eosinophil** (ē-sin'ō-fil) [Gr., *eos*, dawn + *philos*, fond] White blood cell that stains with acidic dyes; inhibits inflammation.
- epicardium** (ep-i-kar'dē-ūm) [Gr., *epi*, on + *kardia*, heart] Serous membrane covering the surface of the heart; also called visceral pericardium.
- epidermis** (ep-i-derm'is) [Gr., *epi*, on + *derma*, skin] Outer portion of the skin formed of epithelial tissue that rests on or covers the dermis.
- epididymis**; pl. **epididymides** (ep-i-did'i-mis, -didim'i-dēz) [Gr., *epi*, on + *didymos*, twin] Elongated structure connected to the posterior surface of the testis, which consists of the head, body, and tail; site of storage and maturation of the spermatozoa.
- epiglottis** (ep-i-glot'is) [Gr., *epi*, on + *glottis*, mouth of the windpipe] Plate of elastic cartilage covered with mucous membrane; serves as a valve over the glottis of the larynx during swallowing.
- epimysium** (ep-i-mis'ē-ūm) [Gr., *epi*, on + *mys*, muscle] Fibrous envelope surrounding a skeletal muscle.
- epinephrine** (ep'i-nef'rin) Hormone (amino acid derivative) similar in structure to the neurotransmitter norepinephrine; major hormone released from the adrenal medulla; increases cardiac output and blood glucose levels; also called adrenaline.
- epineurium** (ep-i-noo'rē-ūm) [Gr., *epi*, on + *neuron*, nerve] Connective tissue sheath surrounding a nerve.
- epiphyseal line** (ep-i-fiz'ē-āl) Dense plate of bone in a bone that is no longer growing, indicating the former site of the epiphyseal plate.
- epiphyseal plate** Site at which bone growth in length occurs; located between the epiphysis and diaphysis of a long bone; area of hyaline cartilage where cartilage growth is followed by endochondral ossification; also called metaphysis or growth plate.
- epiphysis**; pl. **epiphyses** (e-pif'i-sis, e-pif'i-sēz) [Gr., *epi*, on + *physis*, growth] Portion of a bone developed from a secondary ossification center and separated from the remainder of the bone by the epiphyseal plate.
- epiploic appendage** (ep'i-plō'ik) One of a number of little processes of peritoneum projecting from the serous coat of the large intestine except the rectum; they are generally distended with fat.
- epithelium** (ep-i-thē'lē-ūm) [Gr., *epi*, on + *thele*, nipple] One of the four primary tissue types. *Nipple* refers to the tiny capillary-containing connective tissue in the lips, which is where the term was first used. The use of the term was later expanded to include all covering and lining surfaces of the body.
- epitope** (ep'i-tōp) [Gr., *epi*, on + *top*, place] See antigenic determinant.
- eponychium** (ep-ō-nik'ē-ūm) [Gr., *epi*, on + *onyx*, nail] Outgrowth of the skin that covers the proximal and lateral borders of the nail; also called cuticle.
- erection** (ē-rek'shūn) [L., *erectio*, to set up] Condition of erectile tissue when filled with blood; tissue becomes hard and unyielding; especially refers to this state of the penis.
- erythrocyte** (ē-rith'rō-sīt) [Gr., *erythros*, red + *kytos*, cell] Red blood cell; biconcave disk containing hemoglobin.
- erythropoiesis** (ē-rith'rō-poy-ē'sis) [*erythrocyte* + Gr., *poiesis*, a making] Production of erythrocytes.
- erythropoietin (EPO)** (ē-rith'rō-poy'ē-tin) Protein that enhances erythropoiesis by stimulating the

- formation of proerythroblasts and the release of reticulocytes from bone marrow.
- esophagus**; pl. **esophagi** (ē-sof'ā-gūs, ē-sof'ā-gī, ē-sof'ā-jī) [Gr., *oisophagos*, gullet] Portion of the digestive tract between the pharynx and stomach.
- essential amino acid** Amino acid, required by animals, that must be supplied in the diet.
- estrogen** (es'trō-jen) Substance that exerts biologic effects characteristic of estrogen hormone, such as stimulating female secondary sexual characteristics, growth, and maturation of long bones, and help controlling the menstrual cycle.
- evagination** (ē-vaj-i-nā'shūn) [L., *e*, out + *vagina*, sheath] Protrusion of some part or organ from its normal position.
- evaporation** (ē-vap-ō-ra'shūn) [L., *e*, out + *vaporare*, to emit vapor] Change from liquid to vapor form.
- eversion** (ē-ver'zhūn) [L., *everto*, to overturn] Turning outward.
- excitation-contraction coupling** (ek-sī-tā'shūn kon-trak'shūn kŭp'ling) Stimulation of a muscle fiber produces an action potential that results in contraction of the muscle fiber.
- excitatory postsynaptic potential (EPSP)** (ek-sī'tā-tō-rē pōst-si-nap'tik pō-ten'shāl) Depolarization in the postsynaptic membrane that brings the membrane potential close to threshold.
- exocrine gland** (ek'sō-krin) [Gr., *exo*, outside + *krino*, to separate] Gland that secretes to a surface or outward through a duct.
- exocytosis** (ek'sō-sī-to'sis) Elimination of material from a cell through the formation of vacuoles.
- expiratory reserve volume** Maximum volume of air that can be expelled from the lungs after a normal expiration.
- extension** (eks-ten'shūn) [L., *extensio*, to stretch out] To stretch out.
- external anal sphincter** Ring of striated muscular fibers surrounding the anus.
- external auditory canal** Short canal that opens to the exterior environment and terminates at the eardrum; part of the external ear.
- external ear** Portion of the ear that includes the auricle and external acoustic meatus; terminates at the eardrum.
- external nose** Nostril; anterior or external opening of the nasal cavity.
- external spermatic fascia** Outer fascial covering of the spermatic cord.
- external urethral orifice** Slitlike opening of the urethra in the glans penis.
- external urinary sphincter** Sphincter skeletal muscle around the base of the urethra external to the internal urinary sphincter.
- exteroceptor** (eks'ter-ō-sep'ter, eks'ter-ō-sep'tōr) [L., *exterus*, external + *receptor*, receiver] Sensory receptor in the skin or mucous membranes that responds to stimulation by external agents or forces.
- extracellular** (eks-trā-sel'ū-lār) Outside the cell.
- extracellular matrix**; pl. **matrices** (eks-trā-sel'ū-lār mā'triks, mā'tri-sēz) Nonliving chemical substances located between connective tissue cells.
- extrinsic clotting pathway** (eks-trin'sik) Series of chemical reactions resulting in clot formation; begins with chemicals (e.g., tissue thromboplastin) found outside the blood.
- extrinsic muscle** Muscle located outside the structure being moved.
- eyebrow** Short hairs on the bony ridge above the eyes.
- eyelash** Hair at the margins of the eyelids.
- eyelid** Movable fold of skin in front of the eyeball; also called palpebra.
- F**
- F actin** (ak'tin) Fibrous actin molecule that is composed of a series of globular actin molecules (G actin).
- facilitated diffusion** Carrier-mediated process that does not require ATP and moves substances into or out of cells from a high to a low concentration.
- falciform ligament** (fal'si-fōrm lig'ā-ment) Fold of peritoneum extending to the surface of the liver from the diaphragm and anterior abdominal wall.
- fallopian tube** (fa-lō'pē-an) *See* uterine tube.
- false pelvis** Portion of the pelvis superior to the pelvic brim; composed of the bone on the posterior and lateral sides and by muscle on the anterior side; also called greater pelvis.
- falx cerebelli** (falks ser-ē-bel't) Dural fold between the two cerebellar hemispheres.
- falx cerebri** (falk ser'ē-brī) Dural fold between the two cerebral hemispheres.
- far point of vision** Distance from the eye where accommodation is not needed to have the image focused on the retina.
- fascia**; pl. **fasciae** (fash'ē-ā, fash'ē-ē) [L., band or fillet] Loose areolar connective tissue found beneath the skin (hypodermis) or dense connective tissue that encloses and separates muscles.
- fasciculus** (fā-sik'ū-lūs) [L., *fascis*, bundle] Band or bundle of nerve or muscle fibers bound together by connective tissue.
- fat** [A.S., *faet*] Greasy, soft-solid material found in animal tissues and many plants; composed of two types of molecules: glycerol and fatty acids.
- fatigue** (fā-tēg') [L., *fatigo*, to tire] Period characterized by a reduced capacity to do work.
- fat-soluble vitamin** Vitamin, such as A, D, E, and K, that is soluble in lipids and absorbed from the intestine along with lipids.
- fauces** (faw'sēz) [L., throat] Space between the cavity of the mouth and the pharynx.
- female climacteric** Period of life occurring in women, encompassing termination of the reproductive period and characterized by endocrine, somatic, and transitory psychologic changes and ultimately menopause; also called perimenopause.
- female pronucleus** Nuclear material of the ovum after the ovum has been penetrated by the spermatozoon. Each pronucleus carries the haploid number of chromosomes.
- fertilization** (fer'til-i-zā'shūn) Process that begins with the penetration of the secondary oocyte by the spermatozoon and is completed with the fusion of the male and female pronuclei.
- fetus** (fē'tus) Developing human following the embryonic period (after 8 weeks of development).
- fibrin** (fī'brin) Elastic filamentous protein derived from fibrinogen by the action of thrombin, which releases peptides from fibrinogen in coagulation of the blood.
- fibroblast** (fī'brō-blast) [L., *fibra*, fiber + Gr., *blas-tos*, germ] Spindle-shaped or stellate cells that form connective tissue.
- fibrocyte** (fī'brō-sīt) Mature cell of fibrous connective tissue.
- fibrous joint** (fī'brūs) Bones connected by fibrous tissue with no joint cavity; includes sutures, syndesmoses, and gomphoses.
- fibrous tunic** Outer layer of the eye; composed of the sclera and the cornea.
- filiform** (fil'i-fōrm) Filament-shaped.
- filtrate** (fil'trāt) Liquid that has passed through a filter—for example, fluid that enters the nephron through the filtration membrane of the glomerulus.
- filtration** (fil-trā'shūn) Movement, due to a pressure difference, of a liquid through a filter that prevents some or all of the substances in the liquid from passing through.
- filtration fraction** Fraction of the plasma entering the kidney that filters into Bowman's capsule. Normally, it is around 19%.
- filtration membrane** Membrane formed by the glomerular capillary endothelium, the basement membrane, and the podocytes of Bowman's capsule.
- filtration pressure** Pressure gradient that forces fluid from the glomerular capillary through the filtration membrane into Bowman's capsule; glomerular capillary pressure minus glomerular capsule pressure minus colloid osmotic pressure.
- fimbria**; pl. **fimbriae** (fim'brē-ā, fim'brē-ē) [L., fringe] Fringelike structure located at the ostium of the uterine tube.
- first messenger** *See* intercellular chemical signal.
- fixator** (fik-sā'ter) Muscle that stabilizes the origin of a prime mover.
- flagellum**; pl. **flagella** (flā-jel'ŭm, flā-jel'ā) [L., whip] Whiplike locomotory organelle of constant structural arrangement consisting of double peripheral microtubules and two single central microtubules.
- flatus** (flā'tūs) [L., a blowing] Gas or air in the gastrointestinal tract that may be expelled through the anus.
- flexion** (flek'shūn) [L., *flectus*] Bending.
- focal point** Point at which light rays cross after passing through a concave lens, such as the lens of the eye.
- foliate** (fō'lē-āt) Leaf-shaped.
- follicle-stimulating hormone (FSH)** (fol'i-kl) Hormone of the adenohypophysis that, in females, stimulates the Graafian follicles of the ovary and assists in follicular maturation and the secretion of estrogen; in males, FSH stimulates the epithelium of the seminiferous tubules and is partially responsible for inducing spermatogenesis.
- follicular phase** (fō-lik'ū-lār) Time between the end of menses and ovulation, characterized by rapid division of endometrial cells and development of follicles in the ovary; also called proliferative phase.
- foramen**; pl. **foramina** (fō-rā'men, fō-ram'i-nā) Hole.
- foramen ovale** (o-val'ē) In the fetal heart, the oval opening in the septum secundum; the persistent part of septum primum acts as a valve for this interatrial communication during fetal life; postnatally, the septum primum becomes fused to the septum secundum to close the foramen ovale, forming the fossa ovale.
- force** That which produces a motion in the body; pull.
- foregut** Cephalic portion of the primitive digestive tube in the embryo.

foreskin See prepuce.
formed elements Cells (i.e., red and white blood cells) and cell fragments (i.e., platelets) of blood.
formula unit Relative number of cations and ions in an ionic compound.
fornix (fōr'niks) [L., arch, vault] Recess at the cervical end of the vagina. Recess deep to each eyelid where the palpebral and bulbar conjunctivae meet.
fovea centralis (fō'vĕ-ă) Depression in the middle of the macula where there are only cones and no blood vessels.
free energy Total amount of energy that can be liberated by the complete catabolism of food.
frenulum (fren'ū-lŭm) [L., *frenum*, bridle] Fold extending from the floor of the mouth to the midline of the undersurface of the tongue.
frequency-modulated signals Signals, all of which are identical in amplitude, that differ in their frequency—for example, strong stimuli may initiate a high frequency of action potentials and weak stimuli may initiate a low frequency of action potentials.
FSH surge Increase in plasma follicle-stimulating hormone (FSH) levels before ovulation.
fulcrum (F) (ful'krŭm) Pivot point.
fundus (fŭn'dŭs) [L., bottom] Bottom, or rounded end, of a hollow organ—for example, the fundus of the stomach or uterus.
fungiform (fŭn'ji-fŏrm) Mushroom-shaped.

G

G actin (jĕ ak'tin) Globular protein molecules that, when bound together, form fibrous actin (F actin).
gallbladder (gawl'blad-er) Pear-shaped receptacle on the inferior surface of the liver; serves as a storage reservoir for bile.
gamete (gam'ĕt) Ovum or spermatozoon.
gamma globulin (gam'ă glob'ŭ-lin) [L., *globulus*, globule] Plasma proteins that include the antibodies.
ganglion; pl. **ganglia** (gang'glĕ-on, gang'glĕ-ă) [Gr., swelling, or knot] Any group of nerve cell bodies in the peripheral nervous system.
gap junction Small channel between cells that allows the passage of ions and small molecules between cells; provides means of intercellular communication.
gastric gland (gas'trik) Gland located in the mucosa of the fundus and body of the stomach.
gastric inhibitory polypeptide Hormone secreted by the duodenum that inhibits gastric acid secretion.
gastric pit Small pit in the mucosa membrane of the stomach, at the bottom of which are the mouths of the gastric glands that secrete mucus, hydrochloric acid, intrinsic factor, pepsinogen, and hormones.
gastrin (gas'trin) Hormone secreted in the mucosa of the stomach and duodenum that stimulates the secretion of hydrochloric acid by the parietal cells of the gastric glands.
gastrocolic reflex (gas'trŏ-kol'ik) Local reflex resulting in mass movement of the contents of the colon, which occurs after the entrance of food into the stomach.
gastroesophageal opening (gas'trŏ-ĕ-sof'ă-jĕ-ăl) Opening of the esophagus into the stomach; also called cardiac opening.
gene (jĕn) [Gr., *genos*, birth, descent] Functional unit of heredity. Each gene occupies a specific

place, or locus, on a chromosome; it is capable of reproducing itself exactly at each cell division; it often is capable of directing the formation of an enzyme or another protein.
genetics (jĕ-net'iks) [Gr., *genesis*, origin or production] Branch of science that deals with heredity.
genital fold (jen'i-tāl) Paired longitudinal ridges developing in the embryo on each side of the urogenital orifice. In the male, they form part of the penis; in the female, they form the labia minora.
genital tubercle (jen'i-tăl) Median elevation just cephalic to the urogenital orifice of an embryo; gives rise to the penis of the male or the clitoris of the female.
genotype (jen'ŏ-tĭp) [Gr., *genos*, birth, descent + *typos*, type] Genetic makeup of an individual.
germ cell (jĕrm) Spermatozoon or ovum.
germ layer One of three layers in the embryo (ectoderm, endoderm, or mesoderm) from which the four primary tissue types arise.
germinal center Lighter-staining center of a lymphatic nodule; area of rapid lymphocyte division.
gingiva (jin'ji-vă) Dense fibrous tissue, covered by mucous membrane, that covers the alveolar processes of the upper and lower jaws and surrounds the necks of the teeth.
girdle (ger'dl) Belt or zone; the bony region where the limbs attach to the body.
gland [L., *glans*, acorn] Secretory organ from which secretions may be released into the blood, into a cavity, or onto a surface.
glans penis [L., *glans*, acorn] Conical expansion of the corpus spongiosum that forms the head of the penis.
globin (glŏ'bin) Protein portion of hemoglobin.
glomerular capillary pressure (GCP) (glŏ-măr'ŭ-lăr) Blood pressure within the glomerulus.
glomerular filtration rate (GFR) Amount of plasma (filtrate) that filters into Bowman's capsules per minute.
glomerulus (glŏ-măr'ŭ-lŭs) [L., *glomus*, ball of yarn] Mass of capillary loops at the beginning of each nephron, nearly surrounded by Bowman's capsule.
glottis (glot'is) [Gr., aperture of the larynx] Vocal apparatus; includes vocal folds and the cleft between them.
glucocorticoid (gloo-kŏ-kŏr'ti-koyd) Steroid hormone (e.g., cortisol) released by zonula fasciculata of the adrenal cortex; increases blood glucose and inhibits inflammation.
gluconeogenesis (gloo'kŏ-nĕ-ŏ-jen'ĕ-sis) [Gr., *glykys*, sweet + *neos*, new + *genesis*, production] Formation of glucose from noncarbohydrates, such as proteins (amino acids) or lipids (glycerol).
glycogenesis (glĭ'kŏ-jĕ-nŏ'sis) Formation of glycogen from glucose molecules.
glycolysis (glĭ-kol'i-sis) [Gr., *glykys*, sweet + *lysis*, a loosening] Anaerobic process during which glucose is converted to pyruvic acid; net of two ATP molecules is produced during glycolysis.
goblet cell Mucus-producing epithelial cell that has its apical end distended with mucus.
Golgi apparatus (gol'jĕ) Named for Camillo Golgi, Italian histologist and Nobel laureate (1843–1926). Specialized endoplasmic reticulum that

concentrates and packages materials for secretion from the cell.
Golgi tendon organ Proprioceptive nerve ending in a tendon.
gomphosis (gom-fŏ'sis) [Gr., *gomphos*, bolt, nail + *osis*, condition] Fibrous joint in which a peg-like process fits into a hole.
gonad (gŏ'nad) [Gr., *gone*, seed] Organ that produces sex cells; testis of a male or ovary of a female.
gonadal ridge (gŏ-nad'ăl) Elevation on the embryonic mesonephros; primordial germ cells become embedded in it, establishing it as a testis or an ovary.
gonadotropin (gŏ'nad-ŏ-trŏ'pin) Hormone capable of promoting gonadal growth and function. Two major gonadotropins are luteinizing hormone (LH) and follicle-stimulating hormone (FSH).
gonadotropin-releasing hormone (GnRH) Hypothalamic-releasing hormone that stimulates the secretion of gonadotropins (LH and FSH) from the adenohypophysis; also called luteinizing hormone-releasing hormone (LHRH).
granulocyte (gran'ŭ-lŏ-sĭt) Mature granular white blood cell (neutrophil, basophil, or eosinophil).
granulosa cell (gran'ŭ-lŏ-să) Cell in the layer surrounding the primary follicle.
gray matter Collection of nerve cell bodies, their dendritic processes, and associated neuroglial cells within the central nervous system.
gray ramus communicans; pl. **rami communicantes** (ră'mŭs kŏ-mŭ'nĭ-kans, ră'mĭ kŏ-mŭ-nĭ-kan'tĕz) Connection between a spinal nerve and a sympathetic chain ganglion through which unmyelinated postganglionic axons project.
greater omentum Peritoneal fold passing from the greater curvature of the stomach to the transverse colon, hanging like an apron in front of the intestines.
greater vestibular gland One of two mucus-secreting glands on each side of the lower part of the vagina. The equivalent of the bulbourethral glands in the male.
growth hormone Hormone that stimulates general growth of the individual; stimulates cellular amino acid uptake and protein synthesis; also called somatotropin.
gubernaculum (goo'ber-nak'ŭ-lŭm) [L., helm] Column of tissue that connects the fetal testis to the developing scrotum; involved in testicular descent.
gustatory (gŭs'tă-tŏr-ĕ) Associated with the sense of taste.
gustatory hair Microvillus of gustatory cell in a taste bud.
gynecomastia (gĭ'nĕ-kŏ-mas'tĕ-ă) [Gr., *gyne*, woman + *mastos*, breast] Excessive development of the male mammary glands, which sometimes secrete milk.

