ABOUT THE Authors

Cinnamon L. VanPutte

*Professor of Biology
Southwestern Illinois College*

Cinnamon has been teaching biology and human anatomy and physiology since 1998. She is a member of the faculty at Southwestern Illinois College and is an active member of several professional societies, including the Human Anatomy & Physiology Society (HAPS). Her Ph.D. in zoology, with an emphasis in endocrinology, is from Texas A&M University. She worked in Dr. Duncan MacKenzie's lab, where she was indoctrinated in the major principles of physiology and the importance of critical thinking. The critical thinking component of the Seeley titles epitomizes Cinnamon's passion for the field of human anatomy and physiology; she is committed to maintaining this tradition of excellence. Cinnamon and her husband, Robb, have two children: a daughter, Savannah, and a son, Ethan. She and her family, including her parents, Tom and Bobbie Moore, live on a farm where they raise Simmental cattle, Suffolk sheep, and a flock of 20 chickens.

Jennifer L. Regan

*Instructor
University of Southern Mississippi*

For over 15 years, Jennifer has taught introductory biology, human anatomy and physiology, and genetics at the university and community college level. She has received the Instructor of the Year Award at both the departmental and college level while teaching at USM. In addition, she has been recognized for her dedication to teaching by student organizations such as the Alliance for Graduate Education in Mississippi and Increasing Minority Access to Graduate Education. Jennifer has dedicated much of her career to improving lecture and laboratory instruction at her institutions. Critical thinking and lifelong learning are two characteristics Jennifer hopes to instill in her students. She appreciates the Seeley approach to learning and is excited about contributing to further development of the textbook. She received her Ph.D. in biology at the University of Houston, under the direction of Edwin H. Bryant and Lisa M. Meffert. She is an active member of several professional organizations, including the Human Anatomy and Physiology Society. During her free time, Jennifer enjoys spending time with her husband, Hobbie, and two sons, Patrick and Nicholas.

Andrew F. Russo

*Professor of Molecular
Physiology and Biophysics
University of Iowa*

Andrew has over 20 years of classroom experience with human physiology, neurobiology, molecular biology, and cell biology courses at the University of Iowa. He is a recipient of the Collegiate Teaching Award and the J.P. Long Teaching Award in Basic Sciences. He is currently the course director for a new medical school course called Mechanisms of Health and Disease that integrates physiology, histology, and genetics. He is a member of several professional societies, including the Society for Neuroscience. Andrew received his Ph.D. in biochemistry from the University of California at Berkeley. His research interests are focused on the molecular basis of migraine. His decision to join the author team for *Seeley's Human Anatomy & Physiology* is the culmination of a passion for teaching that began in graduate school. He is excited about the opportunity to hook students' interest in learning by presenting cutting-edge clinical and scientific advances. Andy is married to Maureen, a physical therapist, and has three daughters, Eri Lynn, Becky, and Colleen, and three grandchildren. He enjoys all types of outdoor sports, especially bicycling, skiing, running, and open water swimming.

This text is dedicated to the students of human anatomy and physiology. Helping students develop a working knowledge of anatomy and physiology is a satisfying challenge, and we have a great appreciation for the effort and enthusiasm of so many who want to know more. It is difficult to imagine anything more exciting, or more important, than being involved in the process of helping people learn about the subject we love so much.

Brief Contents

PART 1

Organization of the Human Body

- 1 The Human Organism 1
- 2 The Chemical Basis of Life 25
- 3 Cell Biology 58
- 4 Tissues 103

PART 2

Support and Movement

- 5 Integumentary System 141
- 6 Skeletal System: Bones and Bone Tissue 165
- 7 Skeletal System: Gross Anatomy 194
- 8 Joints and Movement 242
- 9 Muscular System: Histology and Physiology 268
- 10 Muscular System: Gross Anatomy 313

PART 3

Integration and Control Systems

- 11 Functional Organization of Nervous Tissue 365
- 12 Spinal Cord and Spinal Nerves 404
- 13 Brain and Cranial Nerves 433
- 14 Integration of Nervous System Functions 465
- 15 The Special Senses 505
- 16 Autonomic Nervous System 553
- 17 Functional Organization of the Endocrine System 575
- 18 Endocrine Glands 600

PART 4

Regulation and Maintenance

- 19 Cardiovascular System: Blood 644
- 20 Cardiovascular System: The Heart 673
- 21 Cardiovascular System: Blood Vessels and Circulation 718
- 22 Lymphatic System and Immunity 779
- 23 Respiratory System 822
- 24 Digestive System 869
- 25 Nutrition, Metabolism, and Temperature Regulation 924
- 26 Urinary System 958
- 27 Water, Electrolyte, and Acid-Base Balance 1001

PART 5

Reproduction and Development

- 28 Reproductive System 1029
- 29 Development, Growth, Aging, and Genetics 1078

Appendices

- A** Periodic Table of the Elements A-1
- B** Selected Abbreviations A-2
- B-1** Scientific Notation A-5
- C** Solution Concentrations A-6
- D** pH A-7
- E** Answers to Review and Comprehension Questions A-8
- F** Answers to Critical Thinking Questions A-9
- G** Answers to Predict Questions A-26

MCGRAW-HILL EDUCATION TEACHING AND Learning Tools

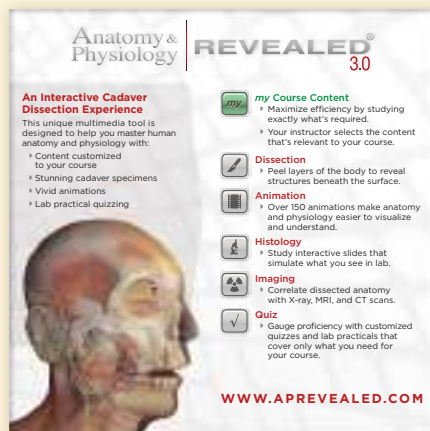

McGraw-Hill Education A&P: We have learning down to a science!

At McGraw-Hill Education we work every day to unlock the full potential of each learner. Our mission is to accelerate learning through intuitive, engaging, efficient and effective experiences—grounded in research. MHE Anatomy & Physiology is your trusted, data-driven partner in A&P education. Since 2009, our adaptive programs in A&P have hosted 600,000 unique users who have answered more than 600 million probes, giving us the only data-driven solutions to help your students get from their first college-level course to program readiness.

LearnSmart® Prep is an adaptive learning tool that prepares students for college level work in Anatomy & Physiology. Prep for Anatomy & Physiology now comes standard to students with Connect. The tool individually identifies concepts the student doesn't fully understand and provides learning resources to teach essential concepts so he or she enters the classroom prepared. Data driven reports highlight areas where students are struggling, helping to accurately identify weak areas.

Concept Overview Interactive modules have assessable, auto graded learning activities in Connect®, can be used as a self study tool for students and are also provided separately to instructors as classroom presentation tools.

Anatomy & Physiology Revealed® is now available in Cat and Fetal Pig versions!

Physiology Interactive Lab Simulations (Ph.I.L.S.) 4.0

Ph.I.L.S. 4.0 is the perfect way to reinforce key physiology concepts with powerful lab experiments. Created by Dr. Phil Stephens at Villanova University, this program offers **42 laboratory simulations** that may be used to supplement or substitute for wet labs. All 42 labs are self-contained experiments—no lengthy instruction manual required. Users

can adjust variables, view outcomes, make predictions, draw conclusions, and print lab reports. This easy-to-use software offers the flexibility to change the parameters of the lab experiment. There are no limits!

Laboratory Manual

The Laboratory Manual to accompany *Seeley's Anatomy & Physiology*, authored by Eric Wise of Santa Barbara City College, contains 43 laboratory exercises that are integrated closely with the textbook. Each exercise demonstrates the anatomical and physiological facts and principles presented in the textbook by investigating specific

concepts in greater detail. Key features of the lab manual include over 12 new cat dissection photos and many new human cadaver images, step-by-step explanations and a complete materials list for each experiment, precisely labeled, full-color drawings and photographs, self-contained presentations with the essentials background needed to complete each exercise, and extensive lab reports at the end of every exercise.

connect[®]

Required=Results

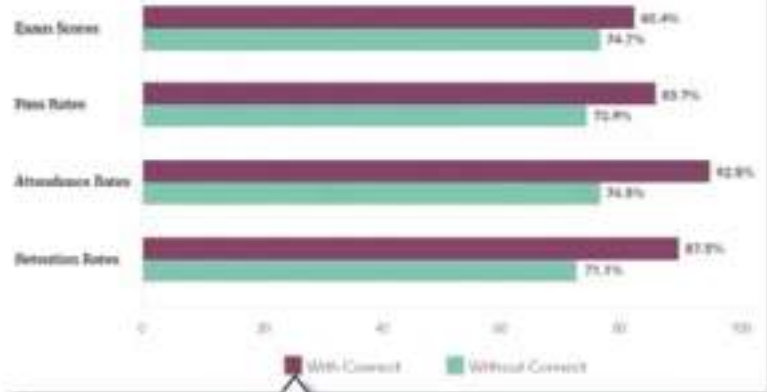

McGraw-Hill Connect[®] Learn Without Limits

Connect is a teaching and learning platform that is proven to deliver better results for students and instructors.

Connect empowers students by continually adapting to deliver precisely what they need, when they need it, and how they need it, so your class time is more engaging and effective.

Course outcomes improve with Connect.

Using Connect improves passing rates by 10.8% and retention by 16.4%.

88% of instructors who use **Connect** require it; instructor satisfaction increases by 38% when **Connect** is required.

Analytics

Connect Insight[®]

Connect Insight is Connect's new one-of-a-kind visual analytics dashboard—now available for both instructors and students—that provides at-a-glance information regarding student performance, which is immediately actionable. By presenting assignment, assessment, and topical performance results together with a time metric that is easily visible for aggregate or individual results, Connect Insight gives the user the ability to take a just-in-time approach to teaching and learning, which was never before available. Connect Insight presents data that empowers students and helps instructors improve class performance in a way that is efficient and effective.

Connect helps students achieve better grades

Students can view their results for any **Connect** course.

Mobile

Connect's new, intuitive mobile interface gives students and instructors flexible and convenient, anytime-anywhere access to all components of the Connect platform.

Adaptive

More students earn **A's** and **B's** when they use McGraw-Hill Education **Adaptive** products.

SmartBook®

Proven to help students improve grades and study more efficiently, SmartBook contains the same content within the print book, but actively tailors that content to the needs of the individual. SmartBook's adaptive technology provides precise, personalized instruction on what the student should do next, guiding the student to master and remember key concepts, targeting gaps in knowledge and offering customized feedback, and driving the student toward comprehension and retention of the subject matter. Available on smartphones and tablets, SmartBook puts learning at the student's fingertips—anywhere, anytime.

Over **4 billion** questions have been answered, making McGraw-Hill Education products more intelligent, reliable, and precise.

www.learnsmartadvantage.com

THE FIRST AND ONLY
**ADAPTIVE READING
EXPERIENCE** DESIGNED
TO TRANSFORM THE
WAY STUDENTS READ

STUDENTS WANT

SMARTBOOK®

of students reported **SmartBook** to be a more effective way of reading material

of students want to use the **Practice Quiz** feature available within **SmartBook** to help them study

of students reported having reliable access to off-campus wifi

of students say they would purchase **SmartBook** over print alone

reported that **SmartBook** would impact their study skills in a positive way

WHAT SETS Seeley APART?

Seeley's Anatomy & Physiology is written for the two-semester anatomy and physiology course. The writing is comprehensive enough to provide the depth necessary for those courses not requiring prerequisites, and yet is presented with such clarity that it nicely balances the thorough coverage. Clear descriptions and exceptional illustrations combine to help students develop a firm understanding of the concepts of anatomy and physiology and to teach them how to use that information.

What Makes this Text a Market Leader?

Seeley Learning System—*Emphasis on Critical Thinking*

An emphasis on critical thinking is integrated throughout this textbook. This approach can be found in questions starting each chapter and embedded within the narrative; in clinical material that is designed to bridge concepts explained in the text with real-life applications and scenarios; in end-of-chapter questions that go beyond rote memorization; and in a visual program that presents material in understandable, relevant images.

- ▶ Problem-solving perspective from the book's inception
- ▶ Pedagogy builds student comprehension from knowledge to application (Predict questions, Critical Thinking questions, and Learn To Predict Answer)

Predict Questions challenge students to use their understanding of new concepts to solve a problem. Answers to the questions are provided at the end of the book, allowing students to evaluate their responses and to understand the logic used to arrive at the correct answer. All Predict question answers have been rewritten in teaching style format to model the answer for the student. Helps students learn how to think critically.

CRITICAL THINKING

- How would body function be affected if the neural synchondrosis and the osteocostal synchondrosis of the first rib were to become synostosis?
- Using an articulated skeleton, describe the type of joint and the movements possible for each of the following joints:
 - joint between the zygomatic bone and the maxilla
 - ligamentous connection between the tibia and the femur
 - elbow joint
- For each of the following areas, describe the motion(s) produced when the muscle contracts. It may be helpful to use an articulated skeleton.
 - The biceps brachii muscle attaches to the coronoid process of the scapula (near head) and to the radial tuberosity of the radius. Name two movements that the arm can accomplish in the forearm.
 - The rectus femoris muscle attaches to the anterior inferior iliac spine and the tibial tuberosity. How does contraction move the right thigh?
 - The supraspinatus muscle is located in and attached to the supraspinatus fossa of the scapula. Its tendon runs over the head of the humerus to the greater tubercle. When it contracts, what movements occur at the glenohumeral (shoulder) joint?
- The gastrocnemius muscle attaches to the medial and lateral condyles of the tibia and to the calcaneus. What movement of the leg results when this muscle contracts? Of the foot?
- At five, Dominic's wife accused her once active 25-year-old husband of trying to get out of his work by constantly complaining about pain and stiffness in his lower back. But over the next 2 months, the pain and stiffness increased and seemed to be spreading up his vertebral column. The family doctor referred Dominic to a rheumatologist, who diagnosed polyosteoarthritis (AO), AS, a chronic inflammation of joints at points where ligaments, tendons, and joint capsules meet one bone, across fibrous (the development of new tissue), osteoarthrosis, and fusion of joints. Careless from knowledge about bone growth, repair, and anatomy (osteoclasts, R and T) and also reaction and function from this chapter to identify the category of joint primarily affected by AS, and explain how chronic inflammation of Dominic's joints led to this illness.

Answers to questions 7

Predict 4

What combination of movements at the shoulder and elbow joints allows a person to move the right upper limb from the anatomical position to touch the right side of the head with the fingertips?

Critical Thinking These innovative exercises encourage students to apply chapter concepts to solve a problem. These questions help build student's knowledge of anatomy & physiology while developing reasoning and critical thinking skills.

Exceptional Art—Always created from the student perspective

A picture is worth a thousand words—especially when you’re learning anatomy and physiology. Because words alone cannot convey the nuances of anatomy or the intricacies of physiology, *Seeley’s Anatomy & Physiology* employs a dynamic program of full-color illustrations and photographs that support and further clarify the textual explanations:

- ▶ Fundamental figures teamed with special online support and now linked to APR
- ▶ Homeostasis figures were revised to draw a correlation from the text description of feedback system components to the figure. Maintains consistency throughout each organ system
- ▶ All figures were visually linked to create consistency throughout the text. The same colors are always used for the same type of arrow, cytoplasm in a cell, symbols for ions, and molecules, etc.
- ▶ Step-by-step process figures
- ▶ Atlas-quality cadaver images
- ▶ Illustrated tables
- ▶ Photos side-by-side with illustrations
- ▶ Color saturation of art makes the art more engaging
- ▶ Macro-to-micro art

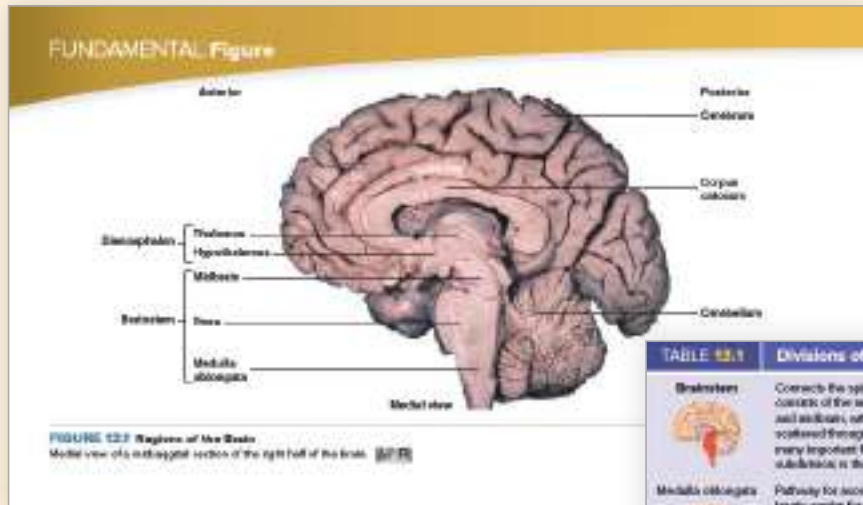

TABLE 33.1 Divisions of the Brain and Their Functions	
Brainstem	Connects the spinal cord to the cerebrum; consists of the midbrain, pons, and medulla, with the reticular formation scattered throughout the three regions; has many important functions, as listed under each subdivision; is the location of cranial nerve nuclei
Midbrain	Contains ascending and descending nerve tracts; serves as visual reflex center; part of auditory pathway
Pons	Contains ascending and descending nerve tracts; relays information between cerebrum and cerebellum; site of reflex centers
Medulla oblongata	Pathway for ascending and descending nerve tracts; center for several important reflexes (e.g., heart rate, breathing, swallowing, vomiting)
Reticular formation	Scattered throughout brainstem; controls many brainstem activities, including motor control, pain perception, rhythmic contractions, and the sleep-wake cycle
Cerebellum	Controls muscle movement and fine-tunes balance; regulates extent of lateral movement; involved in learning motor skills
Diencephalon	Connects the brainstem to the cerebrum; has many relay and homeostatic functions, as listed under each subdivision
Thalamus	Major sensory relay center; influences mood and movement
Subthalamus	Contains nerve tracts and nuclei
Epilethalamus	Contains nuclei responding to olfactory stimulation and contains pineal gland
Hypothalamus	Major control center for maintaining homeostasis and regulating endocrine function
Caudate	Controls conscious perception, thought, and conscious motor activity; can override most other systems
Basal nuclei	Controls muscle activity and posture; largely striated, subcortical movement while at rest
Limbic system	Afferent response to smell, emotion, mood, memory, and other such functions

Clearly labeled photos of dissected human cadavers provide detailed views of anatomical structures, capturing the intangible characteristics of actual human anatomy that can be appreciated only when viewed in human specimens.

Learn to Predict and Learn to Predict Answer— Helping students learn how to think

- ▶ Part of the overall critical thinking Predict questions that appear throughout each chapter, a special Learn to Predict question now opens every chapter. This specifically written scenario takes knowledge acquired from previous chapters and ties it into content in the current chapter.

Learn to Predict

While weight training, Pedro strained his back and damaged a vertebral disk. The bulged disk placed pressure on the left side of the spinal cord, compressing the third lumbar spinal nerve, which innervates the following muscles: psoas major, iliacus, pectineus, sartorius, vastus lateralis, vastus medius, vastus intermedius, and rectus femoris. As a result, action potential conduction to these muscles was reduced.

Using your new knowledge about the histology and physiology of the muscular system from chapter 9 and combining it with the information about gross muscle anatomy in this chapter, predict Pedro's symptoms and which movements of his lower limb were affected, other than walking on a flat surface. What types of daily tasks would be difficult for Pedro to perform?

Photo: The man in this photo has clearly defined muscles. Which muscles can you identify?

Answer

Learn to Predict ◀ From page 313

The description of Pedro's injury provided specific information about the regions of the body affected: the left hip and thigh. In addition, we are told that the injury affected action potential conduction to the muscles of these regions. These facts will help us determine Pedro's symptoms and predict the movements that may be affected by his injury.

Chapter 9 described the relationship between action potential conduction and the force of muscle contractions. The reduction in action potential conduction to the muscles of the hip and thigh reduced the stimulation of these muscles, reducing the contraction force. As a result of his injury, we can predict that Pedro experienced weakness in his left hip and thigh, limiting his activity level.

We read in this chapter that the muscles affected by Pedro's injury (psoas major, iliacus, pectineus, sartorius, vastus lateralis, vastus medius, vastus intermedius, and rectus femoris) are involved in flexing the hip, the knee, or both. Therefore, we can conclude that movements involving hip and knee flexion, such as walking up and down stairs, would be affected. Any tasks that require Pedro to walk up and down stairs would be more difficult for him. Sitting and standing may also be affected, but the weakness in Pedro's left hip and thigh may be compensated for by increased muscle strength on his right side.

Answers to the rest of this chapter's Predict questions are in appendix G.

- ▶ The Learn to Predict Answer box at the end of each chapter teaches students step-by-step how to answer the chapter-opening critical thinking question. This is foundational to real learning and is a crucial part of helping students put facts together to reach that “aha” moment of true comprehension.

ELEVENTH EDITION

Changes

What's New and Improved?

The eleventh edition of *Seeley's Anatomy & Physiology* is the result of extensive analysis of the text. The outcome is a retention of the beloved features that foster student understanding with an emphasis on a sharper focus within many sections, affording an even more logical flow within the text. Throughout every chapter the writing style is clean and more accessible to students.

Learning Outcomes and Assessment—Helping instructors track student progress

- ▶ **UPDATED!** Learning Outcomes are carefully written and labeled to outline expectations for each section
- ▶ **UPDATED!** Online student questions and test bank questions are correlated with Learning Outcomes to further scaffold and measure student progress and understanding
- ▶ **NEW!** Microbes In Your Body feature discussing the many important, and sometimes little known, roles of microbes and the physiology of homeostasis
- ▶ **UPDATED!** The Clinical Genetics feature has been updated and streamlined to provide the newest and most accurate information available
- ▶ **NEW!** Online clinical study questions are based from clinical features within the text including Microbes in your Body and System Pathologies, and are correlated with Learning Outcomes and HAPS Learning Objectives to further develop and measure higher level thinking and application of learned content
- ▶ **NEW!** LearnSmart Based questions help further correlate and emphasize related content and scaffold learning.

5.2 Skin

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the structure and function of the epidermis.
- Discuss the epidermal strata and relate them to the process of keratinization.

ASSESS YOUR PROGRESS

- Compared with young skin, why is aged skin more likely to be damaged, wrinkled, and dry?
- Why is heat potentially dangerous to the elderly?
- Explain what causes age spots and white hair.
- What effect does exposure to sunlight have on skin?

Clinical GENETICS Skin Cancer

Skin cancer is the most common type of cancer. Most skin cancers result from damage caused by the ultraviolet (UV) radiation in sunlight. Some skin cancers are induced by chemicals, x-rays, depression of the immune system, or inflammation, whereas others are inherited.

UV radiation damages the genes (DNA) in epidermal cells, producing mutations. If a mutation is not repaired, the mutation is passed to one of the two daughter cells when a cell divides by mitosis. If mutations affecting oncogenes and tumor suppressor genes in epidermal cells accumulate, uncontrolled cell division and skin cancer can result (see Clinical Genetics, "Genetic Changes in Cancer Cells," in chapter 3).

The amount of protective melanin in the skin affects the likelihood of developing skin cancer. Fair-skinned individuals, who have less melanin, are at an increased risk of developing skin cancer compared with dark-skinned individuals, who have more melanin. Long-term or intense exposure to UV radiation also increases the risk. Thus, individuals who are older than 50, who have engaged in repeated recreational or occupational exposure to the sun, or who have experienced sunburn are at increased risk. Most skin cancers develop on the parts of the body that are frequently exposed to sunlight, such as the face, neck, ears, and dorsum of the forearm and hand. A physician should be consulted if skin cancer is suspected.

There are three types of skin cancer: basal cell carcinoma, squamous cell carcinoma, and melanoma (figure 5A). Basal cell carcinoma, the most common type, affects cells in the stratum basale. Basal cell carcinomas have a varied appearance. Some are open sores that bleed, ooze, or crust for several weeks. Others are reddish patches; shiny, pearly, or translucent bumps; or scarlike areas of shiny, taut skin. Removal or destruction of the tumor cures most cases.

Squamous cell carcinoma is the second most common type of skin cancer. Squamous cell carcinoma affects cells in the stratum spinosum and can appear as a wartlike growth; a persistent, scaly red patch; an open sore; or an elevated growth with a central depression. These lesions may bleed. Removal or destruction of the tumor cures most cases.

Melanoma (mel-uh-may) is the least common, but most deadly, type of skin cancer, accounting for over 75% of the skin cancer deaths in the United States. Because they arise from melanocytes, most melanomas are black or brown, but occasionally a melanoma may produce melanin and appear skin-colored, pink, red, or purple. About 40% of melanomas develop in preexisting moles. Treatment of melanomas when they are confined to the epidermis is almost always successful. However, if a melanoma invades the dermis and metastasizes to other parts of the body, it is difficult to treat and can be deadly.

Early detection and treatment of melanoma before it metastasizes can prevent death. Melanoma can be detected by routine examination of the skin and application of the **ABCDE rule**, which states the signs of melanoma: **A** stands for asymmetry (one side of the lesion does not match the other side), **B** is for border irregularity (the edges are ragged, notched, or blurred), **C** is for color (pigmentation is not uniform), **D** is for diameter (greater than 6 mm), and **E** is for evolving (lesion changes over time).

Evolving lesions change size, shape, elevation, or color; they may bleed, crust, itch, or become tender.

In order for cancer cells to metastasize, they must leave their site of origin, enter the circulation, and become established in a new location. For example, melanoma cells first spread within the epidermis. Some of those cells may then break through the basement membrane and invade the dermis; from there, they may enter lymphatic or blood vessels and spread to other parts of the body. The ability of cancer cells to metastasize requires an accumulation of mutations that enables the cells to detach from similar cells, recognize and digest the basement membrane, and become established elsewhere when surrounded by different cell types.

Basal cell carcinomas very rarely metastasize, and only 2–6% of squamous cell carcinoma metastasize. Compared with keratinocytes, melanocytes are more likely to give rise to tumors that metastasize because, in their developmental past, they had the ability to migrate and become established in new locations. In the embryo, melanocytes are derived from a population of cells called neural crest cells (see chapter 13). A gene called *Slug* regulates neural crest cell migration. In normal melanocytes, the *Slug* gene is inactive, but in metastasizing melanoma cells it is reactivated. The reactivation of embryonic genes, such as *Slug*, may also play a role in other metastasizing cancers.

Most skin cancers result from a series of genetic changes in somatic cells. Some people, however, have a genetic susceptibility to developing skin cancer. **Xeroderma pigmentosum** (zer-oh-deer'nah pig-men'toh'skin) is a rare, inherited disorder in which a DNA

FIGURE 5A Cancer of the Skin

Chapter-by-Chapter Changes

Chapter 1

- The “Learn to Predict” questions were separated from the vignette for clarity.
- Added a “Microbes in Your Body” boxed reading.
- Rewrote section on negative feedback for clarity and in response to heat map data and reviewer feedback.
- Added a predict question on negative feedback because it is a fundamental concept.
- Provided a clear example of the value of etymology and anatomical terminology to provide a point of reference for students to see the value of hard work.
- Revised figure 1.15 to add a photo of serous membranes to provide clarity.
- Revised figure 1.16 to add a photo of mesentery for clarity.

Chapter 2

- Major revision and expansion of the section on Electrons and Chemical Bonding. New text describes how electron shells and electronegativity underlie bond formation. A new figure (figure 2.4) illustrating this concept has been added. In addition, figure 2.6 and table 2.4 have been modified.
- Clinical impact on atomic particles has been shortened to focus on practical applications of X-rays.
- Synthesis and Decomposition Reactions were rewritten along with a simplification of figure 2.10 to focus on the key details of hydration and dehydration reactions.
- Reversible Reactions was rewritten and an analogy using a football team was added to clarify the concepts of reversible reactions and equilibrium.
- The properties of water were rewritten to emphasize the distinction between adhesion and cohesion and to emphasize the physiological functions of water in body temperature, protection, and as a mixing medium.
- Protein Structure section has been rewritten with a new summary paragraph added to highlight the key points of primary to quaternary structures. In addition, description of an enzyme active site has been rewritten and expanded to include how knowledge of the structure of an active site can be used to design drugs to treat diseases, such as Gleevec® for cancer treatment.

Chapter 3

- Added a “Microbes in Your Body” boxed reading.
- Added Clinical Impact box on Tays-Sachs disease.
- Added new section 3.11, Cellular Aspects of Aging.

Chapter 4

- Functions of epithelial tissues have been rewritten to emphasize dual role of the epithelium as a barrier while also permitting passage of molecules, along with improved labeling of epithelial tissues showing lateral surfaces in figure 4.1.
- Cells of Connective Tissue has been rewritten to better distinguish the cells involved in matrix formation, maintenance, remodeling.
- Structure and function of components of the extracellular matrix have been clarified, especially ground substance, reticular fibers, and proteoglycans. In addition, terminology has been made consistent (intercellular matrix changed to extracellular matrix in table 4.7).
- Clarification of the concept and functions of tissue membranes.

Chapter 5

- Added a “Microbes in Your Body” boxed reading.
- Converted Clinical Impact Burns to new section 5.6, Burns.

Chapter 6

- The “Learn to Predict” questions were separated from the vignette for clarity.
- Added a “Microbes in Your Body” boxed reading.
- Provided hierarchical organization reminders and referenced previous chapters where helpful (e.g., section 6.2 referred to chapter 1 to remind students of cellular development).
- Topic sentences added to many paragraphs to help students focus on concepts.
- Added a new predict question to section 6.3 where previously there was none.
- Reorganized section on spongy and compact bone for clarity.

- Added Vitamin D₃ as a calcium homeostasis hormone to section 6.9.
- Revised and updated the Systems Pathology boxed reading, “Osteoporosis” to include new thoughts and research on proton pump inhibitors and new medications.

Chapter 7

- The “Learn to Predict” questions were separated from the vignette for clarity.
- Changed the primary term from “coxal” to “hip” to reflect the more widely accepted and used term.
- Added an x-ray of a normal spine for clarity to the Clinical Impact “Abnormal Spinal Curvatures.”
- Revised Clinical Impact boxed reading “Herniated Intervertebral Disk.” Added an MRI image of fused cervical vertebrae.
- Revised the Clinical Impact boxed reading “Carpal Tunnel Syndrome” to add a clearer image of the median nerve passage. Also, information was revised to reflect the most up-to-date information as to causes of the syndrome.
- Throughout, revised skeletal art for clarity and to increase the realism to help students more readily apply the text information to actual skulls and other anatomical models.