H

H zone Area in the center of the A band in which there are no actin myofilaments; contains only myosin.
hair [A.S., hear] Columns of dead keratinized epithelial cells.
hair follicle Invagination of the epidermis into the dermis; contains the root of the hair and receives the ducts of sebaceous and apocrine glands.
Haldane effect Named for Scottish physiologist John S. Haldane (1860–1936). Hemoglobin that is not bound to carbon dioxide binds more readily

- to oxygen than hemoglobin that is bound to carbon dioxide.
- half-life** Time it takes for one-half of an administered substance to be lost through biologic processes.
- haploid** (hap'loyd) One set of chromosomes, in contrast to diploid; characteristic of gametes.
- haptēn** (hap'ten) [Gr., *hapto*, to fasten] Small molecule that binds to a large molecule; together they stimulate the specific immune system.
- hard palate** Floor of the nasal cavity that separates the nasal cavity from the oral cavity; composed of the palatine processes of the maxillary bones and the horizontal plates of the palatine bones; also called bony palate.
- haustra** (haw'strä) [L., machine for drawing water] Sacs of the colon, caused by contraction of the taenia coli, which are slightly shorter than the gut so that the latter is thrown into pouches.
- haversian canal** (ha-ver'shan) Named for seventeenth-century English anatomist Clopton Havers (1650–1702). Canal containing blood vessels, nerves, and loose connective tissue and running parallel to the long axis of the bone.
- heart skeleton** Fibrous connective tissue that provides a point of attachment for cardiac muscle cells, electrically insulates the atria from the ventricles, and forms the fibrous rings around the valves.
- heat energy** Energy that results from the random movement of atoms, ions, or molecules; the greater the amount of heat energy in an object, the higher the object's temperature.
- helicotrema** (hel'i-kō-trē'mä) [Gr., *helix*, spiral + *traema*, hole] Opening at the apex of the cochlea through which the scala vestibuli and the scala tympani of the cochlea connect.
- helper T cell** Subset of T lymphocytes that increases the activity of B cells and T cells.
- hematocrit** (hē'mā-tō-krit) [Gr., *hemato*, blood + *krin*, to separate] Percentage of blood volume occupied by erythrocytes.
- hematoma** (he-ma-to'ma) Localized mass of blood released from blood vessels but confined within an organ or a space; the blood is usually clotted.
- heme** (hēm) Oxygen-carrying, color-furnishing part of hemoglobin.
- hemidesmosome** (hem-ē-des'mō-sōm) Similar to half a desmosome, attaching epithelial cells to the basement membrane.
- hemocytoblast** (he'mo-si'to-blast) Blood stem cell derived from mesenchyme that can give rise to red and white blood cells and platelets.
- hemoglobin** (hē-mō-glō'bin) Red, respiratory protein of red blood cells; consists of 6% heme and 94% globin; transports oxygen and carbon dioxide.
- hemolysis** (hē-mol'i-sis) [Gr., *haima* + *lysis*, destruction] Destruction of red blood cells in such a manner that hemoglobin is released.
- hemolytic disease of the newborn (HDN)** Destruction of erythrocytes in the fetus or newborn caused by antibodies produced in an Rh-negative mother acting on the Rh-positive blood of the fetus or newborn.
- hemopoiesis** (hē'mō-poy-ē'sis) [Gr., *haima*, blood + *poiesis*, a making] Formation of the formed elements of blood—that is, red blood cells, white blood cells, and platelets; also called hematopoiesis.
- hemopoietic tissue** (hē'mō-poy-et'ik) [Gr., *haima*, blood + *poiesis*, to make] Blood-forming tissue.
- hemostasis** (hē'mō-stā-sis) Arrest of bleeding.
- Henry's law** Named for English chemist William Henry (1775–1837). The concentration of a gas dissolved in a liquid is equal to the partial pressure of the gas over the liquid times the solubility coefficient of the gas.
- heparin** (hep'ā-rin) Anticoagulant that prevents platelet agglutination and thus prevents thrombus formation.
- hepatic artery** (he-pa'tik) Branch of the aorta that delivers blood to the liver.
- hepatic cord** Plate of liver cells that radiates away from the central vein of a liver lobule.
- hepatic portal system** System of portal veins that carries blood from the intestines, stomach, spleen, and pancreas to the liver.
- hepatic portal vein** Portal vein formed by the superior mesenteric and splenic veins and entering the liver.
- hepatic sinusoid** (si'nū-soyd) Terminal blood vessel having an irregular and larger caliber than an ordinary capillary within the liver lobule.
- hepatic vein** Vein that drains the liver into the inferior vena cava.
- hepatocyte** (hep'ā-tō-sīt) Liver cell.
- hepatopancreatic ampulla** Dilation within the major duodenal papilla that normally receives both the common bile duct and the main pancreatic duct.
- hepatopancreatic ampullar sphincter** Smooth muscle sphincter of the hepatopancreatic ampulla; also called sphincter of Oddi.
- Hering-Breuer reflex** (her'ing broy'er) Named for German physiologist Heinrich Ewald Hering (1866–1948) and Austrian internist Josef Breuer (1842–1925). Sensory impulses from stretch receptors in the lungs arrest inspiration; expiration then occurs.
- heterozygous** (het'er-ō-zī'gūs) [Gr., *heteros*, other + *zygon*, yoke] Having different allelic genes at one or more paired loci in homologous chromosomes.
- hiatus** (hī-ā'tūs) [L., aperture, to yawn] Opening.
- hilum** (hī'lūm) [L., small bit or trifle] Indented surface on many organs, serving as a point where nerves and vessels enter or leave.
- hindgut** Caudal or terminal part of the embryonic gut.
- histamine** (his'tā-mēn) Amine released by mast cells and basophils that promotes inflammation.
- histology** (his-tol'ō-jē) [Gr., *histo*, web (tissue) + *logos*, study] Science that deals with the microscopic structure of cells, tissues, and organs in relation to their function.
- holocrine gland** (hol'ō-krin) [Gr., *holos*, complete + *krino*, to separate] Gland whose secretion is formed by the disintegration of entire cells (e.g., sebaceous gland).
- homeostasis** (hō'mē-ō-stā'sis) [Gr., *homoio*, like + *stasis*, a standing] State of equilibrium in the body with respect to functions and composition of fluids and tissues.
- homologous** (hō-mol'ō-gūs) [Gr., ratio or relation] Alike in structure or origin.
- homozygous** (hō-mō-zī'gūs) [Gr., *homos*, the same + *zygon*, yoke] State of having identical allelic genes at one or more paired loci in homologous chromosomes.
- hormone** (hōr'mōn) [Gr., *hormon*, to set into motion] Substance secreted by endocrine tissues into the blood that acts on a target tissue to produce a specific response.
- hormone receptor** Protein or glycoprotein molecule of cells that specifically binds to hormones and produces a response.
- horn** Subdivision of gray matter in the spinal cord. The axons of sensory neurons synapse with neurons in the posterior horn, the cell bodies of motor neurons are in the anterior horn, and the cell bodies of autonomic neurons are in the lateral horn.
- human chorionic gonadotropin (hCG)** Hormone produced by the placenta; stimulates the secretion of testosterone by the fetus; during the first trimester, it stimulates ovarian secretion from the corpus luteum of the estrogen and progesterone required for the maintenance of the placenta. In a male fetus, it stimulates the secretion of testosterone by the fetal testis.
- humoral immunity** (hū'mōr-āl) [L., *humor*, a fluid] Immunity due to antibodies in serum.
- hyaline cartilage** (hī'ā-lin) [Gr., *hyalos*, glass] Gelatinous, glossy cartilage tissue consisting of cartilage cells and their matrix; contains collagen, proteoglycans, and water.
- hyaluronic acid** (hī'ā-loo-ron'ik) Mucopolysaccharide made up of alternating β-(1,4)-linked residues of hyalobiuronic acid, forming a gelatinous material in the tissue spaces and acting as a lubricant and shock absorbant generally throughout the body.
- hydrochloric acid (HCl)** (hī-drō-klōr'ik) Acid of gastric juice.
- hydrogen bond** (hī-drō-jen) Hydrogen atoms bound covalently to either N or O atoms have a small positive charge that is weakly attracted to the small negative charge of other atoms, such as O or N; it can occur within a molecule or between different molecules.
- hydrophilic** (hi-dro-fil'ik) [Gr., *hydro*, water + *philos*, love] Denoting the property of attracting or associating with water molecules, possessed by polar molecules and ions; the opposite of hydrophobic.
- hydrophobic** (hi-dro-fob'ik) [Gr., *hydro*, water + *phobos*, fear] Lacking an attraction to water, possessed by nonpolar molecules; the opposite of hydrophilic.
- hydroxyapatite** (hī-drok'sē-ap'ā-tīt) Mineral with the empiric formula $3\text{Ca}_3(\text{PO}_4)_2 \cdot \text{Ca}(\text{OH})_2$; the main mineral of bone and teeth.
- hymen** (hī'men) [Gr., membrane] Thin, membranous fold partly occluding the vaginal external orifice; normally disrupted by sexual intercourse or other mechanical phenomena.
- hyoid bone** (hī'oyd) (Gr., *hoyoies*, shaped like the Greek letter epsilon [ε]) U-shaped bone between the mandible and larynx.
- hypercalcemia** (hī'per-kal-sē'mē-ā) Abnormally high levels of calcium in the blood.
- hypercapnia** (hī'per-kap'nē-ā) Higher than normal levels of carbon dioxide in the blood or tissues.
- hyperkalemia** (hī'per-kā-lē'mē-ā) Greater than normal concentration of potassium ions in the circulating blood.
- hypernatremia** (hī'per-nā-trē'mē-ā) Abnormally high plasma concentration of sodium ions.
- hyperosmotic** (hī'per-oz-mot'ik) [Gr., *hyper*, above + *osmos*, an impulsion] Having a greater osmotic concentration or pressure than a reference solution.
- hyperpolarization** (hī'per-pō'lār-i-zā'shūn) Increase in the charge difference across the plasma membrane; causes the charge difference to move away from 0 mV.

- hypertonic** (hī-per-ton'ik) [Gr., *hyper*, above + *tonos*, tension] Solution that causes cells to shrink.
- hypertrophy** (hī-per'trō-fē) [Gr., *hyper*, above + *trophe*, nourishment] Increase in bulk or size; not due to an increase in number of individual elements.
- hypocalcemia** (hī-pō-kal-sē'mē-ā) Abnormally low levels of calcium in the blood.
- hypocapnia** (hī'pō-kap'nē-ā) Lower than normal levels of carbon dioxide in the blood or tissues.
- hypodermis** (hī'pō-der'mis) [Gr., *hypo*, under + *dermis*, skin] Loose areolar connective tissue found deep to the dermis that connects the skin to muscle or bone.
- hypokalemia** (hī'pō-ka-lē'mē-ā) Abnormally small concentration of potassium ions in the blood.
- hyponatremia** (hī'pō-nā-trē'mē-ā) Abnormally low plasma concentration of sodium ions.
- hyponychium** (hī-pō-nik'ē-ūm) [Gr., *hypo*, under + *onyx*, nail] Thickened portion of the stratum corneum under the free edge of the nail.
- hypopolarization** Change in the electric charge difference across the plasma membrane that causes the charge difference to be smaller or move closer to 0 mV.
- hyposmotic** (hī'pos-mot'ik) [Gr., *hypo*, under + *osmos*, an impulsion] Having a lower osmotic concentration or pressure than a reference solution.
- hypospadias** (hī'pō-spā'dē-ās) [Gr., one having the orifice of the penis too low; *hyospao*, to draw away from under] Developmental anomaly in the wall of the urethra so that the canal is open for a greater or lesser distance on the undersurface of the penis; a similar defect in the female in which the urethra opens into the vagina.
- hypothalamohypophysial portal system** (hī'pō-thal'ā-mō-hī'pō-fiz'ē-āl) Series of blood vessels that carries blood from the area of the hypothalamus to the anterior pituitary gland; originates from capillary beds in the hypothalamus and terminates as a capillary bed in the anterior pituitary gland.
- hypothalamohypophyseal tract** Nerve tract consisting of the axons of neurosecretory cells and extending from the hypothalamus into the posterior pituitary gland. Hormones produced in the neurosecretory cell bodies in the hypothalamus are transported through the hypothalamohypophyseal tract to the posterior pituitary gland, where they are stored for later release.
- hypothalamus** (hī'pō-thal'ā-mūs) [Gr., *hypo*, under + *thalamus*, bedroom] Important autonomic and neuroendocrine control center beneath the thalamus.
- hypothernar** (hī-pō-thē'nar) [Gr., *hypo*, under + *thenar*, palm of the hand] Fleishy mass of tissue on the medial side of the palm; contains muscles responsible for moving the little finger.
- hypotonic** (hī-pō-ton'ik) [Gr., *hypo*, under + *tonos*, tension] Solution that causes cells to swell.
- I band** Area between the ends of two adjacent myosin myofilaments within a myofibril; Z disk divides the I band into two equal parts.
- ileocecal sphincter** (il'ē-ō-sē'kāl) Thickening of circular smooth muscle between the ileum and the cecum, forming the ileocecal valve.
- ileocecal valve** Valve formed by the ileocecal sphincter between the ileum and the cecum.
- ileum** (il'ē-ūm) [Gr., *eileo*, to roll up, twist] Third portion of the small intestine, extending from the jejunum to the ileocecal opening into the large intestine; the posterior inferior bone of the coxal bone.
- immunity** (i-mū'ni-tē) [L., *immunis*, free from service] Resistance to infectious disease and harmful substances.
- immunization** (im-mū'ni-zā'shun) Process by which a subject is rendered immune by deliberately introducing an antigen or antibody into the subject.
- immunoglobulin (IG)** (im'ū-nō-glob'ū-lin) Antibody found in the gamma globulin portion of plasma.
- implantation** (im-plan-tā'shun) Attachment of the blastocyst to the endometrium of the uterus, occurring 6 or 7 days after fertilization of the ovum.
- impotence** (im'pō-tens) Inability to accomplish the male sexual act; caused by psychic or physical factors; also called erectile dysfunction (ED).
- incisor** (in-sī'zōr) [L., *incido*, to cut into] One of the anterior, cutting teeth.
- incisura** (in'sī-soo'rā) [L., a cutting into] Notch or indentation at the edge of any structure.
- incus (ing'kus)** [L., *anvil*] Middle of the three ossicles in the middle ear.
- inferior colliculus** (ko-lik'ū-lūs) [L., *collis*, hill] One of two rounded eminences of the midbrain; involved with hearing.
- inferior vena cava** Vein that returns blood from the lower limbs and the greater part of the pelvic and abdominal organs to the right atrium.
- inflammatory response** (in-flam'ā-tōr-ē) Complex sequence of events involving chemicals and immune cells that results in the isolation and destruction of antigens and tissues near the antigens.
- infundibulum** (in-fūn-dib'ū-lūm) [L., *funnel*] Funnel-shaped structure or passage—for example, the infundibulum that attaches the hypophysis to the hypothalamus or the funnel-like expansion of the uterine tube near the ovary.
- infusion** Introduction of a fluid other than blood, such as a saline or glucose solution, into the blood.
- inguinal canal** (ing'gwi-nāl) Passage through the lower abdominal wall that transmits the spermatic cord in the male and the round ligament in the female.
- inhibin** (in-hib'in) Polypeptide secreted from the testes that inhibits FSH secretion.
- inhibitory neuron** (in-hib'i-tōr-ē) Neuron that produces IPSPs and has an inhibitory influence.
- inhibitory postsynaptic potential (IPSP)** Hyperpolarization in the postsynaptic membrane, which causes the membrane potential to move away from threshold.
- innate immunity** (i'nāt, i-nāt') Immune system response that is the same with each exposure to an antigen; there is no ability for the system to remember a previous exposure to the antigen.
- inner cell mass** Group of cells at one end of the blastocyst, part of which forms the body of the embryo.
- inner ear** Part of the ear that contains the sensory organs for hearing and balance; contains the bony and membranous labyrinth.
- insensible perspiration** [L., *per*, through + *spiro*, to breathe everywhere] Perspiration that evaporates before it is perceived as moisture on the skin; the term sometimes includes evaporation from the lungs.
- insertion** (in-ser'shūn) More movable attachment point of a muscle; usually, the lateral or distal end of a muscle associated with the limbs; also called mobile end.
- inspiratory capacity** (in-spī'rā-tō-rē) Volume of air that can be inspired after a normal expiration; the sum of the tidal volume and the inspiratory reserve volume.
- inspiratory reserve volume** Maximum volume of air that can be inspired after a normal inspiration.
- insulin (in'sū-lin)** Protein hormone secreted from the pancreas that increases the uptake of glucose and amino acids by most tissues.
- interatrial septum** (in-ter-ā'trē-āl) [L., *saeptum*, partition] Wall between the atria of the heart.
- intercalated disk** (in-ter'kā-lā-ted) Cell-to-cell attachment with gap junctions between cardiac muscle cells.
- intercalated duct** Minute duct of glands, such as the salivary gland, and the pancreas; leads from the acini to the interlobular ducts.
- intercellular** (in-ter-sel'ū-lār) Between cells.
- intercellular chemical signal** Chemical that is released from cells and passes to other cells; acts as a signal that allows cells to communicate with each other; also called first messenger.
- interferons** (in-ter-fēr'onz) Proteins that prevent viral replication.
- interlobar artery** (in-ter-lō'bar) Branch of the segmental arteries of the kidney; runs between the renal pyramids and gives rise to the arcuate arteries.
- interlobular artery** (in-ter-lob'ū-lār) Artery that passes between lobules of an organ; branches of the interlobar arteries of the kidney pass outward through the cortex from the arcuate arteries and supply the afferent arterioles.
- interlobular duct** Any duct leading from a lobule of a gland and formed by the junction of the intercalated ducts draining the acini.
- interlobular vein** Vein that parallels the interlobular arteries; in the kidney, it drains the peritubular capillary plexus, emptying into arcuate veins.
- intermediate olfactory area** Part of the olfactory cortex responsible for the modulation of olfactory sensations.
- internal anal sphincter** [Gr., *sphinkter*, band or lace] Smooth muscle ring at the upper end of the anal canal.
- internal naris; pl. nares** (nā'ris, nā'rēs) Opening from the nasal cavity into the nasopharynx.
- internal spermatic fascia** Inner connective tissue covering of the spermatic cord.
- internal urinary sphincter** Traditionally recognized as a sphincter composed of a thickening of the middle smooth muscle layer of the bladder around the urethral opening.
- interphase (in'ter-fāz)** Period between active cell divisions when DNA replication occurs.
- interstitial** (in-ter-stish'āl) [L., *inter*, between + *sisto*, to stand] Space within tissue. Interstitial growth is growth from within.
- interstitial cell** Cell between the seminiferous tubules of the testes; secretes testosterone; also called Leydig cell.
- interventricular septum** (in-ter-ven-trik'ū-lār) Wall between the ventricles of the heart.

intestinal gland (in-tes'ti-nāl) Tubular gland in the mucous membrane of the small and large intestines; also called crypt.

intracellular (in-trā-sel'ū-lār) Inside a cell.

intracellular mediator Molecule produced within a cell that binds to a macromolecule, such as receptors or enzymes inside that cell, that regulates their activities; also called second messenger.

intramural plexus (in'trā-mū'rāl plek'sus) Combined submucosal and myenteric plexuses.

intrinsic clotting pathway (in-trin'sik) Series of chemical reactions resulting in clot formation that begins with chemicals (e.g., plasma factor XII) within the blood.

intrinsic factor Factor secreted by the parietal cells of gastric glands and required for adequate absorption of vitamin B₁₂.

intrinsic muscles Muscles located within the structure being moved.

intubation (in-too-ba'shun) Insertion of a tube into an opening, a canal, or a hollow organ.

inversion (in-ver'zhūn) [L., *invertō*, to turn about] Turning inward.

ion (ī'on) [Gr., *ion*, going] Atom or group of atoms carrying a charge of electricity by virtue of having gained or lost one or more electrons.

ion channel Pore in the plasma membrane through which ions, such as sodium and potassium, move.

ionic bond (ī-on'ik) Chemical bond that is formed when one atom loses an electron and another accepts that electron.

iris (ī'ris) Specialized portion of the vascular tunic; the “colored” portion of the eye that can be seen through the cornea.

ischemia (is-kē'mē-ā) [Gr., *ischo*, to keep back + *haima*, blood] Reduced blood supply to an area of the body.

ischium (is'kē-ūm) Superior bone of the coxal bone.

isomers (ī'sō-merz) [Gr., *isos*, equal + *meros*, part] Molecules having the same number and types of atoms but differing in their three-dimensional arrangement.

isometric contraction (ī-sō-met'rik) [Gr., *isos*, equal + *metron*, measure] Muscle contraction in which the length of the muscle does not change but the tension produced increases.

isosmotic (ī'sō-os-mot'ik) [Gr., *isos*, equal + *osmos*, an impulsion] Having the same osmotic concentration or pressure as a reference solution.

isotonic (ī'sō-ton'ik) [Gr., *isos*, equal + *tonos*, tension] Type of solution that causes cells to neither shrink nor swell.

isotope (ī'sō-tōp) [Gr., *isos*, equal + *topos*, part, place] Either of two or more atoms that have the same atomic number but a different number of neutrons.

isthmus (is'mūs) Constriction connecting two larger parts of an organ, such as the constriction between the body and the cervix of the uterus or the portion of the uterine tube between the ampulla and the uterus.

J

jaundice (jawn'dis) [Fr., *jaune*, yellow] Yellowish staining of the integument, the sclerae, and the other tissues with bile pigments.

jejunum (jē-joo'nūm) [L., *jejunus*, empty] Second portion of the small intestine; located between the duodenum and the ileum.

juxtaglomerular apparatus (jüks'tā-glō-mer'ū-lār) Complex consisting of juxtaglomerular cells of the afferent arteriole and macular densa cells of the distal convoluted tubule near the renal corpuscle; secretes renin.

juxtaglomerular cell Modified smooth muscle cell of the afferent arteriole located at the renal corpuscle; a component of the juxtaglomerular apparatus.

juxtamedullary nephron (jüks'tā-med'ū-lār-ē) Nephron located near the junction of the renal cortex and medulla.

K

karyotype (kar'ē-ō-tīp) Display of chromosomes arranged by pairs.

keratinization (ker'ā-tin-i-zā'shūn) Production of keratin and changes in the chemical and structural character of epithelial cells as they move to the skin surface.

keratinized (ker'ā-ti-nīzd) [Gr., *keras*, horn] Having become a structure that contains keratin, a protein found in skin, hair, nails, and horns.

keratinocyte (ke-rat'i-nō-sīt) [Gr., *keras*, horn + *kytos*, cell] Epidermal cell that produces keratin.

keratohyalin (ker'ā-tō-hī'ā-lin) Nonmembrane-bound protein granule in the cytoplasm of stratum granulosum cells of the epidermis.

ketogenesis (kē-tō-jen'ē-sis) Production of ketone bodies, such as from acetyl-CoA.

ketone body (kē'tōn) One of a group of ketones, including acetoacetic acid, β-hydrobutyric acid, and acetone.

ketosis (kē-tō'sis) [*ketone* + *osis*, condition] Condition characterized by the enhanced production of ketone bodies, as in diabetes mellitus or starvation.

kidney (kid'nē) [A.S., *cwith*, womb, belly + *neere*, kidney] One of the two organs that excrete urine. The kidneys are bean-shaped organs approximately 11 cm long, 5 cm wide, and 3 cm thick lying on each side of the spinal column, posterior to the peritoneum, approximately opposite the twelfth thoracic and first three lumbar vertebrae.

kilocalorie (kcal) (kil'ō-kal-ō-rē) Quantity of energy required to raise the temperature of 1 kg of water 1°C; 1000 calories. Equal to one dietary calorie.

kinetic energy (ki-net'ik) Motion energy or energy that can do work.

kinetic labyrinth (lab'i-rinth) Part of the membranous labyrinth composed of the semicircular canals; detects dynamic or kinetic equilibrium, such as movement of the head.

kinetochore (ki-nē'tō-kōr, ki-net'o-) [Gr., *kinēto*, moving + Gr., *chōra*, space] Structural portion of the chromosome to which microtubules attach.

Korotkoff sounds (kō-rot'kof) Named for Russian physician Nikolai S. Korotkoff (1874–1920). Sounds heard over an artery when blood pressure is determined by the auscultatory method; caused by turbulent flow of blood.

L

labium majus; pl. **labia majora** (lā'bē-ūm, lā'bē-ā) One of two rounded folds of skin surrounding the labia minora and vestibule; homolog of the scrotum in males.

labium minus; pl. **labia minora** One of two narrow longitudinal folds of mucous membrane enclosed by the labia majora and bounding the vestibule; anteriorly they unite to form the prepuce.

lacrimal apparatus (lak'ri-māl) Lacrimal, or tear, gland in the superolateral corner of the orbit of the eye and a duct system that extends from the eye to the nasal cavity.

lacrimal canaliculus Canal that carries excess tears away from the eye; located in the medial canthus and opening on the lacrimal papilla.

lacrimal gland Tear gland located in the superolateral corner of the orbit.

lacrimal papilla Small lump of tissue in the medial canthus or corner of the eye; the lacrimal canal opens within the lacrimal papilla.

lacrimal sac Enlargement in the lacrimal canal that leads into the nasolacrimal duct.

lactation (lak-tā'shūn) [L., *lactatio*, suckle] Period after childbirth during which milk is formed in the breasts.

lacteal (lak'tē-āl) Lymphatic vessel in the wall of the small intestine that carries chyle from the intestine and absorbs fat.

lactiferous duct (lak-tif'er-ūs) One of 15–20 ducts that drain the lobes of the mammary gland and open onto the surface of the nipple.

lactiferous sinus Dilation of the lactiferous duct just before it enters the nipple.

lacuna; pl. **lacunae** (lā-koo'nā, -koo'nē) [L., *lacus*, a hollow, a lake] Small space or cavity; potential space within the matrix of bone or cartilage normally occupied by a cell that can be visualized only when the cell shrinks away from the matrix during fixation; space containing maternal blood within the placenta.

lag phase One of the three phases of muscle contraction; time between the application of the stimulus and the beginning of muscular contraction. Also called latent phase.

lamella; pl. **lamellae** (lā-mel'ā, lā-mel'ē) Thin sheet or layer of bone.

lamellated corpuscle (lam'ē-lāt-ed) Oval receptor found in the deep dermis or hypodermis (responsible for deep cutaneous pressure and vibration) and in tendons (responsible for proprioception); also called Pacinian corpuscle.

lamina; pl. **laminae** (lam'i-nā, lam'i-nē) [L., *lamina*, plate, leaf] Thin plate—for example, the thinner portion of the vertebral arch.

lamina propria (prō'prē-ā) Layer of connective tissue underlying the epithelium of a mucous membrane.

laminar flow (lam'i-nar) Relative motion of layers of a fluid along smooth, concentric, parallel paths.

Langerhans cell Named for German anatomist Paul Langerhans (1847–1888); dendritic cell found in the skin.

lanugo (lā-noo'gō) [L., *lana*, wool] Fine, soft, unpigmented fetal hair.

Laplace's law Named for French mathematician Pierre S. de Laplace (1749–1827); the force that stretches the wall of a blood vessel is proportional to the radius of the vessel times the blood pressure.

large intestine Portion of the digestive tract extending from the small intestine to the anus.

laryngitis (lar-in-jī'tis) Inflammation of the mucous membrane of the larynx.

- laryngopharynx** (lä-ring/'gō-far-ingks) Part of the pharynx lying posterior to the larynx.
- larynx; pl. larynges** (lar-'ingks, lä-rin/'jēz) Organ of voice production located between the pharynx and the trachea; it consists of a framework of cartilages and elastic membranes housing the vocal folds and the muscles that control the position and tension of these elements.
- last menstrual period (LMP)** Beginning of the last menstruation before pregnancy; used clinically to time events during pregnancy.
- lateral geniculate nucleus** (je-'nik'ū-lāt) Nucleus of the thalamus where fibers from the optic tract terminate.
- lateral olfactory area** (ol-'fak'tō-rē) Part of the olfactory cortex involved in the conscious perception of olfactory stimuli.
- lens** Transparent biconvex structure lying between the iris and the vitreous humor.
- lens fiber** Epithelial cell that makes up the lens of the eye.
- lesser omentum** (ō-men'tūm) [**L.**, **membrane that encloses the bowels**] Peritoneal fold passing from the liver to the lesser curvature of the stomach and to the upper border of the duodenum for a distance of approximately 2 cm beyond the pylorus.
- lesser vestibular gland** (ves-'tib'ū-lār) Number of minute mucous glands opening on the surface of the vestibule between the openings of the vagina and urethra; also called paraurethral gland.
- leukocyte** (loo'kō-sīt) White blood cell.
- leukocytosis** (loo'kō-sī-tō'sis) Abnormally large number of white blood cells in the blood.
- leukopenia** (loo-kō-pē'nē-ā) Lower than normal number of white blood cells in the blood.
- leukotriene** (loo-kō-trī'ēn) Specific class of physiologically active fatty acid derivatives present in many tissues.
- lever** Rigid shaft capable of turning about a fulcrum or pivot point.
- LH surge** Increase in plasma luteinizing hormone (LH) levels before ovulation and responsible for initiating it.
- ligamentum arteriosum** (lig'ā-men'tūm) Remains of the ductus arteriosus.
- ligamentum venosum** Remnant of the ductus venosus.
- ligand** *See* chemical signal.
- ligand-gated ion channel** Ion channel in a plasma membrane caused to either open or close by a ligand binding to a receptor.
- limbic system** (lim'bik) [**L.**, *limbus*, border] Part of the brain involved with emotions and olfaction; includes the cingulate gyrus, hippocampus, habenular nuclei, parts of the basal ganglia, the hypothalamus (especially the mammillary bodies, the olfactory cortex, and various nerve tracts).
- lingual tonsil** (ling'gwäl) Collection of lymphoid tissue on the posterior portion of the dorsum of the tongue.
- lipase** (lip'ās) Any fat-splitting enzyme.
- lipid** (li'pid) [**Gr.**, *lipos*, fat] Substance composed principally of carbon, oxygen, and hydrogen; contains a lower ratio of oxygen to carbon and is less polar than carbohydrates; generally soluble in nonpolar solvents.
- lipid bilayer** Double layer of lipid molecules forming the plasma membrane and other cellular membranes.
- lipochrome** (lip'ō-krōm) Lipid-containing pigment that is metabolically inert.
- lipotropin** (li-pō-trō'pin) One of the peptide hormones released from the adenohypophysis; increases lipolysis in fat cells.
- liver** (liv'er) Largest gland of the body, lying in the upper-right quadrant of the abdomen just inferior to the diaphragm; secretes bile and is of great importance in carbohydrate and protein metabolism and in detoxifying chemicals.
- lobar bronchi** Branch from a primary bronchus that conducts air to each lobe of the lungs. There are two branches in the left lung and three branches from the primary bronchus in the right lung. Also called secondary bronchus.
- lobe** (lōb) Rounded, projecting part, such as the lobe of a lung, the liver, or a gland.
- lobule** (lob'ūl) Small lobe or subdivision of a lobe, such as a lobule of the lung or a gland.
- local inflammation** Inflammation confined to a specific area of the body. Symptoms include redness, heat, swelling, pain, and loss of function.
- local potential** Depolarization that is not propagated and that is graded or proportional to the strength of the stimulus.
- local reflex** Reflex of the intramural plexus of the digestive tract that does not involve the brain or spinal cord.
- locus; pl. loci** (lō'kūs, lō'sī) Place; usually a specific site.
- loop of Henle** Named for German anatomist Friedrich G. J. Henle (1809–1885). U-shaped part of the nephron extending from the proximal to the distal convoluted tubule and consisting of descending and ascending limbs. Some of the loops of Henle extend into the renal pyramids.
- lower respiratory tract** Larynx, trachea, and lungs.
- lung recoil** Decrease in the size of an expanded lung as a result of a decrease in the size (volume) of its alveoli; due to elastic recoil of elastic fibers surrounding alveoli and water surface tension of a thin film of water within alveoli.
- lunula; pl. lunulae** (loo'noo-lā, loo'noo-lē) [**L.**, *luna*, moon] White, crescent-shaped portion of the nail matrix; visible through the proximal end of the nail.
- luteal phase** (loo'tē-āl) Portion of the menstrual cycle extending from the time of formation of the corpus luteum after ovulation to the time when menstrual flow begins; usually 14 days in length; also called secretory phase.
- luteinizing hormone (LH)** (loo'tē-ī-nīz-ing) In females, hormone stimulating the final maturation of the follicles and the secretion of progesterone by them, with their rupture releasing the ovum, and the conversion of the ruptured follicle into the corpus luteum; in males, stimulates the secretion of testosterone in the testes.
- lymph** (limf) [**L.**, *lympa*, clear spring water] Clear or yellowish fluid derived from interstitial fluid and found in lymph vessels.
- lymph node** Encapsulated mass of lymph tissue found among lymph vessels.
- lymphatic capillary** Beginning of the lymphatic system of vessels; lined with flattened endothelium lacking a basement membrane.
- lymphatic nodule** Small accumulation of lymph tissue lacking a distinct boundary.
- lymphatic sinus** Channels in a lymph node crossed by a reticulum of cells and fibers.
- lymphatic vessel** One of the system of vessels carrying lymph from the lymph capillaries to the veins.
- lymphedema** (limf'e-dē'mā) Swelling of tissues resulting from the excessive accumulation of fluid caused by the removal, damage, or blockage of lymphatic vessels or lymph nodes; usually results in swelling of the arm or leg.
- lymphoblast** (lim'fō-blast) Cell that matures into a lymphocyte.
- lymphocyte** (lim'fō-sīt) Nongranulocytic white blood cell formed in lymphoid tissue.
- lymphokine** (lim'fō-kīn) Chemical produced by lymphocytes that activates macrophages, attracts neutrophils, and promotes inflammation.
- lysis** (lī'sis) [**Gr.**, *lysis*, a loosening] Process by which a cell swells and ruptures.
- lysosome** (lī'sō-sōm) [**Gr.**, *lysis*, loosening + *soma*, body] Membrane-bounded vesicle containing hydrolytic enzymes that function as intracellular digestive enzymes.
- lysozyme** (lī'sō-zīm) Enzyme that is destructive to the cell walls of certain bacteria; present in tears and some other fluids of the body.

M

- M line** Line in the center of the H zone made of delicate filaments that holds the myosin myofilaments in place in the sarcomere of muscle fibers.
- macrophage** (mak'rō-fāj) [**Gr.**, *makros*, large + *phagein*, to eat] Any large, mononuclear phagocytic cell.
- macula; pl. maculae** (mak'ū-lā, mak'ū-lē) [**L.**, a spot] Sensory structure in the utricle and saccule, consisting of hair cells and a gelatinous mass embedded with otoliths.
- macula densa** Cells of the distal convoluted tubule located at the renal corpuscle and forming part of the juxtaglomerular apparatus.
- main bronchus; pl. bronchi** (brong'kūs, brong'kī) One of two tubes arising at the inferior end of the trachea; each primary bronchus extends into one of the lungs; also called primary bronchus.
- major duodenal papilla** Point of opening of the common bile duct and pancreatic duct into the duodenum.
- major histocompatibility complex (MHC) molecules** Genes that control the production of major histocompatibility complex proteins, which are glycoproteins found on the surfaces of cells. The major histocompatibility proteins serve as self-markers for the immune system and are used by antigen-presenting cells to present antigens to lymphocytes.
- male pronucleus** Nuclear material of the sperm cell after the ovum has been penetrated by the sperm cell.
- malignant** (mā-lig'nānt) Resistant to treatment; occurring in severe form and frequently fatal; having locally invasive and destructive growth and metastasis.
- malleus; pl. mallei** (mal'ē-ūs, mal'ē-ī) [**L.**, hammer] Largest of the three auditory ossicles; attached to the tympanic membrane.
- mamillary bodies** (mam'i-lār-ē) [**L.**, breast-or nipple-shaped] Nipple-shaped structures at the base of the hypothalamus.
- mamma; pl. mammae** (mam'ā, mam'ē) Breast; the organ of milk secretion; one of two hemispherical projections of variable size situated in

- the subcutaneous layer over the pectoralis major muscle on each side of the chest; it is rudimentary in the male.
- mammary ligaments** (mam'ă-rē) Well-developed ligaments that extend from the overlying skin to the fibrous stroma of mammary gland; also called Cooper's ligaments.
- manubrium**; pl. **manubria** (mă-noo'brē-ūm, mă-noo'bre-ă) [L., handle] Part of a bone representing the handle, such as the manubrium of the sternum representing the handle of a sword.
- mass movement** Forcible peristaltic movement of short duration, occurring only three or four times a day, which moves the contents of the large intestine.
- mass number** Number of protons plus the number of neutrons in each atom.
- mastication** (mas-ti-kă'shūn) [L., *mastico*, to chew] Process of chewing.
- mastication reflex** Repetitive cycle of relaxation and contraction of the muscles of mastication.
- mastoid** (mas'toyd) [Gr., *mastos*, breast] Resembling a breast.
- mastoid air cells** Spaces within the mastoid process of the temporal bone connected to the middle ear by ducts.
- mature follicle** Ovarian follicle in which the oocyte attains its full size. The follicle contains a fluid-filled antrum and is surrounded by the theca interna and externa. Also called Graafian follicle.
- maximal stimulus** Stimulus resulting in a local potential just large enough to produce the maximum frequency of action potentials.
- meatus** (mē-ă'tūs) [L., to go, pass] Passageway or tunnel.
- mechanoreceptor** (mek'ă-nō-rē-sep'tōr) Sensory receptor that responds to mechanical pressures—for example, pressure receptors in the carotid sinus or touch receptors in the skin.
- meconium** (mē-kō'nē-ūm) [Gr., *mekon*, poppy] First intestinal discharges of the newborn infant, greenish in color and consisting of epithelial cells, mucus, and bile.
- medial olfactory area** Part of the olfactory cortex responsible for the visceral and emotional reactions to odors.
- medulla oblongata** (me-dool'ă ob-long-gah'tă) Inferior portion of the brainstem that connects the spinal cord to the brain and contains autonomic centers controlling functions such as heart rate, respiration, and swallowing.
- medullary cavity** (med'ul-er-ē, med'oo-lăr-ē) Large, marrow-filled cavity in the diaphysis of a long bone.
- medullary ray** Extension of the kidney medulla into the cortex, consisting of collecting ducts and loops of Henle.
- megakaryoblast** (meg-ă-kar'ē-ō-blast) [Gr., *mega* + *karyon*, nut, nucleus + *blastos*, germ] Cell that gives rise to platelets or thrombocytes.
- meibomian cyst** (mī-bō'mē-an) Named for German anatomist Hendrik Meibom (1638–1700). A chronic inflammation of a meibomian gland.
- meibomian gland** Sebaceous gland near the inner margins of the eyelid; secretes sebum that lubricates the eyelid and retains tears.
- meiosis** (mī-ō'sis) [Gr., a lessening] Cell division that results in the formation of gametes. Consists of two divisions, which result in one (female) or four (male) gametes, each of which contains one-half the number of chromosomes in the parent cell.
- Meissner corpuscle** (mīs'ner kōr'pūs-l) Named for German histologist Georg Meissner (1829–1905). *See* tactile corpuscle.
- melanin** (mel'ă-nin) [Gr., *melas*, black] Group of related molecules responsible for skin, hair, and eye color. Most melanins are brown to black pigments; some are yellowish or reddish.
- melanocyte** (mel'ă-nō-sīt) [Gr., *melas*, black + *kytos*, cell] Cell found mainly in the stratum basale; produces the brown or black pigment melanin.
- melanocyte-stimulating hormone (MSH)** Peptide hormone secreted by the anterior pituitary; increases melanin production by melanocytes, making the skin darker in color.
- melanosome** (mel'ă-nō-sōm) [Gr., *melas*, black + *soma*, body] Membranous organelle containing the pigment melanin.
- melatonin** (mel'ă-tōn'in) Hormone (amino acid derivative) secreted by the pineal body; inhibits the secretion of gonadotropin-releasing hormone from the hypothalamus.
- membrane attack complex (MAC)** Channel through a plasma membrane produced by activated complement proteins, primarily complement protein C9; in nucleated cells, water enters the channel, causing lysis of cells.
- membrane-bound receptor** Receptor molecule, such as a hormone receptor, that is bound to the plasma membrane of the target cell.
- membranous labyrinth** (mem'bră-nūs lab'i-rinth) Membranous structure within the inner ear consisting of the cochlea, vestibule, and semicircular canals.
- membranous urethra** (ū-rē'thră) Portion of the male urethra, approximately 1 cm in length, extending from the prostate gland to the beginning of the penile urethra.
- memory cell** Small lymphocyte that is derived from a B cell or T cell and that rapidly responds to a subsequent exposure to the same antigen.
- menarche** (me-nar'kē) [Gr., *mensis*, month + *arche*, beginning] Establishment of menstrual function; the time of the first menstrual period or flow.
- meninx**; pl. **meninges** (mē'ninks, mē-nin'jes) [Gr., membrane] Connective tissue membrane surrounding the brain.
- meniscus**; pl. **menisci** (me-nis'kus, me-nis'sī) Crescent-shaped intraarticular fibrocartilage found in certain joints, such as the crescent-shaped fibrocartilaginous structure of the knee.
- menopause** (men'ō-pawz) [Gr., *mensis*, month + *pausis*, cessation] Permanent cessation of the menstrual cycle.
- menses** (men'sēz) [L., *mensis*, month] Periodic hemorrhage from the uterine mucous membrane, occurring at approximately 28-day intervals.
- menstrual cycle** (men'stroo-ăl) Series of changes that occur in sexually mature, nonpregnant women and result in menses. Specifically refers to the uterine cycle but is often used to include both the uterine and ovarian cycles.
- Merkel (tactile) disk** (mer'kel) Named for German anatomist Friedrich Merkel (1845–1919).
- merocrine gland** (mer'ō-krin) [Gr., *meros*, part + *krino*, to separate] Gland that secretes products with no loss of cellular material—for example, water-producing sweat glands.
- mesencephalon** (mez-en-sef'ă-lon) [Gr., *mesos*, middle + *enkephalos*, brain] Midbrain in both the embryo and adult; consists of the cerebral peduncle and the corpora quadrigemini.
- mesentery** (mes'en-ter-ē) [Gr., *mesos*, middle + *enteron*, intestine] Double layer of peritoneum extending from the abdominal wall to the abdominal viscera, conveying to it its vessels and nerves.
- mesoderm** (mez'ō-derm) Middle of the three germ layers of an embryo.
- mesonephros** (mez'ō-nef'ros) One of three excretory organs appearing during embryonic development; forms caudal to the pronephros as the pronephros disappears. It is well developed and is functional for a time before the establishment of the metanephros, which gives rise to the kidney. It undergoes regression as an excretory organ, but its duct system is retained in the male as the efferent ductule and epididymis.
- mesosalpinx** (mez'ō-sal'pinks) [Gr., *mesos*, middle + *salpinx*, trumpet] Part of the broad ligament supporting the uterine tube.
- mesothelium** (mez-ō-thē'lē-ūm) Single layer of flattened cells forming an epithelium that lines serous cavities, such as peritoneum, pleura, pericardium.
- mesovarium** (mez'ō-vă'rē-ūm) Short peritoneal fold connecting the ovary with the broad ligament of the uterus.
- messenger ribonucleic acid (mRNA)** Type of RNA that moves out of the nucleus and into the cytoplasm, where it is used as a template to determine the structure of proteins.
- metabolism** (mē-tab'ō-lizm) [Gr., *metabole*, change] Sum of all the chemical reactions that take place in the body, consisting of anabolism and catabolism. *Cellular metabolism* refers specifically to the chemical reactions within cells.
- metacarpal** (met'ă-kar'pāl) Relating to the fine bones of the hand between the carpus (wrist) and the phalanges.
- metanephros** (met-ă-nef'ros) Most caudally located of the three excretory organs appearing during embryonic development; becomes the permanent kidney of mammals. In mammalian embryos, it is formed caudal to the mesonephros and develops later as the mesonephros undergoes regression.
- metaphase** (met'ă-fās) Time during cell division when the chromosomes line up along the equator of the cell.
- metarteriole** (met'ar-tēr'ē-ōl) One of the small peripheral blood vessels that contain scattered groups of smooth muscle fibers in their walls; located between the arterioles and the true capillaries.
- metastasis** (mē-tas'tă-sis) Shifting of a disease or its local manifestations or the spread of a disease from one part of the body to another, as in a malignant neoplasm.
- metatarsal** (met'ă-tar'sal) [Gr., *meta*, after + *tar-sos*, sole of the foot] Distal bone of the foot.
- metencephalon** (met'en-sef'ă-lon) [Gr., *meta*, after + *enkephalos*, brain] Second most posterior division of the embryonic brain; becomes the pons and cerebellum in the adult.
- micelle** (mi-sel', mī-sel') [L., *micella*, small morsel] Droplets of lipid surrounded by bile salts in the small intestine.
- microfilament** (mī-krō-fil'ă-ment) Small fibril forming bundles, sheets, or networks in the cytoplasm of cells; provides structure to the