Chapter 8

- Fibrous joint revisions include addition of realignment of teeth by braces as an example of type of movement allowed by gomphoses fibrous joint.
- Cartilaginous joint revisions include adding the importance of intervertebral disks as shock absorbers between vertebrae.
- Synovial joint revisions were made to clarify the structure and function of the fibrous capsule, synovial membrane and synovial fluid. In addition, the definition of a meniscus as a type of articular disk has been clarified and the importance of articular disks in joint protection has been emphasized.
- Some types of movement have been clarified with new examples and updated. Circular movements have been exemplified by shaking of the head “no.” Circumduction has been clarified as movement of the arm in an “arc” when throwing a baseball. Opposition has been updated to include all fingers, not just the little finger.
- A major revision of the Flexion and Extension section updated the definition of these movements from anatomical coordinates (coronal plane) to the more commonly accepted angle of the joint. In addition, the section now introduces hyperextension as extension beyond 180 degrees that can be either a normal movement (like looking up at the stars) or an abnormal movement that results in injury. A new figure 8.9 illustrates flexion, extension, and hyperextension of the elbow, knee, neck, and wrist.
- Major revision of the temporomandibular joint to update the current view of the steps involved in opening and motions of the jaw that allow chewing and grinding in mastication. In addition, the Clinical Impact on TMJ Disorders has been updated with new perspectives on therapies.

- Relevant information from several Clinical Impacts (shoulder, elbow, arch) has been moved into the text.
- Mechanisms that strengthen the hip joint have been emphasized.

Chapter 9

- Major reorganization of chapter outline. The sections were placed to fall in a more logical sequence. This reduced repetitious information.
- Used heat map to target areas of difficulty for students.
- Figure 9.3 was redrawn in a hierarchical organization so students can keep track of the relationships amongst fiber and muscle structures.
- The section on energy sources was completely revised and updated.
- Table 9.4 (formerly 9.3) was split into a process figure comparing resting and exercising muscles and a table specifying nutrients and products for each of the three main pathways for ATP production.
- The “Learn to Predict” questions were separated from the vignette for clarity.

Chapter 10

- Heat map data was utilized to identify sections in the chapter, which are difficult for students. These sections were edited for clarity.
- The “Learn to Predict” questions were separated from the vignette for clarity.
- Much of the terminology was clarified. For example, reminders about structures and their makeup were provided: tendons and ligaments, agonists and antagonists, fixators of prime movers, etc.
- Clarified examples of types of lever systems seen within the muscular system.
- Some figures had cadaver photos added (e.g., figure 10.7 and 10.21).
- Clarified the muscles classified as the rotator cuff.
- Clarified usage of movements at joints.
- Updated “coxal” to “hip.”

Chapter 11

- The “Learn to Predict” questions were separated from the vignette for clarity.
- “Neuroglia” and “neuroglial” were changed to “glia” and “glial” to more accurately reflect the modern usage.
- Revised figure 11A for a more logical and clear layout.
- Some boxed readings were converted into chapter text to draw attention to this important information.
- Rewrote the analogy for the all-or-none principle of action potentials to be a more modern example for students to relate to.

- The boxed reading on abnormal membrane potentials was converted into regular text to highlight this material.
- The analogy for saltatory conduction of action potentials was rewritten to be more relatable to everyday life.

Chapter 12

- The Stretch Reflex section has been rewritten to match the Process Figure. Importantly, the section now begins with the readily recognized knee jerk reflex to describe the stretch reflex. The knee jerk had previously been a Clinical Impact.
- Reciprocal innervation has been rewritten to emphasize that it reinforces the withdrawal reflex by allowing the coordinated contraction of flexor muscles and relaxation of the opposing extensor muscles.
- Text was rewritten so that information on innervation and function was consistently introduced upfront for each nerve.
- Clinical Impacts were updated (Bionic Sensors), renamed to highlight the relevant disorder (Crutch Paralysis, Funny Bone), or integrated into the text (Carpal Tunnel Syndrome).

Chapter 13

- Development of the CNS now includes an expanded description of the notochord. In addition, the anatomical terms in table 13.2 are now matched to the text.
- Reticular formation role in arousal and awareness is now included.
- Hypothalamic functions have been clarified.
- Clinical Impact on traumatic brain injuries has been updated to include professional athletes and portions have been integrated into the text since this is an increasingly relevant pathology.
- The clinical importance of hemorrhagic bleeding has been emphasized by moving this information from a Clinical Impact into the main text in the Blood Supply to the Brain section.
- The clinical importance of the blood-brain barrier has been emphasized by inclusion of material previously in the Clinical Impact on Drugs and the Blood-Brain Barrier.

Chapter 14

- The section on Sensation has been revised with changes in Table 14.1. For example, the field sobriety test as an example of proprioception has been added.
- Likewise, the section on Sensory Receptors has similarly been revised.
- The section on Sensory Pathways, especially the Anterolateral System, has been revised to more closely follow the figures.
- Figures 14.8, 14.9, and 14.10 have been clarified by inclusion of numbers to more easily follow the sensory pathway. Figure 14.10 has been simplified by removing anatomical sections not included in the posterior spinocerebellar tract.

- Projection in the somatic sensory cortex has been rewritten and an example of knowing where to slap a mosquito has been added.
- Clinical Impact on ALS has been updated to include rates of progression of the disease, with the example of Stephen Hawking.

Chapter 15

- Improved accuracy of Neural Pathways for Olfaction.

Chapter 16

- Revised section 16.6, Functional Generalizations About the Autonomic Nervous System, to fully describe each generalization relative to the information presented in the chapter.

Chapter 17

- The “Learn to Predict” questions were separated from the vignette for clarity.
- Rewrote the analogy about the difference between the nervous system and the endocrine system using twitter as a delivery system.
- Table 17.2 was completely revised for clarity. New figures for hormone molecules replaced the previous figures. The table is also now more clearly laid out.
- Figure 17.5 was edited to show a portion of the blood stream and the relationship for Ca^{2+} -regulating hormone secretion.
- The boxed reading of agonists and antagonists was integrated into the chapter text to better highlight this information.

Chapter 18

- Used heat map to target areas of difficulty for students.
- Explanations were clarified and comparisons to everyday situations and structures were made to allow for greater understanding.
- Etymologies were given where helpful.
- The “Learn to Predict” questions were separated from the vignette for clarity.
- Clarified the explanation of releasing and inhibiting hormones.
- Revised figure 18.12 for consistency.
- Revised figure 18.7 for consistency.
- Added a “Microbes in Your Body” boxed reading.

Chapter 19

- Revised figure 19.1 clearly identifying buffy coat in centrifuged blood sample.
- Revised ABO Blood Group to better explain the nomenclature of antigens, antibodies, and blood types.

Chapter 20

- Added a “Microbes in Your Body” boxed reading.
- Updated Clinical Impact, Cardiopulmonary Resuscitation (CPR)
- Revised Cardiac Muscle description, comparing and contrasting structure of cardiac muscle cells to skeletal muscle cells
- Revised figure 20.12, providing a clear depiction of cardiac muscle cell anatomy
- Revised figure 20.14, adding information about muscle tension changes associated with stimulation in both cardiac muscle and skeletal muscle.
- Corrected the description of the aortic notch, adding information about the aortic wave.

Chapter 21

- Revised Capillary Exchange and Regulation of Interstitial Fluid Volume to more accurately and sequentially represent the factors affecting Net Filtration Pressure.
- Revised figure 21.36 to better represent fluid volume differences.
- Corrected descriptions of septic shock and blood poisoning in Clinical Impact, Circulatory Shock.

Chapter 22

- Added a “Microbes in Your Body” boxed reading.
- Updated figures 22.18, 22.21, and 22.25 to show plasma cells producing antibodies.
- Updated Clinical Impact, Acquired Immunodeficiency Syndrome.

Chapter 23

- Used heat map to target areas of difficulty for students.
- The “Learn to Predict” questions were separated from the vignette for clarity.
- The description of the anatomy in section 23.2 was heavily revised for clarity.
- Revised figure 23.13 to look more realistic.
- Heavily revised the section “Pleural Pressure” in section 23.3 for logical flow and clearer explanations.
- “Minute ventilation” was changed to “minute volume” to more accurately reflect the widely accepted term.
- Heavily revised section 23.5 for clarity.
- Heavily revised section 23.6 for clarity.
- Figure 23.22 was revised for consistency.

Chapter 24

- Neural control of the muscularis and the enteric nervous system of the digestive tract have been clarified.

- Clinical Impact on Dental Caries has been integrated into the text.
- Mumps has been updated to include the efficacy of the measles/mumps/rubella (MMR) vaccination program.
- The Salivary Glands section has been revised and updated to emphasize the protective functions and de-emphasize the relatively minor digestive functions of saliva.
- Lipid emulsification has been rewritten to emphasize the role of bile.

Chapter 25

- Updated nutrition label information to represent newest FDA recommendations
- Revised anaerobic respiration description to better explain lactate production

Chapter 26

- The “Learn to Predict” questions were separated from the vignette for clarity.
- Revised section 26.1 for clarity.
- Heavily revised section 26.2 for a more clear and simple explanation of the relationship amongst these structures.
- Added a clear definition of a countercurrent mechanism to section 26.3.
- Revised the explanation of ADH secretion for clarity.
- The boxed reading on urine concentration was integrated into the chapter text for clarity.
- Added a “Microbes in Your Body” boxed reading.
- The Clinical Impact boxed reading on Urinary Bladder Control was rewritten for improved understanding.
- The Clinical Impact boxed reading on Polycystic Kidney Disease was revised to become a Clinical Genetics boxed reading.

Chapter 27

- The “Learn to Predict” questions were separated from the vignette for clarity.
- Figure 27.3 was revised for consistency.
- Figure 27.4 was revised for consistency.
- Section 27.3 introduction was rewritten to help students relate to knowledge they had learned in previous chapters.
- Figure 27.8 was revised for consistency.
- Figure 27.9 was revised for consistency.
- Figure 27.10 was revised for consistency.
- Figure 27.12 was revised for consistency.
- The Clinical Impact boxed reading Acidosis and Alkalosis was integrated into the chapter text to highlight this important information.

Chapter 28

- Added a “Microbes in Your Body” boxed reading.
- Added new Section 28.2, Meiosis.
- Clearly define menstrual, ovarian, and uterine cycle.

Chapter 29

- Updated Clinical Impact, Fetal Monitoring, to include new cell-free fetal DNA testing for chromosomal abnormalities.
- Updated Clinical Genetics, The Human Genome Project.

Acknowledgments

A great deal of effort is required to produce a heavily illustrated textbook like *Seeley's Anatomy & Physiology*. Many hours of work are required to organize and develop the components of the textbook while also creating and designing illustrations, but no text is solely the work of the authors. It is not possible to adequately acknowledge the support and encouragement provided by our loved ones. They have had the patience and understanding to tolerate our absences and our frustrations. They have also been willing to provide assistance and unwavering support.

Many hands besides our own have touched this text, guiding it through various stages of development and production. We wish to express our gratitude to the staff of McGraw-Hill for their help and encouragement. We appreciate the guidance and tutelage of Brand Manager Amy Reed. We are sincerely grateful to Product Developer Mandy Clark for her careful scrutiny of the manuscript, her creative ideas and suggestions, and her tremendous patience and encouragement. Special thanks are also offered to Copyeditor Deb DeBord for her attention to detail and for carefully polishing our words. A special acknowledgement of gratitude is owed to Project Manager Jayne Klein for her patience and detail-tracking abilities. Content Licensing Specialist Lori Hancock, Program Manager Angela FitzPatrick, Designer David Hash, and Assessment Project Manager Christina Nelson, we thank you for your time spent turning our manuscript into a book and its accompanying website. The McGraw-Hill employees with whom we have worked are excellent

professionals. They have been consistently helpful and their efforts are truly appreciated. Their commitment to this project has clearly been more than a job to them.

Finally, we sincerely thank the past reviewers and instructors who have provided us time and time again with remarkable feedback. We have continued their recommendations in this edition, while remaining true to our overriding goal of writing a text that is comprehensive enough to provide the depth necessary for a two semester course, yet ensuring it is presented with such clarity that it nicely balances the thorough coverage to be more student centered. Each feature incorporated into this edition has been carefully considered in how it may be used to support student learning and understanding.

Also, in this edition, we are very pleased to have been able to incorporate real student data points and input, derived from thousands of our LearnSmart users, to help guide our revision. LearnSmart Heat Maps provided a quick visual snapshot of usage of portions of the text and the relative difficulty students experienced in mastering the content. With this data, we were able to hone not only our text content but also the LearnSmart probes.

Index I-1

The Human Organism

What lies ahead is an astounding adventure—learning about the structure and function of the human body and the intricate checks and balances that regulate it. Renzo’s (the dancer featured in this chapter’s “Learn to Predict”) response to eating the energy bar is a good example of how important this system of checks and balances is in the body. Perhaps you have had a similar experience, but with a different outcome. You have overslept, rushed to your 8 a.m. class, and missed breakfast. Afterwards, on the way to Anatomy & Physiology class, you bought an energy bar from the vending machine. Eating the energy bar helped you feel better. The explanation for these experiences is the process of homeostasis; for you, homeostasis was maintained, but for Renzo, there was a disruption in homeostasis. Throughout this book, the major underlying theme is homeostasis. As you think about Renzo’s case, you will come to realize just how capable the human body is of an incredible coordination of thousands upon thousands of processes. Knowing human anatomy and physiology is also the basis for understanding disease. The study of human anatomy and physiology is important for students who plan a career in the health sciences because health professionals need a sound knowledge of structure and function in order to perform their duties. In addition, understanding anatomy and physiology prepares all of us to evaluate recommended treatments, critically review advertisements and reports in the popular literature, and rationally discuss the human body with health professionals and nonprofessionals.

Learn to Predict

Renzo, the dancer in the photo, is perfectly balanced, yet a slight movement in any direction would cause him to adjust his position. The human body adjusts its balance among all its parts through a process called homeostasis.

Let’s imagine that Renzo is suffering from a blood sugar disorder. Earlier, just before this photo was taken, he’d eaten an energy bar. As an energy bar is digested, blood sugar rises. Normally, tiny collections of cells embedded in the pancreas respond to the rise in blood sugar by secreting the chemical insulin. Insulin increases the movement of sugar from the blood into his cells. However, Renzo did not feel satisfied from his energy bar. He felt dizzy and was still hungry, all symptoms he worried could be due to a family history of diabetes. Fortunately, the on-site trainer tested his blood sugar and noted that it was much higher than normal. After a visit to his regular physician, Renzo was outfitted with an insulin pump, and his blood sugar levels are now more consistent.

After reading about homeostasis in this chapter, create an explanation for Renzo’s blood sugar levels before and after his visit to the doctor.

1.1 Anatomy and Physiology

LEARNING OUTCOMES

After reading this section, you should be able to

- Define **anatomy** and describe the levels at which anatomy can be studied.
- Define **physiology** and describe the levels at which physiology can be studied.
- Explain the importance of the relationship between structure and function.

Anatomy is the scientific discipline that investigates the body's structures—for example, the shape and size of bones. In addition, anatomy examines the relationship between the structure of a body part and its function. Thus, the fact that bone cells are surrounded by a hard, mineralized substance enables the bones to provide strength and support. Understanding the relationship between structure and function makes it easier to understand and appreciate anatomy. Anatomy can be studied at different levels. **Developmental anatomy** studies the structural changes that occur between conception and adulthood. **Embryology** (em-brē-ol'ō-jē), a subspecialty of developmental anatomy, considers changes from conception to the end of the eighth week of development.

Some structures, such as cells, are so small that they must be studied using a microscope. **Cytology** (sī-tol'ō-jē; *cyto*, cell) examines the structural features of cells, and **histology** (his-tol'ō-jē; *hist*, tissue) examines tissues, which are composed of cells and the materials surrounding them.

Gross anatomy, the study of structures that can be examined without the aid of a microscope, can be approached either systemically or regionally. A **system** is a group of structures that have one or more common functions, such as the cardiovascular, nervous, respiratory, skeletal, or muscular systems. In systemic anatomy, the body is studied system by system. In regional anatomy, the body is studied area by area. Within each region, such as the head, abdomen, or arm, all systems are studied simultaneously. The regional approach is taken in most graduate programs at medical and dental schools. The systemic approach is used in this and most other introductory textbooks.

Surface anatomy involves looking at the exterior of the body to visualize structures deeper inside the body. For example, the sternum (breastbone) and parts of the ribs can be seen and palpated (felt) on the front of the chest. Health professionals use these structures as anatomical landmarks to identify regions of the heart and points on the chest where certain heart sounds can best be heard. **Anatomical imaging** uses radiographs (x-rays), ultrasound, magnetic resonance imaging (MRI), and other technologies to create pictures of internal structures (table 1.1). Anatomical imaging has revolutionized medical science. Some scientists estimate that the past 20 years have seen as much progress in clinical medicine as occurred in all of medicine's previous history. Anatomical imaging has made a major contribution to that progress. Anatomical imaging allows medical personnel to look inside the body with amazing accuracy and without the trauma and risk of exploratory surgery. Although most of the technology used in anatomical imaging is

very new, the concept and earliest technology are quite old. In 1895, Wilhelm Roentgen (1845–1923) became the first medical scientist to use **x-rays** to see inside the body. The rays were called x-rays because no one knew what they were. Whenever the human body is exposed to x-rays, ultrasound, electromagnetic fields, or radioactively labeled substances, a potential risk exists. This risk must be weighed against the medical benefit. Numerous studies have been conducted and are still being done to determine the effects of diagnostic and therapeutic exposure to x-rays. The risk of anatomical imaging is minimized by using the lowest possible doses providing the necessary information. No known risks exist from ultrasound or electromagnetic fields at the levels used for diagnosis. Both surface anatomy and anatomical imaging provide important information for diagnosing disease.

However, no two humans are structurally identical. **Anatomical anomalies** are physical characteristics that differ from the normal pattern. Anatomical anomalies can vary in severity from relatively harmless to life-threatening. For example, each kidney is normally supplied by one blood vessel, but in some individuals a kidney is supplied by two blood vessels. Either way, the kidney receives adequate blood. On the other hand, in the condition called “blue baby” syndrome, certain blood vessels arising from an infant's heart are not attached in their correct locations; blood is not effectively pumped to the lungs, and so the tissues do not receive adequate oxygen.

Physiology is the scientific investigation of the processes or functions of living things. The major goals when studying human physiology are to understand and predict the body's responses to stimuli and to understand how the body maintains conditions within a narrow range of values in a constantly changing environment.

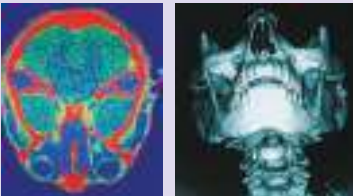

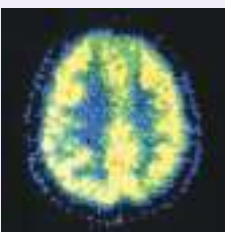

Like anatomy, physiology can be considered at many levels. **Cell physiology** examines the processes occurring in cells, and **systemic physiology** considers the functions of organ systems. **Neurophysiology** focuses on the nervous system, and **cardiovascular physiology** deals with the heart and blood vessels. Physiology often examines systems rather than regions because a particular function can involve portions of a system in more than one region.

Studies of the human body must encompass both anatomy and physiology because structures, functions, and processes are interwoven. **Pathology** (pa-thol'ō-jē) is the medical science dealing with all aspects of disease, with an emphasis on the cause and development of abnormal conditions, as well as the structural and functional changes resulting from disease. **Exercise physiology** focuses on the changes in function and structure caused by exercise.

ASSESS YOUR PROGRESS

- What type of physiology is employed when studying the endocrine system?
- Why are anatomy and physiology normally studied together?

TABLE 1.1 Anatomical Imaging

Imaging Technique	Image	Clinical Examples
X-ray		This extremely shortwave electromagnetic radiation (see chapter 2) moves through the body, exposing a photographic plate to form a radiograph (rā'dē-ō-graf). Bones and radiopaque dyes absorb the rays and create underexposed areas that appear white on the photographic film. Many of us have had an X-ray, either to visualize a broken bone or at the dentist. However, a major limitation of radiographs is that they give only flat, two-dimensional (2-D) images of the body.
Ultrasound		Ultrasound , the second oldest imaging technique, was first developed in the early 1950s from World War II sonar technology. It uses high-frequency sound waves, which are emitted from a transmitter-receiver placed on the skin over the area to be scanned. The sound waves strike internal organs and bounce back to a receiver on the skin. Even though the basic technology is fairly old, the most important advances in this field occurred only after it became possible to analyze the reflected sound waves by when a computer could be used to analyze the pattern of reflected sound waves and transfer. Once a computer analyzes the pattern of sound waves, the information is transferred to a monitor to be visualized as a sonogram (son'ō-gram) image. One of the more recent advances in ultrasound technology is the ability of more advanced computers to analyze changes in position through “real-time” movements. Among other medical applications, ultrasound is commonly used to evaluate the condition of the fetus during pregnancy.
Computed Tomography (CT)	 <p>(a) (b)</p>	Computed tomographic (tō'mō-graf'ik) (CT) scans, developed in 1972 and originally called computerized axial tomographic (CAT) scans, are computer-analyzed x-ray images. A low-intensity x-ray tube is rotated through a 360-degree arc around the patient, and the images are fed into a computer. The computer then constructs the image of a “slice” through the body at the point where the x-ray beam was focused and rotated (a). Some computers are able to take several scans short distances apart and stack the slices to produce a 3-D image of a body part (b).
Digital Subtraction Angiography (DSA)		Digital subtraction angiography (an-jē-og'rā-fē) (DSA) is one step beyond CT scanning. A 3-D radiographic image of an organ, such as the brain, is made and stored in a computer. Then a radiopaque dye is injected into the blood, and a second radiographic computer image is made. The first image is subtracted from the second one, greatly enhancing the differences revealed by the injected dye. These dynamic computer images are the most common way angioplasty, is performed. Angioplasty uses a tiny balloon to unclog an artery.
Magnetic Resonance Imaging (MRI)		Magnetic resonance imaging (MRI) directs radio waves at a person lying inside a large electromagnetic field. The magnetic field causes the protons of various atoms to align (see chapter 2). Because of the large amounts of water in the body, the alignment of hydrogen atom protons is most important in this imaging system. Radio waves of certain frequencies, which change the alignment of the hydrogen atoms, then are directed at the patient. When the radio waves are turned off, the hydrogen atoms realign in accordance with the magnetic field. The time it takes the hydrogen atoms to realign is different for various body tissues. These differences can be analyzed by computer to produce very clear sections through the body. The technique is also very sensitive in detecting some forms of cancer far more readily than can a CT scan.
Positron Emission Tomography (PET)		Positron emission tomographic (PET) scans can identify the metabolic states of various tissues. This technique is particularly useful in analyzing the brain. When cells are active, they are using energy. The energy they need is supplied by the breakdown of glucose (blood sugar). If radioactively treated (“labeled”) glucose is given to a patient, the active cells take up the labeled glucose. As the radioactivity in the glucose decays, positively charged subatomic particles called positrons are emitted. When the positrons collide with electrons, the two particles annihilate each other and gamma rays are given off. The gamma rays can be detected, pinpointing the cells that are metabolically active.

- 1 **Chemical level.** Atoms (colored balls) combine to form molecules.
- 2 **Cell level.** Molecules form organelles, such as the nucleus and mitochondria, which make up cells.
- 3 **Tissue level.** Similar cells and surrounding materials make up tissues.
- 4 **Organ level.** Different tissues combine to form organs, such as the urinary bladder.
- 5 **Organ system level.** Organs, such as the urinary bladder and kidneys, make up an organ system.
- 6 **Organism level.** Organ systems make up an organism.

PROCESS FIGURE 1.1 Levels of Organization for the Human Body

1.2 Structural and Functional Organization of the Human Body

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Name the six levels of organization of the body and describe the major characteristics of each level.
- B. List the 11 organ systems, identify their components, and describe the major functions of each system.

The body can be studied at six levels of organization: the chemical, cell, tissue, organ, organ system, and whole organism levels (figure 1.1).

1. *Chemical level.* The chemical level involves interactions between atoms, which are tiny building blocks of matter. Atoms combine to form molecules, such as water, sugar, lipids, and proteins. The function of a molecule is intimately related to its structure. For example, collagen molecules are ropelike protein fibers that give skin structural strength and flexibility. With old age, the structure of collagen changes, and the skin becomes fragile and more easily torn. We present a brief overview of chemistry in chapter 2.
2. *Cell level.* **Cells** are the basic structural and functional units of plants and animals. Molecules combine to form **organelles** (or'gă-nelz; little organs), which are the small structures inside cells. For example, the nucleus is an organelle that contains the cell's hereditary information, and mitochondria are organelles that manufacture

MICROBES In Your Body

Getting to know your bacteria

Did you know that you have more microbial cells than human cells in your body? Astoundingly, for every cell in your body, there are 10 microbial cells. That's as many as 100 trillion microbial cells, which can collectively account for between 2 and 6 pounds of your body weight! A microbe is any living thing that cannot be seen with the naked eye (for example, bacteria, fungi, and protozoa). The total population of microbial cells on the human body is referred to as the microbiota, while the combination of these microbial cells and their genes is known as the microbiome. The microbiota includes so-called good bacteria, which do not cause disease and may even help us. It also includes pathogenic, or “bad,” bacteria.

With that many microbes in and on our bodies, you might wonder how they affect our health. To answer that question, in October 2007 the National Institutes of Health (NIH) initiated the 5-year Human Microbiome Project, the largest study of its kind. Five significant regions of the human body were examined: the airway, skin, mouth, gastrointestinal tract, and vagina. This project identified over 5000 species and sequenced over 20 million unique microbial genes.

What did scientists learn from the Human Microbiome Project? Human health is dependent upon the health of our microbiota, especially the “good” bacteria. In fact, it seems that our microbiota are so completely intertwined with human cells that it has been suggested that humans are like corals. Corals are marine organisms that are collections of different life forms, all existing together. More specifically, the human microbiome is intimately involved in the development and maintenance of the immune system. And more evidence is mounting for a correlation between a host's microbiota, digestion, and metabolism. Researchers have suggested that microbial genes are more responsible for our survival than human genes. There are even a few consistent pathogens that are present without causing disease, suggesting that their presence may be good for us. However, there does not seem to be a universal healthy human microbiome. Rather, the human microbiome varies across lifespan, ethnicity, nationality, culture, and geographic location. Instead of being a detriment, this variation may actually be very useful for predicting disease. There seems to be a correlation between autoimmune and inflammatory diseases (Crohn's disease, asthma, multiple sclerosis), which have

become more prevalent, and a “characteristic microbiome community.” Early research seems to indicate that any significant change in the profile of the microbiome of the human gut may increase a person's susceptibility to autoimmune diseases. It has been proposed that these changes may be associated with exposure to antibiotics, particularly in infancy. Fortunately, newer studies of microbial transplantations have shown that the protective and other functions of bacteria can be transferred from one person to the next. However, this work is all very new, and much research remains to be done.

Throughout this text, we will highlight specific instances in which our microbes influence our body systems. In light of the importance of our bodies' bacteria and other microbes, the prevalence of antibacterial soap and hand gel usage in everyday life may be something to think about.

► Predict 2

After reading this box and the section on homeostasis in this chapter, predict some possible consequences of high-dose, intravenous (IV) antibiotic administration on the homeostasis of a person's digestive function.

adenosine triphosphate (ATP), a molecule cells use for energy. Although cell types differ in their structure and function, they have many characteristics in common. Knowledge of these characteristics, as well as their variations, is essential to understanding anatomy and physiology. We discuss the cell in chapter 3.

3. *Tissue level.* A **tissue** is composed of a group of similar cells and the materials surrounding them. The characteristics of the cells and surrounding materials determine the functions of the tissue. The body is made up of four basic tissue types: epithelial, connective, muscle, and nervous. We discuss tissues in chapter 4.
4. *Organ level.* An **organ** is composed of two or more tissue types that perform one or more common functions. The urinary bladder, heart, stomach, and lung are examples of organs (figure 1.2).
5. *Organ system level.* An **organ system** is a group of organs that together perform a common function or set of functions and are therefore viewed as a unit. For example, the urinary system consists of the kidneys, ureter, urinary bladder, and urethra. The kidneys produce urine, which the ureters

transport to the urinary bladder, where it is stored until being eliminated from the body through the urethra. In this text, we consider 11 major organ systems: the integumentary, skeletal, muscular, nervous, endocrine, cardiovascular, lymphatic, respiratory, digestive, urinary, and reproductive systems. Figure 1.3 presents a brief summary of these organ systems and their functions.

6. *Organism level.* An **organism** is any living thing considered as a whole—whether composed of one cell, such as a bacterium, or of trillions of cells, such as a human. The human organism is a network of organ systems, all mutually dependent on one another.

ASSESS YOUR PROGRESS

5. From simplest to complex, list and define the body's six levels of organization.
6. What are the four basic types of tissues?
7. Referring to figure 1.3, which two organ systems are responsible for regulating the other organ systems? Which two are responsible for support and movement?

FIGURE 1.2 Major Organs of the Body AP|R

Predict 3

In one type of diabetes, the pancreas fails to produce insulin, a chemical normally made by pancreatic cells and released into the blood. List as many levels of organization as you can at which this disorder could be corrected.

1.3 Characteristics of Life

LEARNING OUTCOME

After reading this section, you should be able to

A. List and define the six characteristics of life.

Humans are organisms, sharing characteristics with other organisms. The most important common feature of all organisms is life. This text recognizes six essential characteristics of life:

1. **Organization** refers to the specific interrelationships among the parts of an organism and how those parts interact to perform specific functions. Living things are highly organized. All organisms are composed of one or more cells. Some cells in turn are composed of highly specialized organelles, which depend on the precise organization of large molecules. Disruption of this organized state can result in loss of functions, or even death.
2. **Metabolism** (mĕ-tab'ō-lizm) refers to all of the chemical reactions taking place in the cells and internal environment of an organism. It includes an organism's ability to break down food molecules, which the organism uses as a source of energy and raw materials to synthesize its own molecules. Energy is also used when one part of a molecule moves relative to another part, changing the shape of the molecule. In single-celled organisms and certain human cells, this change in molecular shape can cause the whole cell to change shape. Sometimes this change in cell shape can allow the entire organism or cell to move to a different location. Metabolism is necessary for other vital functions, such as responsiveness, growth, development, and reproduction.
3. **Responsiveness** is an organism's ability to sense changes in its external or internal environment and adjust to those changes. Responses include actions such as moving toward

Integumentary System

Provides protection, regulates temperature, prevents water loss, and helps produce vitamin D. Consists of skin, hair, nails, and sweat glands.

Skeletal System

Provides protection and support, allows body movements, produces blood cells, and stores minerals and adipose. Consists of bones, associated cartilages, ligaments, and joints.

Muscular System

Produces body movements, maintains posture, and produces body heat. Consists of muscles attached to the skeleton by tendons.

Lymphatic System

Removes foreign substances from the blood and lymph, combats disease, maintains tissue fluid balance, and absorbs dietary fats from the digestive tract. Consists of the lymphatic vessels, lymph nodes, and other lymphatic organs.

Respiratory System

Exchanges oxygen and carbon dioxide between the blood and air and regulates blood pH. Consists of the lungs and respiratory passages.

Digestive System

Performs the mechanical and chemical processes of digestion, absorption of nutrients, and elimination of wastes. Consists of the mouth, esophagus, stomach, intestines, and accessory organs.

FIGURE 1.3 Organ Systems of the Body

food or water and moving away from danger or poor environmental conditions. Organisms can also make adjustments that maintain their internal environment. For example, if the

external environment causes the body temperature to rise, sweat glands produce sweat, which can lower body temperature down to the normal range.

Nervous System

A major regulatory system that detects sensations and controls movements, physiological processes, and intellectual functions. Consists of the brain, spinal cord, nerves, and sensory receptors.