- cytoplasm and mechanical support for microvilli and stereocilia.
- microglia** (mī-krog'lē-ä) [Gr., *micro* + *glia*, glue] Small neuroglial cells that become phagocytic and mobile in response to inflammation; considered to be macrophages within the central nervous system.
- microtubule** (mī-krō-too'būl) Hollow tube composed of tubulin, measuring approximately 25 nm in diameter and usually several micrometers long. Helps provide support to the cytoplasm of the cell and is a component of certain cell organelles, such as centrioles, spindle fibers, cilia, and flagella.
- microvillus; pl. microvilli** (mī'krō-vil'ūs, mī'krō-vil'ī) Minute projection of the cell membrane that greatly increases the surface area.
- micturition reflex** (mik-choo-rish'ŭn) Contraction of the urinary bladder stimulated by stretching of the bladder wall; results in emptying of the bladder.
- middle ear** Air-filled space within the temporal bone; contains auditory ossicles; between the external and internal ear.
- milk letdown** Expulsion of milk from the alveoli of the mammary glands; stimulated by oxytocin.
- mineral** Inorganic nutrient necessary for normal metabolic functions.
- mineralocorticoid** (min'er-al-ō-kōr'ti-koyd) Steroid hormone (e.g., aldosterone) produced by the zona glomerulosa of the adrenal cortex; facilitates exchange of potassium for sodium in the distal renal tubule, causing sodium reabsorption and potassium and hydrogen ion secretion.
- minor duodenal papilla** Site of the opening of the accessory pancreatic duct into the duodenum.
- minute ventilation** Product of tidal volume times the respiratory rate.
- mitochondrion; pl. mitochondria** (mī-tō-kon' drē-on, mī-tō-kon'drē-ä) [Gr., *mitos*, thread + *chondros*, granule] Small, spherical, rod-shaped or thin filamentous structure in the cytoplasm of cells that is a site of ATP production.
- mitosis** (mī-tō'sis) [Gr., thread] Cell division resulting in two daughter cells with exactly the same number and type of chromosomes as the mother cell.
- modiolus** (mō-dī'ō'lūs) [L., nave of a wheel] Central core of spongy bone about which turns the spiral canal of the cochlea.
- molar** (mō'lār) Tricuspid tooth; the three posterior teeth of each dental arch.
- molecule** (mol'ē-kūl) Substance composed of two or more atoms chemically combined to form a structure that behaves as an independent unit.
- monoblast** (mon'ō-blast) Cell that matures into a monocyte.
- monocyte** (mon'ō-sīt) Type of white blood cell; large phagocytic white blood cell that moves from the blood into tissues and becomes a macrophage.
- mononuclear phagocytic system** (mon-ō-noo'klē-ār fag-ō-sit'ik) Phagocytic cells, each with a single nucleus; derived from monocytes; also called reticuloendothelial system.
- monosaccharide** (mon-ō-sak'ā-rīd) Simple sugar carbohydrate that cannot form any simpler sugar by hydrolysis.
- mons pubis** (monz pū'bis) [L., mountain; the genitals] Prominence caused by a pad of fatty tissue over the symphysis pubis in the female.
- morula** (mōr'oo-lā, mōr'ū-lā) [L., *morus*, mulberry] Mass of 12 or more cells resulting from the early cleavage divisions of the zygote.
- motor neuron** Neuron that innervates skeletal, smooth, or cardiac muscle fibers.
- motor unit** Single neuron and the muscle fibers it innervates.
- mucosa** (mū-kō'sā) [L., *mucosus* mucous] Mucous membrane consisting of epithelium and lamina propria. In the digestive tract, there is also a layer of smooth muscle.
- mucous membrane** (mū'kūs) Thin sheet consisting of epithelium and connective tissue (lamina propria) that lines cavities that open to the outside of the body; many contain mucous glands that secrete mucus.
- mucous neck cell** One of the mucous-secreting cells in the neck of a gastric gland.
- mucus** (mū'kūs) Viscous secretion produced by and covering mucous membranes; lubricates mucous membranes and traps foreign substances.
- multiple motor unit summation** Increased force of contraction of a muscle due to recruitment of motor units.
- multiple-wave summation** Increased force of contraction of a muscle due to increased frequency of stimulation.
- multipolar neuron** One of three categories of neurons consisting of a neuron cell body, an axon, and two or more dendrites.
- muscarinic receptor** (mūs'kā-rin'ik) Class of cholinergic receptor that is specifically activated by muscarine in addition to acetylcholine.
- muscle fiber** Muscle cell.
- muscle spindle** Three to 10 specialized muscle fibers supplied by gamma motor neurons and wrapped in sensory nerve endings; detects stretch of the muscle and is involved in maintaining muscle tone.
- muscle tone** Relatively constant tension produced by a muscle for long periods as a result of asynchronous contraction of motor units.
- muscle twitch** Contraction of a whole muscle in response to a stimulus that causes an action potential in one or more muscle fibers.
- muscular fatigue** Fatigue due to a depletion of ATP within the muscle fibers.
- muscularis** (mūs-kū-lā'ris) [Modern L., muscular] Muscular coat of a hollow organ or tubular structure.
- muscularis mucosa** Thin layer of smooth muscle found in most parts of the digestive tube; located outside the lamina propria and adjacent to the submucosa.
- musculi pectinati** (mūs-kū-lī pek'tī-nā'tē) Prominent ridges of atrial myocardium located on the inner surface of much of the right atrium and both auricles.
- mutation** (mū-tā'shūn) Change in the number or kinds of nucleotides in the DNA of a gene.
- myelencephalon** (mī'el-en-sef'ā-lon) [Gr., *myelos*, medulla, marrow + *enkephalos* brain] Most caudal portion of the embryonic brain; also called medulla oblongata.
- myelin sheath** (mī'ē-lin) Envelope surrounding most axons; formed by Schwann cell membranes being wrapped around the axon.
- myelinated axon** (mī'ē-li-nāt-ed ak'son) Nerve fiber having a myelin sheath.
- myeloblast** (mī'ē-lō-blast) Immature cell from which the different granulocytes develop.
- myenteric plexus** (mī'en-ter'ik) Plexus of unmyelinated fibers and postganglionic autonomic cell bodies lying in the muscular coat of the esophagus, stomach, and intestines; communicates with the submucosal plexuses.
- myoblast** (mī'ō-blast) [Gr., *mys*, muscle + *blastos*, germ] Primitive, multinucleated cell with the potential to develop into a muscle fiber.
- myofilament** (mī-ō-fil'ā-ment) Extremely fine molecular thread helping form the myofibrils of muscle; thick myofilaments are formed of myosin, and thin myofilaments are formed of actin.
- myometrium** (mī'ō-mē'trē-ŭm) Muscular wall of the uterus; composed of smooth muscle; also called muscular layer.
- myosin myofilament** (mī'ō-sin mī-ō-fil'ā-ment) Thick myofilament of muscle fibrils; composed of myosin molecules.

N

- nail** (nāl) [A.S., naegel] Several layers of dead epithelial cells containing hard keratin on the ends of the digits.
- nail bed** Epithelial tissue resting on dermis under the nail between the nail matrix and hyponychium; contributes to the formation of the nail.
- nail matrix** Epithelial tissue resting on dermis under the proximal end of a nail; produces most of the nail.
- nasal cavity** (nā'zāl) Cavity between the external nares and the pharynx. It is divided into two chambers by the nasal septum and is bounded inferiorly by the hard and soft palates.
- nasal septum** Bony partition that separates the nasal cavity into left and right parts; composed of the vomer, the perpendicular plate of the ethmoid, and hyaline cartilage.
- nasolacrimal duct** (nā-zō-lak'ri-māl) Duct that leads from the lacrimal sac to the nasal cavity.
- nasopharynx** (nā-zō-far'ingks) Part of the pharynx that lies above the soft palate; anteriorly it opens into the nasal cavity.
- near point of vision** Closest point from the eye at which an object can be held without appearing blurred.
- neck** Slightly constricted part of a tooth, between the crown and the root.
- neoplasm** (nē'ō-plazm) Abnormal tissue that grows by cellular proliferation more rapidly than normal and continues to grow after the stimuli that initiated the new growth ceases.
- nephron** (nef'ron) [Gr., *nephros*, kidney] Functional unit of the kidney, consisting of the renal corpuscle, the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule.
- nerve tract** Bundles of parallel axons with their associated sheaths in the central nervous system.
- neural crest** (noor'āl) Edge of the neural plate as it rises to meet at the midline to form the neural tube.
- neural crest cells** Cells derived from the crests of the forming neural tube in the embryo; together with the mesoderm, they form the mesenchyme of the embryo; they give rise to part of the skull, the teeth, melanocytes, sensory neurons, and autonomic neurons.
- neural layer** Portion of the retina containing rods and cones.
- neural plate** Region of the dorsal surface of the embryo that is transformed into the neural tube and neural crest.

- neural tube** Tube formed from the neuroectoderm by the closure of the neural groove; develops into the spinal cord and brain.
- neuroectoderm** (noor-ō-ek'tō-derm) Part of the ectoderm of an embryo giving rise to the brain and spinal cord.
- neurohormone** (noor'ō-hōr'mōn) Hormone secreted by a neuron.
- neuromodulator** Substance that influences the sensitivity of neurons to neurotransmitters but neither strongly stimulates nor strongly inhibits neurons by itself.
- neuromuscular junction** (noor-ō-mūs'kū-lār) Specialized synapse between a motor neuron and a muscle fiber.
- neuron** (noor'on) [Gr., *nerve*] Morphologic and functional unit of the nervous system, consisting of the nerve cell body, the dendrites, and the axon; also called nerve cell.
- neuron cell body** Enlarged portion of the neuron containing the nucleus and other organelles; also called nerve cell body.
- neurotransmitter** (noor'ō-trans-mit'er) [Gr., *neuro*, nerve + L., *transmitto*, to send across] Any specific chemical agent released by a presynaptic cell on excitation that crosses the synaptic cleft and stimulates or inhibits the postsynaptic cell.
- neutral solution** (noo'trāl) Solution, such as pure water, that has 10^{-7} mol of hydrogen ions per liter and an equal concentration of hydroxide ions; has a pH of 7.
- neutron** (noo'tron) [L., *neuter*, neither] Electrically neutral particle in the nuclei of atoms (except hydrogen).
- neutrophil** (noo'trō-fil) [L., *neuter*, neither + Gr., *philos*, fond] Type of white blood cell; small phagocytic white blood cell with a lobed nucleus and small granules in the cytoplasm.
- nicotinic receptor** (nik-ō-tin'ik) Class of cholinergic receptor molecule that is specifically activated by nicotine and by acetylcholine.
- nipple** (nip'l) Projection at the apex of the mamma, on the surface of which the lactiferous ducts open; surrounded by a circular pigmented area, the areola.
- Nissl substance** (nis'l) Named after German neurologist Franz Nissl (1860–1919). Areas in the neuron cell body containing rough endoplasmic reticulum.
- nociceptor** (nō-si-sep'ter) [L., *noceo*, to injure + *capio*, to take] Sensory receptor that detects painful or injurious stimuli; also called pain receptor.
- nonelectrolyte** (non-ē-lek'trō-lit) [Gr., *electro* + *lytos*, soluble] Molecules that do not dissociate and do not conduct electricity.
- norepinephrine** (nōr'ep-i-nef'rin) Neurotransmitter substance released from most of the postganglionic neurons of the sympathetic division; hormone released from the adrenal cortex that increases cardiac output and blood glucose levels; also called noradrenaline.
- nose**, or **nasus** (nōz, nā'sūs) Visible structure that forms a prominent feature of the face; nasal cavities.
- notochord** (nō'tō-kōrd) [Gr., *notor*, back + *chords*, cord] Small rod of tissue lying ventral to the neural tube. A characteristic of all vertebrates, in humans it becomes the nucleus pulposus of the intervertebral disks.
- nuchal** (noo'kāl) Back of the neck.
- nuclear envelope** (noo'klē-er) Double membrane structure surrounding and enclosing the nucleus.
- nuclear pores** Porelike openings in the nuclear envelope where the inner and outer membranes fuse.
- nucleic acid** (noo-klē'ik, noo-klā'ik) Polymer of nucleotides, consisting of DNA and RNA, forms a family of substances that comprise the genetic material of cells and control protein synthesis.
- nucleolus**; pl. **nucleoli** (noo-klē'ō-lūs, noo-klē'ō-lī) Somewhat rounded, dense, well-defined nuclear body with no surrounding membrane; contains ribosomal RNA and protein.
- nucleotide** (noo'klē-ō-tīd) Basic building block of nucleic acids consisting of a sugar (either ribose or deoxyribose) and one of several types of organic bases.
- nucleus**; pl. **nuclei** (noo'klē-ūs, noo'klē-ī) [L., inside of a thing] Cell organelle containing most of the genetic material of the cell; collection of nerve cell bodies within the central nervous system; center of an atom consisting of protons and neutrons.
- nucleus pulposus** (pūl-pō'sūs) [L., central pulp] Soft central portion of the intervertebral disk.
- nutrient** (noo'trē-ent) [L., *nutriens*, to nourish] Chemicals taken into the body that are used to produce energy, provide building blocks for new molecules, or function in other chemical reactions.
- olecranon process** (ō-lek'rā-nōn, ō'lē-krā'non) Process on the distal end of the ulna, forming the point of the elbow.
- olfaction** (ol-fak'shūn) [L., *olfactus*, smell] Sense of smell.
- olfactory area** Extreme superior region of the nasal cavity.
- olfactory bulb** (ol-fak'tō-rē) Ganglion-like enlargement at the rostral end of the olfactory tract that lies over the cribriform plate; receives the olfactory nerves from the nasal cavity.
- olfactory cortex** Termination of the olfactory tract in the cerebral cortex within the lateral fissure of the cerebrum.
- olfactory epithelium** Epithelium of the olfactory recess containing olfactory receptors.
- olfactory tract** Nerve tract that projects from the olfactory bulb to the olfactory cortex.
- oligodendrocyte** (ol'i-gō-den'drō-sīt) Neuroglial cell that has cytoplasmic extensions that form myelin sheaths around axons in the central nervous system.
- oncogene** (ong'kō-jēn) Gene that can change or be activated to cause cancer.
- oncology** (ong-kol'ō-jē) Study of neoplasms.
- oocyte** (ō'ō-sīt) [Gr., *oon*, egg + *kytos*, a hollow (cell)] Immature ovum.
- oogenesis** (ō-ō-jen'ē-sis) Formation and development of a secondary oocyte or ovum.
- oogonium** (ō-ō-gō'nē-ūm) [Gr., *oon*, egg + *gone*, generation] Primitive cell from which oocytes are derived by meiosis.
- opposition** Movement of the thumb and little finger toward each other; movement of the thumb toward any of the fingers.
- opsin** (op'sin) Protein portion of the rhodopsin molecule; a class of proteins that bind to retinal to form the visual pigments of the rods and cones of the eye.
- opsonin** (op'sō-nin) [Gr., *opsonēin* to prepare food] Substance, such as antibody or complement, that enhances phagocytosis.
- optic chiasm** (op'tik kī'az'm) [Gr., two crossing lines; *chi* the letter χ] Point of crossing of the optic tracts.
- optic disc** Point at which axons of ganglion cells of the retina converge to form the optic nerve, which then penetrates through the fibrous tunic of the eye.
- optic nerve** Nerve carrying visual signals from the eye to the optic chiasm.
- optic stalk** Constricted proximal portion of the optic vesicle in the embryo; develops into the optic nerve.
- optic tract** Tract that extends from the optic chiasma to the lateral geniculate nucleus of the thalamus.
- optic vesicle** One of the paired evaginations from the walls of the embryonic forebrain from which the retina develops.
- oral cavity** (ōr'āl) The mouth; consists of the space surrounded by the lips, cheeks, teeth, and palate; limited posteriorly by the fauces.
- orbit** (ōr'bit) Eye socket; formed by seven skull bones that surround and protect the eye.
- organ of Corti** (ōr'gān) Named for Italian anatomist Marquis Alfonso Corti (1822–1888). Spiral organ; rests on the basilar membrane and supports the hair cells that detect sounds.
- organelle** (or'gā-nel) [Gr., *organon*, tool] Specialized part of a cell with one or more specific individual functions.
- orgasm** (ōr'gazm) [Gr., *orgao*, to swell, be excited] Climax of the sexual act, associated with a pleasurable sensation.
- origin** (ōr'i-jin) Less movable attachment point of a muscle; usually the medial or proximal end of a muscle associated with the limbs; also called fixed end.
- oropharynx** (ōr'ō-far'ingks) Portion of the pharynx that lies posterior to the oral cavity; it is continuous above with the nasopharynx and below with the laryngopharynx.
- oscillating circuit** Neuronal circuit arranged in a circular fashion that allows action potentials produced in the circuit to keep stimulating the neurons of the circuit.
- osmolality** (os-mō-lal'i-tē) Osmotic concentration of a solution; the number of moles of solute in 1 kg of water times the number of particles into which the solute dissociates.
- osmoreceptor cell** (os-mō-rē-sep'ter, os'mō-rē-sep'tōr) [Gr., *osmos*, impulsion] Receptor in the central nervous system that responds to changes in the osmotic pressure of the blood.
- osmosis** (os-mō'sis) [Gr., *osmos*, thrusting or an impulsion] Diffusion of solvent (water) through a membrane from a less concentrated solution to a more concentrated solution.
- osmotic pressure** (os-mot'ik) Force required to prevent the movement of water across a selectively permeable membrane.
- ossification** (os'i-fi-kā'shūn) [L., *os*, bone + *facio*, to make] Bone formation; also called osteogenesis.
- osteoblast** (os'tē-ō-blast) [Gr., *osteon*, bone + *blastos*, germ] Bone-forming cell.
- osteoclast** (os'tē-ō-klast) [Gr., *osteon*, bone + *klastos*, broken] Large, multinucleated cell that absorbs bone.
- osteocyte** (os'tē-ō-sīt) [Gr., *osteon*, bone + *kytos*, cell] Mature bone cell surrounded by bone matrix.
- osteomalacia** (os'tē-ō-mā-lā'shē-ā) Softening of bones due to calcium depletion; adult rickets.

osteon (os'tē-on) Central canal containing blood capillaries and the concentric lamellae around it; occurs in compact bone; also called haversian system.

osteoporosis (os'tē-ō-pō-rō'sis) [Gr., *osteon*, bone + *poros*, pore + *osis*, condition] Reduction in quantity of bone, resulting in porous bone.

ostium (os'tē-ūm) [L., door, entrance, mouth] Small opening—for example, the opening of the uterine tube near the ovary or the opening of the uterus into the vagina.

otolith (ō'tō-lith) Crystalline particles of calcium carbonate and protein embedded in the maculae.

oval window (ō'vāl) Membranous structure to which the stapes attaches; transmits vibrations to the inner ear.

ovarian cycle (ō-var'ē-an) Series of events that occur in a regular fashion in the ovaries of sexually mature, nonpregnant females; results in ovulation and the production of the hormones estrogen and progesterone.

ovarian epithelium Peritoneal covering of the ovary; also called germinal epithelium.

ovarian ligament Bundle of fibers passing to the uterus from the ovary.

ovary (ō'vā-rē) One of two female reproductive glands located in the pelvic cavity; produces the secondary oocyte, estrogen, and progesterone.

oviduct (ō'vi-dūkt) See uterine tube.

ovulation (ōv'ū-lā'shun) Release of an ovum, or secondary oocyte, from the vesicular follicle.

oxidation (ok-si-dā'shūn) Loss of one or more electrons from a molecule.

oxidation-reduction reaction Reaction in which one molecule is oxidized and another is reduced.

oxidative deamination (ok-si-dā'tiv) Removal of the amine group of an amino acid to form a keto acid, ammonia, and NADH.

oxygen deficit (ok'sē-jen) Oxygen necessary for the synthesis of the ATP required to remove lactic acid produced by anaerobic respiration.

oxygen-hemoglobin dissociation curve Graph describing the relationship between the percentage of hemoglobin saturated with oxygen and a range of oxygen partial pressures.

oxyhemoglobin (ox'sē-hē-mō-glō'bin) Oxygenated hemoglobin.

P

P wave First complex of the electrocardiogram representing depolarization of the atria.

Pacinian corpuscle (pa-sin'ē-an) Named for Italian anatomist Filippo Pacini (1812–1883). See lamellated corpuscle.

palate (pal'ät) [L., *palatum*, palate] Roof of the mouth.

palatine tonsil (pal'ä-tīn) One of two large, oval masses of lymphoid tissue embedded in the lateral wall of the oral pharynx.

palpebra; pl. **palpebrae** (pal-pē'brä, pal-pē'brē) [L., eyelid] Eyelid.

palpebral conjunctiva (pal-pē'bräl kon-jūnk-tī'vä) Conjunctiva that covers the inner surface of the eyelids.

palpebral fissure Space between the upper and lower eyelids.

pancreas (pan'krē-as) [Gr., *pankreas*, sweetbread] Abdominal gland that secretes

pancreatic juice into the intestine and insulin and glucagon from the pancreatic islets into the bloodstream.

pancreatic duct (pan-krē-at'ik) Excretory duct of the pancreas that extends through the gland from tail to head, where it empties into the duodenum at the greater duodenal papilla.

pancreatic islet Cellular mass varying from a few to hundreds of cells lying in the interstitial tissue of the pancreas; composed of different cell types that make up the endocrine portion of the pancreas and are the source of insulin and glucagon; also called islets of Langerhans.

pancreatic juice [L., *jus*, broth] External secretion of the pancreas; clear, alkaline fluid containing several enzymes.

papilla (pä-pil'ä) [L., nipple] Small, nipplelike process; projection of the dermis, containing blood vessels and nerves, into the epidermis; projections on the surface of the tongue.

papillary muscle (pap'i-lär'ē) Nipplelike, conical projection of myocardium within the ventricle; the chordae tendineae are attached to the apex of the papillary muscle.

parafollicular cell (par-ä-fo-lik'ū-lär) Endocrine cell in the thyroid gland; secretes the hormone calcitonin.

paramesonephric duct (par-ä-mes-ō-nef'rik) One of two embryonic tubes extending along the mesonephros and emptying into the cloaca; in the female, the duct forms the uterine tube, the uterus, and part of the vagina; in the male, it degenerates.

paranasal sinus (par-ä-nä'säl) Air-filled cavities within certain skull bones that connect to the nasal cavity; located in the frontal, maxillary, sphenoid, and ethmoid bones.

parasympathetic division (par-ä-sim-pa-thet'ik) Subdivision of the autonomic nervous system; characterized by having the cell bodies of its preganglionic neurons located in the brainstem and the sacral region of the spinal cord (craniosacral division); usually involved in activating vegetative functions, such as digestion, defecation, and urination.

parathyroid gland (par-ä-thī'royd) One of four glandular masses embedded in the posterior surface of the thyroid gland; secretes parathyroid hormone.

parathyroid hormone (PTH) Peptide hormone produced by the parathyroid gland; increases bone breakdown and blood calcium levels.

parietal (pä-rī'ē-täl) [L., *paries*, wall] Relating to the wall of any cavity.

parietal cell Gastric gland cell that secretes hydrochloric acid.

parietal pericardium Serous membrane lining the fibrous portion of the pericardial sac.

parietal peritoneum Layer of peritoneum lining the abdominal walls.

parietal pleura Serous membrane that lines the different parts of the wall of the pleural cavity.

parotid gland (pä-rōt'id) Largest of the salivary glands; situated anterior to each ear.

partial pressure Pressure exerted by a single gas in a mixture of gases.

passive tension Tension applied to a load by a muscle without contracting; produced when an external force stretches the muscle.

patella (pa-tel'ä) [L., *patina*, shallow disk] Kneecap.

pectoral girdle (pek'tō-räl) Site of attachment of the upper limb to the trunk; consists of the scapula and the clavicle; also called shoulder girdle.

pedicle (ped'ī-kl) [L., *pes*, feet] Stalk or base of a structure, such as the pedicle of the vertebral arch.

pelvic brim (pel'vik) Imaginary plane passing from the sacral promontory to the pubic crest.

pelvic girdle Site of attachment of the lower limb to the trunk; ring of bone formed by the sacrum and the coxal bones.

pelvic inlet Superior opening of the true pelvis.

pelvic outlet Inferior opening of the true pelvis.

pelvis (pel'vis) [L., basin] Any basin-shaped structure; cup-shaped ring of bone at the lower end of the trunk, formed from the ossa coxal bones, sacrum, and coccyx.

pennate (bipennate) (pen'ät) [L., *penna*, feather] Muscles with fasciculi arranged like the barbs of a feather along a common tendon.

pepsin (pep'sin) [Gr., *pepsis*, digestion] Principal digestive enzyme of the gastric juice, formed from pepsinogen; digests proteins into smaller peptide chains.

pepsinogen (pep-sin'ō-jen) [*pepsin* + Gr. *gen*, producing] Proenzyme formed and secreted by the chief cells of the gastric mucosa; the acidity of the gastric juice and pepsin itself converts pepsinogen into pepsin.

peptidase (pep'ti-dās) Enzyme capable of hydrolyzing one of the peptide links of a peptide.

peptide bond (pep'tid) Chemical bond between amino acids.