Endocrine System

A major regulatory system that influences metabolism, growth, reproduction, and many other functions. Consists of glands, such as the pituitary, that secrete hormones.

Cardiovascular System

Transports nutrients, waste products, gases, and hormones throughout the body; plays a role in the immune response and the regulation of body temperature. Consists of the heart, blood vessels, and blood.

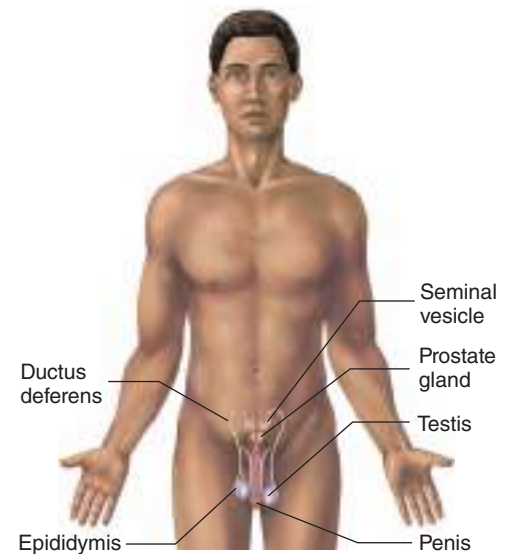

Urinary System

Removes waste products from the blood and regulates blood pH, ion balance, and water balance. Consists of the kidneys, urinary bladder, and ducts that carry urine.

Female Reproductive System

Produces oocytes and is the site of fertilization and fetal development; produces milk for the newborn; produces hormones that influence sexual function and behaviors. Consists of the ovaries, uterine tubes, uterus, vagina, mammary glands, and associated structures.

Male Reproductive System

Produces and transfers sperm cells to the female and produces hormones that influence sexual functions and behaviors. Consists of the testes, accessory structures, ducts, and penis.

FIGURE 1.3 (continued)

4. **Growth** refers to an increase in the size or number of cells, which produces an overall enlargement of all or part of an organism. For example, a muscle enlarged by exercise is composed of larger muscle cells than those of an untrained muscle, and the skin of an adult has more cells than the skin of an infant. An increase in the materials surrounding cells can also contribute to growth. For instance, bone grows because of an increase in cell number and the deposition of mineralized materials around the cells.
5. **Development** includes the changes an organism undergoes through time, beginning with fertilization and ending at death. The greatest developmental changes occur before birth, but many changes continue after birth, and some go on throughout life. Development usually involves growth, but it also involves differentiation and morphogenesis. **Differentiation** involves changes in a cell's structure and function from an immature, generalized state to a mature, specialized state. For example, following fertilization, immature cells differentiate to become specific cell types, such as skin, bone, muscle, or nerve cells. These differentiated cells form tissues and organs. **Morphogenesis** (mōr-fō-jen'ē-sis) is the change in shape of tissues, organs, and the entire organism.
6. **Reproduction** is the formation of new cells or new organisms. Without reproduction of cells, growth and development are not possible. Without reproduction of organisms, species become extinct.

ASSESS YOUR PROGRESS

8. What are the six characteristics of living things? Briefly explain each.
9. How does differentiation differ from morphogenesis?

1.4 Biomedical Research

LEARNING OUTCOME

After reading this section, you should be able to

- A. Explain why it is important to study other organisms along with humans.

Studying other organisms has increased our knowledge about humans because humans share many characteristics with other organisms. For example, studying single-celled bacteria provides much information about human cells. However, some biomedical research cannot be accomplished using single-celled organisms or isolated cells. Sometimes other mammals must be studied, as evidenced by the great progress in open heart surgery and kidney transplantation made possible by perfecting surgical techniques on other mammals before attempting them on humans. Strict laws govern the use of animals in biomedical research; these laws are designed to ensure minimal suffering on the part of the animal and to discourage unnecessary experimentation.

Although much can be learned from studying other organisms, the ultimate answers to questions about humans can be

obtained only from humans because other organisms differ from humans in significant ways. A failure to appreciate the differences between humans and other animals led to many misconceptions by early scientists. One of the first great anatomists was a Greek physician, Claudius Galen (ca. 130–201). Galen described a large number of anatomical structures supposedly present in humans but observed only in other animals. For example, he described the liver as having five lobes. This is true for rats, but not for humans, who have four-lobed livers. The errors introduced by Galen persisted for more than 1300 years until a Flemish anatomist, Andreas Vesalius (1514–1564), who is considered the first modern anatomist, carefully examined human cadavers and began to correct the textbooks. This example should serve as a word of caution: Some current knowledge in molecular biology and physiology has not been confirmed in humans.

ASSESS YOUR PROGRESS

10. Why is it important to recognize that humans share many, but not all, characteristics with other animals?

1.5 Homeostasis

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Define *homeostasis* and explain why it is important for proper body function.
- B. Describe a *negative-feedback mechanism* and give an example.
- C. Describe a *positive-feedback mechanism* and give an example.

Homeostasis (hō'mē-ō-stā'sis) is the existence and maintenance of a relatively constant environment within the body. To achieve homeostasis, the body must actively regulate conditions that are constantly changing. As our bodies undergo their everyday processes, we are continuously exposed to new conditions. These conditions are called **variables** because their values can change. For example, a small amount of fluid surrounds each body cell; for cells to function normally, the volume, temperature, and chemical content of this fluid must be maintained within a narrow range.

One variable familiar to all of us is body temperature. Body temperature is a variable that can increase in a hot environment or decrease in a cold one. Homeostatic mechanisms, such as sweating or shivering, normally maintain body temperature near an ideal normal value, or **set point** (figure 1.4). Note that these mechanisms are not able to maintain body temperature *precisely* at the set point. Instead, body temperature increases and decreases slightly around the set point to produce a **normal range** of values. As long as body temperature remains within this normal range, homeostasis is maintained. Keep in mind that the fluctuations are minimal, however. Note in figure 1.4 that the normal body temperature range is no more than 1 degree Fahrenheit above or below normal. Our *average* body temperature is 98.6 degrees Fahrenheit.

FIGURE 1.4 Homeostasis

Homeostasis is the maintenance of a variable around an ideal normal value, or set point. The value of the variable fluctuates around the set point to establish a normal range of values.

Just as your home's thermostat does not keep the air temperature exactly at 75 degrees Fahrenheit at all times, your body's temperature does not stay perfectly stable.

The organ systems help keep the body's internal environment relatively constant. For example, the digestive, respiratory, cardiovascular, and urinary systems work together, so that each cell in the body receives adequate oxygen and nutrients and waste products do not accumulate to a toxic level. If body fluids deviate from homeostasis, body cells do not function normally and can even die. Disease disrupts homeostasis and sometimes results in death. Modern medicine attempts to understand disturbances in homeostasis and works to reestablish a normal range of values.

Negative Feedback

Most systems of the body are regulated by **negative-feedback** mechanisms, which maintain homeostasis. *Negative* means that any deviation from the set point is made smaller or is resisted; therefore, in a negative-feedback mechanism, the response to the original stimulus results in deviation from the set point, becoming smaller. An example of important negative-feedback mechanisms in the body are those maintaining normal body temperature. Normal body temperature is critical to our health because it allows molecules and enzymes to keep their normal shape so they can function optimally. An optimal body temperature prevents molecules from being permanently destroyed. Picture the change in appearance of egg whites as they are cooked; the egg whites change from a transparent fluid to a white solid because the heat changes the shape of the egg white molecules. Similarly, if the body is exposed to extreme heat, the shape of the molecules in the body could change, which would eventually prevent them from functioning normally. Most negative-feedback mechanisms have three components: (1) a **receptor**, which monitors the value of a variable such as body temperature; (2) a **control center**, such as part of the brain, which establishes the set point around which the variable is maintained through communication with the receptors and effectors; and (3) an **effector**, such as sweat glands, which can adjust the value of the variable, usually back toward the set point. A changed variable is a **stimulus** because it initiates a

Case STUDY

Orthostatic Hypotension

Molly is a 75-year-old widow who lives alone. For 2 days, she had a fever and chills and mainly stayed in bed. On rising to go to the bathroom, she felt dizzy, fainted, and fell to the floor. Molly quickly regained consciousness and managed to call her son, who took her to the emergency room, where a physician diagnosed orthostatic hypotension.

Orthostasis literally means “to stand,” and *hypotension* refers to low blood pressure; thus, **orthostatic hypotension** is a significant drop in blood pressure upon standing. When a person moves from lying down to standing, blood “pools” within the veins below the heart because of gravity, and less blood returns to the heart. Consequently, blood pressure drops because the heart has less blood to pump.

➤ Predict 4

Although orthostatic hypotension has many causes, in the elderly it can be due to age-related decreases in neural and cardiovascular responses. Decreased fluid intake while feeling ill and sweating due to a fever can result in dehydration. Dehydration can decrease blood volume and lower blood pressure, increasing the likelihood of orthostatic hypotension.

- Describe the normal response to a decrease in blood pressure on standing.
- What happened to Molly's heart rate just before she fainted? Why did Molly faint?
- How did Molly's fainting and falling to the floor help establish homeostasis (assuming she was not injured)?

homeostatic mechanism. Several negative-feedback mechanisms regulate body temperature, and they are described more fully in chapter 5.

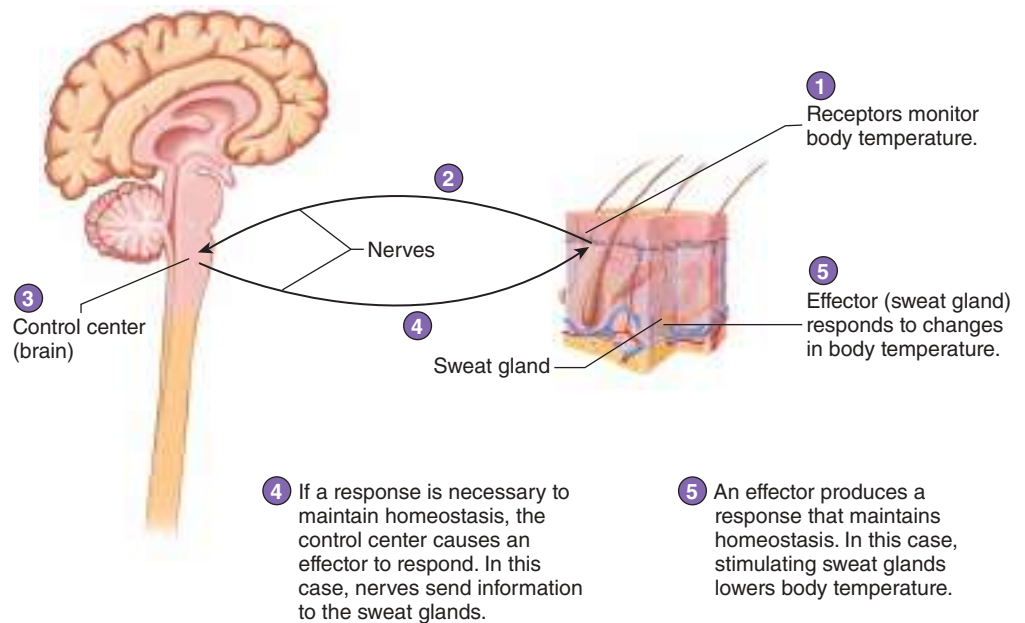

Normal body temperature depends on the coordination of multiple structures, which are regulated by the control center, or hypothalamus, in the brain. If body temperature rises, sweat glands (the effectors) produce sweat and the body cools. If body temperature falls, sweat glands do not produce sweat (figure 1.5). The stepwise process that regulates body temperature involves the interaction of receptors, the control center, and effectors. Often, there is more than one effector, and the control center must integrate them. In the case of elevated body temperature, thermoreceptors in the skin and hypothalamus detect the increase in temperature and send the information to the hypothalamus control center. In turn, the hypothalamus stimulates blood vessels in the skin to relax and sweat glands to produce sweat, which sends more blood to the body's surface for the radiation of heat away from the body. The sweat glands and skin blood vessels are the effectors in this scenario. Once body temperature returns to normal, the control center signals the sweat glands to reduce sweat production, and the blood vessels constrict to their normal diameter. On

FUNDAMENTAL Figure

1 Receptors monitor the value of a variable. In this case, receptors in the skin monitor body temperature.

2 Information about the value of the variable is sent to a control center. In this case, nerves send information to the part of the brain responsible for regulating body temperature.

3 The control center compares the value of the variable against the set point.

PROCESS FIGURE 1.5 Negative-Feedback Mechanism: Body Temperature

the other hand, if body temperature drops, the control center does not stimulate the sweat glands. Instead, the skin blood vessels constrict more than normal and blood is directed to deeper regions of the body, conserving heat in the interior of the body. In addition, the hypothalamus stimulates shivering, quick cycles of skeletal muscle contractions, which generates a great amount of heat. Again, once the body temperature returns to normal, the effectors stop. In both cases, the effectors do not produce their responses indefinitely and are controlled by negative feedback. Negative feedback acts to return the variable to its normal range (figure 1.6).

Although homeostasis is the maintenance of a normal range of values, this does not mean that all variables remain within the same narrow range of values at all times. Sometimes a deviation from the usual range of values can be beneficial. For example, during exercise the normal range for blood pressure differs from the range under resting conditions and the blood pressure is significantly elevated (figure 1.7). Muscle cells require increased oxygen and nutrients and increased removal of waste products to support their heightened level of activity during exercise. Elevated blood pressure increases delivery of blood to muscles during exercise, thereby increasing the delivery of oxygen and nutrients and the removal of waste products—ultimately maintaining muscle cell homeostasis.

► Predict 5

What effect would swimming in cool water have on body temperature regulation? What would happen if a negative-feedback mechanism did not return the value of a variable, such as body temperature, to its normal range?

Positive Feedback

Positive-feedback mechanisms occur when a response to the original stimulus results in the deviation from the set point becoming even greater. At times, this type of response is required to re-achieve homeostasis. For example, during blood loss, a chemical responsible for blood clot formation, called thrombin, stimulates production of even more thrombin (figure 1.8). In this way, a disruption in homeostasis is resolved through a positive-feedback mechanism. What prevents the entire vascular system from clotting? The clot formation process is self-limiting. Eventually, the components needed to form a clot will be depleted in the damaged area and no more clot material can be formed.

Birth is another example of a normally occurring positive-feedback mechanism. Near the end of pregnancy, the baby's larger size stretches the uterus. This stretching, especially around the opening of the uterus, stimulates contractions of the uterine muscles. The uterine contractions push the baby against the opening of the uterus and stretch it further. This stimulates additional contractions, which result in additional stretching. This positive-feedback sequence ends only when the baby is delivered from the uterus and the stretching stimulus is eliminated.

Two basic principles to remember are that (1) many disease states result from the failure of negative-feedback mechanisms to maintain homeostasis and (2) some positive-feedback mechanisms can be detrimental instead of helpful. One example of a detrimental positive-feedback mechanism is inadequate delivery of blood to cardiac (heart) muscle. Contraction of cardiac muscle generates blood pressure and the heart pumps blood to itself through a system of blood vessels on the outside of the heart. Just as with other

HOMEOSTASIS FIGURE 1.6 Negative-Feedback Control of Body Temperature

Throughout this book, all homeostasis figures have the same format as shown here. The changes caused by the increase of a variable outside the normal range are shown in the *green boxes*, and the changes caused by a decrease are shown in the *red boxes*. To help you learn how to interpret homeostasis figures, some of the steps in this figure are numbered. (1) Body temperature is within its normal range. (2) Body temperature increases outside the normal range, which causes homeostasis to be disturbed. (3) The body temperature control center in the brain responds to the change in body temperature. (4) The control center causes sweat glands to produce sweat and blood vessels in the skin to dilate. (5) These changes cause body temperature to decrease. (6) Body temperature returns to its normal range, and homeostasis is restored. Observe the responses to a decrease in body temperature outside its normal range by following the *red arrows*.

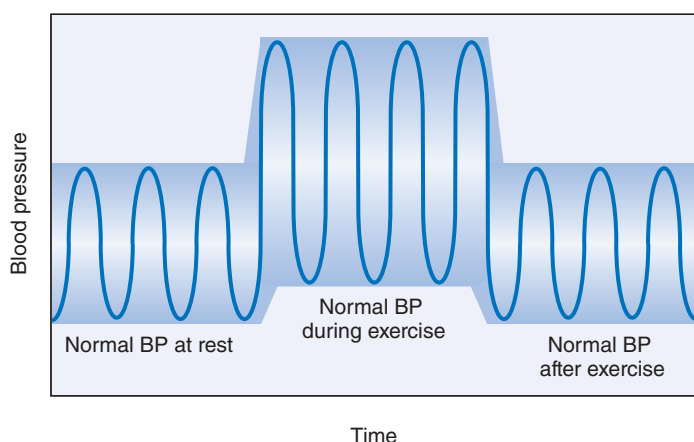

FIGURE 1.7 Changes in Blood Pressure During Exercise

During exercise, muscle tissue demands more oxygen. To meet this demand, blood pressure (BP) increases, resulting in an increase in blood flow to the tissues. The increased blood pressure is not an abnormal or nonhomeostatic condition but a resetting of the normal homeostatic range to meet the increased demand. The reset range is higher and broader than the resting range. After exercise ceases, the range returns to that of the resting condition.

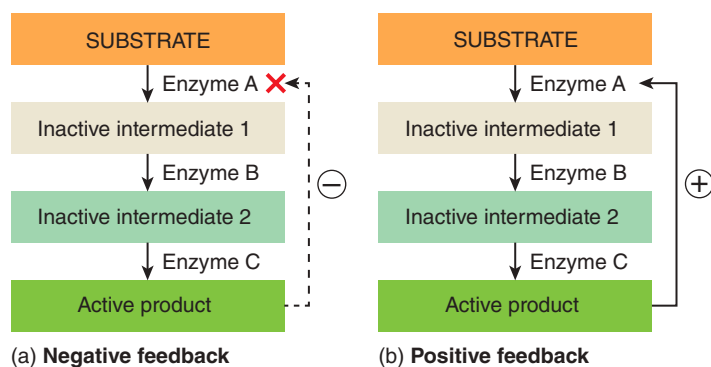

FIGURE 1.8 Comparison of Negative-Feedback and Positive-Feedback Mechanisms

(a) In negative feedback, the response *stops* the effector as indicated by the dashed line, the negative symbol, and the red X. (b) In positive feedback, the response keeps the reaction going as indicated by the solid line and the positive symbol. For example, during blood clotting, the “active product” represents thrombin, which triggers “enzyme A,” the first step in the cascade that leads to the production of thrombin.

tissues, blood pressure must be maintained to ensure adequate delivery of blood to the cardiac muscle. Following extreme blood loss, blood pressure decreases to the point that the delivery of blood to cardiac muscle is inadequate. As a result, cardiac muscle does not function normally. The heart pumps less blood, which causes the blood pressure to drop even further—a deviation further from the setpoint. The additional decrease in blood pressure further reduces blood delivery to cardiac muscle, and the heart pumps even less blood, which again decreases the blood pressure. The process self-propagates until the blood pressure is too low to sustain the cardiac muscle, the heart stops beating, and death results. In this example, we see the deviation from the heart rate set point

becoming larger and larger—this is a positive-feedback mechanism. Thus, if blood loss is severe, negative-feedback mechanisms may not be able to maintain homeostasis, and the positive feedback of ever-decreasing blood pressure can develop. On the other hand, following a moderate amount of blood loss (e.g., after donating a pint of blood), *negative-feedback mechanisms* result in an increase in heart rate, which restores blood pressure.

ASSESS YOUR PROGRESS

- How do variables, set points, and normal ranges relate to homeostasis?
- Distinguish between negative feedback and positive feedback.
- What are the three components of a negative-feedback mechanism?
- Give an example of how a negative-feedback mechanism maintains homeostasis.
- Give an example of a positive-feedback mechanism that may be harmful to the body and an example of one that is not harmful.

Predict 6

Ashley is on the track team and is running an 800-meter race. Throughout the race, her respiratory rate increases rapidly. Does this represent negative or positive feedback? Explain.

1.6 Terminology and the Body Plan

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe a person in the anatomical position.
- Define the directional terms for the human body and use them to locate specific body structures.
- Know the terms for the parts and regions of the body.
- Name and describe the three major planes of the body.
- Name and describe the three major ways to cut an organ.
- Describe the major trunk cavities and their divisions.
- Locate organs in their specific cavity, abdominal quadrant, or region.
- Describe the serous membranes, their locations, and their functions.

As you study anatomy and physiology, you will be learning many new words. Knowing the derivation, or **etymology** (et’uh-mol’ō-jē), of these words can make learning them easy and fun. Most anatomical terms are derived from Latin or Greek. For example, *foramen* is a Latin word for “hole,” and *magnum* means “large.” The foramen magnum is therefore a large hole in the skull through which the spinal cord attaches to the brain.

FIGURE 1.9 Directional Terms

All directional terms are in relation to the body in the anatomical position: a person standing erect with the face directed forward, the arms hanging to the sides, and the palms of the hands facing forward. **APR**

Prefixes and suffixes can be added to words to expand their meaning. For example, the suffix *-itis* means an inflammation, so appendicitis is an inflammation of the appendix. As new terms are introduced in this text, their meanings are often explained. The glossary and the list of word roots, prefixes, and suffixes on the inside back cover provide additional information about the new terms.

It is very helpful to learn these new words, so that your message is clear and correct when you speak to colleagues or write reports. Additionally, you will find many of the roots of words appearing over and over again. For example, in chapter 7, you will learn a specific region of the scapula called the *infraspinous fossa*. Later, in chapter 10, you learn that the muscle in that region is named the *infraspinatus*.

Body Positions

Anatomical position refers to a person standing erect with the face directed forward, the upper limbs hanging to the sides, and the palms of the hands facing forward (figure 1.9). A person is **supine** when lying face upward and **prone** when lying face downward.

The position of the body can affect the description of body parts relative to each other. In the anatomical position, the elbow

is above the hand but, in the supine or prone position, the elbow and hand are at the same level. To avoid confusion, relational descriptions are always based on the anatomical position, no matter the actual position of the body. Thus, the chest is always described as being “above” (superior to) the stomach, whether the person is lying down or is even upside down.

Directional Terms

Directional terms describe parts of the body relative to each other. Important directional terms are illustrated in figure 1.9 and summarized in table 1.2. It is important to become familiar with these directional terms as soon as possible because you will see them repeatedly throughout this text. **Right** and **left** are used as directional terms in anatomical terminology. *Up* is replaced by **superior**, *down* by **inferior**, *front* by **anterior**, and *back* by **posterior**.

In humans, the term *superior* is interchangeable with the term **cephalic** (se-fal’ik). They are both used for “toward the head,” because, when we are in the anatomical position, the head is the highest point. Similarly, in humans, the term *inferior* is interchangeable with the term **caudal** (kaw’däl). These two terms are used for “toward the tail,” the area located at the end of the

TABLE 1.2 Directional Terms for Humans

Terms	Etymology*	Definition	Examples
Right		Toward the right side of the body	Right ear
Left		Toward the left side of the body	Left eye
Superior	L. higher	A structure above another	The chin is superior to the navel.
Inferior	L. lower	A structure below another	The navel is inferior to the chin.
Cephalic	G. <i>kephale</i> , head	Closer to the head than another structure (usually synonymous with <i>superior</i>)	The chin is cephalic to the navel.
Caudal	L. <i>cauda</i> , a tail	Closer to the tail than another structure (usually synonymous with <i>inferior</i>)	The navel is caudal to the chin.
Anterior	L. before	The front of the body	The navel is anterior to the spine.
Posterior	L. <i>posterus</i> , following	The back of the body	The spine is posterior to the breastbone.
Ventral	L. <i>ventr-</i> , belly	Toward the belly (synonymous with <i>anterior</i>)	The navel is ventral to the spine.
Dorsal	L. <i>dorsum</i> , back	Toward the back (synonymous with <i>posterior</i>)	The spine is dorsal to the breastbone.
Proximal	L. <i>proximus</i> , nearest	Closer to the point of attachment to the body than another structure	The elbow is proximal to the wrist.
Distal	L. <i>di-</i> plus <i>sto</i> , to stand apart or be distant	Farther from the point of attachment to the body than another structure	The wrist is distal to the elbow.
Lateral	L. <i>latus</i> , side	Away from the midline of the body	The nipple is lateral to the breastbone.
Medial	L. <i>medialis</i> , middle	Toward the midline of the body	The nose is medial to the eye.
Superficial	L. <i>superficialis</i> , toward the surface	Toward or on the surface (not shown in figure 1.10)	The skin is superficial to muscle.
Deep	O.E. <i>deop</i> , deep	Away from the surface, internal (not shown in figure 1.10)	The lungs are deep to the ribs.

*Origin and meaning of the word: L., Latin; G., Greek; O.E., Old English.

vertebral column where a tail would be. In other animals, such as a cat, the terms *cephalic* and *caudal* can be used to describe directional movements on the trunk, but they are not used to describe directional movements on the limbs.

The word *anterior* means “that which goes before,” and **ventral** means “belly.” The anterior surface of the human body is therefore the ventral surface, or belly, because the belly “goes first” when we are walking. The word *posterior* means “that which follows,” and **dorsal** means “back.” The posterior surface of the body is the dorsal surface, or back, which follows as we are walking.

➤ Predict 7

The anatomical position of a cat refers to the animal standing erect on all four limbs and facing forward. On the basis of the etymology of the directional terms, which two terms indicate movement toward the cat’s head? What two terms mean movement toward the cat’s back? Compare these terms with those referring to a human in the anatomical position.

Proximal means “nearest,” whereas **distal** means “distant.” These terms are used to refer to linear structures, such as the limbs, in which one end is near another structure and the other end is farther away. Each limb is attached at its proximal end to the body, and the distal end, such as the hand, is farther away.

Medial means “toward the midline,” and **lateral** means “away from the midline.” The nose is in a medial position in the

face, and the eyes are lateral to the nose. **Superficial** describes a structure close to the surface of the body, and **deep** is toward the interior of the body. The skin is superficial to muscle and bone.

ASSESS YOUR PROGRESS

16. What is anatomical position in humans? Why is it important?
17. What two directional terms indicate “toward the head” in humans? What are the opposite terms?
18. What two directional terms indicate “the back” in humans? What are the opposite terms?
19. Define the following directional terms and give the term that means the opposite: proximal, lateral, and superficial.

➤ Predict 8

Use as many directional terms as you can to describe the relationship between your kneecap and your heel.

Body Parts and Regions

Health professionals use a number of terms when referring to different parts or regions of the body. Figure 1.10 shows the anatomical terms, with the common terms in parentheses.

FIGURE 1.10 Body Parts and Regions

The anatomical and common (*in parentheses*) names are indicated for the major parts and regions of the body. (a) Anterior view. **APIR**

The central region of the body consists of the **head, neck, and trunk**. The trunk can be divided into the **thorax, abdomen, and pelvis**. The thorax is the chest cavity where the heart and lungs are located. The abdomen contains organs such as the liver, stomach, and intestines. The pelvis contains the bladder and reproductive organs. The upper limb is divided into the arm, forearm, wrist, and hand. The **arm** extends from the shoulder to the elbow, and the **forearm** extends from the elbow to the wrist. The lower limb is divided into the thigh, leg, ankle, and foot. The **thigh** extends from the hip to the knee, and the **leg** extends from the knee to the ankle. Note that, contrary to popular usage, the terms *arm* and *leg* refer to only a part of the limb.

The abdomen is often subdivided superficially into **quadrants** by two imaginary lines—one horizontal and one vertical—that intersect at the navel (figure 1.11a). The quadrants formed are the right-upper, left-upper, right-lower, and left-lower quadrants. In addition to these quadrants, the abdomen is sometimes subdivided into **regions** by four imaginary lines: two horizontal and two vertical. These four lines create a “virtual” tic-tac-toe grid on the abdomen, resulting in nine regions: epigastric, right and left hypochondriac, umbilical, right and left lumbar, hypogastric, and right and left iliac (figure 1.11b). Health professionals use the

quadrants and regions as reference points for locating underlying organs. For example, the appendix is in the right-lower quadrant, and the pain of an acute appendicitis is usually felt there.

Planes

At times, it is useful to describe the body as having imaginary flat surfaces, called **planes**, passing through it (figure 1.12). A plane divides, or sections, the body, making it possible to “look inside” and observe the body’s structures. A **sagittal** (saj’i-tāl) **plane** runs vertically through the body, separating it into right and left portions. The word *sagittal* literally means “the flight of an arrow” and refers to the way the body would be split by an arrow passing anteriorly to posteriorly. A **median plane** is a sagittal plane that passes through the midline of the body, dividing it into equal right and left halves. A **transverse (horizontal) plane** runs parallel to the ground, dividing the body into superior and inferior portions. A **frontal (coronal)** (kōr’ō-nāl, kō-rō’nāl; crown) **plane** runs vertically to divide the body into anterior (front) and posterior (back) parts.

Organs are often sectioned to reveal their internal structure (figure 1.13). A cut through the length of the organ is a

FIGURE 1.10 (continued)

(b) Posterior view.

FIGURE 1.11 Subdivisions of the Abdomen

Lines are superimposed over internal organs to demonstrate the subdivisions they lie in. (a) Abdominal quadrants. (b) There are nine abdominal regions.

FIGURE 1.12 Planes Through the Body

(a) Planes through the body are indicated by “glass” sheets. Also shown are actual sections through (b) the head (viewed from the right), (c) the abdomen (*inferior view*), and (d) the hip (*anterior view*). **APR**

FIGURE 1.13 Planes Through an Organ

Planes through the small intestine are indicated by “glass” sheets. The views of the small intestine after sectioning are also shown. Although the small intestine is basically a tube, the sections appear quite different in shape.

longitudinal section, and a cut at a right angle to the length of an organ is a **transverse (cross) section**. If a cut is made across the length of an organ at other than a right angle, it is called an **oblique section**.

ASSESS YOUR PROGRESS

20. What makes up the central region of the body?
21. What is the difference between the arm and the upper limb? Between the leg and the lower limb?
22. What are the anatomical terms for the following common body terms—neck, mouth, hand, front of elbow, calf, sole?
23. In what quadrant would the majority of the stomach be located? In which region(s)?
24. List and describe the three planes of the body.
25. In what three ways can you cut an organ?

Body Cavities

The body contains many cavities. Some of these cavities, such as the nasal cavity, open to the outside of the body, and some do not. The trunk contains three large cavities that do not open to the outside of the body: the thoracic, the abdominal, and the pelvic cavities (figure 1.14). The rib cage surrounds the **thoracic cavity**, and the muscular diaphragm separates it from the abdominal cavity. The thoracic cavity is divided into right and left parts by a middle section called the **mediastinum** (mē'dē-as-tī'nūm; middle wall). The mediastinum contains the heart, the thymus, the trachea, the

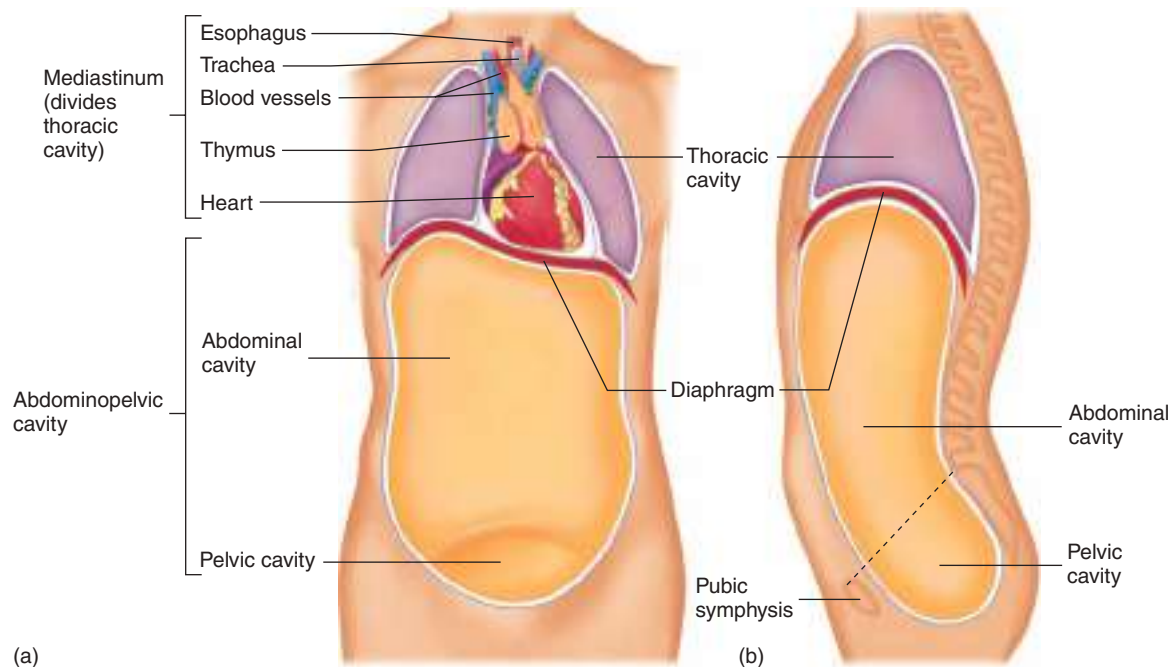

FIGURE 1.14 Trunk Cavities

(a) Anterior view showing the major trunk cavities. The diaphragm separates the thoracic cavity from the abdominal cavity. The mediastinum, which includes the heart, is a partition of organs dividing the thoracic cavity. (b) Sagittal section of the trunk cavities viewed from the left. The dashed line shows the division between the abdominal and pelvic cavities. The mediastinum has been removed to show the thoracic cavity. **APR**

FIGURE 1.15 Serous Membranes

(a) A fist pushing into a balloon. A “glass” sheet indicates the location of a section through the balloon. (b) Interior view produced by the section in (a). The fist represents an organ, and the walls of the balloon represent the serous membranes. The inner wall of the balloon represents a visceral serous membrane in contact with the fist (organ). The outer wall of the balloon represents a parietal serous membrane. (c) The relationship of the parietal and serous membranes to the lungs. Figure 1.16 shows the relationship of the parietal and visceral membranes to the heart.

esophagus, and other structures, such as blood vessels and nerves. The two lungs are located on each side of the mediastinum.

Abdominal muscles primarily enclose the **abdominal cavity**, which contains the stomach, the intestines, the liver, the spleen, the pancreas, and the kidneys. Pelvic bones encase the small space known as the **pelvic cavity**, where the urinary bladder, part of the large intestine, and the internal reproductive organs are housed. The abdominal and pelvic cavities are not physically separated and sometimes are called the **abdominopelvic cavity**.

Serous Membranes

Serous (sēr'ūs) **membranes** line the trunk cavities and cover the organs within these cavities. *Parietal* membranes are found against the outer wall of a body cavity, and *visceral* membranes are found covering the organs in a body cavity. Imagine pushing your fist into an inflated balloon (figure 1.15). Your fist represents an organ; the inner balloon wall in contact with your fist represents the **visceral** (vis'er-āl; organ) **serous membrane** covering the organ; and the outer part of the balloon wall represents the **parietal** (pā-rī'ě-tāl; wall) **serous membrane**. The cavity, or space, between the visceral and parietal serous membranes is normally filled with a thin, lubricating film of serous fluid produced by the membranes. As organs rub against the body wall or against another organ, the combination of serous fluid and smooth serous membranes reduces friction.

The thoracic cavity contains three serous membrane-lined cavities: a cavity for the heart called the **pericardial** (per-i-kar'dē-āl; around the heart) **cavity** and two lung cavities called the **pleural** (ploor'āl; associated with the ribs) **cavities**. The pericardial cavity surrounds the heart (figure 1.16a). The visceral pericardium covers the heart, which is contained within a connective tissue sac lined with the parietal pericardium. The pericardial cavity, which

contains pericardial fluid, is located between the visceral pericardium and the parietal pericardium.

Each lung is covered by visceral pleura and surrounded by a pleural cavity (figure 1.16b). Parietal pleura line the inner surface of the thoracic wall, the outer surface of the parietal pericardium, and the superior surface of the diaphragm. The pleural cavity lies between the visceral pleura and the parietal pleura and contains pleural fluid.

The abdominopelvic cavity contains a serous membrane-lined cavity called the **peritoneal** (per'i-tō-nē'āl; to stretch over) **cavity** (figure 1.16c). **Visceral peritoneum** covers many of the organs of the abdominopelvic cavity. **Parietal peritoneum** lines the wall of the abdominopelvic cavity and the inferior surface of the diaphragm. The peritoneal cavity is located between the visceral peritoneum and the parietal peritoneum and contains peritoneal fluid.

The serous membranes can become inflamed, usually as a result of an infection. **Pericarditis** (per'i-kar-dī'tis; -itis, inflammation) is inflammation of the pericardium, **pleurisy** (ploor'i-sē) is inflammation of the pleura, and **peritonitis** (per'i-tō-nī'tis) is inflammation of the peritoneum.

The abdominopelvic cavity also has other specialized membranes in addition to the parietal and visceral membranes, called **mesenteries** (mes'en-ter-ēz). The mesenteries anchor the organs to the body wall and provide a pathway for nerves and blood vessels to reach the organs. The mesenteries consist of two layers of peritoneum fused together (figure 1.16d). They connect the visceral peritoneum of some abdominopelvic organs to the parietal peritoneum on the body wall. The mesenteries also connect certain organs' visceral peritoneum to the visceral peritoneum of other abdominopelvic organs. Other abdominopelvic organs are more closely attached to the body wall and do not have mesenteries. Parietal peritoneum covers these other organs, which

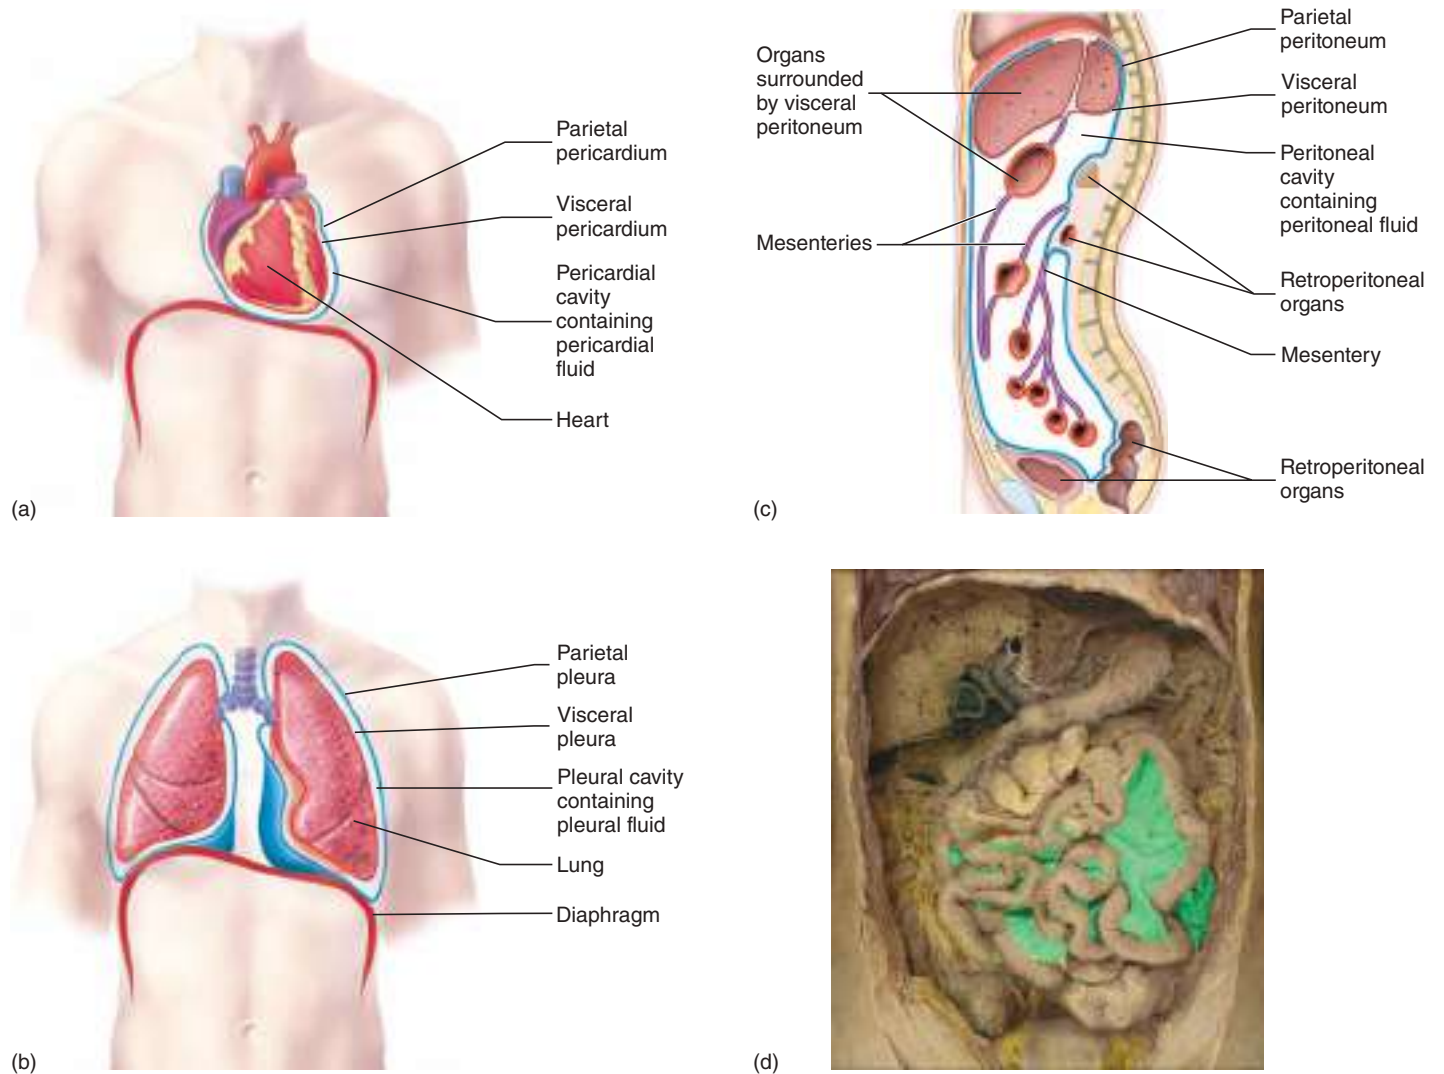

FIGURE 1.16 Location of Serous Membranes

(a) Frontal section showing the parietal pericardium (*blue*), the visceral pericardium (*red*), and the pericardial cavity. (b) Frontal section showing the parietal pleura (*blue*), the visceral pleura (*red*), and the pleural cavities. (c) Sagittal section through the abdominopelvic cavity showing the parietal peritoneum (*blue*), the visceral peritoneum (*red*), the peritoneal cavity, mesenteries (*purple*), and parts of the retroperitoneal organs. (d) Photo of mesentery (*green*) in a cadaver.

are said to be **retroperitoneal** (re'trō-per'i-tō-nē'ăl; behind the peritoneum). The retroperitoneal organs include the kidneys, the adrenal glands, the pancreas, parts of the intestines, and the urinary bladder (see figure 1.16c).

ASSESS YOUR PROGRESS

26. What structure separates the thoracic cavity from the abdominal cavity? The abdominal cavity from the pelvic cavity?
27. What structure divides the thoracic cavity into right and left parts?

28. What is a serous membrane and its function? Differentiate between the parietal and visceral portions of a serous membrane.
29. Name the serous membrane-lined cavities of the trunk.
30. What are mesenteries? Explain their function.
31. What are retroperitoneal organs? List five examples.

Predict 9

Explain how an organ can be located within the abdominopelvic cavity but not be within the peritoneal cavity.

Answer

Learn to Predict From page 1

The first Predict in every chapter of this text is designed to help you develop the skills to successfully answer critical thinking questions. The first step in the process is always to analyze the question itself. In this case, the question asks you to evaluate the mechanisms governing Renzo's blood sugar levels, and it provides the clue that there's a homeostatic mechanism involved. In addition, the question describes a series of events that help create an explanation: Renzo doesn't feel satisfied after eating, has elevated blood sugar, and then is prescribed an insulin pump. In chapter 1, we learn that homeostasis is the existence and maintenance of a relatively constant internal environment. Renzo experienced hunger despite eating, and his blood sugar levels were higher

than normal. In this situation, we saw a disruption in homeostasis because his blood sugar stayed too high after eating. Normally, increased blood sugar after a meal would return to the normal range by the activity of insulin secreted by the pancreas. When blood sugar returns to normal, insulin secretion stops. In Renzo's case, his pancreas has stopped making insulin. Thus, the doctor prescribed an insulin pump to take over for his pancreas. Now when Renzo eats, the insulin pump puts insulin into his blood, and his blood sugar levels are maintained near the set point.

Answers to the rest of this chapter's Predict questions are in appendix G.

Knowledge of anatomy and physiology can be used to solve problems concerning the body when healthy or diseased.

1.1 Anatomy and Physiology (p. 2)

1. Anatomy is the study of the body's structures.
 - Developmental anatomy considers anatomical changes from conception to adulthood. Embryology focuses on the first 8 weeks of development.
 - Cytology examines cells, and histology examines tissues.
 - Gross anatomy studies organs from either a systemic or a regional perspective.
2. Surface anatomy uses superficial structures to locate internal structures, and anatomical imaging is a noninvasive technique for identifying internal (deep) structures.
3. Physiology is the study of the body's functions. It can be approached from a cellular or a systems point of view.
4. Pathology deals with all aspects of disease. Exercise physiology examines changes caused by exercise.

1.2 Structural and Functional Organization of the Human Body (p. 4)

1. Basic chemical characteristics are responsible for the structure and functions of life.
2. Cells are the basic structural and functional units of organisms, such as plants and animals. Organelles are small structures within cells that perform specific functions.
3. Tissues are composed of groups of cells of similar structure and function and the materials surrounding them. The four primary tissue types are epithelial, connective, muscle, and nervous tissues.
4. Organs are structures composed of two or more tissues that perform specific functions.

Summary

5. Organs are arranged into the 11 organ systems of the human body (see figure 1.3).
6. Organ systems interact to form a whole, functioning organism.

1.3 Characteristics of Life (p. 6)

Humans share many characteristics with other organisms, such as organization, metabolism, responsiveness, growth, development, and reproduction.

1.4 Biomedical Research (p. 9)

Much of our knowledge about humans is derived from research on other organisms.

1.5 Homeostasis (p. 9)

Homeostasis is the condition in which body functions, body fluids, and other factors of the internal environment are maintained at levels suitable to support life.

Negative Feedback

1. Negative-feedback mechanisms maintain homeostasis.
2. Many negative-feedback mechanisms consist of a receptor, a control center, and an effector.

Positive Feedback

1. Positive-feedback mechanisms usually result in deviations further from the set point.
2. Although a few positive-feedback mechanisms are normal for maintaining homeostasis in the body, some positive-feedback mechanisms can be harmful.
3. Normal positive-feedback mechanisms include blood clotting and childbirth labor. Harmful positive-feedback examples include decreased blood flow to the heart.

1.6 Terminology and the Body Plan (p. 13)

Body Positions

1. A human standing erect with the face directed forward, the arms hanging to the sides, and the palms facing forward is in the anatomical position.
2. A person lying face upward is supine; a person lying face downward is prone.

Directional Terms

Directional terms always refer to the anatomical position, no matter what the actual position of the body (see table 1.2).

Body Parts and Regions

1. The body can be divided into a central region, consisting of the head, neck, and trunk, and the upper limbs and lower limbs.
2. Superficially, the abdomen can be divided into quadrants or into nine regions. These divisions are useful for locating internal organs or describing the location of a pain or a tumor.

Planes

1. Planes of the body
 - A sagittal plane divides the body into right and left parts. A median plane divides the body into equal right and left halves.
 - A transverse (horizontal) plane divides the body into superior and inferior portions.
 - A frontal (coronal) plane divides the body into anterior and posterior parts.

2. Sections of an organ
 - A longitudinal section of an organ divides it along the length of the organ.
 - A transverse (cross) section cuts at a right angle to the length of the organ.
 - An oblique section cuts across the length of an organ at an angle other than a right angle.

Body Cavities

1. The mediastinum subdivides the thoracic cavity.
2. The diaphragm separates the thoracic and abdominal cavities.
3. Pelvic bones surround the pelvic cavity.

Serous Membranes

1. Serous membranes line the trunk cavities. The parietal portion of a serous membrane lines the wall of the cavity, and the visceral portion is in contact with the internal organs.
 - The serous membranes secrete fluid, which fills the space between the visceral and parietal membranes. The serous membranes protect organs from friction.
 - The pericardial cavity surrounds the heart, the pleural cavities surround the lungs, and the peritoneal cavity surrounds certain abdominal and pelvic organs.
2. Mesenteries are parts of the peritoneum that hold the abdominal organs in place and provide a passageway for blood vessels and nerves to the organs.
3. Retroperitoneal organs are located “behind” the parietal peritoneum.

REVIEW AND COMPREHENSION

1. Physiology
 - a. deals with the processes or functions of living things.
 - b. is the scientific discipline that investigates the body’s structures.
 - c. is concerned with organisms and does not deal with levels of organization, such as cells and systems.
 - d. recognizes the static (as opposed to the dynamic) nature of living things.
 - e. can be used to study the human body without considering anatomy.

2. The following are organizational levels for considering the body.

- (1) cell
- (2) chemical
- (3) organ
- (4) organ system
- (5) organism
- (6) tissue

Choose the correct order for these organizational levels, from simplest to most complex.

- | | | |
|----------------|----------------|----------------|
| a. 1,2,3,6,4,5 | c. 3,1,6,4,5,2 | e. 1,6,5,3,4,2 |
| b. 2,1,6,3,4,5 | d. 4,6,1,3,5,2 | |

For questions 3–7, match each organ system with one of the following functions.

- a. regulates other organ systems
- b. removes waste products from the blood; maintains water balance
- c. regulates temperature; reduces water loss; provides protection
- d. removes foreign substances from the blood; combats disease; maintains tissue fluid balance
- e. produces movement; maintains posture; produces body heat

3. Endocrine system
4. Integumentary system
5. Muscular system
6. Nervous system
7. Urinary system
8. The characteristic of life that is defined as “all the chemical reactions taking place in an organism” is
 - a. development.
 - b. growth.
 - c. metabolism.
 - d. organization.
 - e. responsiveness.
9. The following events are part of a negative-feedback mechanism.
 - (1) Blood pressure increases.
 - (2) The control center compares actual blood pressure to the blood pressure set point.
 - (3) The heart beats faster.
 - (4) Receptors detect a decrease in blood pressure.

Choose the arrangement that lists the events in the order they occur.

- | | | |
|------------|------------|------------|
| a. 1,2,3,4 | c. 3,1,4,2 | e. 4,3,2,1 |
| b. 1,3,2,4 | d. 4,2,3,1 | |

10. Which of these statements concerning positive feedback is correct?
 - a. Positive-feedback responses maintain homeostasis.
 - b. Positive-feedback responses occur continuously in healthy individuals.
 - c. Birth is an example of a normally occurring positive-feedback mechanism.

- d. When cardiac muscle receives an inadequate supply of blood, positive-feedback mechanisms increase blood flow to the heart.
- e. Medical therapy seeks to overcome illness by aiding positive-feedback mechanisms.
11. A term that means nearer the attached end of a limb is
- distal.
 - lateral.
 - medial.
 - proximal.
 - superficial.
12. Which of these directional terms are paired most appropriately as opposites?
- superficial and deep
 - medial and proximal
 - distal and lateral
 - superior and posterior
 - anterior and inferior
13. The part of the upper limb between the elbow and the wrist is called the
- arm.
 - forearm.
 - hand.
 - inferior arm.
 - lower arm.
14. A patient with appendicitis usually has pain in the _____ quadrant of the abdomen.
- left-lower
 - right-lower
 - left-upper
 - right-upper
15. A plane that divides the body into anterior and posterior parts is a
- frontal (coronal) plane.
 - sagittal plane.
 - transverse plane.
16. The lungs are
- part of the mediastinum.
 - surrounded by the pericardial cavity.
 - found within the thoracic cavity.
 - separated from each other by the diaphragm.
 - surrounded by mucous membranes.
17. Given the following organ and cavity combinations:
- heart and pericardial cavity
 - lungs and pleural cavity
 - stomach and peritoneal cavity
 - kidney and peritoneal cavity
- Which of the organs is correctly paired with a space that surrounds that organ?
- 1,2
 - 1,2,3
 - 1,2,4
 - 2,3,4
 - 1,2,3,4
18. Which of the following membrane combinations are found on the superior and inferior surface of the diaphragm?
- parietal pleura—parietal peritoneum
 - parietal pleura—visceral peritoneum
 - visceral pleura—parietal peritoneum
 - visceral pleura—visceral peritoneum
19. Which of the following organs are *not* retroperitoneal?
- adrenal glands
 - urinary bladder
 - kidneys
 - pancreas
 - stomach

Answers in appendix E

CRITICAL THINKING

- Exposure to a hot environment causes the body to sweat. The hotter the environment, the greater the sweating. Two anatomy and physiology students are arguing about the mechanisms involved. Student A claims that they are positive feedback, and student B claims they are negative feedback. Do you agree with student A or student B, and why?
- A male has lost blood as a result of a gunshot wound. Even though the bleeding has been stopped, his blood pressure is low and dropping, and his heart rate is elevated. Following a blood transfusion, his blood pressure increases and his heart rate decreases. Which of the following statement(s) is (are) consistent with these observations?
 - Negative-feedback mechanisms can be inadequate without medical intervention.
 - The transfusion interrupted a positive-feedback mechanism.
 - The increased heart rate after the gunshot wound and before the transfusion is a result of a positive-feedback mechanism.
 - a and b
 - a, b, and c
- Provide the correct directional term for the following statement: When a boy is standing on his head, his nose is _____ to his mouth.
- During pregnancy, which of the mother's body cavities increases most in size?
- A woman falls while skiing and is accidentally impaled by her ski pole. The pole passes through the abdominal body wall and into and through the stomach, pierces the diaphragm, and finally stops in the left lung. List, in order, the serous membranes the pole pierces.

Answers in appendix F

The Chemical Basis of Life

Life is chemistry. Chemicals compose the structures of the body, and the interactions of chemicals with one another are responsible for the body's functions. Nerve impulse generation, digestion, muscle contraction, and metabolism can be described in chemical terms, and so can many abnormal conditions and illnesses, as well as their treatments. These diverse functions all involve intricate interactions between molecules. For example, chemicals in saliva interact with food to aid in digestion, and membrane proteins assemble to form a pore for ions to pass into and out of our cells to aid in nerve impulse generation and muscle contraction. To understand anatomy and physiology, it is essential to have a basic knowledge of chemistry—the scientific discipline concerned with the atomic composition of substances and the reactions they undergo. This chapter is not a comprehensive treatment of chemistry, but it does review some of the basic chemical concepts related to living systems. When necessary, refer back to this chapter when chemical processes are discussed later in the book.

Learn to Predict

Brad and his lab partner, Angie, mixed a small amount of starch into a test tube of water. Then they added iodine, which stained the starch molecules blue. Next they added saliva to the test tube. After 30 minutes, the blue color disappeared. This exercise demonstrates the consequences of metabolism in the absence of homeostasis (described in chapter 1). Homeostasis often involves a balance of chemical reactions that will make and break molecules, such as starch. In the test tube, only one reaction occurred. After reading the chapter, you will have learned that the rate of a chemical reaction can be greatly increased by enzymes in cells and body fluids, and you will understand the roles of two chemical phenomena—activation energy and decomposition reactions. **Considering the properties of enzymes and chemical reactions, can you explain why the blue color in the test tube disappeared?**

Photo: The chemical composition of the body's structures determines their function. This ribbon diagram of a potassium channel protein (Kv1.2) shows the four subunits (in different colors) assembled together to create a pore for the passage of potassium ions (purple balls) across the plasma membrane. A view from the side (right) and a top-down view (left) of the channel are shown.

2.1 Basic Chemistry

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Define **matter**, **mass**, and **weight**.
- B. Distinguish between **elements and atoms**, and state the **four most abundant elements in the body**.
- C. Name the **subatomic particles of an atom**, and indicate their **mass, charge, and location in an atom**.
- D. Define **atomic number**, **mass number**, **isotope**, **atomic mass**, and **mole**.
- E. Compare and contrast **ionic and covalent bonds**.
- F. Differentiate between a **molecule and a compound**.
- G. Explain what creates a **hydrogen bond**, and relate its **importance**.
- H. Describe **solubility and the process of dissociation**, and predict if a **compound or molecule is an electrolyte or a nonelectrolyte**.

Matter, Mass, and Weight

All living and nonliving things are composed of **matter**, which is anything that occupies space and has mass. **Mass** is the amount of matter in an object, and **weight** is the gravitational force acting on an object of a given mass. For example, the weight of an apple results from the force of gravity “pulling” on the apple’s mass.

Predict 2

The difference between mass and weight can be illustrated by considering an astronaut. How do an astronaut’s mass and weight in outer space compare with the astronaut’s mass and weight on the earth’s surface?

The international unit for mass is the **kilogram (kg)**, which is the mass of a platinum-iridium cylinder kept at the International Bureau of Weights and Measurements in France. The mass of all other objects is compared with this cylinder. For example, a 2.2-pound lead weight and 1 liter (L) (1.06 qt) of water each have a mass of approximately 1 kg. An object with 1/1000 the mass of a kilogram has a mass of 1 **gram (g)**.

Elements and Atoms

An **element** is the simplest type of matter, having unique chemical properties. A list of the elements commonly found in the human body appears in table 2.1. About 96% of the body’s weight results from the elements oxygen, carbon, hydrogen, and nitrogen. The majority of the body’s weight is from oxygen. Oxygen is also the most abundant element in the earth’s crust. Carbon plays an especially important role in the chemistry of the body, due in part to its propensity to form covalent bonds with itself and other molecules. Many elements are present in only trace amounts but still play essential roles in the body. Elements can have multiple roles and exist in different states in the body. For example, mineralized calcium contributes to the solid matrix of bones, while dissolved calcium helps regulate enzyme activities and nervous system signaling.

An **atom** (*atomos*, indivisible) is the smallest particle of an element that has the chemical characteristics of that element. An element is composed of atoms of only one kind. For example, the element carbon is composed of only carbon atoms, and the element oxygen is composed of only oxygen atoms.

An element, or an atom of that element, is often represented by a symbol. Usually, the symbol is the first letter or letters of the element’s name—for example, C for carbon, H for hydrogen, and

TABLE 2.1 Common Elements in the Human Body

Element	Symbol	Atomic Number	Mass Number	Atomic Mass	Percent in Human Body by Weight (%)	Percent in Human Body by Number of Atoms (%)
Hydrogen	H	1	1	1.008	9.5	63.0
Carbon	C	6	12	12.01	18.5	9.5
Nitrogen	N	7	14	14.01	3.3	1.4
Oxygen	O	8	16	16.00	65.0	25.5
Fluorine	F	9	19	19.00	Trace	Trace
Sodium	Na	11	23	22.99	0.2	0.3
Magnesium	Mg	12	24	24.31	0.1	0.1
Phosphorus	P	15	31	30.97	1.0	0.22
Sulfur	S	16	32	32.07	0.3	0.05
Chlorine	Cl	17	35	35.45	0.2	0.03
Potassium	K	19	39	39.10	0.4	0.06
Calcium	Ca	20	40	40.08	1.5	0.31
Iron	Fe	26	56	55.85	Trace	Trace
Iodine	I	53	127	126.9	Trace	Trace

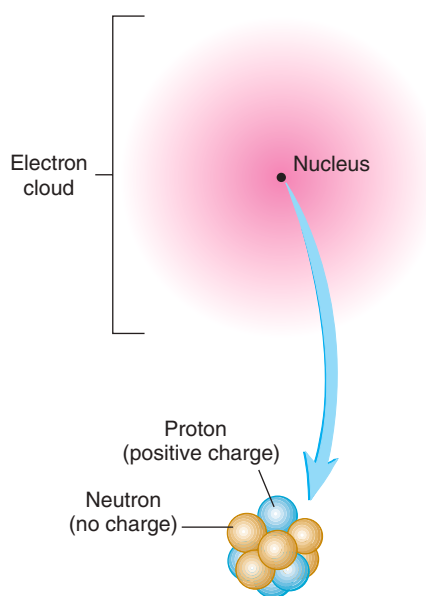

FIGURE 2.1 Model of an Atom

The tiny, dense nucleus consists of positively charged protons and uncharged neutrons. Most of the volume of an atom is occupied by rapidly moving, negatively charged electrons, which can be represented as an electron cloud. The probable location of an electron is indicated by the color of the electron cloud. The darker the color in each small part of the electron cloud, the more likely the electron is located there. **APR**

Ca for calcium. Occasionally, the symbol is taken from the Latin, Greek, or Arabic name for the element—for example, the symbol for sodium is Na, from the Latin word *natrium*.

Atomic Structure

The characteristics of matter result from the structure, organization, and behavior of atoms. Atoms are composed of subatomic particles, some of which have an electrical charge. The three major types of subatomic particles are neutrons, protons, and electrons (figure 2.1). A **neutron** has no electrical charge, a **proton** has one positive charge, and an **electron** has one negative charge. The positive charge of a proton is equal in magnitude to the negative charge of an electron. The number of protons and the number of electrons in each atom are equal, and the individual charges cancel each other. Therefore, each atom is electrically neutral.

Protons and neutrons form the **nucleus** at the center of an atom, and electrons move around the nucleus (figure 2.1). The nucleus accounts for 99.97% of an atom's mass but only 1 ten-trillionth of its volume. Most of the volume of an atom is occupied by the electrons. Because electrons are always moving around the nucleus, the region where they are most likely to be found can be represented by an **electron cloud**.

Atomic Number and Mass Number

Each element is uniquely defined by the number of protons in the atoms of that element. For example, only hydrogen atoms have 1 proton, only carbon atoms have 6 protons, and only oxygen atoms have 8 protons (figure 2.2; table 2.1). The **atomic number** of an element is equal to the number of protons in each atom and, because the number of electrons is equal to the number of

FIGURE 2.2 Hydrogen, Carbon, and Oxygen Atoms

Within the nucleus, the number of positively charged protons (p^+) and uncharged neutrons (n^0) is indicated. The negatively charged electrons (e^-) are around the nucleus. Atoms are electrically neutral because the number of protons and the number of electrons within an atom are equal.

protons, the atomic number is also the number of electrons. There are 90 naturally occurring elements, but additional elements have been synthesized by altering atomic nuclei. See the periodic table in appendix A for additional information about the elements.