Percent Daily Value (% Daily Value) Percent of the recommended daily value of a nutrient found in one serving of a particular food.

perforating canal Canal containing blood vessels and nerves and running through bone perpendicular to the haversian canals; also called Volkmann's canal.

periarterial lymphatic sheath (per'ē-ar-tē'rē-äl) Dense accumulation of lymphocytes (white pulp) surrounding arteries within the spleen.

pericapillary cell One of the slender connective tissue cells in close relationship to the outside of the capillary wall; it is relatively undifferentiated and may become a fibroblast, macrophage, or smooth muscle cell.

pericardial cavity (per-i-kar'dē-äl) Space within the mediastinum in which the heart is located.

pericardial fluid Viscous fluid contained within the pericardial cavity between the visceral and parietal pericardium; functions as a lubricant.

pericardium (per-i-kar'dē-ūm) [Gr., *pericardion*, membrane around the heart] Membrane covering the heart; also called pericardial sac.

perichondrium (per-i-kon'drē-ūm) [Gr., *peri*, around + *chondros*, cartilage] Double-layered connective tissue sheath surrounding cartilage.

perilymph (per'i-limf) [Gr., *peri*, around + L., *lymph*, clear fluid (lymph)] Fluid contained within the bony labyrinth of the inner ear.

perimetrium (per-i-mē'trē-ūm) Outer serous coat of the uterus; also called serous layer.

perimysium (per-i-mis'ē-ūm, per-i-miz'ē-ūm) [Gr., *peri*, around + *mys*, muscle] Fibrous sheath enveloping a bundle of skeletal muscle fibers (muscle fascicle).

perineum (per'i-nē-ūm) Area inferior to the pelvic diaphragm between the thighs; extends from the coccyx to the pubis.

- perineurium** (per-i-noo'ré-üm) [L., *peri*, around + Gr., *neuron*, nerve] Connective tissue sheath surrounding a nerve fascicle.
- periodontal ligament** (per'ē-ō-don'täl) Connective tissue that surrounds the tooth root and attaches it to its bony socket.
- periosteum** (per-ē-os'tē-üm) [Gr., *peri*, around + *osteon*, bone] Thick, double-layered connective tissue sheath covering the entire surface of a bone, except the articular surface, which is covered with cartilage.
- peripheral nervous system (PNS)** (pē-rif'ē-räl) Major subdivision of the nervous system consisting of nerves and ganglia.
- peripheral resistance (PR)** Resistance to blood flow in all the blood vessels.
- peristaltic wave** (per-i-stal'tik) Contraction in a tube, such as the intestine, characterized by a wave of contraction in smooth muscle preceded by a wave of relaxation that moves along the tube.
- peritubular capillary** Capillary network located in the cortex of the kidney; associated with the distal and proximal convoluted tubules.
- permanent tooth** One of the 32 teeth belonging to the permanent dentition; also called secondary tooth.
- peroneal** (per-ō-nē'äl) [Gr., *perone*, fibula] Associated with the fibula.
- peroxisome** (per-ok'si-söm) Membrane-bounded body similar to a lysosome in appearance but often smaller and irregular in shape; contains enzymes that either decompose or synthesize hydrogen peroxide.
- Peyer patch** Named for Swiss anatomist Johann K. Peyer (1653–1712). Lymphatic nodule found in the lower half of the small intestine and the appendix.
- phagocyte** (fag'ō-sīt) Cell that ingests bacteria, foreign particles, and other cells.
- phagocytosis** (fag'ō-sī-tō'sis) [Gr., *phagein*, to eat + *kytos*, cell + *osis*, condition] Cells' ingestion of solid substances, such as other cells, bacteria, bits of necrosed tissue, and foreign particles.
- phalange; pl. phalanges** (fä-lanj', fä-lan'jēz) [Gr., *phalanx*, line of soldiers] Bone of a finger or toe.
- pharyngeal pouch** (fä-rin'jē-äl) Paired evagination of embryonic pharyngeal endoderm between the brachial arches that gives rise to the thymus, thyroid gland, tonsils, and parathyroid glands.
- pharyngeal tonsil** (fä-rin'jē-äl) One of two collections of aggregated lymphoid nodules on the posterior wall of the nasopharynx.
- pharynx** (far'ingks) [Gr., *pharynx*, throat, the joint opening of the gullet and windpipe] Upper expanded portion of the digestive tube between the esophagus below and the oral and nasal cavities above and in front.
- phenotype** (fē'nō-tīp) [Gr., *phaino*, to display, show forth + *typos*, model] Characteristic observed in an individual due to the expression of his or her genotype.
- phosphodiesterase** (fos'fō-dī-es'ter-ās) Enzyme that splits phosphodiester bonds—that is, that breaks down cyclic AMP to AMP.
- phospholipid** (fos'fō-lip'id) Lipid with phosphorus, resulting in a molecule with a polar end and a nonpolar end; main component of the lipid bilayer.
- phosphorylation** (fos'fōr-i-lä'shün) Addition of phosphate to an organic compound.
- photoreceptor** (fō'tō-rē-sep'ter, fō'tō-rē-sep'tör) [L., *photo*, light + *ceptus*, to receive] Sensory receptor that is sensitive to light—for example, rods and cones of the retina.
- phrenic nerve** (fren'ik) Nerve derived from spinal nerves C3–C5; supplies the diaphragm.
- physiologic contracture** (fiz-ē-ō-loj'ik kon-trak'chūr) Temporary inability of a muscle to either contract or relax because of a depletion of ATP so that active transport of calcium ions into the sarcoplasmic reticulum cannot occur.
- physiological dead space** Sum of anatomical dead air space plus the volume of any nonfunctional alveoli.
- physiologic shunt** Deoxygenated blood from the alveoli plus deoxygenated blood from the bronchi and bronchioles.
- pia mater** (pī'ä mā'ter, pē'a mah'ter) [L., tender mother] Delicate membrane forming the inner covering of the brain and spinal cord.
- pigmented layer** Pigmented portion of the retina.
- pineal gland** (pin'ē-äl) [L., *pineus*, relating to pine trees] A small, pine cone-shaped structure that projects from the epiphysis of the diencephalon; produces melatonin; also called pineal body.
- pinna** (pin'ä) [L., *pinna* or *penna*, feather] See auricle.
- pinocytosis** (pin'ō-sī-tō'sis, pī'no-sī-tō'sis) [Gr., *pineo*, to drink + *kytos*, cell + *osis*, condition] Cell drinking; uptake of liquid by a cell.
- pituitary gland** Endocrine gland attached to the hypothalamus by the infundibulum; also called hypophysis.
- plane** (plān) [L., *planus*, flat] Flat surface; an imaginary surface formed by extension through any axis or two points—for example, a midsagittal plane, a coronal plane, and a transverse plane.
- plasma** (plaz'mä) [Gr., something formed] Fluid portion of blood.
- plasma cell** Cell derived from B cells; produces antibodies.
- plasma clearance** Volume of plasma per minute from which a substance can be completely removed by the kidneys.
- plasmin** (plaz'min) Enzyme derived from plasminogen; dissolves clots by converting fibrin into soluble products.
- plateau phase** Prolongation of the depolarization phase of a cardiac muscle cell membrane; results in a prolonged refractory period.
- platelet** (plät'let) Irregularly shaped disk found in blood; contains granules in the central part and clear protoplasm peripherally but has no definite nucleus; also called thrombocyte.
- platelet plug** Accumulation of platelets that stick to each other and to connective tissue; prevents blood loss from damaged blood vessels.
- pleural cavity** (ploor'äl) Potential space between the parietal and visceral layers of the pleura.
- plexus; pl. plexuses** (plek'sūs, plek'sūs-ez) [L., a braid] Intertwining of nerves or blood vessels.
- plicae circulares** (plī'kä, plī'sē) Numerous folds of the mucous membrane of the small intestine.
- pluripotent** (plo-rip'ō-tent) [L., *pluris*, more + *potentia*, power] In development, a cell or group of cells that have not yet become fixed or determined as to what specific tissues they are going to become.
- podocytes** (pod'ō-sīts) [Gr., *pous*, *podos*, foot + *kytos*, a hollow (cell)] Epithelial cell of Bowman's capsule attached to the outer surface of the glomerular capillary basement membrane by cytoplasmic foot processes.
- Poiseuille's law** (pwah-zuh'yēz) Named for French physiologist and physicist Jean Léonard Marie Poiseuille (1797–1869). The volume of a fluid passing per unit of time through a tube is directly proportional to the pressure difference between its ends and to the fourth power of the internal radius of the tube and inversely proportional to the tube's length and the viscosity of the fluid.
- polar body** (pō'lär) One of the two small cells formed during oogenesis because of unequal division of the cytoplasm.
- polar covalent bond** Covalent bond in which atoms do not share their electrons equally.
- polarization** Development of differences in potential between two points in living tissues, as between the inside and outside of the plasma membrane.
- polycythemia** (pol'ē-sī-thē'mē-ä) Increase in red blood cell number above the normal.
- polygenic** (pol-ē-jen'ik) Relating to a hereditary disease or normal characteristic controlled by the interaction of genes at more than one locus.
- polysaccharide** (pol-ē-sak'ä-rīd) Carbohydrate containing a large number of monosaccharide molecules.
- polyunsaturated fat** Fatty acid that contains two or more double covalent bonds between its carbon atoms.
- pons** (ponz) [L., bridge] Portion of the brainstem between the medulla and midbrain.
- popliteal** (pop-lit'ē-äl, pop-li-tē'äl) [L., ham] Posterior region of the knee.
- porta** (pōr'tä) [L., gate] Fissure on the inferior surface of the liver where the portal vein, hepatic artery, hepatic nerve plexus, hepatic ducts, and lymphatic vessels enter or exit the liver.
- portal system** (pōr'tal) System of vessels in which blood, after passing through one capillary bed, is conveyed through a second capillary network.
- portal triad** Branches of the portal vein, hepatic artery, and hepatic duct bound together in the connective tissue that divides the liver into lobules.
- postabsorptive state** State following the absorptive state; blood glucose levels are maintained because of the conversion of other molecules to glucose.
- posterior chamber** (pos-tēr'ē-ör) Chamber of the eye between the iris and the lens.
- posterior interventricular sulcus** Groove on the diaphragmatic surface of the heart, marking the location of the septum between the two ventricles.
- posterior pituitary gland** Portion of the hypophysis derived from the brain. Major secretions include antidiuretic hormone and oxytocin. Also called neurohypophysis.
- postganglionic neuron** (pōst'gang-glē-on'ik) Autonomic neuron that has its cell body located within an autonomic ganglion and sends its axon to an effector organ.
- postovulatory age** Age of the developing fetus based on the assumption that fertilization occurs 14 days after the last menstrual period before the pregnancy.
- postsynaptic** (pōst-si-nap'tik) Relating to the membrane of a nerve, muscle, or gland that is in close association with a presynaptic terminal. The postsynaptic membrane has receptor molecules within it that bind to neurotransmitter molecules.

- potential difference** (pō-ten'shāl) Difference in electrical potential, measured as the charge difference across the plasma membrane.
- potential energy** [Gr., *en*, in + *ergon*, work] Energy in a chemical bond that is not being exerted or used to do work.
- PQ interval** Time elapsing between the beginning of the P wave and the beginning of the QRS complex in the electrocardiogram; also called PR interval.
- precapillary sphincter** (prē-kap'i-lār-ē s'fing'k'ter) Smooth muscle sphincter that regulates blood flow through a capillary.
- preganglionic neuron** (prē'gang-glē-on'ik) Autonomic neuron that has its cell body located within the central nervous system and sends its axon through a nerve to an autonomic ganglion, where it synapses with postganglionic neurons.
- premolar** (prē-mō'lār) Bicuspid tooth.
- prenatal** (prē-nā'tal) [*pre* + L., *natus*, born] Preceding birth.
- prepuce** (prē'poos) In males, the free fold of skin that more or less completely covers the glans penis; the foreskin. In females, the external fold of the labia minora that covers the clitoris.
- pressoreceptor** (pres'ō-rē-sep'ter, pres'ō-rē-sep'tōr) See baroreceptor.
- presynaptic terminal** (prē'si-nap'tik) Enlarged axon terminal or terminal bouton.
- primary palate** In the early embryo, the structure that gives rise to the upper jaw and lips.
- primary response** Immune response that occurs as a result of the first exposure to an antigen.
- primary spermatocyte** (sper'mā-tō-sīt) Spermatocyte arising by a growth phase from a spermatogonium; gives rise to secondary spermatocytes after the first meiotic division.
- prime mover** Muscle that plays a major role in accomplishing a movement.
- primitive streak** (prim'i-tiv) Ectodermal ridge in the midline of the embryonic disk, from which arises the mesoderm by the inward and then lateral migration of cells.
- primordial germ cell** (prī-mōr'dē-āl) Most primitive undifferentiated sex cell, found initially outside the gonad on the surface of the yolk sac.
- PR interval** See PQ interval.
- process** (pros'es, prō'ses) Projection on a bone.
- processus vaginalis** (prō-ses'ūs vaj'i-nāl-ūs) Peritoneal outpocketing in the embryonic lower anterior abdominal wall that traverses the inguinal canal; in the male, it forms the tunica vaginalis testis and normally loses its connection with the peritoneal cavity.
- proerythroblast** Cell that matures into an erythrocyte.
- progeria** (prō-jēr'ē-ā) [Gr., *pro*, before + *ge* + *amras*, old age] Severe retardation of growth after the first year accompanied by a senile appearance and death at an early age.
- progesterone** (prō-jēs'tē-rōn) Steroid hormone secreted by the corpus luteum and one of the hormones secreted by the placenta.
- prolactin** (prō-lak'tin) Hormone of the adenohypophysis that stimulates the production of milk.
- prolactin-inhibiting hormone** (PIH) Neurohormone released from the hypothalamus that inhibits prolactin release from the adenohypophysis.
- prolactin-releasing hormone** (PRH) Neurohormone released from the hypothalamus that stimulates prolactin release from the adenohypophysis.
- proliferative phase** (prō-lif'er-ā-tiv) See follicular phase.
- pronation** (prō-nā'shūn) [L., *pronare*, to bend forward] Rotation of the forearm so that the anterior surface is down (prone).
- pronephros** (prō-nef'ros) In the embryos of higher vertebrates, a series of tubules emptying into the celomic cavity. It is a temporary structure in the human embryo, followed by the mesonephros and still later by the metanephros, which gives rise to the kidney.
- prophase** (prō'fāz) First stage in cell division when chromatin strands condense to form chromosomes.
- proprioception** (prō-prē-ō-sep'shun) [L., *proprius*, one's own + *capio*, to take] Information about the position of the body and its various parts.
- proprioceptor** (prō'prē-ō-sep'ter) Sensory receptor associated with joints and tendons.
- prostaglandin** (pros'tā-glan'din) Class of physiologically active substances present in many tissues; among its effects are vasodilation, stimulation and contraction of uterine smooth muscle and the promotion of inflammation and pain.
- prostate gland** (pros'tāt) [Gr., *prostates*, one standing before] Gland that surrounds the beginning of the urethra in the male. The secretion of the gland is a milky fluid that is discharged by 20–30 excretory ducts into the prostatic urethra as part of the semen.
- prostatic urethra** (pros-tat'ik) Part of the male urethra, approximately 2.5 cm in length, that passes through the prostate gland.
- protease** (prō'tē-ās) Enzyme that breaks down proteins.
- protein** (prō'tēn, prō'tē-īn) [Gr., *proteios*, primary] Macromolecule consisting of long sequences of amino acids linked together by peptide bonds.
- protein kinase** (kin-āz) Class of enzymes that phosphorylates other proteins. Many of these kinases are responsive to other chemical signals (e.g., cAMP, cGMP, insulin, epidermal growth factor, calcium and calmodulin).
- proteoglycan** (prō'tē-ō-glī'kan) Macromolecule consisting of numerous polysaccharides attached to a common protein core.
- prothrombin** (prō-throm'bin) Glycoprotein present in blood that, in the presence of prothrombin activator, is converted to thrombin.
- proton** (prō'ton) [Gr., *protos*, first] Positively charged particle in the nuclei of atoms.
- protraction** (prō-trak'shūn) [L., *protractus*, to draw forth] Movement forward or in the anterior direction.
- provitamin** (prō-vī'tā-min) Substance that may be converted into a vitamin.
- proximal convoluted tubule** (prok'si-māl) Part of the nephron that extends from the glomerulus to the descending limb of the loop of Henle.
- pseudostratified epithelium** Epithelium consisting of a single layer of cells but having the appearance of multiple layers.
- pseudo-unipolar neuron** One of the three categories of neurons consisting of a nerve cell body with a single axon projecting from it.
- psychologic fatigue** (sī-kō-loj'ik) Fatigue caused by the central nervous system.
- ptosis** (tō'sis) [G., *ptosis*, a falling] Falling down of an organ—for example, the drooping of the upper eyelid.
- puberty** (pū'ber-tē) [L., *pubertas*, grown up] Series of events that transform a child into a sexually mature adult; involves an increase in the secretion of GnRH.
- pubis** (pū'bis) Anterior inferior bone of the coxal bone.
- pubental cleft** (pū-den'dāl) Cleft between the labia majora.
- pubendum** (pū-den'dūm) See vulva.
- pulmonary artery** (pūl'mō-nār-ē) One of the arteries that extend from the pulmonary trunk to the right or left lungs.
- pulmonary capacity** Sum of two or more pulmonary volumes.
- pulmonary trunk** Large, elastic artery that carries blood from the right ventricle of the heart to the right and left pulmonary arteries.
- pulmonary vein** One of the veins that carry blood from the lungs to the left atrium of the heart.
- pulp** (pūlp) [L., *pulpa*, flesh] Soft tissue within the pulp cavity of the tooth, consisting of connective tissue containing blood vessels, nerves, and lymphatics.
- pulse pressure** (pūls) Difference between systolic and diastolic pressure.
- pupil** (pū'pīl) Circular opening in the iris through which light enters the eye.
- Purkinje fiber** (pūr-kīn'jē) Named for Bohemian anatomist Johannes E. von Purkinje (1787–1869). Modified cardiac muscle cells found beneath the endocardium of the ventricles. Specialized to conduct action potentials.
- pus** (pūs) Fluid product of inflammation; contains white blood cells, the debris of dead cells, and tissue elements liquefied by enzymes.
- pyloric opening** (pī-lōr'ik) Opening between the stomach and the superior part of the duodenum.
- pyloric sphincter** Thickening of the circular layer of the gastric musculature encircling the junction between the stomach and duodenum; also called pylorus.
- pyrogen** (pī'rō-jen) Chemical released by microorganisms, neutrophils, monocytes, and other cells that stimulates fever production by acting on the hypothalamus.

Q

- QRS complex** Principal deflection in the electrocardiogram, representing ventricular depolarization.
- QT interval** Time elapsing from the beginning of the QRS complex to the end of the T wave, representing the total duration of electrical activity of the ventricles.

R

- radial pulse** (rā'dē-āl) Pulse detected in the radial artery.
- radiation** (rā'dē-ā'shūn) [L., *radius*, ray, beam] Sending forth of light, short radiowaves, ultraviolet or x-rays, or any other rays for treatment or diagnosis or for other reasons; radiant heat.
- radioactive isotope** (rā'dē-ō-ak'tiv) Isotope with a nuclear composition that is unstable from which subatomic particles and electromagnetic waves are emitted.
- ramus; pl. rami** (rā'mūs, rā'mī) [L., branch] One of the primary subdivisions of a nerve or blood vessel; the part of a bone that forms an angle with the main body of the bone.