Protons and neutrons have about the same mass, and they are responsible for most of the mass of atoms. Electrons, on the other hand, have very little mass. The **mass number** of an element is the number of protons plus the number of neutrons in each atom. For example, the mass number for carbon is 12 because it has 6 protons and 6 neutrons.

Predict 3

The atomic number of potassium is 19, and the mass number is 39. How many protons, neutrons, and electrons are in an atom of potassium?

Isotopes and Atomic Mass

Isotopes (*ī'sō-tōpz*) are two or more forms of the same element that have the same number of protons and electrons but a different number of neutrons. Thus, isotopes have the *same* atomic number but *different* mass numbers. There are three isotopes of hydrogen: hydrogen, deuterium, and tritium. All three isotopes have 1 proton and 1 electron, but hydrogen has no neutrons in its nucleus, deuterium has 1 neutron, and tritium has 2 neutrons (figure 2.3). Isotopes can be denoted using the symbol of the element preceded by the mass number (number of protons and neutrons) of the isotope. Thus, hydrogen is ^1H , deuterium is ^2H , and tritium is ^3H .

FIGURE 2.3 Isotopes of Hydrogen

(a) Hydrogen has 1 proton and no neutrons in its nucleus. (b) Deuterium has 1 proton and 1 neutron in its nucleus. (c) Tritium has 1 proton and 2 neutrons in its nucleus.

Individual atoms have very little mass. A hydrogen atom has a mass of 1.67×10^{-24} g (see appendix B for an explanation of the scientific notation of numbers). To avoid working with such small numbers, scientists use a system of relative atomic mass. In this system, a **dalton (Da)**, or *unified atomic mass unit (u)*, is 1/12 the mass of ^{12}C , a carbon atom with 6 protons and 6 neutrons. Thus, ^{12}C has an atomic mass of exactly 12 Da. However, a naturally occurring sample of carbon contains mostly ^{12}C and a small quantity of other carbon isotopes, such as ^{13}C , which has 6 protons and 7 neutrons. The **atomic mass** of an element is the *average* mass of its naturally occurring isotopes, taking into account the relative abundance of each isotope. For example, the atomic mass of the element carbon is 12.01 Da (table 2.1), which is slightly more than 12 Da because of the additional mass of the small amount of other carbon isotopes. Because the atomic mass is an average, a sample of carbon can be treated as if all the carbon atoms had an atomic mass of 12.01 Da.

The Mole and Molar Mass

Just as a grocer sells eggs in lots of a dozen, a chemist groups atoms in lots of 6.022×10^{23} , which is called **Avogadro's number**, or **1 mole** (abbreviated **mol**). Stated another way, a mole of a substance contains Avogadro's number of entities, such as atoms, ions, or molecules. The mass of 1 mole of a substance expressed in grams is called the **molar mass**. Molar mass is a convenient way to determine the number of atoms in a sample of an element. Because 12 g of ^{12}C is used as the standard, the atomic mass of an entity expressed in unified atomic mass units is the same as the molar mass expressed in grams. Thus, carbon atoms have an atomic mass of 12.01 Da, and 12.01 g of carbon has Avogadro's number (1 mol) of carbon atoms. By the same token, 1.008 g of hydrogen (1 mol) has the same number of atoms as 12.01 g of carbon (1 mol).

ASSESS YOUR PROGRESS

1. Define matter. How are the mass and the weight of an object different?
2. Differentiate between element and atom. What four elements are found in the greatest abundance in the human body?
3. For each subatomic particle of an atom, state its charge and location. Which region of an atom is most responsible for the mass of the atom? Its volume?
4. Which subatomic particle determines the atomic number? What determines the mass number?
5. What is an isotope? How are isotopes denoted?
6. What is Avogadro's number? How is it related to a mole and molar mass?

Electrons and Chemical Bonding

Recall from chapter 1 that the human body has six levels of organization. The key to the first level, the chemical level, is the concept of how atoms interact to form molecules by sharing and transferring their outermost electrons to form **chemical bonds**.

The *chemical behavior* of an atom is dependent on its electrons. The electron cloud around an atom's nucleus is organized into different energy levels, depending on the distance from the

nucleus. For simplicity, the energy levels are often depicted as concentric rings, called **electron shells**, around the nucleus. Each shell can hold a maximum number of electrons. Outer shells do not contain electrons until the inner shells have reached their maximum. The innermost shell (the shell closest to the nucleus) holds a maximum of 2 electrons, and the remaining shells hold a maximum of 8 electrons. The outermost shell is called the **valence shell**. The number of electrons in the valence shell determines an atom's chemical nature. If the valence shell is full (contains 8 electrons), the atom is *inert*, that is, it does not form chemical bonds with other atoms. For example, helium has 2 electrons in its valence shell and does not naturally form chemical bonds with other atoms. However, if an atom's valence shell is not full, the atom is *chemically reactive* and forms chemical bonds with other atoms to achieve a full valence shell, called an octet. Thus, most atoms follow the **octet rule**, the tendency of atoms to combine with other atoms until each has 8 electrons (2 electrons for hydrogen) in its valence shell.

Atoms achieve an octet in two major ways: the transfer of electrons between atoms and the sharing of electrons between atoms. The fate of electrons as being either transferred or shared determines the type of chemical bond: ionic or covalent, as discussed in the following paragraphs.

The decision whether an electron is transferred or shared between two atoms is determined by the relative electronegativity of the two atoms. **Electronegativity** is the ability of an atom's nucleus to attract electrons. In general, atoms that lack only 1 or 2 electrons from having an octet in their valence shell have a strong electronegativity. In contrast, atoms that lack 6 or 7 electrons from having an octet in their valence shell have a weak electronegativity. The major exception to this generalization is hydrogen. Hydrogen lacks only 1 electron from its valence shell to be full. Based on the definition, it might seem that hydrogen should be strongly electronegative; however, hydrogen's pull on electrons is less than that of other atoms with more protons, which means hydrogen's electronegativity is lower than that of other atoms.

In a chemical bond, the fate of the electrons between two atoms depends on the relative difference in electronegativity between the atoms. When the electronegativities of two atoms forming a chemical bond are similar, the atoms tend to share, rather than transfer, the electrons. Under these conditions, covalent bonds are formed. In contrast, when electronegativities are very different, the atoms tend to transfer electrons. For example, an atom with 7 electrons in its valence shell has a strong pull on electrons, while an atom with 1 electron in its valence shell has a weak pull on electrons. Thus, the "strong" atom can "steal" the valence electron from the "weak" atom, resulting in a transfer of electrons. The relationship between electronegativity and the resultant chemical bond types is illustrated in figure 2.4. The two major types of chemical bonds are ionic and covalent bonds.

Ionic Bonds

Recall that an atom is electrically neutral because it has equal numbers of protons and electrons. However, an atom can donate or lose electrons to other atoms depending on its electronegativity. When this occurs, the numbers of protons and electrons are

FIGURE 2.4 Relationship Between Electronegativity and Chemical Bonding

Sharing of electrons between atoms with the same or similar electronegativities results in covalent bonds, while transferring electrons between atoms with very different electronegativities results in ionic bonds.

no longer equal, and a charged particle, called an **ion** (ī'on), is formed. After a weakly electronegative atom loses an electron, it has 1 more proton than it has electrons and is positively charged. A sodium atom (Na) can lose an electron to become a positively charged sodium ion (Na^+) (figure 2.5a). After an atom gains an electron, it has 1 more electron than it has protons and is negatively charged. A chlorine atom (Cl) can accept an electron to become a negatively charged chloride ion (Cl^-). After this transfer of electrons, both chlorine and sodium have full valence shells.

Positively charged ions are called **cations** (kat'ī-onz), and negatively charged ions are called **anions** (an'ī-onz). Because oppositely charged ions are attracted to each other, cations and anions tend to remain close together. Thus, an **ionic** (ī-on'ik) **bond** forms when electrons are transferred between atoms, creating oppositely charged ions. For example, Na^+ and Cl^- are held together by ionic bonding to form an array of ions called sodium

chloride (NaCl), or table salt (figure 2.5b,c). Some ions commonly found in the body are listed in table 2.2.

Covalent Bonds

A **covalent bond** forms when atoms share one or more pairs of electrons. The sharing of electrons, rather than transfer of electrons, occurs because the atoms have similar electronegativities. The resulting combination of atoms is called a molecule. An example is the covalent bond between two hydrogen atoms to form a hydrogen molecule (figure 2.6). Each hydrogen atom has 1 electron. As the two hydrogen atoms get closer together, the positively charged nucleus of each atom begins to attract the electron of the other atom. At an optimal distance, the 2 nuclei mutually attract the 2 electrons, and each electron is shared by both nuclei because the electronegativities of the two hydrogens are equal. The two hydrogen atoms are now held together by a covalent bond.

The sharing of one pair of electrons by two atoms results in a **single covalent bond**. A single line between the symbols of the atoms involved (e.g., $\text{H}-\text{H}$) represents a single covalent bond. A **double covalent bond** results when two atoms share 4 electrons, 2 from each atom. When a carbon atom combines with two oxygen atoms to form carbon dioxide (CO_2), two double covalent bonds form. Double covalent bonds are indicated by a double line between the atoms ($\text{O}=\text{C}=\text{O}$).

When electrons are shared equally between atoms, as in a hydrogen molecule, the bonds are called **nonpolar covalent bonds**. However, atoms bound to one another by a covalent bond do not always share their electrons equally because in these situations the electronegativity of one atom is stronger than the electronegativity of the other atom. Bonds of this type are called **polar covalent bonds** and are common in both living and nonliving matter.

FIGURE 2.5 Ionic Bonds

(a) A sodium atom (Na) loses an electron to become a smaller, positively charged ion, and a chlorine atom (Cl) gains an electron to become a larger, negatively charged ion. The attraction between the oppositely charged ions results in ionic bonding and the formation of sodium chloride. (b) The sodium ions (Na^+) and the chloride ions (Cl^-) are organized to form a cube-shaped array. (c) A photomicrograph of salt crystals reflects the cubic arrangement of the ions.

TABLE 2.2 Important Ions in the Human Body

Common Ions	Symbols	Significance*
Calcium	Ca^{2+}	Part of bones and teeth; functions in blood clotting, muscle contraction, release of neurotransmitters
Sodium	Na^+	Membrane potentials, water balance
Potassium	K^+	Membrane potentials
Hydrogen	H^+	Acid-base balance
Hydroxide	OH^-	Acid-base balance
Chloride	Cl^-	Water balance
Bicarbonate	HCO_3^-	Acid-base balance
Ammonium	NH_4^+	Acid-base balance
Phosphate	PO_4^{3-}	Part of bones and teeth; functions in energy exchange, acid-base balance
Iron	Fe^{2+}	Red blood cell formation
Magnesium	Mg^{2+}	Necessary for enzymes
Iodide	I^-	Present in thyroid hormones

*The ions are part of the structures or play important roles in the processes listed.

- 1 The two hydrogen atoms do not interact because they are too far apart.

- 2 The positively charged nucleus of each hydrogen atom begins to attract the electron of the other.

- 3 A covalent bond forms when the electrons are shared between the nuclei because the electrons are equally attracted to each nucleus.

PROCESS FIGURE 2.6 Covalent Bonding

**FIGURE 2.7** Polar Covalent Bonds

(a) A water molecule forms when two hydrogen atoms form covalent bonds with an oxygen atom. (b) The hydrogen atoms and oxygen atom are sharing electron pairs (indicated by the black dots), but the sharing is unequal. The dashed outline shows the expected location of the electron cloud if the electrons are shared equally. But the actual electron cloud (yellow) is shifted toward the oxygen. Consequently, the oxygen side of the molecule has a slightly negative charge (indicated by δ^-), and the hydrogen side of the molecule has a slightly positive charge (indicated by δ^+).

Polar covalent bonds can result in polar molecules, which are electrically asymmetric. For example, oxygen atoms have a higher electronegativity than do hydrogen atoms. When covalent bonding between an oxygen atom and two hydrogen atoms forms a water molecule, the electron cloud is closer to the oxygen nucleus than to the hydrogen nuclei. Because electrons have a negative charge, the oxygen side of the molecule is slightly more negative than the hydrogen side (figure 2.7).

Molecules and Compounds

A **molecule** is composed of two or more atoms chemically combined to form a structure that behaves as an independent unit. Sometimes the atoms that combine are of the same type, such as two hydrogen atoms combining to form a hydrogen molecule. However, more typically, a molecule consists of two or more different types of atoms, such as two hydrogen atoms and an oxygen atom combining to form water. Thus, a glass of water consists of a collection of individual water molecules positioned next to one another.

A **compound** is a substance resulting from the chemical combination of two or more *different types* of atoms. Water is a molecule that is also a compound because it is a combination of two different atoms, hydrogen and oxygen. But not all molecules are compounds. For example, a hydrogen molecule is not a compound because it does not consist of different types of atoms.

Some compounds are molecules and some are not. (Remember that, to be a molecule, a structure must be an independent unit.) Covalent compounds, in which different types of atoms are held together by covalent bonds, are molecules because the sharing of electrons results in distinct units. On the other hand, ionic compounds, in which ions are held together by the force of attraction between opposite charges, are not molecules because they do not consist of distinct units. Table salt (NaCl) is an example of a substance that is a compound but not a molecule. A piece of NaCl does not consist of individual sodium chloride molecules positioned next to one another. Instead, NaCl is an organized array of individual

Clinical IMPACT

Applications of Atomic Particles

Protons, neutrons, and electrons are responsible for the chemical properties of atoms. They also have other properties that can be useful in a clinical setting. For example, they have been used to develop methods for examining the inside of the body.

X-rays are electromagnetic radiations with a much shorter wavelength than visible light. When electric current is used to heat a filament to very high temperatures, the energy of the electrons becomes so great that some electrons are emitted from the hot filament. When these electrons strike a positive electrode at high speeds, they release some of their energy in the form of x-rays.

X-rays do not penetrate dense material as readily as they penetrate less dense material, and x-rays can expose photographic film. Consequently, an x-ray beam can pass through a person and onto photographic film. Dense tissues of the body absorb the x-rays; on the film, these areas are underexposed and, so, appear white or light in color. By contrast, the x-rays readily pass through less dense tissue, so the film in these areas is overexposed and they appear black or dark in color. In an x-ray film of the skeletal system, the dense bones are white, and the less dense soft tissues are dark, often so dark that no details can be seen. Health professionals use x-rays

to determine whether bones are broken or have other abnormalities.

Soft tissues can be photographed by using low-energy x-rays. Mammograms are low-energy x-rays of the breast that can reveal tumors because tumors are slightly denser than normal tissue.

Radiopaque substances are dense materials that absorb x-rays. If a radiopaque liquid is given to a patient, the liquid assumes the shape of the organ into which it is placed. For example, if a patient swallows a barium solution, the outline of the upper digestive tract can be photographed using x-rays to detect any abnormality, such as an ulcer.

Na^+ and individual Cl^- in which each charged ion is surrounded by several ions of the opposite charge (see figure 2.5*b*).

The properties of elements can change when they are combined to form compounds. For example, the element hydrogen is extremely flammable, and oxygen, although not flammable on its own, promotes fire. However, when combined, hydrogen and oxygen form the very nonflammable compound water. Likewise, elements that are dangerous or toxic to humans can become useful as compounds. For example, sodium is very explosive when placed in water, and chlorine is a strong disinfectant in solutions, such as bleach and swimming pool water. Chlorine is so toxic that it was used as a poison gas in World War I, yet, when combined, sodium and chloride form the relatively safe and nonexplosive compound table salt.

The kinds and numbers of atoms (or ions) in a molecule or compound are typically represented by a formula consisting of the symbols of the atoms (or ions) plus subscripts denoting the quantity of each type of atom (or ion). The formula for glucose (a sugar) is $\text{C}_6\text{H}_{12}\text{O}_6$, indicating that glucose has 6 carbon, 12 hydrogen, and 6 oxygen atoms (table 2.3). The formulas for some common substances, such as O_2 for oxygen and CO_2 for carbon dioxide, will be used throughout the text.

The **molecular mass** of a molecule or compound can be determined by adding up the atomic masses of its atoms (or ions). The term *molecular mass* is used for convenience for ionic compounds, even though they are not molecules. For example, the atomic mass of sodium is 22.99 and that of chloride is 35.45. The molecular mass of NaCl is therefore 58.44 ($22.99 + 35.45$).

Intermolecular Forces

Intermolecular forces are the weak electrostatic attractions that exist between oppositely charged parts of molecules, or between ions and molecules. There is no exchange of electrons

in intermolecular forces. This differs from other chemical bonds. Intermolecular forces are much weaker than the forces producing chemical bonding. Intermolecular forces include hydrogen bonds and the properties of solubility and dissociation.

Hydrogen Bonds

Molecules with polar covalent bonds have positive and negative “ends.” Intermolecular force results from the attraction of the positive end of one polar molecule to the negative end of another polar molecule. When hydrogen forms a covalent bond with oxygen, nitrogen, or fluorine, the resulting molecule becomes very polarized. If the positively charged hydrogen of one molecule is attracted to the negatively charged oxygen, nitrogen, or fluorine of another molecule, a **hydrogen bond** forms. For example, the positively charged hydrogen atoms of a water molecule form hydrogen bonds with the negatively charged oxygen atoms of other water molecules (figure 2.8). These hydrogen bonds are essential for the unique properties of water (see section 2.3).

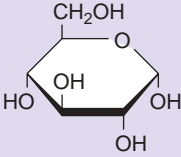

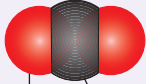

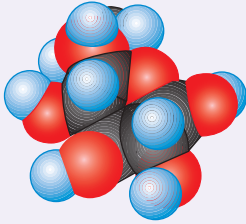

An important role of hydrogen bonds is to help build the shape of complex molecules. The bonds can occur between different polar parts of a molecule to stabilize the final three-dimensional shape (see “Proteins” and “Nucleic Acids: DNA and RNA” in section 2.4).

Table 2.4 summarizes the important characteristics of chemical bonds (ionic and covalent) and intermolecular forces (hydrogen bonds).

Solubility and Dissociation

Solubility is the ability of one substance to dissolve in another—for example, sugar dissolving in water. Charged substances, such as sodium chloride, and polar substances, such as glucose, readily dissolve in water, whereas nonpolar substances, such as oils, do not. We all have seen how oil floats on water. Substances dissolve

in water when they become surrounded by water molecules. If the positive and negative ends of the water molecules are more attracted to the charged ends of other molecules than to each other, the hydrogen bonds between the ends of the water molecules break, and water molecules surround the other molecules, which become dissolved in water.

When ionic compounds dissolve in water, their ions **dissociate**, or separate, from one another because cations are attracted to the negative ends of water molecules and anions are attracted to the positive ends of water molecules. When NaCl dissociates in water, sodium and chloride ions separate, and water molecules surround and isolate the ions, thereby keeping them in solution (figure 2.9).

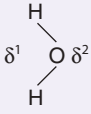

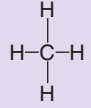

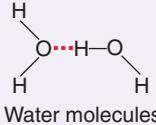

When molecules (covalent compounds) dissolve in water, they usually remain intact, even though they are surrounded by water molecules. Thus, in a glucose solution, glucose molecules are surrounded by water molecules.

Cations and anions that dissociate in water are sometimes called **electrolytes** (ē-lek'trō-lītz) because they have the capacity to conduct an electric current, which is the flow of charged particles. An electrocardiogram (ECG) is a recording of electric currents produced by the heart. These currents can be detected by electrodes on the surface of the body because the ions in the body fluids conduct electric currents. Molecules that do not dissociate form solutions that do not conduct electricity and are called **nonelectrolytes**. Pure water is a nonelectrolyte.

Maintaining the proper balance of electrolytes is important for keeping the body hydrated, controlling blood pH, and ensuring the proper function of muscles and nerves. Under most conditions,

including moderate exercise, the body's usual regulatory mechanisms are sufficient to maintain electrolyte homeostasis. However, people engaging in prolonged exercise, such as competing in a

triathlon, are advised to consume sports drinks containing electrolytes. In an emergency, administering intravenous solutions can restore electrolyte and fluid balance.

ASSESS YOUR PROGRESS

7. Describe how an ionic bond is formed. What are a cation and an anion?
8. What occurs in the formation of a covalent bond? What is the difference between polar and nonpolar covalent bonds?
9. Distinguish between a molecule and a compound. Give an example of each. Are all molecules compounds? Are all compounds molecules?
10. What are intermolecular forces, and how do they create a hydrogen bond?
11. What is meant by the statement “table sugar is soluble in water”?
12. Describe what occurs during the dissociation of NaCl in water. What occurs when glucose ($C_6H_{12}O_6$) dissolves in water?
13. Explain the difference between electrolytes and nonelectrolytes. Classify each of the following water solutions as an electrolyte or a nonelectrolyte: potassium iodide (KCl), sucrose ($C_{12}H_{22}O_{11}$), magnesium bromide ($MgBr_2$), lactose ($C_{12}H_{22}O_{11}$).

FIGURE 2.9 Dissociation

Sodium chloride (table salt) dissociates in water. The positively charged Na^+ are attracted to the negatively charged (δ^-) oxygen (red) end of the water molecule, and the negatively charged Cl^- are attracted to the positively charged (δ^+) hydrogen (blue) end of the water molecule. **AP®**

2.2 Chemical Reactions and Energy

LEARNING OUTCOMES

After reading this section, you should be able to

- Summarize the characteristics of synthesis, decomposition, reversible reactions, and oxidation-reduction reactions.
- Illustrate what occurs in dehydration and hydrolysis reactions.
- Explain how reversible reactions produce chemical equilibrium.
- Contrast potential and kinetic energy.
- Distinguish between chemical reactions that release energy and those that take in energy.
- Describe the factors that can affect the rate of chemical reactions.

A **chemical reaction** occurs when atoms, ions, molecules, or compounds interact either to form or to break chemical bonds. The substances that enter into a chemical reaction are called **reactants**, and the substances that result from the chemical reaction are called **products**.

For our purposes, three important points can be made about chemical reactions. First, in some reactions, less complex

reactants are combined to form a larger, more complex product. An example is the synthesis of the complex proteins of the human body from amino acid “building blocks” obtained from food (figure 2.10a). Second, in other reactions, a reactant can be broken down, or decomposed, into simpler, less complex products. An example is the breakdown of carbohydrate molecules into glucose molecules (figure 2.10b). Third, atoms are generally associated with other atoms through chemical bonding or intermolecular forces; therefore, to synthesize new products or break down reactants, it is necessary to change the relationship between atoms.

Synthesis Reactions

A **synthesis reaction** is when two or more reactants chemically combine to form a new and larger product. The synthesis reactions occurring in the body are collectively referred to as **anabolism** (ă-nab’ ō-lizm). These reactions produce the molecules characteristic of life, such as ATP, proteins, carbohydrates, lipids, and nucleic acids. The growth, maintenance, and repair of the body could not take place without anabolic reactions.

An example of a synthesis reaction is the combination of two amino acids to form a dipeptide (figure 2.10a). As the amino acids are bound together, water results. Synthesis reactions in which water is a product are called **dehydration reactions**. As the atoms rearrange as a result of a synthesis reaction, old chemical bonds are broken and new chemical bonds are formed.

FIGURE 2.10 Synthesis and Decomposition Reactions

(a) A synthesis reaction in which two amino acids combine to form a dipeptide. This reaction is also a dehydration reaction because it results in the removal of a water molecule from the amino acids. (b) A decomposition reaction in which a disaccharide breaks apart into individual glucose molecules. This reaction is also a hydrolysis reaction because it involves the splitting of a water molecule.

Another example of a synthesis reaction in the body is the formation of adenosine triphosphate (ATP; see section 2.4 for the details of ATP structure). ATP, which is composed of adenosine and three phosphate groups, is synthesized from adenosine diphosphate (ADP), which has two phosphate groups, and an inorganic phosphate (H_2PO_4^-) that is often symbolized as P_i :

Decomposition Reactions

A **decomposition reaction** is the reverse of a synthesis reaction—a larger reactant is chemically broken down into two or more smaller products. The decomposition reactions occurring in the body are collectively called **catabolism** (kă-tab'-ō-lizm). They include the digestion of food molecules in the intestine and within cells, the breakdown of fat stores, and the breakdown of foreign matter and microorganisms in certain blood cells that protect the body. All of the anabolic and catabolic reactions in the body are collectively defined as **metabolism**. An example of a decomposition reaction is the breakdown of a disaccharide (a type of carbohydrate) into glucose molecules (figure 2.10b). Note that this reaction requires that water be split into two parts and that each part be contributed to one of the new glucose molecules. Reactions that use water in this manner are called **hydrolysis** (hī-drol'i-sis; water dissolution) **reactions**.

The breakdown of ATP to ADP and an inorganic phosphate is another example of a decomposition reaction:

Reversible Reactions

Some chemical reactions are reversible. In a **reversible reaction**, the reaction can run in the opposite direction, so that the products are converted back to the original reactants. When the rate of product formation is equal to the rate of the reverse reaction, the reaction system is said to be at **equilibrium**. At equilibrium, the amount of reactants relative to the amount of products remains constant.

The following analogy may help clarify the concept of reversible reactions and equilibrium. Imagine a football team. The team is divided into two groups: players on the field and those on the bench. Because the players can move in either direction (on or off the field), this is like a reversible reaction. Imagine that the players on the bench are the reactant and the players on the field (lined up in formation) are the product. At equilibrium, the amount of reactant relative to the amount of product is always the same. When some players on the bench run onto the field an equal number of players run off the field, so equilibrium is maintained.

An important reversible reaction in the human body involves carbon dioxide and hydrogen ions. Carbon dioxide (CO_2) and water (H_2O) combine to form carbonic acid (H_2CO_3). Carbonic

acid then separates by a reversible reaction to form hydrogen ions (H^+) and bicarbonate ions (HCO_3^-):

If more CO_2 is added to the reaction, then additional H_2CO_3 forms, which causes more H^+ and HCO_3^- to form. The amount of H^+ and HCO_3^- relative to CO_2 therefore remains constant. Maintaining a constant level of H^+ in the body can be achieved, in part, by regulating blood CO_2 levels. For example, slowing down the respiration rate causes blood CO_2 levels to increase and thus increase H^+ levels.

Predict 4

If the respiration rate increases, CO_2 is eliminated from the blood. What effect does this change have on blood H^+ levels?

Oxidation-Reduction Reactions

Chemical reactions that result from the exchange of electrons between the reactants are called oxidation-reduction reactions. When sodium and chlorine react to form sodium chloride, the sodium atom loses an electron and the chlorine atom gains an electron. The loss of an electron by an atom is called **oxidation**, and the gain of an electron is called **reduction**. The transfer of the electron can be complete, resulting in an ionic bond, or it can be partial, resulting in a covalent bond. Because one atom partially or completely loses an electron and another atom gains that electron, these reactions are called **oxidation-reduction reactions**. Synthesis and decomposition reactions can be oxidation-reduction reactions. Thus, a chemical reaction can be described in more than one way.

Predict 5

When hydrogen gas combines with oxygen gas to form water, is the hydrogen reduced or oxidized? Explain.

ASSESS YOUR PROGRESS

- Using the terms reactant and product, describe what occurs in a chemical reaction.
- Contrast synthesis and decomposition reactions, and explain how catabolism and anabolism relate to these two types of reactions.
- Describe the role of water in dehydration and hydrolysis reactions.
- What is a reversible reaction? How does this type of reaction lead to chemical equilibrium?
- What are oxidation-reduction reactions?

Energy

Energy is the capacity to do **work**—that is, to move matter. Energy can be subdivided into potential energy and kinetic energy. **Potential energy** is stored energy that could do work but is not

doing so. **Kinetic** (ki-net'ik) **energy** is the form of energy that is actually doing work and moving matter. A ball held at arm's length above the floor has potential energy. No energy is expended as long as the ball does not move. However, if the ball is released and falls toward the floor, it has kinetic energy.

According to the conservation of energy principle, the total energy of the universe is constant. Therefore, energy is neither created nor destroyed, but it can take on different forms. For example, the potential energy in the ball is converted into kinetic energy as the ball falls toward the floor. Conversely, the kinetic energy required to raise the ball from the floor is converted back into potential energy.

Potential and kinetic energy exist in many different forms. Here we consider mechanical, chemical, and heat energy. **Mechanical energy** results from the position or movement of objects. Many of the activities of the human body, such as moving a limb, breathing, and circulating blood, involve mechanical energy.

Chemical Energy

Chemical energy is a form of potential energy stored within the chemical bonds of a substance. In any chemical reaction, the potential energy in the chemical bonds of the reactants can be compared with the potential energy in the chemical bonds of the products. If the potential energy in the reactants is less than that in the products, energy must be supplied for the reaction to occur. An example is the synthesis of ATP from ADP:

For simplicity, the H_2O is often not shown in this reaction, and P_i is used to represent inorganic phosphate (H_2PO_4^-). For this reaction to occur, bonds in H_2PO_4^- are broken, and bonds are formed in ATP and H_2O . As a result of the breaking of existing bonds, the formation of new bonds, and the input of energy, these products have more potential energy than the reactants (figure 2.11a).

If the potential energy in the chemical bonds of the reactants is greater than that of the products, the reaction releases energy. For example, the chemical bonds of food molecules contain more potential energy than the waste products that are produced when food molecules are decomposed. The energy released from the chemical bonds of food molecules is used by living systems to synthesize ATP. Once ATP is produced, the breakdown of ATP to ADP results in the release of energy:

For this reaction to occur, the bonds in ATP and H_2O are broken and bonds in H_2PO_4^- are formed. As a result of breaking the existing bonds and forming new bonds, these products have less potential energy than the reactants, and energy is released (figure 2.11b). Note that there are two quantities of energy in this reaction. The first is energy required to break the reactant chemical bonds. The second is energy released from those chemical bonds,

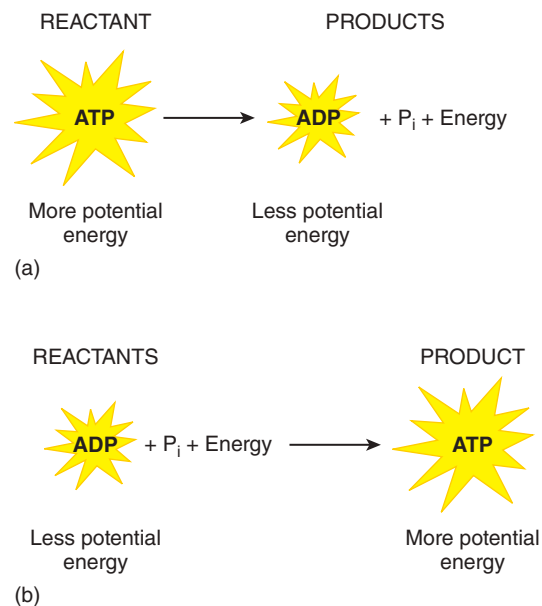

FIGURE 2.11 Energy and Chemical Reactions

In the two reactions shown here, the larger “sunburst” represents greater potential energy and the smaller “sunburst” represents less potential energy. (a) Energy is released as a result of the breakdown of ATP. (b) The input of energy is required for the synthesis of ATP. **APIR**

which yields the net release of energy in the reaction. Thus, breakdown of ATP results in the net release of energy when the overall reaction is considered. This energy from ATP can be used to synthesize and transport other molecules, to do mechanical work (such as muscle contraction), or to produce heat.

Heat Energy

Heat energy is a form of energy that flows from a hotter object to a cooler object. Temperature is a measure of how hot or cold a substance is relative to another substance.

All other forms of energy can be converted into heat energy. For example, when a moving object comes to rest, its kinetic energy is converted into heat energy by friction. Some of the potential energy of chemical bonds is released as heat energy during chemical reactions. Human body temperature is maintained by heat produced as a by-product of chemical reactions.

► Predict 6

Energy from the breakdown of ATP provides the kinetic energy for muscle movement. Why does body temperature increase during exercise?

Speed of Chemical Reactions

Molecules are constantly in motion and therefore have kinetic energy. A chemical reaction occurs only when molecules with sufficient kinetic energy collide with each other. As two molecules move closer together, the negatively charged electron cloud of one molecule repels the negatively charged electron cloud of the other molecule. If the molecules have sufficient kinetic energy, they overcome

this repulsion and come together. The nuclei in some atoms attract the electrons of other atoms, resulting in the breaking and formation of new chemical bonds. **Activation energy** is the minimum amount of energy that the reactants must have to start a chemical reaction (figure 2.12). Even reactions that release energy must overcome the activation energy barrier for the reaction to proceed. For example, heat in the form of a spark is required to start the reaction between oxygen and gasoline vapor. Once some oxygen molecules react with gasoline, the energy released can start additional reactions.

Given any population of molecules, some of them have more kinetic energy and move about faster than others. Even so, at normal body temperatures, most of the chemical reactions necessary for life proceed too slowly to support life because few molecules have enough energy to start a chemical reaction. **Catalysts** (kat'ă-lizt) are substances that increase the rate of chemical reactions without being permanently changed or depleted themselves. **Enzymes** (en'zīmz), which are discussed in greater detail later in the chapter, are proteins that act as catalysts. Enzymes increase the rate of chemical reactions by lowering the activation energy necessary for the reaction to begin (figure 2.12). As a result, more molecules have sufficient energy to undergo chemical reactions. An enzyme allows the rate of a chemical reaction to take place more than a million times faster than it would without the enzyme.

Temperature can also affect the speed of chemical reactions. As temperature increases, reactants have more kinetic energy, move at faster speeds, and collide with one another more frequently and with greater force, thereby increasing the likelihood of a chemical reaction. For example, when a person has a fever of only a few degrees, reactions occur throughout the body at an accelerated rate, increasing activity in the organ systems, such as the heart and respiratory rates. When body temperature drops, various metabolic processes slow. For example, in cold weather, the fingers are less agile, largely because of the reduced rate of chemical reactions in cold muscle tissue.

Within limits, the greater the concentration of the reactants, the greater the rate at which a given chemical reaction proceeds.

FIGURE 2.12 Activation Energy and Enzymes

Activation energy is required to initiate chemical reactions. Without an enzyme, a chemical reaction can proceed, but it needs more energy input. Enzymes lower the activation energy, making it easier for the reaction to proceed.

This is true because, as the concentration of reactants increases, they are more likely to come into contact with one another. For example, the normal concentration of oxygen inside cells enables oxygen to come into contact with other molecules and produce the chemical reactions necessary for life. If the oxygen concentration decreases, the rate of chemical reactions decreases. A decrease in oxygen in cells can impair cell function and even result in death.

ASSESS YOUR PROGRESS

19. Define energy. How are potential and kinetic energies different from each other?
20. Summarize the characteristics of mechanical, chemical, and heat energies.
21. Use ATP and ADP to illustrate the release or input of energy in chemical reactions.
22. Define activation energy, catalyst, and enzymes; then explain how they affect the rate of chemical reactions.
23. What effect does increasing temperature or increasing concentration of reactants have on the rate of a chemical reaction?

2.3 Inorganic Chemistry

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Distinguish between inorganic and organic compounds.
- B. Describe how the properties of water contribute to its physiological functions.
- C. Describe the pH scale and its relationship to acidic, basic, and neutral solutions.
- D. Explain the importance of buffers in organisms.
- E. Compare the roles of oxygen and carbon dioxide in the body.

Inorganic chemistry generally deals with substances that do not contain carbon, although a more rigorous definition is the lack of carbon-hydrogen bonds. **Organic chemistry** is the study of carbon-containing substances, with a few exceptions. For example, carbon monoxide (CO), carbon dioxide (CO₂), and bicarbonate ions (HCO₃⁻) are several important inorganic substances that contain carbon but lack C—H bonds.

Inorganic substances play many vital roles in human anatomy and physiology. Examples include the oxygen we breathe, the calcium phosphate that makes up our bones, and the many metals required for protein functions, ranging from iron in blood gas transport to zinc in alcohol detoxification. In this section, we discuss the important roles of oxygen, carbon dioxide, and water—all inorganic molecules—in the body.

Water

Water has remarkable properties due to its polar nature. A molecule of **water** is formed when an atom of oxygen forms polar covalent bonds with two atoms of hydrogen. This gives a partial positive

charge to the hydrogen atoms and a partial negative charge to the oxygen atom. Because of water's polarity, hydrogen bonds form between the positively charged hydrogen atoms of one water molecule and the negatively charged oxygen atoms of another water molecule. These hydrogen bonds organize the water molecules into a lattice, which holds the water molecules together and are responsible for many unique properties of water (see figures 2.7 and 2.8). Two of these properties are cohesion and adhesion. **Cohesion** is the attraction of water to another water molecule. Examples of cohesion are the surface tension exhibited when water bulges over the top of a full glass without spilling over and when beads of water form on the skin. **Adhesion** is the same attractive force of hydrogen bonds of water that will also attract other molecules. An example of adhesion is the surface tension that draws water across a glass plate and holds a bead of water to the skin before it falls to the ground. The combination of cohesion and adhesion helps hold cells together and move fluids through the body.

Water accounts for approximately 50% of the weight of a young adult female and 60% of a young adult male. Females have a lower percentage of water than males because they typically have more body fat, which is relatively free of water. Plasma, the liquid portion of blood, is 92% water. Water has physical and chemical properties well suited for its many functions in living organisms. These properties are outlined in the following discussion.

Stabilizing Body Temperature

Water tends to resist large temperature fluctuations because it can absorb large amounts of heat and remain at a fairly stable temperature. As a result of this property, blood, which is mostly water, can transfer heat from deep in the body to the surface, where the heat is released. In addition, when water evaporates, it changes from a liquid to a gas; because heat is required for that process, the evaporation of water from the surface of the body rids the body of excess heat.

Protection

Water protects the body by acting as a lubricant and a cushion for organs. Lubrication reduces damage from friction. For example, tears protect the surface of the eye from rubbing of the eyelids. By forming a fluid cushion around organs, water helps protect the organs from trauma. For example, the cerebrospinal fluid helps protect the brain.

Chemical Reactions

Many of the chemical reactions necessary for life do not take place unless the reacting molecules are dissolved in water. For example, NaCl must dissociate in water into Na^+ and Cl^- , which can then react with other ions. Water also directly participates in many chemical reactions. As previously mentioned, a dehydration reaction is a synthesis reaction that produces water, and a hydrolysis reaction is a decomposition reaction that requires water (see figure 2.10).

Mixing Medium

A **mixture** is a combination of two or more substances physically blended together, but not chemically combined. A **solution**

is any mixture in which the substances are uniformly distributed. Solutions can be liquid, gas, or solid. For example, a salt solution consists of salt dissolved in water, air is a solution containing a variety of gases, and wax is a solid solution composed of several fatty substances. Solutions are often described in terms of one substance dissolving in another: The **solute** (sol'ūt) dissolves in the **solvent**. In a salt solution, water is the solvent and the dissolved salt is the solute. Sweat is a salt solution in which sodium chloride and other solutes are dissolved in water. In contrast to the uniform distribution of substances in solutions, in two other types of mixtures called suspensions and colloids, substances are not evenly distributed.

A **suspension** is a mixture containing materials that separate from each other unless they are continually, physically blended together. Blood is a suspension—that is, red blood cells are suspended in a liquid called plasma. As long as the red blood cells and plasma are mixed together as they pass through blood vessels, the red blood cells remain suspended in the plasma. However, if the blood is allowed to sit in a container, the red blood cells and plasma separate from each other.

A **colloid** (kol'oyd) is a mixture in which a dispersed substance or particle is unevenly distributed throughout the mixture. Unlike a suspension, the dispersed particles are small enough that they do not settle out. Proteins are common dispersed particles; proteins and water form colloids. For instance, the plasma portion of blood and the liquid interior of cells are colloids containing many important proteins.

In living organisms, the complex fluids inside and outside cells consist of solutions, suspensions, and colloids. Blood is an example of all of these mixtures. It is a solution containing dissolved nutrients, such as sugar; a suspension holding red blood cells; and a colloid containing proteins.

Water's ability to mix with other substances enables it to act as a medium for transport, moving substances from one part of the body to another. Body fluids, such as plasma, transport nutrients, gases, waste products, and a variety of molecules involved in regulating body functions.

Solution Concentrations

The concentration of solute particles dissolved in solvents can be expressed in two ways. One way is to indicate the percent of solute by weight per volume of solution. A 10% solution of sodium chloride can be made by dissolving 10 g of sodium chloride into enough water to make 100 mL of solution.

A second way, often used by physiologists, is to express concentrations in **osmoles** (os'mōlz), which indicate the number of particles in a solution. A particle can be an atom, an ion, or a molecule. An osmole (Osm) is Avogadro's number of particles of a substance in 1 kilogram (kg) of water. The **osmolality** (os-mō-lal'i-tē) of a solution reflects the number, not the type, of particles in a solution. For example, a 1 Osm glucose solution and a 1 Osm NaCl solution both contain Avogadro's number of particles per kg of water. The glucose solution has 1.0 Osm of glucose molecules, whereas the NaCl solution has 0.5 Osm of Na^+ and 0.5 Osm of Cl^- because NaCl dissociates into Na^+ and Cl^- in water.

Because the concentration of particles in body fluids is so low, physiologists use the measurement **milliosmole** (mOsm), 1/1000 of an osmole. Most body fluids have a concentration of about 300 mOsm and contain many different ions and molecules. The concentration of body fluids is important because it influences the movement of water into or out of cells (see chapter 3). Appendix C contains more information on calculating concentrations.

ASSESS YOUR PROGRESS

24. What is the difference between inorganic and organic chemistry?
25. What two properties of water are the result of hydrogen bonding, and how are these two properties different?
26. List and briefly describe the four functions that water performs in living organisms.
27. Using the terms solute and solvent, summarize the properties of solutions, suspensions, and colloids.
28. How is the osmolality of a solution determined? What is a milliosmole?

Acids and Bases

The body contains many molecules and compounds, called acids and bases, that can alter body functions by releasing and binding protons. A normal balance of acids and bases is maintained by homeostatic mechanisms involving buffers, the respiratory system, and the kidneys (see chapter 27).

An **acid** is defined as a proton donor. A hydrogen ion (H^+) is a proton because it results when an electron is lost from a hydrogen atom, which leaves just the proton nucleus. Therefore, a molecule or compound that releases H^+ is an acid. Hydrochloric acid (HCl) forms hydrogen ions (H^+) and chloride ions (Cl^-) in solution and therefore is an acid:

A **base** is defined as a proton acceptor. Any substance that binds to (accepts) H^+ is a base. Many bases function as proton acceptors by releasing hydroxide ions (OH^-) when they dissociate. The base sodium hydroxide (NaOH) dissociates to form Na^+ and OH^- :

The OH^- are proton acceptors that combine with H^+ to form water:

Acids and bases are classified as strong or weak. Strong acids or bases dissociate almost completely when dissolved in water. Consequently, they release almost all of their H^+ or OH^- . The more completely the acid or base dissociates, the stronger it is. For example, HCl is a strong acid because it completely dissociates in water:

Weak acids or bases only partially dissociate in water. Consequently, they release only some of their H^+ or OH^- . For example, when acetic acid (CH_3COOH) is dissolved in water, some of it dissociates, but some of it remains in the undissociated form. An

equilibrium is established between the ions and the undissociated weak acid:

For a given weak acid or base, the amount of the dissociated ions relative to the weak acid or base is a constant.

The pH Scale

The **pH scale** is a means of referring to the H^+ concentration in a solution (figure 2.13). The scale ranges from 0 to 14. A **neutral solution** has equal concentrations of H^+ and OH^- ; pure water is considered a neutral solution and has a pH of 7. Solutions with a pH less than 7 are **acidic** and have a greater concentration of H^+ than OH^- . Solutions with a pH greater than 7 are **alkaline** (al'kă-līn), or **basic**, and have fewer H^+ than OH^- .

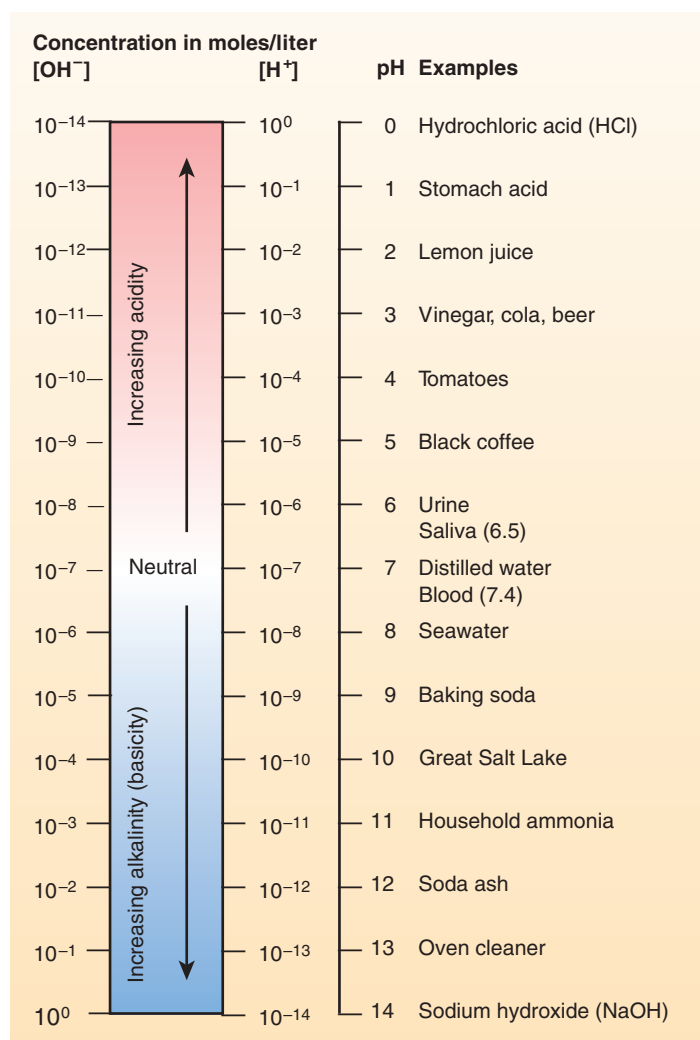

FIGURE 2.13 The pH Scale

A pH of 7 is considered neutral. Values less than 7 are acidic (the lower the number, the more acidic). Values greater than 7 are basic (the higher the number, the more basic). Representative fluids and their approximate pH values are listed.

A change in the pH of a solution by 1 pH unit represents a 10-fold change in the H^+ concentration. For example, a solution of pH 6 has a H^+ concentration 10 times greater than a solution of pH 7 and 100 times greater than a solution of pH 8. As the pH value becomes smaller, the solution has more H^+ and is more acidic; as the pH value becomes larger, the solution has fewer H^+ and is more basic. Appendix D considers pH in greater detail.

The normal pH range for human blood is 7.35 to 7.45. **Acidosis** results if blood pH drops below 7.35, in which case the nervous system becomes depressed and the individual may become disoriented and possibly comatose. **Alkalosis** results if blood pH rises above 7.45. Then the nervous system becomes overexcitable, and the individual may become extremely nervous or have convulsions. Both acidosis and alkalosis can be fatal.

Salts

A **salt** is a compound consisting of a cation other than H^+ and an anion other than OH^- . Salts are formed by the interaction of an acid and a base in which the H^+ of the acid are replaced by the positive ions of the base. For example, in a solution in which hydrochloric acid (HCl) reacts with the base sodium hydroxide (NaOH), the salt sodium chloride (NaCl) is formed:

Typically, when salts such as sodium chloride dissociate in water, they form positively and negatively charged ions (see figure 2.9).

Buffers

The chemical behavior of many molecules changes as the pH of the solution in which they are dissolved changes. For example, many enzymes work best within narrow ranges of pH. The survival of an organism depends on its ability to maintain homeostasis by keeping body fluid pH within a narrow range. Deviations from the normal pH range for human blood are life-threatening.

One way body fluid pH is regulated involves the use of buffers. **Buffers** are chemicals that resist changes in pH when either acids or bases are added to a solution. For example, when an acid is added to a buffered solution, the buffer binds to the H^+ , preventing these ions from causing a decrease in the pH of the solution (figure 2.14).

Important buffers in living systems are composed of bicarbonate, phosphates, amino acids, and proteins. Buffers prevent large changes in pH values by acting as **conjugate acid-base pairs**. A conjugate base is what remains of an acid after the H^+ (proton) is lost. A conjugate acid is formed when a H^+ is transferred to the conjugate base. Two substances related in this way are a conjugate acid-base pair.

A major buffer in our body fluids is the bicarbonate system. A bicarbonate ion (HCO_3^-) is formed by the dissociation of carbonic acid (H_2CO_3).

Carbonic acid and bicarbonate are a conjugate acid-base pair. The sodium salt of bicarbonate ($NaHCO_3$) also known as baking soda, is an active ingredient in some antacids taken to reduce

FIGURE 2.14 Buffers

(a) The addition of an acid to a nonbuffered solution results in an increase of H^+ and a decrease in pH. (b) The addition of an acid to a buffered solution results in a much smaller change in pH. The added H^+ bind to the buffer (symbolized by the letter *B*).

stomach acidity. In the forward reaction, H_2CO_3 loses a H^+ to produce HCO_3^- , which is a conjugate base. In the reverse reaction, a H^+ is transferred to the HCO_3^- (conjugate base) to produce H_2CO_3 , which is a conjugate acid.

For a given condition, this reversible reaction results in an equilibrium, in which the amounts of H_2CO_3 relative to the amounts of H^+ and HCO_3^- remain constant. The conjugate acid-base pair can resist changes in pH because of this equilibrium. If an acid is added to a buffer, the H^+ from the added acid can combine with the base component of the conjugate acid-base pair. As a result, the concentration of H^+ does not increase as much as it would without this reaction. If H^+ is added to a H_2CO_3 solution, many of the H^+ combine with HCO_3^- to form H_2CO_3 .

On the other hand, if a base is added to a buffered solution, the conjugate acid can release H^+ to counteract the effects of the added base. For example, if OH^- are added to a H_2CO_3 solution, the OH^- combine with H^+ to form water. As the H^+ are incorporated into water, H_2CO_3 dissociates to form H^+ and HCO_3^- , thereby maintaining the H^+ concentration (pH) within a normal range.

The greater the buffer concentration, the more effectively it can resist a change in pH; however, buffers cannot entirely prevent some change in the pH of a solution. For example, when an acid is added to a buffered solution, the pH decreases, but not to the extent it would have without the buffer.

Predict 7

Dihydrogen phosphate ion ($H_2PO_4^-$) and monohydrogen phosphate ion (HPO_4^{2-}) form the phosphate buffer system. Identify the conjugate acid and the conjugate base in the phosphate buffer system:

Explain how they function as a buffer when either H^+ or OH^- are added to the solution.

Oxygen and Carbon Dioxide

Oxygen is an inorganic molecule consisting of two oxygen atoms bound together by a double covalent bond. About 21% of the gas in the atmosphere is oxygen, and it is essential for most living organisms. Humans require oxygen in the final step of a series of reactions that extract energy from food molecules (see chapter 25).

Carbon dioxide consists of one carbon atom bound to two oxygen atoms. Each oxygen atom is bound to the carbon atom by a double covalent bond. Carbon dioxide is produced when organic molecules, such as glucose, are metabolized within the cells of the body (see chapter 25). Much of the energy stored in the covalent bonds of glucose is transferred to other organic molecules when glucose is broken down and carbon dioxide is released. Once carbon dioxide is produced, it is eliminated from the cell as a metabolic by-product, transferred to the lungs by the blood, and exhaled during respiration. If carbon dioxide is allowed to accumulate within cells, it becomes toxic.

ASSESS YOUR PROGRESS

29. Define acid and base, and describe the pH scale.
30. What is the difference between a strong acid or base and a weak acid or base?
31. The blood pH of a patient is 7.30. What condition does this patient have, and what are the symptoms?
32. How are salts related to acids and bases?
33. What is a buffer, and why are buffers important in the body?
34. What is a conjugate acid-base pair?
35. What are the functions of oxygen and carbon dioxide in living systems?

2.4 Organic Chemistry

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the structural organization and major functions of carbohydrates, lipids, proteins, and nucleic acids.
- B. Explain how enzymes work.
- C. Describe the roles of nucleotides in the structures and functions of DNA, RNA, and ATP.

Carbon's ability to form covalent bonds with other atoms makes possible the formation of the large, diverse, complicated molecules necessary for life. Carbon atoms bound together by covalent bonds constitute the "backbone" of many large molecules. Two mechanisms that allow the formation of a wide variety of molecules are (1) variation in the length of the carbon chains and (2) the combination of the atoms involved. For example, some protein molecules have thousands of carbon atoms bound by covalent bonds to one another or to other atoms, such as nitrogen, sulfur, hydrogen, and oxygen. A functional group gives distinctive properties, such as polarity, to organic molecules. Selected major functional groups of organic compounds are listed in table 2.5.

The four major groups of organic molecules essential to living organisms are carbohydrates, lipids, proteins, and nucleic acids. In addition, a high energy form of a nucleic acid building block, called ATP, is an important organic molecule in cellular processes. Each of these groups and ATP have specific structural and functional characteristics.

Carbohydrates

Carbohydrates are organic molecules composed primarily of carbon, hydrogen, and oxygen atoms and range in size from small to very large. In most carbohydrates, there are approximately two hydrogen atoms and one oxygen atom for each carbon atom. Note that this two-to-one ratio is the same as in water (H₂O). The molecules are called carbohydrates because carbon (*carbo*) atoms are combined with the same atoms that form water (*hydrated*). The large number of oxygen atoms in carbohydrates makes them relatively polar molecules. Consequently, they are soluble in polar solvents, such as water.

Carbohydrates are important parts of other organic molecules, and they can be broken down to provide the energy necessary for life. Undigested carbohydrates also provide bulk in feces, which helps maintain the normal function and health of the digestive tract. Table 2.6 summarizes the roles of carbohydrates in the body.

Monosaccharides

Large carbohydrates are composed of numerous, relatively simple building blocks called **monosaccharides** (mon-ō-sak'ă-rīdz; *mono-*, one + *saccharide*, sugar), or simple sugars. Monosaccharides commonly contain 3 carbons (trioses), 4 carbons (tetroses), 5 carbons (pentoses), or 6 carbons (hexoses).

The monosaccharides most important to humans include both 5- and 6-carbon sugars. Common 6-carbon sugars, such as glucose, fructose, and galactose, are **isomers** (ī'sō-merz), which are molecules that have the same number and types of atoms but differ in their three-dimensional arrangement (figure 2.15). Glucose, or blood sugar, is the major carbohydrate in the blood and a major nutrient for most cells of the body. Blood glucose levels are tightly regulated by insulin and other hormones. In people with diabetes, the body is unable to regulate glucose levels properly. Diabetics need to monitor their blood glucose carefully to minimize the deleterious effects of this disease. Fructose and galactose are also important dietary nutrients. Important 5-carbon sugars include ribose and deoxyribose (see figure 2.25), which are components of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA), respectively.

Disaccharides

Disaccharides (dī-sak'ă-rīdz; *di-*, two) are composed of two monosaccharides bound together through a dehydration reaction. For example, glucose and fructose combine to form a disaccharide called **sucrose** (table sugar) plus a molecule of water (figure 2.16a). In addition to sucrose, two other disaccharides important to humans are lactose and maltose. Lactose, or milk sugar, is glucose combined with galactose. Maltose, or malt sugar, is two glucose molecules joined together.

Polysaccharides

Polysaccharides (pol-ē-sak'ă-rīdz; *poly-*, many) are long chains of monosaccharides. These chains can be either straight or branched.

TABLE 2.5 Major Functional Groups of Organic Compounds

Name and Structural Formula*	Functional Significance
Hydroxyl $\text{R} - \text{O} - \text{H}$	<i>Alcohols</i> contain a hydroxyl group, which is polar and hydrophilic. Hydroxyl groups greatly increase the solubility of molecules in water.
Sulfhydryl $\text{R} - \text{S} - \text{H}$	<i>Thiols</i> have a sulfhydryl group, which is polar and hydrophilic. The amino acid cysteine contains a sulfhydryl group that can form a disulfide bond with another cysteine to help stabilize protein structure.
Carbonyl $\begin{array}{c} \text{O} \\ \\ \text{R} - \text{C} - \text{R} \end{array}$	<i>Ketones</i> and <i>aldehydes</i> have a carbonyl group, which is polar and hydrophilic. Ketones contain a carbonyl group within the carbon chain. Ketones are formed during normal metabolism, but they can be elevated in the blood during starvation or certain diabetic states. Aldehydes are similar to ketones, but they have the carbonyl group at the end of the carbon chain.
Carboxyl $\begin{array}{c} \text{O} \\ \\ \text{R} - \text{C} - \text{OH} \end{array}$	<i>Carboxylic acids</i> have a carboxyl group, which is hydrophilic and can act as an acid by donating a hydrogen ion. All amino acids have a carboxyl group at one end. At physiological pH, the amino acid carboxyl group is predominantly negatively charged.
Ester $\begin{array}{c} \text{O} \\ \\ \text{R} - \text{C} - \text{O} - \text{R} \end{array}$	<i>Esters</i> are structures with an ester group, which is less hydrophilic than hydroxyl or carboxyl groups. Triglycerides and dietary fats are esters. Other types of esters include the volatile compounds in perfumes.
Amino $\begin{array}{c} \text{H} \\ / \\ \text{R} - \text{N} \\ \backslash \\ \text{H} \end{array}$	<i>Amines</i> have an amino group, which is less hydrophilic than carboxyl groups. Amines can act as a base by accepting a hydrogen ion. All amino acids have an amine group at one end. At physiological pH, the amino acid amine group is predominantly positively charged.
Phosphate $\begin{array}{c} \text{O} \\ \\ \text{R} - \text{O} - \text{P} - \text{O}^- \\ \\ \text{O}^- \end{array}$	<i>Phosphates</i> have a phosphate group, which is very hydrophilic due to the double negative charge. Phosphates are used as an energy source (adenosine triphosphate), in biological membranes (phospholipids), and as intracellular signaling molecules (protein phosphorylation).

*R = variable group.

TABLE 2.6 Roles of Carbohydrates in the Body

Role	Example
Structure	Ribose forms part of RNA and ATP molecules, and deoxyribose forms part of DNA.
Energy	Monosaccharides (glucose, fructose, galactose) can be used as energy sources. Disaccharides (sucrose, lactose, maltose) and polysaccharides (starch, glycogen) must be broken down to monosaccharides before they can be used for energy. Glycogen is an important energy-storage molecule in muscles and in the liver.
Bulk	Cellulose forms bulk in the feces.

Glycogen, or animal starch, is a multibranched polysaccharide composed of many glucose molecules (figure 2.16b). Glycogen is the main storage form of glucose in humans. Because glucose can be metabolized rapidly and the resulting energy can be used by cells, glycogen is an important energy-storage molecule. A substantial amount of the glucose that is metabolized to produce energy for muscle contraction during exercise is stored in the form of glycogen in the cells of the liver and skeletal muscles.

Starch and **cellulose** are two important polysaccharides found in plants. Like glycogen, both are composed of long chains of glucose. Plants use starch as an energy-storage molecule in the same way that animals use glycogen. Cellulose is an important structural component of plant cell walls. When humans ingest plants, the starch can be broken down and used as an energy source. Humans, however, do not have the digestive enzymes necessary to break down cellulose. Cellulose is eliminated in the feces, where it provides bulk.

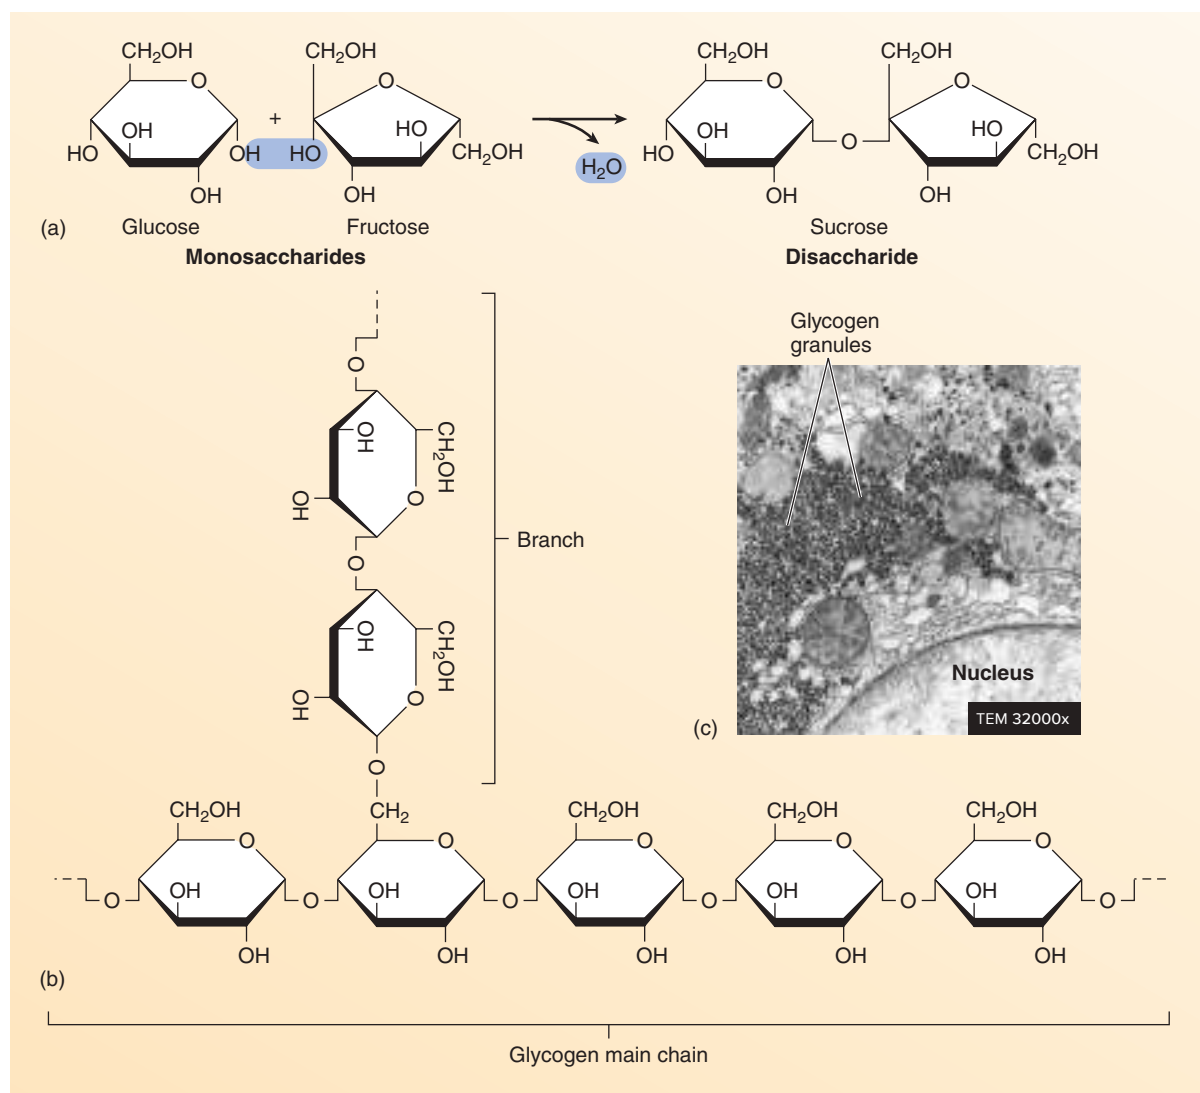

ASSESS YOUR PROGRESS

- Why is carbon such a versatile element?
- What is the building block of carbohydrates? What are isomers?
- List the 5- and 6-carbon sugars that are important to humans.
- What are disaccharides and polysaccharides, and what type of reaction is used to make them?
- Which carbohydrates are used for energy? What is the function of starch and cellulose in plants? What is the function of glycogen and cellulose in animals?