- raphe** (rā'fē) [Gr., *rhaphe*, suture, seam] Central line running over the scrotum from the anus to the root of the penis.
- receptor** Structural protein or glycoprotein molecule on the cell surface or within the cytoplasm that binds to a specific factor (chemical signal).
- recessive** (rē-sēs'iv) Gene that may not be expressed because of suppression by a contrasting dominant gene.
- Recommended Dietary Allowances (RDAs)** Guide for estimating the nutritional needs of groups of people based on their age, sex, and other factors; first established in 1941.
- Recommended Daily Intake (RDI)** Generally, the highest RDA value in each of four categories: infants, toddlers, people over 4 years of age, and pregnant or lactating women. The RDIs used to determine the Daily Values are based on the 1968 RDAs.
- rectum** (rek'tūm) [L., *rectus*, straight] Portion of the digestive tract that extends from the sigmoid colon to the anal canal.
- red marrow** (mar'o) Soft, pulpy connective tissue filling the cavities of bones; consists of reticular fibers and the development stages of blood cells and platelets; gradually replaced by yellow marrow in long bones and the skull.
- red pulp** [L., *pulpa*, flesh] Reddish brown substance of the spleen consisting of venous sinuses and the tissues intervening between them, called pulp cords.
- reduction** (rē-dūk'shūn) Gain of one or more electrons by a molecule.
- refraction** (rē-frac-shūn) Bending of a light ray when it passes from one medium into another of different density.
- refractory period** (rē-frac'tōr-ē) [Gr., *periodos*, a way around, a cycle] Period following effective stimulation during which excitable tissue, such as heart muscle, fails to respond to a stimulus of threshold intensity.
- regeneration** (rē'jen-er-ā'shūn) Reproduction or reconstruction of a lost or injured part.
- regulatory gene** Gene involved with controlling the activity of structural genes.
- relative refractory period** Portion of the action potential following the absolute refractory period during which another action potential can be produced with a greater-than-threshold stimulus strength.
- relaxation phase** (rē-lak-sā'shūn) Phase of muscle contraction following the contraction phase; the time from maximal tension production until tension decreases to its resting level.
- relaxin** Polypeptide hormone secreted by the corpus luteum and placenta during pregnancy; facilitates the birth process by causing a softening and lengthening of the pubic symphysis and cervix.
- renal artery** (rē'nāl) Artery that originates from the aorta and delivers blood to the kidney.
- renal blood flow rate** Volume at which blood flows through the kidneys per minute; an average of approximately 1200 mL/min.
- renal column** Cortical substance separating the renal pyramids.
- renal corpuscle** Glomerulus and Bowman's capsule that encloses it.
- renal fascia** (fāsh'i-ā) Connective tissue surrounding the kidney that forms a sheath or capsule for the organ.
- renal fat pad** Fat layer that surrounds the kidney and functions as a shock-absorbing material.
- renal fraction** Portion of the cardiac output that flows through the kidneys; averages 21%.
- renal pelvis** Funnel-shaped expansion of the upper end of the ureter that receives the calyces.
- renal pyramid** One of a number of pyramidal masses seen on longitudinal section of the kidney; they contain part of the loops of Henle and the collecting tubules.
- renin** (rē'nin) Enzyme secreted by the juxtaglomerular apparatus that converts angiotensinogen to angiotensin I.
- renin-angiotensin-aldosterone mechanism** Renin, released from the kidneys in response to low blood pressure, converts angiotensinogen to angiotensin I. Angiotensin I is converted by angiotensin-converting enzyme to angiotensin II, which causes vasoconstriction, resulting in increased blood pressure. Angiotensin II also increases aldosterone secretion, which increases blood pressure by increasing blood volume.
- repolarization phase** (rē'pō-lār-i-zā'shūn) Phase of the action potential in which the membrane potential moves from its maximum degree of depolarization toward the value of the resting membrane potential.
- reposition** Return of a structure to its original position.
- residual volume** (rē-zid'ū-āl) Volume of air remaining in the lungs after a maximum expiratory effort.
- resolution** (rez-ō-loo'shūn) [L., *resolutio*, a slackening] Phase of the male sexual act after ejaculation during which the penis becomes flaccid; feeling of satisfaction; inability to achieve erection and second ejaculation. Last phase of the female sexual act, characterized by an overall sense of satisfaction and relaxation.
- respiration** (res-pi-rā'shūn) [L., *respiratio*, to exhale, breathe] Process of life in which oxygen is used to oxidize organic fuel molecules, providing a source of energy, carbon dioxide, and water; movement of air into and out of the lungs, the exchange of gases with blood, the transportation of gases in the blood, and gas exchange between the blood and the tissues.
- respiratory bronchiole** (res'pi-rā-tōr-ē, rē-spīr'ā-tōr-ē) Smallest bronchiole (0.5 mm in diameter) that connects the terminal bronchiole to the alveolar duct.
- respiratory membrane** Membrane in the lungs across which gas exchange occurs with blood.
- resting membrane potential (RMP)** Electric charge difference inside a plasma membrane, measured relative to just outside the plasma membrane.
- reticular** (re-tik'ū-lār) [L., *rete*, net] Relating to a fine network of cells or collagen fibers.
- reticular cell** Cell with processes making contact with those of other similar cells to form a cellular network; along with the network of reticular fibers, the reticular cells form the framework of bone marrow and lymphatic tissues.
- reticulocyte** (re-tik'ū-lō-sīt) Young red blood cell with a network of basophilic endoplasmic reticulum occurring in larger numbers during the process of active red blood cell synthesis.
- reticuloendothelial system** (re-tik'ū-lō-en-dō-thē'lē-āl) See mononuclear phagocytic system.
- retina** (ret'i-nā) Nervous tunic of the eyeball.
- retinaculum** (ret-i-nak'ū-lūm) [L., band, halter, to hold back] Dense regular connective tissue sheath holding down the tendons at the wrist, ankle, or other sites.
- retraction** (rē-trak'shūn) [L., *retractio*, a drawing back] Movement in the posterior direction.
- retroperitoneal** (re'trō-per'i-tō-nē'āl) Behind the peritoneum.
- rhodopsin** (rō-dop'sin) Light-sensitive substance found in the rods of the retina; composed of opsin loosely bound to retinal.
- ribonuclease** (rī-bō-nū'klē-ās) Enzyme that splits RNA into its component nucleotides.
- ribonucleic acid (RNA)** (rī'bō-noo-klē'ik) Nucleic acid containing ribose as the sugar component; found in all cells in both nuclei and cytoplasm; helps direct protein synthesis.
- ribosomal RNA (rRNA)** (rī'bō-sōm-āl) RNA that is associated with certain proteins to form ribosomes.
- ribosome** (rī'bō-sōm) Small, spherical, cytoplasmic organelle where protein synthesis occurs.
- right lymphatic duct** Lymphatic duct that empties into the right subclavian vein; drains the right side of the head and neck, the right-upper thorax, and the right-upper limb.
- rigor mortis** (rig'er mōr'tis) Increased rigidity of muscle after death due to cross-bridge formation between actin and myosin as calcium ions leak from the sarcoplasmic reticulum.
- rod** Photoreceptor in the retina of the eye; responsible for noncolor vision in low-intensity light.
- root** Part below the neck of a tooth covered by cementum rather than enamel and attached by the periodontal ligament to the alveolar bone.
- root of the penis** Proximal attached part of the penis, including the two crura and the bulb.
- rotation** (rō-tā'shun) Movement of a structure about its axis.
- rotator cuff** (rō-tā'ter, rō-tā'tor) Four deep muscles that attach the humerus to the scapula.
- round ligament** Fibromuscular band that is attached to the uterus on each side in front of and below the opening of the uterine tube; it passes through the inguinal canal to the labium majus.
- round ligament of the liver** Remains of the umbilical vein.
- round window** Membranous structure separating the scala tympani of the inner ear from the middle ear.
- Ruffini end organ** (roo-fē'nēz) Named for Italian histologist Angelo Ruffini (1864–1929); receptor located deep in the dermis and responding to continuous touch or pressure.
- rugae**; pl. **rugae** (roo'gā, roo'gē) [L., a wrinkle] Fold or ridge; fold of the mucous membrane of the stomach when the organ is contracted; transverse ridge in the mucous membrane of the vagina.

S

- sacculae** (sak'yūl) Part of the membranous labyrinth; contains a sensory structure, the macula, that detects static equilibrium.
- salivary amylase** (sal'i-vār-ē am'il-ās) Enzyme secreted in the saliva that breaks down starch to maltose and isomaltose.
- salivary gland** Gland that produces and secretes saliva into the oral cavity. The three major pairs of salivary glands are the parotid, submandibular, and sublingual glands.

- salt** Molecule consisting of a cation other than hydrogen and an anion other than hydroxide.
- sarcolemma** (sar'kō-lem'ă) [Gr., *sarco*, muscle + *lemma*, husk] Plasma membrane of a muscle fiber.
- sarcoma** (sar-kō'mă) Malignant neoplasm derived from connective tissue.
- sarcomere** (sar'kō-mēr) [Gr., *sarco*, muscle + *meros*, part] Part of a myofibril between adjacent Z disks.
- sarcoplasm** (sar'kō-plazm) [Gr., *sarco*, muscle + *plasma*, a thing formed] Cytoplasm of a muscle fiber, excluding the myofilaments.
- sarcoplasmic reticulum** (sar'kō-plaz'mik) [Gr., *sarco*, muscle + *plasma*, a thing formed + *reticulum*, net] Endoplasmic reticulum of muscle.
- satellite cell** (sat'ē-līt) Specialized cell that surrounds the cell bodies of neurons within ganglia.
- saturated** (satch'ū-rāt-ēd) Fatty acid in which the carbon chain contains only single bonds between carbon atoms.
- saturation** (satch-ū-rā'shun) Point when all carrier molecules or enzymes are attached to substrate molecules and no more molecules can be transported or reacted.
- scala tympani** (skā'lă tim'pă-nī) [L., stairway] Division of the spiral canal of the cochlea lying below the spiral lamina and basilar membrane.
- scala vestibuli** (skā'lă ves-tib'ū-lī) Division of the cochlea lying above the spiral lamina and vestibular membrane.
- scapula** (skap'ū-lă) Bone forming the shoulder blade.
- scar** (skar) [Gr., *eschara*, scab] Fibrous tissue replacing normal tissue; also called cicatrix.
- sciatic nerve** (sī-at'ik) Tibial and common peroneal nerves bound together; also called ischiadic nerve.
- sclera** (sklēr'ă) White of the eye; white, opaque portion of the fibrous tunic of the eye.
- scleral venous sinus** Series of veins at the base of the cornea that drain excess aqueous humor from the eye.
- scrotum; pl. scrota, scrotums** (skrō'tŭm, skrō'tă, skrō'tŭmz) Musculocutaneous sac containing the testes.
- sebaceous gland** (sē-bă'shŭs) [L., *sebum*, tallow] Gland of the skin, usually associated with a hair follicle, that produces sebum.
- second messenger** See intracellular mediator.
- secondary follicle** Follicle in which the secondary oocyte is surrounded by granulosa cells at the periphery; contains fluid-filled antral spaces.
- secondary oocyte** (ō'ō-sīt) Oocyte in which the second meiotic division stops at metaphase II unless fertilization occurs.
- secondary palate** Roof of the mouth in the early embryo that gives rise to the hard and the soft palates.
- secondary response** Immune response that occurs when the immune system is exposed to an antigen against which it has already produced a primary response; also called memory response.
- secondary spermatocyte** (sper'mă-tō-sīt) Spermatocyte derived from a primary spermatocyte by the first meiotic division; each secondary spermatocyte gives rise by the second meiotic division to two spermatids.
- secretin** (se-krē'tin) Hormone formed by the epithelial cells of the duodenum; stimulates secretion of pancreatic juice high in bicarbonate ions.
- secretion** (se-krē'shŭn) Substance produced inside a cell and released from the cell.
- secretory phase** (se-krēt'ē-rē, sē'krē-tōr-ē) See luteal phase.
- segmental artery** One of five branches of the renal artery, each supplying a segment of the kidney.
- segmental bronchi** Extend from the secondary bronchus and conducts air to each lobule of the lungs.
- self-antigen** Antigen produced by the body that is capable of initiating an immune response against the body.
- semen** (sē'men) [L., seed (of plants, men, animals)] Penile ejaculate; thick, yellowish white, viscous fluid containing spermatozoa and secretions of the testes, seminal vesicles, prostate, and bulbourethral glands.
- semicircular canal** (sem'ē-sir'kū-lăr) Canal in the petrous portion of the temporal bone that contains sensory organs that detect kinetic or dynamic equilibrium. Three semicircular canals are within each inner ear.
- seminal vesicle** (sem'i-năl) One of two glandular structures that empty into the ejaculatory ducts; its secretion is one of the components of semen.
- seminiferous tubule** (sem'i-nif'er-ŭs) Tubule in the testis in which spermatozoa develop.
- sensible perspiration** (sen'si-bl pers-pi-ră'shŭn) Perspiration excreted by the sweat glands that appears as moisture on the skin; produced in large quantity when there is much humidity in the atmosphere.
- septum primum** (sep'tŭm prī'mŭm) First septum in the embryonic heart that arises on the wall of the originally single atrium of the heart and separates it into right and left chambers.
- septum secundum** (sek'ŭn-dŭm) Second of two major septal structures involved in the partitioning of the atrium, arising later than the septum primum and located to the right of it; it remains an incomplete partition until after birth, with its unclosed area constituting the foramen ovale.
- serosa** (se-rō'să) [L., *serosus*, serous] Outermost covering of an organ or a structure that lies in a body cavity.
- serous fluid** (ser'ŭs) Fluid similar to lymph that is produced by and covers serous membrane; it lubricates the serous membrane.
- serous membrane** Thin sheet composed of epithelial and connective tissues; it lines cavities that do not open to the outside of the body or contain glands but do secrete serous fluid.
- serous pericardium** Lining of the pericardial sac composed of a serous membrane.
- Sertoli cell** (ser-tō'lē) Named for Italian histologist Enrico Sertoli (1842–1910). Elongated cell in the wall of the seminiferous tubules to which spermatids are attached during spermatogenesis.
- serum** (sēr'ŭm) [L., whey] Fluid portion of blood after the removal of fibrin and blood cells.
- sesamoid bone** (ses'ă-moyd) [Gr., *sesamoceies*, like a sesame seed] Bone found within a tendon, such as the patella.
- sex chromosomes** Pair of chromosomes responsible for sex determination, XX in female and XY in male.
- sex-linked trait** Characteristic resulting from the expression of a gene on a sex chromosome.
- sigmoid colon** (sig'moyd) Part of the colon between the descending colon and the rectum.
- sigmoid mesocolon** Fold of peritoneum attaching the sigmoid colon to the posterior abdominal wall.
- simple epithelium** Epithelium consisting of a single layer of cells.
- sinoatrial (SA) node** (si'nō-ă'trē-ăl) Mass of specialized cardiac muscle fibers; acts as the “pace-maker” of the cardiac conduction system.
- sinus** (sī'nŭs) [L., cavity] Hollow in a bone or other tissue; enlarged channel for blood or lymph.
- sinus venosus** End of the embryonic cardiac tube where blood enters the heart; becomes a portion of the right atrium, including the SA node.
- sinusoid** (sī'nŭ-soyd) [L., sinus + Gr., *eidos*, resemblance] Terminal blood vessel having a larger diameter than an ordinary capillary.
- sinusoidal capillary** (si'nŭ-soy'dăl) Capillary with caliber of 10–20 μm or more; lined with a fenestrated type of endothelium.
- small intestine** [L., *intestinus*, entrails] Portion of the digestive tube between the stomach and the cecum; consists of the duodenum, jejunum, and ileum.
- sodium-potassium (Na⁺-K⁺) pump** Biochemical mechanism that uses energy derived from ATP to achieve the active transport of potassium ions opposite to that of sodium ions; also called sodium potassium ATP-ase.
- soft palate** Posterior muscular portion of the palate, forming an incomplete septum between the mouth and the oropharynx and between the oropharynx and the nasopharynx.
- solute** (sol'ŭt, sō'loo) [L., *solutus*, dissolved] Dissolved substance in a solution.
- solution** (sō-loo'shŭn) [L., *solutio*] Homogenous mixture formed when a solute is dissolved in a solvent.
- solvent** (sol'vent) [L., *solvens*, to dissolve] Liquid that holds another substance in solution.
- soma** (sō'mă) [Gr., body] Neuron cell body or the enlarged portion of the neuron containing the nucleus and other organelles.
- somatic** (sō-mat'ik) [Gr., *somatikos*, bodily] Relating to the body; the cells of the body except the reproductive cells.
- somatic nervous system** Composed of nerve fibers that send impulses from the central nervous system to skeletal muscle.
- somatomedin** (sō'mă-tō-mē'din) Peptide synthesized in the liver capable of stimulating certain anabolic processes in bone and cartilage, such as synthesis of DNA, RNA, and protein.
- somatotropin** (sō'mă-tō-trō'pin) Protein hormone of the anterior pituitary gland; it promotes body growth, fat mobilization, and inhibition of glucose utilization.
- somite** (sō'mīt) [Gr., *soma*, body + *ite*] One of the paired segments consisting of cell masses formed in the early embryonic mesoderm on each side of the neural tube.
- somitomere** (sō'mīt-ō-mēr) Indistinct somite in the head region of the embryo.
- spatial summation** Summation of the local potentials in which two or more action potentials arrive simultaneously at two or more presynaptic terminals that synapse with a single neuron.
- specific heat** Heat required to raise the temperature of any substance 1°C compared with the heat required to raise the same volume of water 1°C.
- speech** Use of the voice in conveying ideas.

- spermatic cord** (sper-mat'ik) Cord formed by the ductus deferens and its associated structures; extends through the inguinal canal into the scrotum.
- spermatid** (sper'mă-tid) [Gr., *sperma*, seed + *id*] Cell derived from the secondary spermatocyte; gives rise to a spermatozoon.
- spermatogenesis** (sper'mă-tō-jen'ē-sis) Formation and development of the spermatozoon.
- spermatogonium** (sper'mă-tō-gō'nē-ūm) [Gr., *sperma*, seed + *gone*, generation] Cell that divides by mitosis to form primary spermatocytes.
- spermatozoon**; pl. **spermatozoa** (sper'mă-tō-zō'on, sper'mă-to-zō'ă) [Gr., *sperma*, seed + *zoon*, animal] Male gamete or sex cell, composed of a head and a tail. The spermatozoon contains the genetic information transmitted by the male. Also called sperm cell.
- sphenoid** (sfē'noyd) [Gr., *shen*, wedge] Wedge-shaped.
- sphincter pupillae** (sfingkt'er pū-pil'ē) Circular smooth muscle fibers of the iris's diaphragm that constrict the pupil of the eye.
- sphygmomanometer** (sfīg'mō-mă-nom'ē-ter) [Gr., *sphygmos*, pulse + *manos*, thin, scanty + *metron*, measure] Instrument for measuring blood pressure.
- spinal nerve** (spī'nāl) One of 31 pairs of nerves formed by the joining of the dorsal and ventral roots that arise from the spinal cord.
- spindle fiber** (spin'dl) Specialized microtubule that develops from each centrosome and extends toward the chromosomes during cell division.
- spiral artery** (spī'rāl) One of the corkscrewlike arteries in premenstrual endometrium; most obvious during the secretory phase of the uterine cycle.
- spiral ganglion** Cell bodies of sensory neurons that innervate hair cells of the organ of Corti are located in the spiral ganglion.
- spiral lamina** Attached to the modiolus and supports the basilar and vestibular membranes.
- spiral ligament** Attachment of the basilar membrane to the lateral wall of the bony labyrinth.
- spiral organ** Organ of Corti; rests on the basilar membrane and consists of the hair cells that detect sound; also called organ of Corti.
- spiral tubular gland** Well-developed simple or compound tubular gland; spiral in shape; within the endometrium of the uterus; prevalent in the secretory phase of the uterine cycle.
- spirometer** (spī-rom'ē-ter) [L., *spiro*, to breathe + Gr., *metron*, measure] Gasometer used for measuring the volume of respiratory gases; usually understood to consist of a counterbalanced cylindrical bell sealed by dipping into a circular trough of water.
- spirometry** (spī-rom'ē-trē) Making pulmonary measurements with a spirometer.
- spleen** (splēn) Large lymphatic organ in the upper part of the abdominal cavity on the left side between the stomach and diaphragm, composed of white and red pulp. It responds to foreign substances in the blood, destroys worn-out red blood cells, and is a storage site for blood cells.
- spongy urethra** Portion of the male urethra, approximately 15 cm in length, that traverses the corpus spongiosum of the penis.
- squamous** (skwă'mūs) [L., *squama*, a scale] Scale-like, flat.
- stapedius** (stă-pē'dē-ūs) Small skeletal muscles attached to the stapes.
- stapes** (stă'pēz) [L., *stirrup*] Smallest of the three auditory ossicles; attached to the oval window.
- Starling law of the heart** Named for English physiologist Ernest H. Starling (1866–1927). Force of contraction of cardiac muscle is a function of the length of its muscle fibers at the end of diastole; the greater the ventricular filling, the greater the stroke volume produced by the heart.
- sternum** (ster'nūm) [L., *sternon*, chest] Breastbone.
- steroid** (stēr'oyd, ster'oyd) Large family of lipids, including some reproductive hormones, vitamins, and cholesterol.
- stomach** (stūm'ūk) Large sac between the esophagus and the small intestine, lying just beneath the diaphragm.
- stratified epithelium** (strat'ī-fid ep-i-thē'lē-ūm) Epithelium consisting of more than one layer of cells.
- stratum basale** (strat-ūm bāh-sāl'ē) [L., *layer*; *basal*] Basal, or deepest, layer of the epidermis; also called stratum germinativum.
- stratum corneum** (kōr'nē-ūm) [L., *layer* + *corneus*, horny] Most superficial layer of the epidermis consisting of flat, keratinized, dead cells.
- stratum granulosum** (gran'ū-lō'sūm) [L., *layer*; *granulum*, a small grain] Layer of cells in the epidermis filled with granules of keratohyalin.
- stratum lucidum** (lū'sid-ūm) [L., *layer* + *lucidus*, clear] Clear layer of the epidermis found in thick skin between the stratum granulosum and the stratum corneum.
- stratum spinosum** (spī'nōs-ūm) [L., *layer* + *spina*, spine] Layer of many-sided cells in the epidermis with intercellular connections (desmosomes) that give the cells a spiny appearance.
- stria**; pl. **striae** (strī'ă, strī'ē) [L., *channel*] Line or streak in the skin that is a different texture or color from the surrounding skin; also called stretch mark.
- striated** (strī'ăt-ēd) [L., *striatus*, furrowed] Striped; marked by stripes or bands.
- stroke volume (SV)** [L., *volumen*, something rolled up, scroll, from *volvo*, to roll] Volume of blood pumped out of one ventricle of the heart in a single beat.
- structural gene** Gene that determines the structure of a specific protein or peptide.
- sty** (stī) Inflamed ciliary gland of the eye.
- subcutaneous** (süb'koo-tă'nē-ūs) [L., *sub*, under + *cutis*, skin] Under the skin; same tissue as the hypodermis.
- sublingual gland** (süb-ling'gwäl) One of two salivary glands in the floor of the mouth beneath the tongue.
- submandibular gland** (süb-man-dib'ū-lăr) One of two salivary glands in the neck, located in the space bounded by the two bellies of the digastric muscle and the angle of the mandible.
- submucosa** (süb-moo-kō'să) Layer of tissue beneath a mucous membrane.
- submucosal plexus** (süb-mū-kō'săl) [L., a braid] Gangliated plexus of unmyelinated nerve fibers in the intestinal submucosa.
- substantia nigra** (süb-stan'shē-ă nī'gră) [L., *substance*; *black*] Black nuclear mass in the midbrain; involved in coordinating movement and maintaining muscle tone.
- subthreshold stimulus** Stimulus resulting in a local potential so small that it does not reach threshold and produce an action potential.
- sucrose** (soo'krōs) Disaccharide composed of glucose and fructose; table sugar.
- sulcus**; pl. **sulci** (sool'kūs, sül'sī) [L., *furrow* or *ditch*] Furrow or groove on the surface of the brain between the gyri; may also refer to a fissure.
- superficial inguinal ring** (ing'gwi-nāl) Slitlike opening in the aponeurosis of the external oblique muscle of the abdominal wall through which the spermatic cord (round ligament in the female) emerges from the inguinal canal.
- superior colliculus** (ko-lik'ū-lūs) [L., *collis*, hill] One of two rounded eminences of the midbrain; aids in coordination of eye movements.
- superior vena cava** (vē'nă cāvă) Vein that returns blood from the head and neck, upper limbs, and thorax to the right atrium.
- supination** (soo'pi-nă'shūn) [L., *supino*, to bend backward, place on back] Rotation of the forearm (when the forearm is parallel to the ground) so that the anterior surface is up (supine).
- supramaximal stimulus** Stimulus of greater magnitude than a maximal stimulus; however, the frequency of action potentials is not increased above that produced by a maximal stimulus.
- suppressor T cell** Subset of T lymphocytes that decreases the activity of B cells and T cells.
- surfactant** (ser-fak'tânt) Lipoproteins forming a monomolecular layer over pulmonary alveolar surfaces; stabilizes alveolar volume by reducing surface tension and the tendency for the alveoli to collapse.
- suspension** (sūs-pen'shūn) Liquid through which a solid is dispersed and from which the solid separates unless the liquid is kept in motion.
- suspensory ligament** (sūs-pen'sō-rē) Band of peritoneum that extends from the ovary to the body wall; contains the ovarian vessels and nerves. Small ligament attached to the margin of the lens in the eye and the ciliary body to hold the lens in place.
- suture** (soo'choor) [L., *sutura*, a seam] Junction between flat bones of the skull.
- sweat** (swet) [A.S., *swat*] Perspiration; secretions produced by the sweat glands of the skin; also called sensible perspiration.
- sweat gland** Usually means structure that produces a watery secretion called sweat. Some sweat glands, however, produce viscous organic secretions. Also called sudoriferous gland.
- sympathetic chain ganglion** (sim-pă-thet'ik) Collection of sympathetic postganglionic neurons that are connected to each other to form a chain along both sides of the spinal cord; also called paravertebral ganglion.
- sympathetic division** Subdivision of the autonomic division of the nervous system characterized by having the cell bodies of its preganglionic neurons located in the thoracic and upper lumbar regions of the spinal cord (thoracolumbar division); usually involved in preparing the body for physical activity; also called thoracolumbar division.
- symphysis**; pl. **symphyses** (sim'fi-sis, sim'fă-sēz) [Gr., a growing together] Fibrocartilage joint between two bones.
- synapse**; pl. **synapses** (sin'aps, sī-naps', sī-nap'sēz) [Gr., *syn*, together + *haptain*, to clasp] Functional membrane-to-membrane contact of a nerve cell with another nerve cell, muscle cell, gland cell, or sensory receptor; functions in the transmission of action potentials from one cell to another; also called neuromuscular junction.