**FIGURE 2.15 Monosaccharides**

These monosaccharides almost always form a ring-shaped molecule. Although not labeled with a C, carbon atoms are located at the corners of the ring-shaped molecules. Fructose is a structural isomer of glucose because it has identical chemical groups bonded in a different arrangement in the molecule (*red shading*). Galactose is a stereoisomer of glucose because it has exactly the same groups bonded to each carbon atom but located in a different three-dimensional orientation (*yellow shading*).

**FIGURE 2.16 Carbohydrates**

(a) Sucrose, a disaccharide, forms by a dehydration reaction involving glucose and fructose (monosaccharides). (b) Glycogen is a polysaccharide formed by combining many glucose molecules. (c) The transmission electron micrograph shows glycogen granules in a liver cell.

Lipids

Lipids are a major group of organic molecules that are relatively insoluble in water. Like carbohydrates, they are composed principally of carbon, hydrogen, and oxygen but lipids have a lower ratio of oxygen to carbon than do carbohydrates. This makes them less polar. Consequently, lipids can be readily dissolved in nonpolar organic solvents, such as alcohol or acetone, but they are relatively insoluble in water. Some lipids also contain small amounts of other elements, such as phosphorus and nitrogen, which can aid solubility in water.

Lipids have many important functions in the body (table 2.7). They provide protection and insulation, help regulate many physiological processes, and form plasma membranes. In addition, lipids are major energy-storage molecules and can be broken down and used as a source of energy. The major classes of lipids are fats, phospholipids, eicosanoids, steroids, and fat-soluble vitamins.

Fats are a major type of lipid. Like carbohydrates, the fats humans ingest are broken down by hydrolysis reactions in cells to release energy for use by those cells. Conversely, if fat intake exceeds need, excess chemical energy from any source can be stored in the body as fat for later use. Fats also provide protection by surrounding and padding organs, and under-the-skin fats act as an insulator to prevent heat loss.

Triglycerides (trī-glis'er-īdz) constitute 95% of the fats in the human body. Triglycerides consist of two different types of building blocks: one glycerol and three fatty acids. **Glycerol** is a 3-carbon molecule with a hydroxyl group attached to each carbon atom. Each **fatty acid** is a straight chain of carbon atoms with a carboxyl group attached at one end (figure 2.17). A **carboxyl**

Role	Example
Protection	Fat surrounds and pads organs.
Insulation	Fat under the skin prevents heat loss. Myelin surrounds nerve cells and electrically insulates the cells from one another.
Regulation	Steroid hormones regulate many physiological processes. For example, estrogen and testosterone are the reproductive hormones responsible for many of the differences between males and females. Prostaglandins help regulate tissue inflammation and repair.
Vitamins	Fat-soluble vitamins perform a variety of functions. Vitamin A forms retinol, which is necessary for seeing in the dark; active vitamin D promotes calcium uptake by the small intestine; vitamin E promotes wound healing; and vitamin K is necessary for the synthesis of proteins responsible for blood clotting.
Structure	Phospholipids and cholesterol are important components of the membranes of cells.
Energy	Lipids can be stored and broken down later for energy; per unit of weight, they yield more energy than carbohydrates or proteins.

(kar-bok'sil) **group** ($-\text{COOH}$) consists of both an oxygen atom and a hydroxyl group attached to a carbon atom:

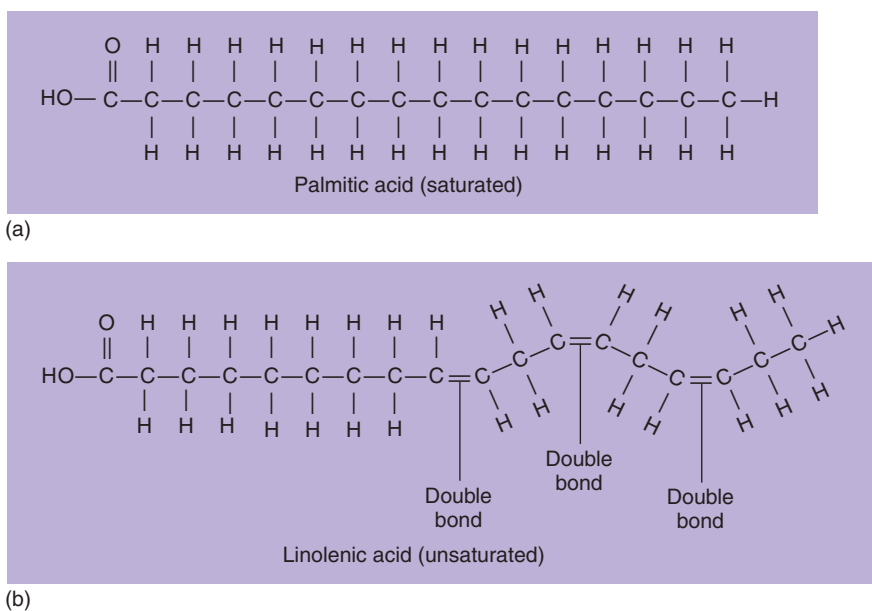

FIGURE 2.17 Triglyceride

A triglyceride is produced from one glycerol molecule and three fatty acid molecules. One water molecule (H_2O) is given off for each covalent bond formed between a fatty acid molecule and glycerol.

**FIGURE 2.18 Fatty Acids**

- (a) Palmitic acid is a saturated fatty acid; it contains no double bonds between the carbons.
 (b) Linolenic acid is an unsaturated fatty acid; note the three double bonds between the carbons.

The carboxyl group is responsible for the acidic nature of the molecule because it releases hydrogen ions into solution. Glycerides can be described according to the number and kinds of fatty acids that combine with glycerol through dehydration reactions. Monoglycerides have one fatty acid, diglycerides have two fatty acids, and triglycerides have three fatty acids bound to glycerol.

Fatty acids differ from one another according to the length and the degree of saturation of their carbon chains. Most naturally occurring fatty acids contain an even number of carbon atoms, with 14- to 18-carbon chains the most common. *Saturation* refers to the number of hydrogen atoms in the carbon chain. A fatty acid is **saturated** if it contains only single covalent bonds between the carbon atoms (figure 2.18a). Sources of saturated fats include beef, pork, whole milk, cheese, butter, eggs, coconut oil, and palm oil. The carbon chain is **unsaturated** if it has one or more double covalent bonds between carbon atoms (figure 2.18b). The double covalent bond introduces a kink into the carbon chain, which tends to keep them liquid at room temperature. **Monounsaturated fats**, such as olive and peanut oils, have one double covalent bond between carbon atoms. **Polyunsaturated fats**, such as safflower, sunflower, corn, and fish oils, have two or more double covalent bonds between carbon atoms. Unsaturated fats are the best type of fats in the diet because, unlike saturated fats, they do not contribute to the development of cardiovascular disease.

Trans fats are unsaturated fats that have been chemically altered by the addition of hydrogen. The process makes the fats more saturated and hence more solid and stable (longer shelf life). However, the double covalent bonds that do not become saturated are changed from the usual *cis* configuration (H on the same side of the double bond) to a *trans* configuration (H on different sides). This change in structure makes the consumption of *trans* fats an even greater factor than saturated fats in the risk for cardiovascular disease.

Phospholipids are similar to triglycerides, except that one of the fatty acids bound to the glycerol is replaced by a phosphate-containing region (figure 2.19). A phospholipid is polar at the end of the molecule to which the phosphate is bound and nonpolar at the other end. The polar end of the molecule is attracted to water and is said to be **hydrophilic** (water-loving). The nonpolar end is repelled by water and is said to be **hydrophobic** (water-fearing). Phospholipids are important structural components of the membranes of cells (see figure 3.2). The presence of phospholipids with unsaturated fatty acids contributes to the fluidity of the plasma membrane (see chapter 3).

The **eicosanoids** (ī'kō-sā-noydz) are a group of important chemicals derived from fatty acids. They include **prostaglandins** (pros'tā-glan'dinz), **thromboxanes** (throm'bok-zānz), and **leukotrienes** (loo-kō-trī'ēnz). Eicosanoids are made in most cells and are important regulatory molecules. Among their numerous effects is their role in the response of tissues to injuries. Prostaglandins have been implicated in regulating the secretion of certain hormones, blood clotting, some reproductive functions, and many other processes. Many of the therapeutic effects of aspirin and other anti-inflammatory drugs result from their ability to inhibit prostaglandin synthesis.

Steroids are composed of carbon atoms bound together into four ringlike structures (figure 2.20). Steroids differ in chemical structure from other lipid molecules, but their solubility characteristics are similar. Important steroid molecules include cholesterol, bile salts, estrogen, progesterone, and testosterone. **Cholesterol** is an especially important steroid because other steroid molecules are synthesized from it. Steroids derived from cholesterol include bile salts, which increase fat absorption in the intestines, and the reproductive hormones estrogen, progesterone, and testosterone. In addition, cholesterol is an important component of the plasma membrane of all cells in the body. Although high levels of cholesterol in the blood increase the risk for cardiovascular disease, a certain amount of cholesterol is vital for normal function.

Another class of lipids is the **fat-soluble vitamins**. Their structures are not closely related to one another, but they are nonpolar molecules essential for many normal body functions.

ASSESS YOUR PROGRESS

- State six roles of lipids in the body, and give an example of each.
- What is the most common fat in the body, and what are its basic building blocks?
- What is the difference between a saturated fat and an unsaturated fat? What is a trans fat?
- Describe the structure of a phospholipid. Which end of the molecule is hydrophilic? Explain why.
- What are three examples of eicosanoids and their general functions?
- Why is cholesterol an important steroid?

**FIGURE 2.19 Phospholipids**

(a) A molecular model of a phospholipid. The phosphate-containing region usually includes a nitrogen. The bent carbon chain indicates a kink from a double covalent bond. (b) A simplified depiction of a phospholipid.

**FIGURE 2.20 Steroids**

Steroids are four-ringed molecules that differ from one another according to the groups attached to the rings. Cholesterol, the most common steroid, can be modified to produce other steroids.

Proteins

All **proteins** are organic macromolecules that contain carbon, hydrogen, oxygen, and nitrogen bound together by covalent

bonds. Most proteins also contain some sulfur. In addition, some proteins contain small amounts of phosphorus, iron, and iodine. The molecular mass of proteins can be very large. For

TABLE 2.8 Roles of Proteins in the Body

Role	Example
Regulation	Enzymes control chemical reactions. Hormones regulate many physiological processes; for example, insulin affects glucose transport into cells.
Transport	Hemoglobin transports oxygen and carbon dioxide in the blood. Plasma proteins transport many substances in the blood. Proteins in plasma membranes control the movement of materials into and out of the cell.
Protection	Antibodies protect against microorganisms and other foreign substances.
Contraction	Actin and myosin in muscle are responsible for muscle contraction.
Structure	Collagen fibers form a structural framework in many parts of the body. Keratin adds strength to skin, hair, and nails.
Energy	Proteins can be broken down for energy; per unit of weight, they yield as much energy as carbohydrates do.

the purpose of comparison, the molecular mass of water is approximately 18, sodium chloride 58, and glucose 180, but the molecular mass of proteins ranges from approximately 1000 to several million.

Proteins regulate body processes, act as a transportation system, provide protection, help muscles contract, and provide structure and energy. Table 2.8 summarizes the role of proteins in the body.

Protein Structure

The basic building blocks for proteins are the 20 **amino acid** molecules. Each amino acid has an amine (ă-mē'nō) group ($-\text{NH}_2$), a carboxyl group ($-\text{COOH}$), a hydrogen atom, and a side chain designated by the symbol R attached to the same carbon atom. The side chain can be a variety of chemical structures, and the differences in the side chains make the amino acids different from one another (figure 2.21).

Covalent bonds formed between amino acid molecules during protein synthesis are called **peptide bonds** (figure 2.22). A dipeptide is two amino acids bound together by a peptide bond, a tripeptide is three amino acids bound together by peptide bonds, and a polypeptide is many amino acids bound together by peptide bonds. Proteins are polypeptides composed of hundreds of amino acids.

The **primary structure** of a protein is determined by the sequence of the amino acids bound by peptide bonds (figure 2.23a). The potential number of different protein molecules is enormous because 20 different amino acids exist, and each amino acid can be located at any position along a polypeptide chain. The characteristics of the amino acids in a protein ultimately determine the three-dimensional shape of the protein, and the shape of the protein determines its function. A change in one or a few amino acids in the primary structure can alter protein function, usually making the protein less functional or even nonfunctional.

The **secondary structure** results from the folding or bending of the polypeptide chain caused by the hydrogen bonds between amino acids (figure 2.23b). Two common shapes that result are pleated (folded) sheets and helices (sing. helix, coil). If the hydrogen bonds that maintain the shape of the protein are broken, the protein becomes denatured and nonfunctional.

FIGURE 2.21 Amino Acids

FIGURE 2.22 Peptide Bond

A dehydration reaction between two amino acids forms a dipeptide and a water molecule. The covalent bond between the amino acids is called a peptide bond.

Denaturation is the change in shape caused by the breaking of hydrogen bonds. It can be caused by abnormally high temperatures or changes in the pH of body fluids. An everyday example of denaturation is the change in the proteins of egg whites when they are cooked.

The **tertiary structure** results from large-scale folding of the protein driven by interactions within the protein and with the immediate environment (figure 2.23c). These interactions allow the pleated sheets and helices of the secondary structure to be arranged and organized relative to each other. Some amino acids are quite polar (hydrophilic) and therefore form hydrogen bonds with water. The polar portions of proteins tend to remain unfolded, maximizing their contact with water, whereas the less polar (hydrophobic) regions tend to fold into a globular shape, minimizing their contact with water. The formation of covalent bonds between sulfur atoms located at different locations along the polypeptide chain produces disulfide bridges that hold different regions of the protein together in the tertiary structure. The tertiary structure determines the shape of a **domain**, which is a folded sequence of 100–200 amino acids within a protein. The functions of proteins occur at one or more domains. Therefore, changes in the primary or secondary structure that affect the shape of the domain can change protein function.

The **quaternary structure** results from the association of two or more proteins to form a functional unit (figure 2.23d). The individual proteins are called subunits. Interactions between subunits result in the quaternary structure.

In summary, protein structure is determined first by the amino acid sequence (primary structure). The chain of amino acids is then folded or bent into helices and sheets due to

hydrogen bonding (secondary structure). This is followed by large-scale folding of the protein that is driven by hydrophilic and hydrophobic interactions and stabilized by disulfide bridges (tertiary structure). The final structure of some proteins is determined by their association with other proteins in multisubunit complexes (quaternary structure).

Enzymes

Proteins perform many roles in the body, including acting as enzymes. An **enzyme** is a protein catalyst that increases the rate at which a chemical reaction proceeds without the enzyme being permanently changed. The **active site** is the region of the enzyme that binds reactants and catalyzes their conversion to products. According to the **lock-and-key model** of enzyme action, a reaction occurs when the reactants (key) bind to the active site (lock) on the enzyme. This view of enzymes and reactants as rigid structures fitting together has been modified by the **induced fit model**, in which the enzyme is able to change shape slightly and better fit the reactants. The enzyme is like a glove that does not achieve its functional shape until the hand (reactants) moves into place.

At the active site, reactants are brought into close proximity and the reaction occurs (figure 2.24). After the reactants combine, they are released from the active site, and the enzyme is capable of catalyzing additional reactions. The activation energy required for a chemical reaction to occur is lowered by enzymes (see figure 2.12) because they orient the reactants toward each other in such a way that a chemical reaction is more likely to occur.

Slight changes in the structure of an enzyme can destroy the active site's ability to function. Enzymes are very sensitive to changes in temperature or pH, which can break the hydrogen bonds within them. As a result, the relationship between amino acids changes, thereby producing a change in shape that prevents the enzyme from functioning normally.

To be functional, some enzymes require additional, nonprotein substances called **cofactors**. A cofactor can be an ion, such as magnesium or zinc, or an organic molecule. Cofactors that are organic molecules, such as certain vitamins, may be referred to as **coenzymes**. Cofactors normally form part of the enzyme's active site and are required to make the enzyme functional.

An enzyme's active site can bind only to certain reactants because of its unique three-dimensional structure. Therefore, each enzyme catalyzes a specific chemical reaction and no others. This specificity has also allowed scientists to design drugs that block specific active sites to treat diseases, such as Gleevec[®] for treating certain cancers. An important consequence of the specificity of active sites is that many different enzymes are needed to catalyze the many chemical reactions of the body. Enzymes are often named by adding the suffix *-ase* to the name of the molecules on which they act. For example, an enzyme that catalyzes the breakdown of lipids is a **lipase** (lip'ās, lī'pās), and an enzyme that breaks down proteins is a **protease** (prō'tē-ās).

(a) Primary structure—the amino acid sequence. A protein consists of a chain of different amino acids (represented by different-colored spheres).

(b) Secondary structure results from hydrogen bonding (dotted red lines). The hydrogen bonds cause the amino acid chain to form pleated (folded) sheets or helices (coils).

(c) Tertiary structure with secondary folding caused by interactions within the polypeptide and its immediate environment

(d) Quaternary structure—the relationships between individual subunits

FIGURE 2.23 Protein Structure

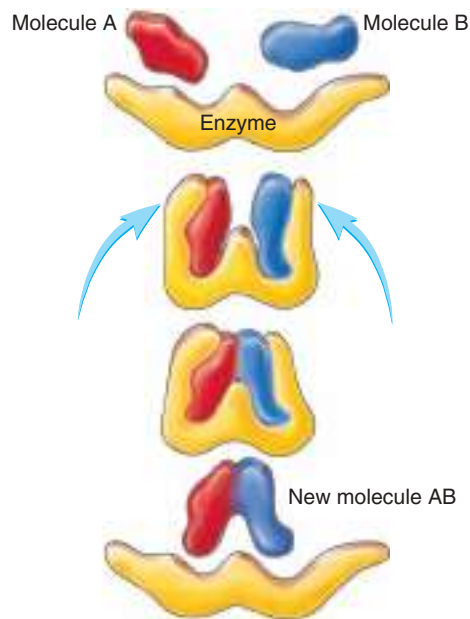

FIGURE 2.24 Enzyme Action

The enzyme brings the two reacting molecules together. After the reaction, the unaltered enzyme can be used again.

Enzymes control the rate at which most chemical reactions proceed in living systems. Consequently, they control essentially all cellular activities. At the same time, the activity of enzymes themselves is regulated by several mechanisms within the cells. Some mechanisms control the enzyme concentration by influencing the rate at which the enzymes are synthesized; others alter the activity of existing enzymes. Much of our knowledge about the regulation of cellular activity involves understanding how enzyme activity is controlled.

ASSESS YOUR PROGRESS

47. What are the building blocks of proteins? What type of bond chemically connects these building blocks? What is the importance of the R group?
48. What determines the primary, secondary, tertiary, and quaternary structures of a protein?
49. What is denaturation? Name two factors that can cause it.
50. Compare the lock-and-key and the induced fit models of enzyme activity. What determines the active site of an enzyme? State the difference between a cofactor and a coenzyme.

Nucleic Acids: DNA and RNA

The **nucleic** (noo-klē'ik, noo-klā'ik) **acids** are large molecules composed of carbon, hydrogen, oxygen, nitrogen, and phosphorus.

Deoxyribonucleic (dē-oks'ē-rī'bō-noo-klē'ik) **acid (DNA)** is the genetic material of cells, and copies of DNA are transferred from one generation of cells to the next generation. DNA contains the information that determines the structure of proteins. **Ribonucleic** (rī'bō-noo-klē'ik) **acid (RNA)** is structurally related to DNA, and three types of RNA also play important roles in protein synthesis. Chapter 3 describes the means by which DNA and RNA direct the functions of the cell.

The basic building blocks of DNA and RNA are called **nucleotides** (noo'klē-ō-tīdz). Each nucleotide is composed of a monosaccharide to which a nitrogenous base and a phosphate group are attached (figure 2.25). The 5-carbon monosaccharide is **deoxyribose** for DNA; it is **ribose** for RNA. The **nitrogenous bases** consist of carbon and nitrogen atoms organized into rings. They are bases because the nitrogen atoms tend to take up H^+ from solution. The nitrogenous bases are cytosine (sī'tō-sēn), thymine (thī'mēn, thī'min), and uracil (ūr'ă-sil), which have a single ring, and guanine (gwahn'ēn) and adenine (ad'ē-nēn), which have two rings each. Single-ringed bases are called pyrimidines (pī-rim'i-dēnz), and double-ringed bases are called purines (pūr'ēnz; figure 2.26).

DNA has two strands of nucleotides joined together to form a twisted, ladderlike structure called a double helix (figure 2.27). The sides of the ladder are formed by covalent bonds between the deoxyribose molecules and phosphate groups of adjacent nucleotides. The rungs of the ladder are formed by the nitrogenous bases of the nucleotides of one side connected to the nitrogenous bases of the other side by hydrogen bonds. Each nucleotide of DNA contains one of the nitrogenous bases: adenine, thymine, cytosine,

FIGURE 2.25 Components of Nucleotides

(a) Deoxyribose sugar, which forms nucleotides used in DNA production. (b) Ribose sugar, which forms nucleotides used in RNA production. Note that deoxyribose is ribose minus an oxygen atom. (c) A deoxyribonucleotide consists of deoxyribose, a nitrogenous base, and a phosphate group.

FIGURE 2.26 Nitrogenous Bases

The organic bases found in nucleic acids are separated into two groups. Pyrimidines are single-ringed molecules, and purines are double-ringed molecules.

or guanine. **Complementary base pairs** are bases held together by hydrogen bonds. Adenine and thymine are complementary base pairs because the structure of these bases allows two hydrogen bonds to form between them. Cytosine and guanine are complementary base pairs because the structure of these bases allows three hydrogen bonds to form between them. The two strands of a DNA molecule are said to be complementary. If the sequence of bases in one DNA strand is known, the sequence of bases in the other strand can be predicted because of complementary base pairing.

The two nucleotide strands of a DNA molecule are **antiparallel**, meaning that the two strands lie side by side but their sugar-phosphate “backbones” extend in opposite directions because of the orientation of their nucleotides (figure 2.27). A nucleotide has a 5' end and a 3' end. The prime sign is used to indicate the carbon atoms of the deoxyribose sugar, which are numbered 1' to 5'.

The sequence of nitrogenous bases in DNA is a “code” that stores information used to determine the structures and functions of cells. A sequence of DNA bases that directs the synthesis of proteins or RNA molecules is called a **gene** (see chapter 3 for more information on genes). Genes determine the type and sequence of amino acids in protein molecules. Because enzymes are proteins, DNA structure determines the rate and type of chemical reactions that occur in cells by controlling enzyme structure. Therefore, the information contained in DNA ultimately defines all cellular activities. Other proteins that are coded by DNA, such as collagen, determine many of the structural features of humans.

RNA's structure is similar to a single strand of DNA. Like DNA, four different nucleotides make up the RNA molecule, and the nitrogenous bases are the same, except that thymine is replaced with uracil (see figure 2.26). Uracil can bind only to adenine.

Adenosine Triphosphate

Adenosine triphosphate (ă-den'ō-sēn trī-fos'fāt; **ATP**) is an especially important molecule for storing and providing energy in all living organisms. It consists of adenosine (the sugar ribose with the nitrogenous base adenine) and three phosphate groups (figure 2.28). The close proximity of the three negatively charged phosphate groups make ATP a very unstable molecule. As a result, cleavage of the phosphate bonds releases a large amount of energy; hence, the second and third phosphate bonds are referred to as “high-energy” bonds. In particular, the potential energy stored in the covalent bond between the second and third phosphate groups of ATP is important to living organisms because it provides the energy used in nearly all of the chemical reactions within cells. Removal of the third phosphate generates adenosine diphosphate (ADP), which has only two phosphate groups.

The catabolism of glucose and other nutrient molecules results in chemical reactions that release energy. Some of that energy is used to synthesize ATP from ADP and an inorganic phosphate group (P_i):

The transfer of energy from nutrient molecules to ATP involves a series of oxidation-reduction reactions in which a high-energy electron is transferred from one molecule to the next molecule in the series. In chapter 25, the oxidation-reduction reactions of metabolism are considered in greater detail.

Once produced, ATP is used to provide energy for other chemical reactions (anabolism) or to drive cell processes, such as muscle contraction. In the process, ATP is converted back to ADP and an inorganic phosphate group:

ATP is often called the energy currency of cells because it is capable of both storing and providing energy. The concentration of ATP is maintained within a narrow range of values, and essentially all energy-requiring chemical reactions stop when the ATP levels become inadequate.

FUNDAMENTAL Figure

- 1 The building blocks of nucleic acids are nucleotides, which consist of a phosphate group, a sugar, and a nitrogenous base.
- 2 The phosphate groups connect the sugars to form two strands of nucleotides (purple columns).
- 3 Hydrogen bonds (dotted red lines) between the nucleotides join the two nucleotide strands together. Adenine binds to thymine and cytosine binds to guanine.
- 4 Deoxyribose carbon atoms are numbered. One end of a DNA strand has a 3' end because of the orientation of its nucleotides.
- 5 The other end of a DNA strand has a 5' end.
- 6 The complementary strands are antiparallel in that the 5' → 3' direction of one strand runs counter to the 5' → 3' direction of the other strand.
- 7 The nucleotide strands coil to form a double-stranded helix.

ASSESS YOUR PROGRESS

51. Name two types of nucleic acids, and state their functions.
52. What are the basic building blocks of nucleic acids? What kinds of sugars and bases are found in DNA? In RNA?
53. DNA is like a twisted ladder. What forms the sides of the ladder? The rungs?
54. Name the complementary base pairs in DNA and RNA.

Clinical IMPACT

Cyanide Poisoning

Cyanide compounds can be lethal to humans because they interfere with the production of ATP in mitochondria (see chapter 25). Without sufficient ATP, cells die because there is inadequate energy for anabolic chemical reactions, active transport, and other energy-requiring cell processes. The heart and brain are especially susceptible to cyanide poisoning. The most common cause of cyanide poisoning is inhalation of smoke released by the burning of rubber and plastic in household fires. Cyanide poisoning by inhalation or absorption through the skin can also occur in certain manufacturing processes, and cyanide gas was used to kill people during the Holocaust. Deliberate suicide by ingesting cyanide is rare but was made famous by suicide capsules in spy movies. Cyanide has only rarely been used as a weapon, although in 1982 seven people died after taking Tylenol that someone had laced with cyanide, which led to the widespread current use of tamper-proof capsules and packaging.

55. What is meant by the statement “DNA strands are antiparallel”?
56. Define gene, and explain how genes determine the structures and functions of cells.
57. Describe the structure of ATP. Where does the energy to synthesize ATP come from? What is the energy stored in ATP used for?

Answer

Learn to Predict ◀ From page 25

To understand the reactions occurring in the test tube, you will need to ask yourself the following questions: (1) What was in the saliva that changed the starch? (2) How do enzymes speed up chemical reactions in the body? To answer these questions, let us determine what important information was provided in the question. First, we know that starch, which is a polysaccharide, is the primary material in the test tube and that iodine stains starch a blue color. Also, saliva is added to the test tube. Saliva contains digestive enzymes that break down carbohydrates, such as starch. Finally, we are told that after 30 minutes the blue color disappeared, indicating that starch was no longer present in the test tube. We can therefore conclude that digestive enzymes in

the saliva catalyzed a decomposition reaction, breaking down the starch to a different material.

Chapter 2 teaches us that enzymes are protein catalysts that speed up chemical reactions by lowering the activation energy. Activation energy is the minimum energy that the reactants must have to start the chemical reaction. Therefore, the digestive enzymes in the saliva lowered the activation energy needed to break the bonds in the starch molecules.

Answers to the rest of this chapter's Predict questions are in appendix G.

Summary

Chemistry is the study of the composition, structure, and properties of substances and the reactions they undergo. Much of the structure and function of healthy or diseased organisms can be understood at the chemical level.

2.1 Basic Chemistry (p. 26)

Matter, Mass, and Weight

1. Matter is anything that occupies space and has mass.
2. Mass is the amount of matter in an object.
3. Weight results from the force exerted by earth's gravity on matter.

Elements and Atoms

1. An element is the simplest type of matter having unique chemical and physical properties.
2. An atom is the smallest particle of an element that has the chemical characteristics of that element. An element is composed of only one kind of atom.
3. Atoms consist of protons, neutrons, and electrons.
 - Protons are positively charged, electrons are negatively charged, and neutrons have no charge.
 - Protons and neutrons are in the nucleus; electrons are located around the nucleus and can be represented by an electron cloud.
4. The atomic number is the unique number of protons in an atom. The mass number is the sum of the protons and the neutrons.
5. Isotopes are atoms that have the same atomic number but different mass numbers.
6. The atomic mass of an element is the average mass of its naturally occurring isotopes weighted according to their abundance.
7. A mole of a substance contains Avogadro's number (6.022×10^{23}) of atoms, ions, or molecules. The molar mass of a substance is the mass of 1 mole of the substance expressed in grams.

Electrons and Chemical Bonding

1. The chemical behavior of atoms is determined mainly by their outermost electrons. A chemical bond occurs when atoms share or transfer electrons.
2. Ions are atoms that have gained or lost electrons.
 - An atom that loses 1 or more electrons becomes positively charged and is called a cation. An anion is an atom that becomes negatively charged after accepting 1 or more electrons.
 - An ionic bond results from the attraction of the oppositely charged cation and anion to each other.
3. A covalent bond forms when electron pairs are shared between atoms. A polar covalent bond results when the sharing of electrons is unequal and can produce a polar molecule that is electrically asymmetric.