synaptic cleft (si-nap'tik) Space between the pre-synaptic and the postsynaptic membranes.

synaptic fatigue Fatigue due to depletion of neurotransmitter vesicles in the presynaptic terminals.

synaptic vesicle Secretory vesicle in the presynaptic terminal containing neurotransmitter substances.

synchondrosis; pl. **synchondroses** (sin'kon-drō'sis, -sēz) [Gr., *syn*, together + *chondros*, cartilage + *osis*, condition] Union between two bones formed by hyaline cartilage.

syncytiotrophoblast (sin-sish'ē-ō-trō'fō-blast) Outer layer of the trophoblast composed of multinucleated cells.

syndesmosis; pl. **syndesmoses** (sin'dez-mō'sis, sin'dez-mō'sēz) [Gr., *syndeo*, to bind + *osis*, condition] Form of fibrous joint in which opposing surfaces that are some distance apart are united by ligaments.

synergist (sin'er-jist) Muscle that works with other muscles to cause a movement.

synovial (si-nō've-äl) [Gr., *syn*, together + *oon*, egg] Relating to or containing synovia (a substance that serves as a lubricant in a joint, tendon sheath, or bursa).

synovial fluid Slippery fluid found inside synovial joints and bursae; produced by the synovial membranes.

systemic inflammation (sis-tem'ik) Inflammation that occurs in many areas of the body. In addition to symptoms of local inflammation, increased neutrophil numbers in the blood, fever, and shock can occur.

ystole (sis'tō-lē) [Gr., *ystole*, a contracting] Contraction of the heart chambers during which blood leaves the chambers; usually refers to ventricular contraction.

T

T cell Thymus-derived lymphocyte of immunologic importance; it is of long life and is responsible for cell-mediated immunity.

T wave Deflection in an electrocardiogram following the QRS complex, representing ventricular repolarization.

tactile corpuscle (tak'til) Oval receptor found in the papillae of the dermis; responsible for fine, discriminative touch; also called Meissner corpuscle.

tactile disk Cuplike receptor found in the epidermis; responsible for light touch and superficial pressure; also called Merkel's disk.

talus (tā'lūs) [L., ankle bone, heel] Tarsal bone contributing to the ankle.

target tissue Tissue on which a hormone acts.

tarsal bone (tar'säl) [Gr., *tarsos*, sole of foot] One of seven ankle bones.

tarsal plate (tar'säl) Crescent-shaped layer of connective tissue that helps maintain the shape of the eyelid.

taste (täst) Sensations created when a chemical stimulus is applied to the taste receptors in the tongue.

taste bud Sensory structure, mostly on the tongue, that functions as a taste receptor.

tectum (tek'tüm) Roof of the midbrain.

tegmentum (teg-men'tüm) Floor of the midbrain.

telencephalon (tel-en-sef'ä-lon) [Gr., *telos*, end + *enkephalos*, brain] Anterior division of the embryonic brain from which the cerebral hemispheres develop.

telophase (tel'ō-fāz) Time during cell division when the chromosomes are pulled by spindle fibers away from the cell equator and into the two halves of the dividing cell.

temporal summation (tem'pō-räl) Summation of the local potential that results when two or more action potentials arrive at a single synapse in rapid succession.

tendon (ten'dōn) Band or cord of dense connective tissue that connects a muscle to a bone or another structure.

tensor tympani (ten'sōr tim'pa-nī) Small skeletal muscle attached to the malleus.

tentorium cerebelli (ten-tō'rē-üm ser'ē-bel't) Dural folds between the cerebrum and the cerebellum.

terminal bouton (bū-ton') [Fr., button] Enlarged axon terminal or presynaptic terminal.

terminal cisterna (sis-ter'nä) [L., *terminus*, limit + *cista*, box] Enlarged end of the sarcoplasmic reticulum in the area of the T tubules.

terminal hair [L., *terminus*, a boundary, limit] Long, coarse, usually pigmented hair found in the scalp, eyebrows, and eyelids and replacing vellus hair.

terminal sulcus (sū'l'kūs) [L., furrow or ditch] V-shaped groove on the surface of the tongue at the posterior margin.

testis; pl. **testes** (tes'tis, tes'tēz) One of two male reproductive glands located in the scrotum; produces spermatozoa, testosterone, and inhibin.

testosterone (tes-tos'tē-rōn) Steroid hormone secreted primarily by the testes; aids in spermatogenesis, maintenance and development of male reproductive organs, secondary sexual characteristics, and sexual behavior.

tetraiodothyronine (T₄) (tet'rā-ī-ō'dō-thī'rō-nēn) One of the iodine-containing thyroid hormones; also called thyroxine.

thalamus (thal'ä-mūs) [Gr., *thalamos*, bed, bedroom] Large mass of gray matter that forms the larger dorsal subdivision of the diencephalon.

theca (thē'kä) [Gr., *theke*, box] Sheath or capsule.

theca externa External fibrous layer of the theca of a vesicular follicle.

theca interna Inner vascular layer of the theca of the secondary and mature follicle; produces estrogen and contributes to the formation of the corpus luteum after ovulation.

thenar eminence (thē'nar) [Gr., palm of the hand] Fleshy mass of tissue at the base of the thumb; contains muscles responsible for thumb movements.

thick skin Skin in the palms, soles, and tips of the digits; has all five epidermal strata.

thin skin Skin over most of the body, usually without a stratum lucidum; has fewer layers of cells than thick skin.

thoracic cavity (thō-ras'ik) Space within the thoracic walls, bounded below by the diaphragm and above by the neck.

thoracic duct Largest lymph vessel in the body, beginning at the cisterna chyli and emptying into the left subclavian vein; drains the left side of the head and neck, the left-upper thorax, the left-upper limb, and the inferior half of the body.

thoracolumbar division (thōr'ä-kō-lüm'bar) See sympathetic division.

thoroughfare channel Channel for blood through a capillary bed from an arteriole to a venule.

threshold potential (thresh'öld) Value of the membrane potential at which an action potential is

produced as a result of depolarization in response to a stimulus.

threshold stimulus Stimulus resulting in a local potential just large enough to reach threshold and produce an action potential.

thrombocyte (throm'bō-sīt) Platelet.

thrombocytopenia (throm'bō-sī'tō-pē'nē-ä) [*thrombocyte* + Gr., *penia*, poverty] Condition in which there is an abnormally small number of platelets in the blood.

thromboxane (throm-bok'sän) Specific class of physiologically active fatty acid derivatives present in many tissues.

thrombus; pl. **thrombi** (throm'būs, throm'bī) [Gr., *thrombos*, a clot] Clot in the cardiovascular system formed from constituents of blood; may be occlusive or attached to the vessel or heart wall without obstructing the lumen.

thymus (thī'mūs) [Gr., *thymos*, sweetbread] Bilobed lymph organ located in the inferior neck and superior mediastinum; secretes the hormone thymosin.

thyroid cartilage (thī'royd) Largest laryngeal cartilage. It forms the laryngeal prominence, or Adam's apple.

thyroid gland [Gr., *thyroeoidea*, shield] Endocrine gland located inferior to the larynx and consisting of two lobes connected by the isthmus; secretes the thyroid hormones triiodothyronine (T₃) and tetraiodothyronine (T₄).

thyroid-stimulating hormone (TSH) Glycoprotein hormone released from the hypothalamus; stimulates thyroid hormone secretion from the thyroid gland; also called thyrotropin.

thyrotropin (thī-rot'rō-pin, thī-rō-trō'pin) See thyroid-stimulating hormone (TSH).

thyroxine (thi-rok'sēn, thi-rok'sin) See tetraiodothyronine.

tidal volume (tī'däl) Volume of air that is inspired or expired in a single breath during regular, quiet breathing.

tissue repair (tish'ū) Substitution of viable cells for damaged or dead cells by regeneration or replacement.

tolerance (tol'er-äns) Failure of the specific immune system to respond to an antigen.

tongue (tūng) Muscular organ occupying most of the oral cavity when the mouth is closed; major attachment is through its posterior portion.

tonicity (tō-nis'tē) [Gr., *tonos*, tone] Osmotic pressure or tension of a solution, usually relative to that of blood; a state of continuous activity or tension caused by muscle contraction beyond the tension related to physical properties of muscle.

tonsil; pl. **tonsils** (ton'sil, ton'silz) [L., *tonsilla*, stake] Collection of lymphoid tissue; usually refers to a large collection of lymphatic tissue beneath the mucous membrane of the oral cavity and pharynx; lingual, pharyngeal, and palatine tonsils.

total lung capacity Volume of air contained in the lungs at the end of a maximum inspiration; equals vital capacity plus residual volume.

total tension Sum of active and passive tension.

trabecula; pl. **trabeculae** (trä-bek'ū-lä, trä-bek'ū-lē) [L., *trabs*, beam] One of the supporting bundles of fibers traversing the substance of a structure, usually derived from the capsule or one of the fibrous septa, such as trabeculae of lymph nodes, testes; a beam or plate of cancellous bone.

trachea (trä'kē-ä) [Gr., *tracheia arteria*, rough artery] Air tube extending from the larynx into the thorax,

where it divides to form the bronchi; composed of 16–20 rings of hyaline cartilage.

tracheostomy (tra'ke-os'to-me) [*tracheo*, *trachea* + Gr., *stoma*, mouth] Operation to make an opening into the trachea; usually the opening is intended to be permanent, and a tube is inserted into the trachea to allow airflow.

tracheotomy (tra'ke-ot'o-me) [*tracheo*, *trachea* + Gr., *tome*, incision] Act of cutting into the trachea.

transcription (tran-skip'shŭn) Process of forming RNA from a DNA template.

transfer RNA (tRNA) RNA that attaches to individual amino acids and transports them to the ribosomes, where they are connected to form a protein polypeptide chain.

transfusion (trans-fŭ'zhŭn) [L., *trans*, across + *fundo*, to pour from one vessel to another] Transfer of blood from one person to another.

transitional epithelium (tran-sish'in-äl) Stratified epithelium that may be either cuboidal or squamouslike, depending on the presence or absence of fluid in the organ (as in the urinary bladder).

translation (trans-lä'shŭn) Synthesis of polypeptide chains at the ribosome in response to information contained in mRNA molecules.

transverse colon (trans-vers' kō'lon) Part of the colon between the right and left colic flexures.

transverse mesocolon (mez'ō-kō'lon) Fold of peritoneum attaching the transverse colon to the posterior abdominal wall.

transverse (T) tubule [L., *tubus*, tube] Tubule that extends from the sarcolemma to a myofibril of striated muscles.

trappe (trep'eh) [Ger., staircase] Series of successively stronger contractions that occur when a rested muscle fiber receives closely spaced stimuli of the same strength but with a sufficient stimulus interval to allow complete relaxation of the fiber between stimuli.

triacylglycerol (trī-as'il-glis'er-ol) *See* triglyceride.

triad (trī'ad) Two terminal cisternae and a T tubule between them.

tricuspid valve (trī-kŭs'pid) Valve closing the orifice between the right atrium and the right ventricle of the heart.

triglyceride (tri-glis'er-id) Three-carbon glycerol molecule with a fatty acid attached to each carbon; constitute approximately 95% of the fats in the human body. Also called triacylglycerol.

trigone (trī'gōn) [Gr., *trigonon*, triangle] Triangular, smooth area at the base of the bladder between the openings of the two ureters and that of the urethra.

triiodothyronine (T₃) (trī-ī'ō-dō-thī'rō-nēn) One of the iodine-containing thyroid hormones.

trochlea (trok'lē-ä) [L., pulley] Structure shaped like or serving as a pulley or spool.

trochlear nerve (trok'lē-ar) [L., *trochlea*, pulley] Cranial nerve IV, to the muscle (superior oblique) turning around a pulley.

trophoblast (trof'ō-blast) [Gr., *trophe*, nourishment + *blastos*, germ] Cell layer forming the outer layer of the blastocyst, which erodes the uterine mucosa during implantation; the trophoblast does not become part of the embryo but contributes to the formation of the placenta.

tropomyosin (trō-pō-mī'ō-sin) Fibrous protein found as a component of the actin myofilament.

troponin (trō'pō-nin) Globular protein component of the actin myofilament.

true pelvis Portion of the pelvis inferior to the pelvic brim.

true rib (ver-tē'brō-ster'näl) Rib that attaches by an independent costal cartilage directly to the sternum; also called vertebrosteral rib.

trypsin (trip'sin) Proteolytic enzyme formed in the small intestine from the inactive pancreatic precursor trypsinogen.

tubercle (too'ber-kl) Lump on a bone.

tubular load (too'bŭ-lär) Amount of a substance per minute that crosses the filtration membrane into Bowman's capsule.

tubular maximum Maximum rate of secretion or reabsorption of a substance by the renal tubules.

tubular reabsorption Movement of materials, by means of diffusion, active transport, or symport, from the filtrate within a nephron to the blood.

tubular secretion Movement of materials, by means of active transport, from the blood into the filtrate of a nephron.

tumor (too'mör) Any swelling or growth; a neoplasm.

tunic (too'nik) [L., coat] One of the enveloping layers of a part; one of the coats of a blood vessel; one of the coats of the eye; one of the coats of the digestive tract.

tunica adventitia (too'ni-kä ad-ven-tish'ä) Outermost fibrous coat of a vessel or an organ that is derived from the surrounding connective tissue.

tunica albuginea (al-bŭ-jin'ē-ä) Dense, white, collagenous tunic surrounding a structure, such as the capsule around the testis.

tunica intima (in'ti-mä) Innermost coat of a blood vessel; consists of endothelium, a lamina propria, and an inner elastic membrane.

tunica media Middle, usually muscular, coat of an artery or another tubular structure.

turbulent flow Flow characterized by eddy currents exhibiting nonparallel blood flow.

tympanic membrane (tim-pan'ik) Eardrum; cellular membrane that separates the external from the middle ear; vibrates in response to sound waves.

U

unmyelinated axon (ün-mī'ē-li-nä-ted) Nerve fibers lacking a myelin sheath.

unsaturated (ün-sach'ŭr-ät-ed) Carbon chain of a fatty acid that possesses one or more double or triple bonds.

upper respiratory tract Nasal cavity, pharynx, and associated structures.

up-regulation Increase in the concentration of receptors in response to a signal.

ureter (ŭ-rē'ter, ŭ'rē-ter) [Gr., *oureter*, urinary canal] Tube conducting urine from the kidney to the urinary bladder.

urethral gland (ŭ-rē'thräl) One of numerous mucous glands in the wall of the spongy urethra in the male.

urogenital triangle Anterior portion of the perineal region containing the openings of the urethra and vagina in the female and the urethra and root structures of the penis in the male.

uterine cycle (ŭ'ter-in, ŭ'ter-ĭn) Series of events that occur in a regular fashion in the uterus of sexually mature, nonpregnant females; prepares the uterine lining for implantation of the embryo.

uterine part Portion of the uterine tube that passes through the wall of the uterus.

uterine tube One of the tubes leading on each side from the uterus to the ovary; consists of the infundibulum, ampulla, isthmus, and uterine parts; also called fallopian tube or oviduct.

uterus (ŭ'ter-ŭs) Hollow, muscular organ in which the fertilized ovum develops into a fetus.

utricle (oo'tri-kl) Part of the membranous labyrinth; contains a sensory structure, the macula, that detects static equilibrium.

uvula (ŭ'vŭ-lä) [L., *uva*, grape] Small, grapelike appendage at the posterior margin of the soft palate.

V

vaccination (vak'si-nä'shŭn) Deliberate introduction of an antigen into a subject to stimulate the immune system and produce immunity to the antigen.

vaccine (vak'sēn, vak-sēn') [L., *vaccinus*, relating to a cow] Preparation of killed microbes, altered microbes, or derivatives of microbes or microbial products intended to produce immunity. The method of administration is usually inoculation, but ingestion is preferred in some instances, and nasal spray is used occasionally.

vagina (vä-jī'nä) [L., sheath] Genital canal in the female, extending from the uterus to the vulva.

vapor pressure Partial pressure exerted by water vapor.

variable region Part of an antibody that combines with an antigen.

vas deferens (vas def'er-enz) *See* ductus deferens.

vasa recta (vä'sä rek'tä) Specialized capillary that extends from the cortex of the kidney into the medulla and then back to the cortex.

vasa vasorum (vä'sor-ŭm) [L., vessel, dish] Small vessels distributed to the outer and middle coats of larger blood vessels.

vascular tunic (vas'kü-lär) Middle layer of the eye; contains many blood vessels.

vasoconstriction (vä'sō-kon-strik'shŭn, vas'ō-kon-strik'shŭn) Decreased diameter of blood vessels.

vasodilation (vä'sō-dī-lä'shŭn) Increased diameter of blood vessels.

vasomotion (vä-sō-mō'shŭn) Periodic contraction and relaxation of the precapillary sphincter, resulting in cyclic blood flow through capillaries.

vasomotor center (vä-sō-mō'ter, vas-ō-mō'ter) Area within the medulla oblongata that regulates the diameter of blood vessels by way of the sympathetic nervous system.

vasomotor tone Relatively constant frequency of sympathetic impulses that keep blood vessels partially constricted in the periphery.

vasopressin (vä-sō-pres'in, vas-ō-pres'in) *See* antidiuretic hormone.

vellus hair (vel'ŭs) [L., fleece] Short, fine, usually unpigmented hair that covers the body except for the scalp, eyebrows, and eyelids. Much of the vellus is replaced at puberty by terminal hairs.

venous capillary (vē'nŭs) Capillary opening into a venule.

venous return Volume of blood returning to the heart.

venous sinus Endothelium-lined venous channel in the dura mater that receives cerebrospinal fluid from the arachnoid granulations.

ventilation (ven-ti-lä'shŭn) [L., *ventus*, the wind] Movement of gases into and out of the lungs.

ventral root (ven'träl) Motor (efferent) root of a spinal nerve.

ventricle (ven'tri-kl) [L., *venter*, belly] Chamber of the heart that pumps blood into arteries (i.e., the

left and right ventricles); in the brain, a fluid-filled cavity.

ventricular diastole (ven-trik'ū-lār) Dilation of the heart ventricles.

ventricular systole Contraction of the ventricles.

venule (ven'ool, vē'nool) Minute vein, consisting of endothelium and a few scattered smooth muscles, that carries blood away from capillaries.

vermiform appendix (ver'mi-fōrm) [L., *vermis*, worm + *forma*, form; appendage] Wormlike sac extending from the blind end of the cecum.

vesicle (ves'i-kl) [L., *vesica*, bladder] Small sac containing a liquid or gas, such as a blister in the skin or an intracellular, membrane-bounded sac.

vestibular fold (ves-tib'ū-lār) One of two folds of mucous membrane stretching across the laryngeal cavity from the angle of the thyroid cartilage to the arytenoid cartilage superior to the vocal cords; helps close the glottis; also called false vocal cord.

vestibular membrane Membrane separating the cochlear duct and the scala vestibuli.

vestibule (ves'ti-bool) [L., antechamber, entrance court] Anterior part of the nasal cavity just inside the external nares that is enclosed by cartilage; space between the lips and the alveolar processes and teeth; middle region of the inner ear containing the utricle and saccule; space behind the labia minora containing the openings of the vagina, urethra, and vestibular glands.

vestibulocochlear nerve (ves-tib'ū-lō-kok'lē-ār) Nerve formed by the cochlear and vestibular nerves; extends to the brain.

villus; pl. **villi** (vil'ūs, vil'tī) [L., shaggy hair (of beasts)] Projection of the mucous membrane of the intestine; leaf-shaped in the duodenum; becomes shorter, more finger-shaped, and sparser in the ileum.

visceral (vis'er-āl) Relating to the internal organs.

visceral pericardium (per'i-kar'dē-ūm) Serous membrane covering the surface of the heart; also called epicardium.

visceral peritoneum (per'i-tō-nē'ūm) [Gr., *periteino*, to stretch over] Layer of peritoneum covering the abdominal organs.

visceral pleura (vis'er-āl plūr'ā) Serous membrane investing the lungs and dipping into the fissures between the several lobes.

visceroreceptor (vis'er-ō-rē-sep'tōr) Sensory receptor associated with the organs.

viscosity (vis-kos'i-tē) [L., *viscosus*, viscous] Resistance to flow or alteration of shape by any substance as a result of molecular cohesion.

visual cortex (vizh'oo-āl) Area in the occipital lobe of the cerebral cortex that integrates visual information and produces the sensation of vision.

visual field Area of vision for each eye.

vital capacity (vīt-āl) Greatest volume of air that can be exhaled from the lungs after a maximum inspiration.

vitamin (vīt'ā-min) [L., *vita*, life + amine] One of a group of organic substances present in minute amounts in natural foodstuffs that are essential to normal metabolism; insufficient amounts in the diet may cause deficiency diseases.

vitamin D Fat-soluble vitamin produced from precursor molecules in skin exposed to ultraviolet light; increases calcium and phosphate uptake from the intestines.

vitreous humor (vit'rē-ūs) Transparent, jellylike material that fills the space between the lens and the retina.

Volkmann's canal Named for German surgeon Richard Volkmann (1830–1889). Canal in bone containing blood vessels; not surrounded by lamellae; runs perpendicular to the long axis of the bone and the haversian canals, interconnecting the latter with each other and the exterior circulation.

vulva (vül'vā) [L., wrapper or covering, seed covering, womb] External genitalia of the female, composed of the mons pubis, the labia majora and minora, the clitoris, the vestibule of the vagina and its glands, and the opening of the urethra and of the vagina. Also called pudendum.

W

water-soluble vitamin Vitamin, such as B complex and C, that is absorbed with water from the intestinal tract.

white matter Bundles of parallel axons with their associated sheath in the central nervous system.

white pulp Part of the spleen consisting of lymphatic nodules and diffuse lymphatic tissue; associated with arteries.

white ramus communicans; pl. **rami communicantes** (rā'mūs kō-mū'nī-kans, rā'mī kō-mū-nī kan'tēz) Connection between a spinal nerve

and a sympathetic chain ganglion through which myelinated preganglionic axons project.

wisdom tooth Third molar tooth on each side in each jaw.

X

xiphoid (zi'floyd) [Gr., *xiphos*, sword] Sword-shaped, with special reference to the sword tip; the inferior part of the sternum.

X-linked Gene located on an X chromosome.

Y

yellow marrow (mar'o) Connective tissue filling the cavities of bones; consists primarily of reticular fibers and fat cells; replaces red marrow in long bones and the skull.

Y-linked Gene located on a Y chromosome.

yolk sac (yōk, yōlk) Highly vascular layer surrounding the yolk of an embryo.

Z

Z disk Delicate, membranelike structure found at each end of a sarcomere to which actin myofilaments attach.

zona fasciculata (zō'nā fa-sik'ū-lā'tā) [L., *zone*, a girdle, one of the zones of the sphere] Middle layer of the adrenal cortex that secretes cortisol.

zona glomerulosa (glō-mār-ū-lōs-ā) Outer layer of the adrenal cortex that secretes aldosterone.

zona pellucida (pe-lū'sī-dā) Layer of viscous fluid surrounding the oocyte.

zona reticularis (rē-tik'ū-lar'is) Inner layer of the adrenal cortex that secretes androgens and estrogens.

zonula adherens (zō'nū-lā ad-her'enz) [L., a small zone; adhering] Small zone holding or adhering cells together.

zonula occludens (ō-klūd'enz) [L., occluding] Junction between cells in which the plasma membranes may be fused; occludes or blocks off the space between the cells.

zygomatic (zī-gō-mat'ik) [Gr., *zygon*, yoke] Yoking or joining; bony arch created by the junction of the zygomatic and temporal bones.

zygote (zī'gōt) [Gr., *zygotos*, yoked] Diploid cell resulting from the union of a sperm cell and an oocyte.

Index

Page numbers followed by *f* denote figures; those followed by *t* denote tables.

A

- A bands, 273, 274*f*
ABCDE rule, 147
Abdomen
 blood supply to, 733*f*, 734, 734*t*, 735*f*
 muscles of, 834, 836*f*
 veins from, 723–24*f*, 736, 743–47, 744–46*f*, 745*t*, 747*t*
 wall muscles of, 335–38, 336*t*, 337*f*
Abdominal aorta and branches, 732–34, 733*f*, 734*t*, 735*f*
Abdominal thrusts, 824
Abducens nerve, 452, 453*f*, 456*t*
Abduction, 251, 251*f*, 255, 258
Abductor digiti minimi, 349, 349*t*, 350*f*
Abductor pollicis brevis, 349, 350*f*
Abductor pollicis longus, 347*f*, 348
ABO blood group, 662–64, 663–64*f*
Abruptio placentae, 1084
Absolute refractory period, 383–84*f*, 384–86
Absorption
 digestive system and, 871*t*, 872, 893*f*, 908–9
 tissues and, 106, 111, 112*t*
Absorptive cells, 892, 893*f*
Absorptive state, 947, 948*f*
Abstinence, 1068
Acceptable Macronutrient Distribution Range (AMDR), 927, 929
Accessory glands, 1034*f*, 1040*f*, 1042–43
Accessory hemiazygos vein, 741, 741*f*, 743*t*, 744*f*
Accessory nerve, 453*f*, 458*t*, 459
Accommodation of lens, 520–21, 521*f*
Accutane, 1088
ACE. *See* Angiotensin-converting enzyme
ACE inhibitors, 983
Acetabular labrum, 258, 258*f*
Acetabulum of hipbone, 230, 231*f*, 232*f*, 234, 237, 237*f*, 258, 258*f*
Acetic acid, 282, 283*f*
Acetone, 944
Acetylcholine and acetylcholine esterase (Acetyl-CoA)
 digestive system and, 874
 metabolism and, 936*f*, 939, 941*f*, 943*f*
 muscles and, 276, 282, 283*f*, 285, 291
 nerve tissue and, 390, 390*f*
 special senses and, 564–65, 566*t*
Achilles tendon, 357, 359*f*
Acid-base balance, 1018–24
 acidosis and alkalosis, 1023–24, 1024*t*
 acids and bases, defined, 1018, 1018*f*
 buffer systems, 1019, 1019*t*
 overview, 1018, 1021*f*
 regulation of, 1019, 1020*f*
 renal regulation and, 1022–23, 1022–23*f*
 respiratory regulation and, 1021, 1021*f*
Acidic solutions, 39
Acidosis, 40, 299, 1023–24, 1024*t*
Acids, 39–40, 1018, 1018*f*
Acinar glands, 114*f*, 115, 879, 880*f*
Acini and acinar cells, 901, 902*f*
ACL (Anterior cruciate ligament), 259, 260–61*f*, 262, 262*f*
Acquired Immunodeficiency syndrome (AIDS), 809
Acromegaly, 610
Acromion process, 225, 226*f*
Acrosomal reaction, 1079
Acrosome, 1037, 1038*f*
ACTH (adrenocorticotrophic hormone), 148, 610–11, 623, 624*t*
Actin filaments, 78, 79*f*, 86, 96, 96*f*
Actin myofilaments, 272, 274–75, 274–75*f*, 284, 285*f*, 287, 300–301, 301–2*f*
Action potentials
 of cardiac muscle, 687–90, 689*f*
 cardiac muscle and, 685–91, 687*f*, 689*f*, 690*f*
 defined, 274, 367
 frequency of, 281–82, 384–85, 385*f*
 graded potentials and, 380–82, 380*f*, 381*t*
 muscular system and, 279–82, 280–83*f*
 myelin sheaths and, 371–74, 374*f*
 nerve tissue and, 369
 production of, 380–84, 381*f*, 382*t*, 383*f*
 propagation of, 280, 282*f*, 385–87, 386–87*f*
 smooth muscle and, 303
Activation energy, 37, 37*f*, 48, 291
Activation gates, 382, 383*f*
Active artificial immunity, 810, 810*f*
Active immunity, 808, 810*f*
Active membrane transport, 75–77, 75–78*f*
Active natural immunity, 810, 810*f*
Active range of motion, 253
Active sites of enzymes, 48, 50*f*
Active tension, 291, 292, 292*f*
Active tension curve, 291, 292, 292*f*
Active transport, 85
Active ventricular filling, 695*f*, 696–97*t*, 699
Acute rejection of transplant, 800
Acute renal failure, 994–95, 994*f*
Adam's apple, 826, 826*f*
Adaption to stimuli, 471
Adaptive immune responses, 809
Adaptive immunity, 788–89, 791
Adduction, 251, 251*f*, 255, 258
Adductor tubercle, 234, 234*f*
Adenine-thymine base pairs, 51, 51–52*f*, 89, 91*f*
Adenine-uracil base pairs, 51, 51*f*, 89, 91*f*
Adenoids, 784, 785*f*
Adenosine triphosphate. *See* ATP (adenosine triphosphate)
Adenylate cyclase, 591–92, 592*f*
ADH, 58, 98
Adhesion, 38
Adhesion belts, 113, 113*f*
Adhesive molecules, 117
Adipocytes, 116, 149
Adipose tissues, 116, 119, 120*t*, 149, 943
Adolescence, 1079
ADP (adenosine diphosphate), 298, 300*t*, 934, 935*f*
Adrenal cortex, 610–11, 621–22*t*, 621–23, 623*f*, 624*t*
Adrenal glands
 autonomic nervous system and, 557*f*, 558
 blood supply to, 733*f*, 734, 734*t*, 735*f*
 cortex of, 610–11, 621–22*t*, 621–23, 623*f*, 624*t*
 diseases and disorders of, 624*t*, 626
 medulla of, 618–21, 621*t*, 622*f*
 overview, 618, 620*f*
 tissues of, 104
Adrenaline. *See* Epinephrine
Adrenal medulla
 endocrine system and, 618–21, 621*t*, 622*f*
 mean arterial pressure and, 765–66*f*, 766
Adrenergic neuron, 564
Adrenergic receptors, 565–68, 565*f*, 566*t*, 567
Adrenocorticotrophic hormone (ACTH), 148, 610–11, 623, 624*t*
Adult, 1079
Adult connective tissue, 117*t*, 119
Adult stem cells, 116
Advance glycosylation end products, 983
Aerobic exercise. *See* Exercise
Aerobic respiration, 294–97, 298*f*, 299–300, 300*t*, 936*f*, 939–43, 939*t*, 940–42*f*
Afferent arteriole, 963, 964*f*
Afferent division of PNS, 367, 367–68*f*
Afferent lymphatic vessels, 784
Afferent neurons. *See* Sensory neurons
After-discharge, 398–99, 398*f*
Afterpotentials, 381–84, 381*f*, 383*f*
Age spots, 160
Aging
 arteries and, 725
 of blood vessels, 1109
 bone and bone tissue and, 187–90
 cardiovascular system and, 712–13, 1109
 cells and, 96
 central nervous system (CNS) and, 1109
 development and, 1109–10
 digestive system and, 915–17

- endocrine system and, 638
 heart and, 712–13
 immunity and, 817
 integumentary system and, 147, 160, 160*f*
 joints and, 263–65, 264*t*
 muscular system and, 307
 nervous system and, 496–97
 reproductive system and, 1067–72
 respiratory system and, 860, 864
 special senses and, 546–48
 tissues and, 135
 urinary system and, 993
 Agonists, 314, 586–87
 AIDS, 809
 Airflow, 824, 862–63, 862*f*
 Airway, 862–63, 862*f*
 Alae, 222, 223*f*
 Albinism, 146, 522, 1111–12, 1112*f*, 1116–17, 1116*f*
 Albumin, 645, 646*f*, 647*t*
 Alcohol, 985
 Aldosterone
 cardiovascular system and, 767–70, 769*f*
 electrolytes and, 1013*f*, 1014
 endocrine system and, 621–22
 urinary system and, 982, 982*f*
 Alimentary canal. *See* Digestive tract
 Alimentary tract. *See* Digestive tract
 Alkaline solutions, 39
 Alkaline tide, 886
 Alkalosis, 40, 1023–24, 1024*t*
 Allantois, 1089*f*, 1094
 Alleles, 1111–13, 1113*f*
 Allelic variant, 1114
 Allergic reactions, 150, 795, 796, 862–63, 862*f*
 All-or-none principle, 280, 280*f*, 382
 Alpha-linolenic acid, 929
 Alpha motor neurons, 409, 410*f*
 Alpha waves, 490, 492*f*
 ALS (Amyotrophic lateral sclerosis), 483
 Alternative pathway, 791, 791*f*
 Alternative splicing, 90
 Alveolar ducts, 830, 832*f*
 Alveolar glands, 114*f*, 115
 Alveolar nerves, 452
 Alveolar processes, 206, 206*t*
 Alveolar sacs, 830, 832*f*
 Alveolar ventilation, 845, 847–48, 859
 Alveolar volume, 840–43, 843*f*
 Alveoli
 of breasts, 1055–56, 1056*f*
 of lungs, 111, 112*t*, 830–32, 832*f*, 834*f*
 of teeth, 877*f*, 879
 Alzheimer disease, 496
 Amacrine cells, 522*f*, 530
 Amenorrhea, 1062
 Amino acids, 47, 47*t*, 929
 Amniotic cavity, 1084, 1085*f*
 Amorphosynthesis, 491
 Amplitude-modulated signals, 578, 578*f*
 Ampulla, 1039, 1040*f*, 1049*f*, 1052
 Amygdala, 445, 446*f*, 493, 508, 508*f*
 Amyloid plaques, 496
 Amyotrophic lateral sclerosis (ALS), 483
 Anabolic steroids, 296, 1045
 Anabolism, 34, 51, 934
 Anaerobic exercise. *See* exercise
 Anaerobic glycolysis, 936–38, 939*f*
 Anaerobic respiration, 294–97, 298*f*, 299–300, 300*t*
 Anal canal, 904*f*, 905–7
 Analgesics, 476
 Anal sphincter, 904*f*, 907
 Anal triangle, 1033, 1040*f*
 Anaphase of mitosis, 96, 97*f*
 Anastomoses, 680, 680*f*
 Anatomical crown, 878, 879*f*
 Anatomical dead space, 845
 Anatomical imaging, types of, 2, 3*t*
 Anatomical neck of humerus, 226, 227*f*
 Anatomical shunt, 845, 847–48
 Anatomical snuff box, 347*f*, 348
 Anatomy, study of, 2
 Androgen, 1044–45
 Androgen-binding protein, 1037
 Androgens, 623
 Anemia
 cells and, 98
 genetics, 1115
 integumentary system and, 150
 sickle-cell disease, 104
 Anencephaly, 1094
 Anergy, 802
 Anesthesia, 453
 Aneuploidy, 1119
 Aneurysms, 724, 752
 Angina, 688
 Angiotensin-converting enzyme (ACE) inhibitors, 983
 Angiotensin I and II
 body fluids and, 1003, 1004*f*
 circulation and, 767–70, 769*f*
 urinary system and, 981–82, 982*f*
 Angiotensinogen, 981, 982*f*
 Angular movement, 250–51, 250–51*f*
 ANH (Atrial natriuretic hormone), 987, 1005*f*,
 1006–8, 1007*f*
 Animals, 9
 Anions, 29, 32
 Anisotropic (A) bands, 273, 274*f*
 Ankle
 joint, 259, 263, 263*f*, 263*t*
 movement of, 253, 253*f*
 skeletal muscle and, 356–57, 356*t*, 357–60*f*, 360*t*
 Annular ligament, 532*f*, 533
 Annulus fibrosus, 217, 217*f*
 Anomalies, anatomical, 2
 Anomic aphasia, 489
 ANS. *See* Autonomic nervous system
 Ansa cervicalis, 418, 418*f*
 Antacids, 889, 890
 Antagonists, 314, 586–87
 Anterior and medial nuclei of thalamus, 441, 441*f*
 Anterior cerebral artery, 451, 728*f*, 729, 730*f*
 Anterior compartment of leg, 351, 354*t*
 Anterior corticospinal tract, 481, 484*f*
 Anterior cranial fossa, 204, 205*f*
 Anterior crest of tibia, 235, 235*f*
 Anterior cruciate ligament (ACL), 259, 260–61*f*,
 262, 262*f*
 Anterior horn, 407, 407*f*
 Anterior intercostal artery, 732, 733*f*, 734*t*
 Anterior intercostal vein, 741, 741*f*, 743*t*, 744*f*
 Anterior interventricular sulcus, 678, 678–79*f*
 Anterior leg muscles, 356, 358*f*
 Anterior median fissure, 407, 407*f*
 Anterior pituitary, 1045
 Anterior pituitary hormones, 604*t*, 607–9, 609*f*
 Anterior spinocerebellar tract, 474
 Anterior superior iliac spine, 231, 233*f*
 Anterior thigh muscles, 354*t*, 355
 Anterior tibial artery, 734, 736–37*f*, 737*t*
 Anterior tibial vein, 747, 747*t*, 748–49*f*
 Anterior triangle, 1033, 1040*f*
 Anterograde movement, 369
 Anterolateral system, 471–72, 472*t*, 473–74*f*
 Antibiotics, 186, 889, 905
 Antibodies
 bone and, 189
 effect of, 791*f*, 804, 806*f*
 immunity and, 795
 production of, 804–5, 807*f*
 structure of, 804, 804*t*, 805*f*
 Antibody-mediated immunity, 795
 Anticoagulants, 661
 Anticodons, 91, 93*f*
 Antidiuretic hormone (ADH), 605–6, 607*f*, 983–85,
 984*f*, 1003–8, 1005–7*f*
 Antidiuretic hormone mechanism, 770, 770*f*
 Antigen determinants, 796, 796*f*
 Antigen-presenting cells, 798, 799*f*
 Antigen receptors, 796
 Antigens, 795
 Anti-inflammatory medications, 45
 Anti-inflammatory response. *See* Inflammation
 Antioxidants, 930
 Antiparallel strands, of DNA, 51, 52*f*
 Antithrombin, 661
 Antrum, 1050*f*, 1052
 Anus, 111, 112*t*, 904*f*, 907
 Aorta
 abdominal, 732–34, 733*f*, 734*t*, 735*f*
 ascending, 726, 733*f*
 circulatory system and, 678, 678–79*f*
 thoracic, 732, 733*f*, 734*t*
 Aortic arch reflex, 763, 764*f*
 Aortic pressure curve, 698*f*, 700
 Apgar score, 1104–5, 1107*t*
 Aphasia, 489
 Apical ectodermal ridge, 1088, 1090*f*
 Apical foramen, 879, 879*f*
 Apical membrane, 909, 971, 973*f*
 Apical surfaces, 105, 111–12
 Apnea, 856
 Apocrine glands and apocrine secretion, 115, 115*f*
 Apocrine sweat glands, 152*f*, 153
Apolipo-protein E gene, 496
 Aponeuroses, 314
 Apoptosis, 96, 98
 Appendicitis, 904
 Appendicular skeleton
 joints of, 246, 249*f*
 lower limb, 230–31*f*, 232–38, 233–38*f*
 pectoral girdle, 217*f*, 224–26*f*, 225–26
 pelvic girdle, 230–32, 230–33*f*, 233*t*
 upper limb, 224–25*f*, 226–29, 227–29*f*
 Appendix, 904, 904*f*

 Volkmann's canals. *See* Perforating canals
 Voltage-gated ion channels
 of cardiac muscle, 688, 690
 cells and, 65, 66*f*
 muscular system and, 278
 nerve tissue and, 376, 382, 383*f*
 Volume
 of body fluids, 1005–8, 1005*f*, 1007–8*f*
 respiratory system and, 830–40, 839*t*, 841*f*, 844, 844*f*
 Voluntary movements, 479
 Vomer, 205, 207*f*
 Vomiting, 891
 von Willebrand factor (vWF), 657, 657*f*
 Vulva, 1054, 1055
W
 Warm receptor, 468
 Warren, Robin, 889
 Waste removal, 71, 171
 Water
 body fluid regulation and, 1003–4, 1003–4*t*, 1004*f*
 chemical reactions and, 34–35, 34*f*
 digestive system and, 914, 915*f*
 facilitated diffusion and, 74
 homeostasis and, 38, 98
 lipids and, 44–45, 44*f*
 membrane lipids and, 63
 molecules of, 30–32, 30*f*, 33*f*
 osmosis and, 70*t*, 72–73, 73–74*f*
 peptide bonds and, 48, 48*f*
 properties of, in human body, 38
 solutions and, 39–40
 Water channel proteins, 72
 Water loss, 155
 Water-soluble hormones, 580–82, 581*t*
 Water-soluble vitamins, 930
 Water vapor pressure, 839*t*, 846
 Watson, James, 1112
 Waves of movement, 890, 891*f*
 WBC (White blood count), 668
 Weak acid, 1018, 1018*t*
 Weak base, 1018, 1018*t*
 Weight, 26
 Weightlifting, 291, 295, 307, 361, 361*f*
 Wernicke aphasia, 489
 Wernicke area, 478*f*, 489
 Wharton's jelly. *See* Mucous connective tissue
 Whiplash, 218–20
 White blood cells
 as blood cell, 646*f*, 648*t*, 655–56, 655*t*
 cells and, 76, 76*f*, 83
 tissues and, 116, 125, 126*t*
 White blood count (WBC), 668
 White commissures, 407–8, 407*f*
 White matter, 374, 443*f*, 444
 White pulp, 785, 786*f*
 White ramus communicans, 556, 557*f*
 Whooping cough, 831
 Windpipe. *See* Trachea
 Wisdom teeth, 878, 878*f*
 Withdrawal method, 1068
 Withdrawal reflex, 411–13, 412–13*f*

Wolffian ducts, 1096
Women. *See* Female reproductive system; Females
Working memory, 491
Woven bone, 170, 174–76, 183, 183*f*; 184–85
Wrinkles, 160
Wrist, 228–29, 229*f*
Wrists, 230, 230*f*

X

Xanthines, 985
Xanthomas, 914
X chromosomes, 1113, 1115
Xeroderma pigmentosum, 147–48

Xiphoid process, 224–25, 224*f*
X-linked traits, 529, 1115
X-rays, 2, 31, 406

Y

Y chromosomes, 1113, 1115
Yellow adipose tissue, 119, 120*t*
Yellow marrow, 125, 126*t*, 172–74, 173, 647
Y-linked traits, 1115
Yolk sac, 1084, 1085*f*

Z

Z disks, 272–74, 273–75*f*

Zoledronic acid, 189
Zona pellucida, 1050–52, 1051*f*, 1079
Zone of hypertrophy, 178
Zone of proliferation, 178
Zone of resting cartilage, 178
Zones of calcification, 178
ZP3 glycoprotein, 1079, 1080
Zygomatic arch, 199–200, 200*f*
Zygomatic bone, 199, 200*f*
Zygomaticus major and muscle, 320, 324–25*f*
Zygote, 1050, 1051*f*, 1080, 1081*f*
Zymogen granules, 886
Zymogenic cells, 885*f*, 886