Molecules and Compounds

1. A molecule is two or more atoms chemically combined to form a structure that behaves as an independent unit. A compound is two or more *different* types of atoms chemically combined.
2. The kinds and numbers of atoms (or ions) in a molecule or compound can be represented by a formula consisting of the symbols of the atoms (or ions) plus subscripts denoting the number of each type of atom (or ion).
3. The molecular mass of a molecule or compound can be determined by adding up the atomic masses of its atoms (or ions).

Intermolecular Forces

1. A hydrogen bond is the weak attraction between a positively charged hydrogen and negatively charged oxygen or other polar molecule. Hydrogen bonds are important in determining properties of water and the three-dimensional structure of large molecules.
2. Solubility is the ability of one substance to dissolve in another. Ionic substances that dissolve in water by dissociation are electrolytes. Molecules that do not dissociate are nonelectrolytes.

2.2 Chemical Reactions and Energy (p. 34)

Synthesis Reactions

1. A synthesis reaction is the chemical combination of two or more substances to form a new or larger substance.
2. A dehydration reaction is a synthesis reaction in which water is produced.
3. The sum of all the synthesis reactions in the body is called anabolism.

Decomposition Reactions

1. A decomposition reaction is the chemical breakdown of a larger substance to two or more different and smaller substances.
2. A hydrolysis reaction is a decomposition reaction in which water is depleted.
3. The sum of all the decomposition reactions in the body is called catabolism.

Reversible Reactions

Reversible reactions produce an equilibrium condition in which the amount of reactants relative to the amount of products remains constant.

Oxidation-Reduction Reactions

Oxidation-reduction reactions involve the complete or partial transfer of electrons between atoms.

Energy

1. Energy is the ability to do work. Potential energy is stored energy, and kinetic energy is energy resulting from the movement of an object.
2. Chemical energy
 - Chemical bonds are a form of potential energy.
 - Chemical reactions in which the products contain more potential energy than the reactants require the input of energy.
 - Chemical reactions in which the products have less potential energy than the reactants release energy.
3. Heat energy
 - Heat energy is energy that flows between objects that are at different temperatures.
 - Heat energy is released in chemical reactions and is responsible for body temperature.

Speed of Chemical Reactions

1. Activation energy is the minimum energy that the reactants must have to start a chemical reaction.
2. Enzymes are specialized protein catalysts that lower the activation energy for chemical reactions. Enzymes speed up chemical reactions but are not consumed or altered in the process.
3. Increased temperature and concentration of reactants can increase the rate of chemical reactions.

2.3 Inorganic Chemistry (p. 37)

Inorganic chemistry is mostly concerned with non-carbon-containing substances but does include some carbon-containing substances, such as carbon dioxide and carbon monoxide that lack carbon-hydrogen bonds. Some inorganic chemicals play important roles in the body.

Water

1. Water is a polar molecule composed of one atom of oxygen and two atoms of hydrogen.
2. Because water molecules form hydrogen bonds with each other, water is good at stabilizing body temperature, protecting against friction and trauma, making chemical reactions possible, directly participating in chemical reactions (e.g., dehydration and hydrolysis reactions), and serving as a mixing medium (e.g., solutions, suspensions, and colloids).
3. A mixture is a combination of two or more substances physically blended together, but not chemically combined.
4. A solution is any liquid, gas, or solid in which the substances are uniformly distributed, with no clear boundary between the substances.
5. A solute dissolves in a solvent.
6. A suspension is a mixture containing materials that separate from each other unless they are continually, physically blended together.
7. A colloid is a mixture in which a dispersed (solutelike) substance is distributed throughout a dispersing (solventlike) substance. Particles do not settle out of a colloid.

Solution Concentrations

1. One measurement of solution concentration is the osmole, which contains Avogadro's number (6.022×10^{23}) of particles (i.e., atoms, ions, or molecules) in 1 kilogram of water.
2. A milliosmole is 1/1000 of an osmole.

Acids and Bases

1. Acids are proton (H^+) donors, and bases (e.g., OH^-) are proton acceptors.
2. A strong acid or base almost completely dissociates in water. A weak acid or base partially dissociates.
3. The pH scale shows the H^+ concentrations of various solutions.
 - A neutral solution has an equal number of H^+ and OH^- and is assigned a pH of 7.
 - Acidic solutions, in which the number of H^+ is greater than the number of OH^- , have pH values less than 7.
 - Basic, or alkaline, solutions have more OH^- than H^+ and a pH greater than 7.
4. A salt is a molecule consisting of a cation other than H^+ and an anion other than OH^- . Salts form when acids react with bases.
5. A buffer is a solution of a conjugate acid-base pair that resists changes in pH when acids or bases are added to the solution.

Oxygen and Carbon Dioxide

Oxygen is necessary for the reactions that extract energy from food molecules in living organisms. When the organic molecules are broken down during metabolism, carbon dioxide and energy are released.

2.4 Organic Chemistry (p. 41)

Organic molecules contain carbon and hydrogen atoms bound together by covalent bonds.

Carbohydrates

1. Monosaccharides are the basic building blocks of other carbohydrates. Examples are ribose, deoxyribose, glucose, fructose, and galactose. Glucose is an especially important source of energy.

2. Disaccharide molecules are formed by dehydration reactions between two monosaccharides. They are broken apart into monosaccharides by hydrolysis reactions. Examples of disaccharides are sucrose, lactose, and maltose.
3. A polysaccharide is composed of many monosaccharides bound together to form a long chain. Examples include cellulose, starch, and glycogen.

Lipids

1. Triglycerides are composed of glycerol and fatty acids. One, two, or three fatty acids can attach to the glycerol molecule.
 - Fatty acids are straight chains of carbon molecules with a carboxyl group. Fatty acids can be saturated (having only single covalent bonds between carbon atoms) or unsaturated (having one or more double covalent bonds between carbon atoms).
 - Energy is stored in fats.
2. Phospholipids are lipids in which a fatty acid is replaced by a phosphate-containing molecule. Phospholipids are a major structural component of plasma membranes.
3. Steroids are lipids composed of four interconnected ring molecules. Examples are cholesterol, bile salts, and sex hormones.
4. Other lipids include fat-soluble vitamins, prostaglandins, thromboxanes, and leukotrienes.

Proteins

1. The building blocks of a protein are amino acids, which are joined by peptide bonds.
2. The number, kind, and arrangement of amino acids determine the primary structure of a protein. Hydrogen bonds between amino acids determine secondary structure, and hydrogen bonds between amino acids and water determine tertiary structure. Interactions between different protein subunits determine quaternary structure.
3. Enzymes are protein catalysts that speed up chemical reactions by lowering their activation energy.
4. The active sites of enzymes bind only to specific reactants.
5. Cofactors are ions or organic molecules, such as vitamins, that are required for some enzymes to function.

Nucleic Acids: DNA and RNA

1. The basic unit of nucleic acids is the nucleotide, which is a monosaccharide with an attached phosphate and a nitrogenous base.
2. DNA nucleotides contain the monosaccharide deoxyribose and the nitrogenous base adenine, thymine, guanine, or cytosine. DNA occurs as a double strand of joined nucleotides. Each strand is complementary and antiparallel to the other strand.
3. A gene is a sequence of DNA nucleotides that determines the structure of a protein or RNA.
4. RNA nucleotides are composed of the monosaccharide ribose. The nitrogenous bases are the same as for DNA except that thymine is replaced with uracil.

Adenosine Triphosphate

Adenosine triphosphate (ATP) stores energy derived from catabolism. The energy released from ATP is used in anabolism and other cell processes.

REVIEW AND COMPREHENSION

- The smallest particle of an element that still has the chemical characteristics of that element is a(n)
 - electron.
 - molecule.
 - neutron.
 - proton.
 - atom.
- ^{12}C and ^{14}C are
 - atoms of different elements.
 - isotopes.
 - atoms with different atomic numbers.
 - atoms with different numbers of protons.
 - compounds.
- A cation is a(n)
 - uncharged atom.
 - positively charged atom.
 - negatively charged atom.
 - atom that has gained an electron.
- A polar covalent bond between two atoms occurs when
 - one atom attracts shared electrons more strongly than another atom.
 - atoms attract electrons equally.
 - an electron from one atom is completely transferred to another atom.
 - the molecule becomes ionized.
 - a hydrogen atom is shared between two different atoms.
- Table salt (NaCl) is
 - an atom.
 - organic.
 - a molecule.
 - a compound.
 - a cation.
- The weak attractive force between two water molecules forms a(n)
 - covalent bond.
 - hydrogen bond.
 - ionic bond.
 - compound.
 - isotope.
- Electrolytes are
 - nonpolar molecules.
 - covalent compounds.
 - substances that usually don't dissolve in water.
 - found in solutions that do not conduct electricity.
 - cations and anions that dissociate in water.
- In a decomposition reaction,
 - anabolism occurs.
 - proteins are formed from amino acids.
 - large molecules are broken down to form small molecules.
 - a dehydration reaction may occur.
 - All of these are correct.
- Oxidation-reduction reactions
 - can be synthesis or decomposition reactions.
 - have one reactant gaining electrons.
 - have one reactant losing electrons.
 - can create ionic or covalent bonds.
 - All of these are correct.
- Potential energy
 - is energy caused by movement of an object.
 - is the form of energy that is actually doing work.
 - includes energy within chemical bonds.
 - can never be converted to kinetic energy.
 - All of these are correct.
- Which of these descriptions of heat energy is *not* correct?
 - Heat energy flows between objects that are at different temperatures.
 - Heat energy can be produced from all other forms of energy.
 - Heat energy can be released during chemical reactions.
 - Heat energy must be added to break apart ATP molecules.
 - Heat energy is always transferred from a hotter object to a cooler object.
- Which of these statements concerning enzymes is correct?
 - Enzymes increase the rate of reactions but are permanently changed as a result.
 - Enzymes are proteins that function as catalysts.
 - Enzymes increase the activation energy requirement for a reaction to occur.
 - Enzymes usually can only double the rate of a chemical reaction.
 - Enzymes increase the kinetic energy of the reactants.
- Water
 - is composed of two oxygen atoms and one hydrogen atom.
 - has a low specific heat.
 - is composed of polar molecules into which ionic substances dissociate.
 - is produced in a hydrolysis reaction.
 - is a very small organic molecule.
- When sugar is dissolved in water, the water is called the
 - solute.
 - solution.
 - solvent.
- Which of these is an example of a suspension?
 - sweat
 - water and proteins inside cells
 - sugar dissolved in water
 - red blood cells in plasma
- A solution with a pH of 5 is _____ and contains _____ H^+ than (as) a neutral solution.
 - a base, more
 - a base, fewer
 - an acid, more
 - an acid, fewer
 - neutral, the same number of
- A buffer
 - slows down chemical reactions.
 - speeds up chemical reactions.
 - increases the pH of a solution.
 - maintains a relatively constant pH.
 - works by forming salts.
- A conjugate acid-base pair
 - acts as a buffer.
 - can combine with H^+ in a solution.
 - can release H^+ to combine with OH^- .
 - describes carbonic acid (H_2CO_3) and bicarbonate ions (HCO_3^-).
 - All of these are correct.
- The polysaccharide used for energy storage in the human body is
 - cellulose.
 - glycogen.
 - lactose.
 - sucrose.
 - starch.
- The basic units or building blocks of triglycerides are
 - simple sugars (monosaccharides).
 - double sugars (disaccharides).
 - amino acids.
 - glycerol and fatty acids.
 - nucleotides.
- A _____ fatty acid has one double covalent bond between carbon atoms.
 - cholesterol
 - monounsaturated
 - phospholipid
 - polyunsaturated
 - saturated

22. The _____ structure of a protein results from the folding of the pleated sheets or helices.
- primary
 - secondary
 - tertiary
 - quaternary
23. According to the lock-and-key model of enzyme action,
- reactants must first be heated.
 - enzyme shape is not important.
 - each enzyme can catalyze many types of reactions.
 - reactants must bind to an active site on the enzyme.
 - enzymes control only a small number of reactions in the cell.
24. DNA molecules
- contain genes.
 - contain a single strand of nucleotides.
 - contain the nucleotide uracil.
 - are of three different types that have roles in protein synthesis.
 - contain up to 100 nitrogenous bases.
25. ATP
- is formed by the addition of a phosphate group to ADP.
 - is formed with energy released during catabolic reactions.
 - provides the energy for anabolic reactions.
 - contains three phosphate groups.
 - All of these are correct.

Answers in appendix E

CRITICAL THINKING

- Iron has an atomic number of 26 and a mass number of 56. How many protons, neutrons, and electrons are in an atom of iron? If an atom of iron lost 3 electrons, what would be the charge of the resulting ion? Write the correct symbol for this ion.
- Why is the conversion of a triglyceride molecule to fatty acids and glycerol a catabolic hydrolysis reaction? Would the reverse anabolic reaction generate water?
- A mixture of chemicals is warmed slightly. As a consequence, although no more heat is added, the solution becomes very hot. Explain what has occurred to make the solution so hot.
- Two solutions, when mixed together at room temperature, produce a chemical reaction. However, when the solutions are boiled and allowed to cool to room temperature before mixing, no chemical reaction takes place. Explain.
- In terms of the potential energy in food, explain why eating food is necessary for increasing muscle mass.
- Solution A is a strong acid of pH 2, and solution B is an equally strong base of pH 8. Each chemical can donate or receive a single proton. If equal amounts of solutions A and B are mixed, is the resulting solution acidic or basic?
- Carbon dioxide that accumulates in the blood can become toxic, in part because it alters the blood pH. Some of the carbon dioxide molecules react with water to form carbonic acid ($\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3$). Ned can swim across the swimming pool under water. Before diving into the water, he breathes rapidly for a few seconds, and while he is under the water he does not breathe at all. Explain how the pH of his blood changes while breathing rapidly and while swimming under water. Also explain why the pH of his blood does not change dramatically.
- An enzyme (E) catalyzes the following reaction:

$$\text{A} + \text{B} \xrightarrow{\text{E}} \text{C}$$

However, the product (C) binds to the active site of the enzyme in a reversible fashion and keeps the enzyme from functioning. What happens if A and B are continually added to a solution that contains a fixed amount of the enzyme?
- Using the materials commonly found in a kitchen, explain how to distinguish between a protein and a lipid.

Learn to Predict

Carlos always carries a water bottle, and he never likes to be too far from a restroom. Carlos has diabetes insipidus, an incurable disease that causes his kidneys to produce an unusually large volume of dilute urine. To keep his body fluids in a state of homeostasis (see chapter 1), Carlos has to drink enough water and other solutes to replace what he loses as urine. Diabetes insipidus results from a gene mutation, a change in the DNA, that prevents the kidneys from responding normally to an important hormone, called ADH, that regulates water loss from the kidneys. **After reading about cell structure and gene expression in this chapter, explain how Carlos's condition developed at the cellular level.**

Cell Biology

The human body is composed of trillions of cells. If each of these cells were the size of a standard brick, the colossal human statue erected from those bricks would be 6 miles high! In reality, an average-sized cell is only one-fifth the size of the smallest dot you can make on a sheet of paper with a sharp pencil. Although they are minute, cells act as complex factories to carry out the functions of life.

All of the cells of an individual originate from a single fertilized cell. During development, cell division and specialization give rise to a wide variety of cell types, such as nerve, muscle, bone, and blood cells. Each cell type has important characteristics that are critical to normal body function, including cell metabolism and energy use; synthesis of molecules, such as proteins and nucleic acids; communication between cells; reproduction; and inheritance. One of the important reasons for maintaining homeostasis is to keep the trillions of cells that form the body functioning normally.

Photo: Model of an aquaporin, or water channel, in the plasma membrane of a cell. The image also represents water molecules (*blue shapes*) moving through the channel.

FIGURE 3.1 A Human Cell

A generalized human cell showing the plasma membrane, nucleus, and cytoplasm with its organelles. Although no single cell contains all these organelles, many cells contain a large number of them. **APR**

3.1 Functions of the Cell

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the general parts of a cell.**
- B. Relate and explain the four main functions of cells.**

Cells are the basic units of all living things, including humans. Cells within the body may have quite different structures and functions, yet they share several common characteristics (figure 3.1; table 3.1). The **plasma** (plaz'mă) **membrane**, or *cell membrane*, forms the outer boundary of the cell, through which the cell interacts with its external environment. The **nucleus** (noo'klē-ŭs) is usually located centrally; it directs cell activities, most of which take place in the **cytoplasm** (sī'tō-plazm), located between the plasma membrane and the nucleus. Within cells, specialized structures called **organelles** (or'gă-nelz) perform specific functions.

The characteristic functions of the cell include the following:

1. **Cell metabolism and energy use.** Cell metabolism involves all chemical reactions that occur within a cell. These metabolic reactions often involve energy transfers, meaning the energy released by one reaction is then used in another reaction. For example, the energy released from the digestion of large nutrient molecules fuels cellular activities, such as the synthesis of other molecules and muscle cell contraction. During some metabolic reactions, energy is also released as heat, which helps maintain body temperature.
2. **Synthesis of molecules.** The different cells of the body synthesize, or produce, various types of molecules, including proteins, nucleic acids, and lipids. The structural and functional characteristics of cells are determined by the types of molecules they produce.
3. **Communication.** Cells communicate with each other by using chemical and electrical signals. For example, nerve cells produce chemical signals by which they communicate with muscle cells. Then, muscle cells respond to the chemical signals by contracting or relaxing.

TABLE 3.1 Summary of Cell Parts and Functions

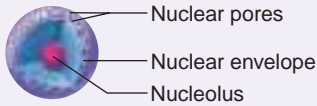

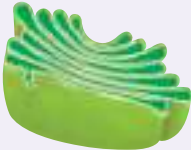

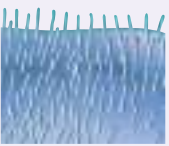

Cell Parts	Structure	Function
Plasma Membrane 	Lipid bilayer composed of phospholipids and cholesterol; proteins extend across or are embedded in either surface of the lipid bilayer	Functions as the outer boundary of the cell; controls the entry and exit of substances; receptor proteins function in intercellular communication; marker molecules enable cells to recognize one another
Nucleus 	Enclosed by nuclear envelope, a double membrane with nuclear pores; contains chromatin (dispersed, thin strands of DNA and associated proteins), which condenses to become visible mitotic chromosomes during cell division; also contains one or more nucleoli, dense bodies consisting of ribosomal RNA and proteins	Is the control center of the cell; DNA within the nucleus regulates protein (e.g., enzyme) synthesis and therefore the chemical reactions of the cell
Cytoplasmic Organelles Ribosome 	Ribosomal RNA and proteins form large and small subunits; some are attached to endoplasmic reticulum, whereas others (free ribosomes) are distributed throughout the cytoplasm	Serves as site of protein synthesis
Rough endoplasmic reticulum 	Membranous tubules and flattened sacs with attached ribosomes	Synthesizes proteins and transports them to Golgi apparatus
Smooth endoplasmic reticulum 	Membranous tubules and flattened sacs with no attached ribosomes	Manufactures lipids and carbohydrates; detoxifies harmful chemicals; stores calcium
Golgi apparatus 	Flattened membrane sacs stacked on each other	Modifies, packages, and distributes proteins and lipids for secretion or internal use
Lysosome 	Membrane-bound vesicle pinched off Golgi apparatus	Contains digestive enzymes
Peroxisome 	Membrane-bound vesicle	Serves as one site of lipid and amino acid degradation; breaks down hydrogen peroxide
Proteasomes 	Tubelike protein complexes in the cytoplasm	Break down proteins in the cytoplasm
Mitochondria 	Spherical, rod-shaped, or threadlike structures; enclosed by double membrane; inner membrane forms projections called cristae	Are major sites of ATP synthesis when oxygen is available

TABLE 3.1 Summary of Cell Parts and Functions—Continued

Cell Parts	Structure	Function
Centrioles 	Pair of cylindrical organelles consisting of triplets of parallel microtubules; located in the centrosome, a specialized area of the cytoplasm where microtubule formation occurs	Serve as centers for microtubule formation; determine cell polarity during cell division; form the basal bodies of cilia and flagella
Cilia 	Extensions of the plasma membrane containing doublets of parallel microtubules; 10 μm in length	Move materials over the surface of cells
Flagellum 	Extension of the plasma membrane containing doublets of parallel microtubules; 55 μm in length	In humans, propels spermatozoa
Microvilli 	Extensions of the plasma membrane containing microfilaments	Increase surface area of the plasma membrane for absorption and secretion; modified to form sensory receptors

4. *Reproduction and inheritance.* Most cells contain a complete copy of all the genetic information of the individual. This genetic information ultimately determines the structural and functional characteristics of the cell. As a person grows, cells divide to produce new cells, each containing the same genetic information. Specialized cells called gametes are responsible for transmitting genetic information to the next generation.

ASSESS YOUR PROGRESS

1. What parts are common to most cells?
2. Explain the four characteristic functions of the cell.

3.2 How We See Cells

LEARNING OUTCOME

After reading this section, you should be able to

- A. Relate the kinds of microscopes used to study cells.**

Most cells are too small to be seen with the unaided eye, so we must use microscopes to study them. Two major types of microscopes are used to study cells: light microscopes and electron microscopes. **Light microscopes** allow us to visualize the general features of cells, such as the nucleus. But the magnification of light microscopes is limited, so not all cell structures can be thoroughly investigated. In order to study the fine structures of cells, researchers use **electron microscopes**. A **scanning electron microscope (SEM)** can reveal features of the cell surface and the surfaces of internal structures. A **transmission electron microscope (TEM)** allows us to see “through” parts of the cell and thus to discover detailed aspects of cell structure. A more detailed description of microscopes and their use appears in Clinical Impact, “Microscopic Imaging,” in this chapter.

ASSESS YOUR PROGRESS

3. Which cell features can be seen with a light microscope? With electron microscopes?

3.3 Plasma Membrane

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the functions and general structure of the plasma membrane.**
B. Relate why a membrane potential is formed.

The plasma membrane is the outermost component of a cell. It functions as a boundary separating the **intracellular** substances, those inside the cell, from **extracellular** substances, those outside the cell. The plasma membrane encloses and supports the cell contents. It attaches cells to the extracellular environment or to other cells. The cells’ ability to recognize and communicate with each other takes place through the plasma membrane. In addition, the plasma membrane determines what moves into and out of cells. As a result, the intracellular contents of cells are different from the extracellular environment.

An electrical charge difference across the plasma membrane called the **membrane potential** is a result of the cell’s regulation of ion movement into and out of the cell. Because there are more positively charged ions immediately on the outside of the plasma membrane and more negatively charged ions and proteins inside, the outside of the plasma membrane is positively charged, compared with the inside of the plasma membrane. The membrane potential, an important feature of a living cell’s normal function, is considered in greater detail in chapters 9 and 11.

Clinical IMPACT

Microscopic Imaging

We see objects because light either passes through them or is reflected off them and enters our eyes (see chapter 15). However, vision with the unaided eye has limitations. The smallest objects we can resolve, or identify as separate objects, are approximately $100\ \mu\text{m}$, or $0.1\ \text{mm}$, in diameter, which is approximately the size of a fine pencil dot. The details of cells and tissues, which are much smaller than $100\ \mu\text{m}$, cannot be examined without the aid of a microscope.

Two basic types of microscopes have been developed: light microscopes and electron microscopes. As their names imply, light microscopes use light to produce an image, and electron microscopes use beams of electrons to produce an image. The resolution of light microscopes is limited by the wavelength of light, the lower limit being approximately $0.1\ \mu\text{m}$ —about the size of a small bacterium.

Light microscopy is regularly used to examine biopsy specimens because samples

can be quickly prepared and the resolution is adequate to diagnose most conditions that cause changes in tissue structure. Because most tissues are colorless and transparent when thinly sectioned, the tissue must be stained with a dye, so that the structural details can be seen, or must be stained with antibodies that recognize specific molecules. The bound antibodies are detected by fluorescent tags.

To see objects much smaller than a cell requires an electron microscope, which has a limit of resolution of approximately $0.1\ \text{nm}$, about the size of some molecules. In a transmission electron microscope (TEM), a beam of electrons is passed through the object to be viewed; using a scanning electron microscope (SEM), the beam of electrons is reflected off the surface of the object. For TEM, the specimen must be embedded in plastic and thinly sectioned (0.01 – $0.15\ \mu\text{m}$ thick). The magnification ability of SEM is not as great as that of TEM; however, the depth of focus of SEM

is much greater and produces a clearer three-dimensional image of tissue structure.

A newer type of microscopy, which expands on the advantages of SEM, is the atomic force microscope (AFM). This type of microscope scans the sample using a tiny mechanical probe that can be deflected by small forces between the probe and sample. This generates a three-dimensional surface map of the sample. AFM combines the high resolution of TEM with the topographical visualization of SEM. AFM also has the benefit that samples can generally be viewed under more physiological conditions. Because TEM, SEM, and AFM do not transmit color information, the micrographs are black and white unless assigned false colors.

Examples of various microscopic images of nuclear pores (see “The Nucleus and Cytoplasmic Organelles,” later in this chapter) are shown in figure 3A.

FIGURE 3A Microscopic Images of Nuclear Pores

(a) Light microscopy image of a cell. The nucleus is labeled with antibodies that bind nuclear pores (green) and proteins on the plasma membrane (red). (b) Transmission electron micrograph of a single nuclear pore. (c) Scanning electron micrograph of a single nuclear pore. View is from the cytoplasm of the cell into the pore. (d) Color-enhanced atomic force microscopy image of nuclear pores.

The plasma membrane consists primarily of lipids and proteins, with a very small amount of carbohydrates. Lipids account for 45–50% of the plasma membrane volume, and proteins make up 45–50% of the plasma membrane. A small percentage of the plasma membrane (4–8%) is carbohydrates, which are found only on the outer surface of the plasma membrane (figure 3.2). The carbohydrates combine with lipids to form glycolipids and with proteins to form glycoproteins. The **glycocalyx** (glī'kō-kā'liks) is the collection of glycolipids, glycoproteins, and carbohydrates on the outer surface of the plasma membrane. The glycocalyx also contains molecules absorbed from the extracellular environment, so there is often

no precise boundary between the plasma membrane and the extracellular environment.

ASSESS YOUR PROGRESS

4. Explain five functions of the plasma membrane.
5. Differentiate between intracellular and extracellular.
6. What is the membrane potential? Is the outside of the plasma membrane positively or negatively charged compared with the inside?
7. What are the main chemical components of the plasma membrane?

FIGURE 3.2 Plasma Membrane

(a) Fluid-mosaic model of the plasma membrane. The membrane is composed of a bilayer of phospholipids and cholesterol with proteins “floating” in the membrane. The nonpolar, hydrophobic region of each phospholipid molecule is directed toward the center of the membrane, and the polar, hydrophilic region is directed toward either the extracellular fluid or the cytoplasm. (b) Transmission electron micrograph showing the plasma membrane of a single cell. Proteins at either surface of the lipid bilayer stain more readily than the lipid bilayer does and give the membrane the appearance of having three parts: The two outer parts consist of proteins and the phospholipid heads, and the central part is composed of the phospholipid tails and cholesterol. **AP/R**

3.4 Membrane Lipids

LEARNING OUTCOMES

After reading this section, you should be able to

- List and describe the functions of membrane lipids.
- Explain the nature of the fluid-mosaic model of membrane structure.

The predominant lipids of the plasma membrane are phospholipids and cholesterol. **Phospholipids** readily assemble to form a **lipid**

bilayer, a double layer of phospholipid molecules, because they have a polar (charged) head and a nonpolar (uncharged) tail (see chapter 2). The polar heads are attracted to water molecules, so they are also called **hydrophilic** (water-loving) heads. The polar, hydrophilic heads are exposed to the aqueous extracellular and intracellular fluids of the cell. The tails of the phospholipids are nonpolar and are not attracted to water molecules, so the tails are also called **hydrophobic** (water-fearing). The nonpolar, hydrophobic tails face one another in the interior of the plasma membrane (figure 3.2). The **fluid-mosaic model** of the plasma membrane describes the plasma membrane as being neither rigid nor static in structure. Instead, the

plasma membrane is highly flexible and can change its shape and composition through time. The lipid bilayer functions as a dense liquid in which other molecules, such as proteins, are suspended. The fluid nature of the lipid bilayer has several important consequences: It provides an important means of distributing molecules within the plasma membrane. In addition, slight damage to the membrane can be repaired because the phospholipids tend to reassemble around damaged sites and close them. The fluid nature of the lipid bilayer also enables membranes to fuse with one another.

Phospholipids are not the only lipid of the plasma membrane. **Cholesterol** is the other major lipid (see chapter 2). It is interspersed among the phospholipids and accounts for about one-third of the total lipids in the plasma membrane. The hydrophilic hydroxyl (–OH) group of cholesterol extends between the phospholipid heads to the hydrophilic surface of the membrane, whereas the hydrophobic part of the cholesterol molecule lies within the hydrophobic region of the phospholipids. The amount of cholesterol in a particular plasma membrane is a major factor in determining the fluid nature of the membrane. Cholesterol limits the movement of phospholipids, providing stability to the plasma membrane.

ASSESS YOUR PROGRESS

- How do the hydrophilic heads and hydrophobic tails of phospholipid molecules result in a plasma membrane?
- Summarize the characteristics of the fluid-mosaic model of membrane structure.
- What is the function of cholesterol in plasma membranes?

3.5 Membrane Proteins

LEARNING OUTCOMES

After reading this section, you should be able to

- List and explain the functions of membrane proteins.
- Describe the characteristics of specificity, competition, and saturation of transport proteins.

Although the basic structure of the plasma membrane and some of its functions are determined by its lipids, many of its other functions are determined by its proteins. Based on their location among or attached to the phospholipid molecules, membrane proteins can be classified as integral or peripheral. **Integral membrane proteins** penetrate deeply into the lipid bilayer, in many cases extending from one surface to the other (figure 3.2). **Peripheral membrane proteins** are attached to either the inner or the outer surfaces of the lipid bilayer. Integral membrane proteins consist of regions made up of amino acids with hydrophobic R groups and other regions of amino acids with hydrophilic R groups (see chapter 2). The hydrophobic regions are located within the hydrophobic part of the membrane, and the hydrophilic regions lie at the inner or outer surface of the membrane or line channels through the membrane. Some peripheral proteins may be bound to integral membrane proteins, whereas others are bound to the polar heads of the phospholipid molecules. Membrane proteins can function as marker molecules, attachment proteins, transport proteins, receptor proteins, or enzymes (table 3.2).

The ability of membrane proteins to function depends on their three-dimensional shapes and their chemical characteristics.

ASSESS YOUR PROGRESS

- Describe the difference between integral and peripheral proteins in the plasma membrane.
- What are the five roles that proteins can play as part of the plasma membrane?

Marker Molecules

Marker molecules are cell surface molecules that allow cells to identify other cells or other molecules. They are mostly **glycoproteins** (proteins with attached carbohydrates; table 3.2) or **glycolipids** (lipids with attached carbohydrates). The protein portions of glycoproteins may be either integral or peripheral membrane proteins. Examples of marker molecule function include a sperm cell's recognition of an oocyte and the immune system's ability to distinguish between self-cells and foreign cells, such as bacteria or donor cells in an organ transplant. Intercellular communication and recognition are important because cells are not isolated entities; they must work together to ensure normal body function.

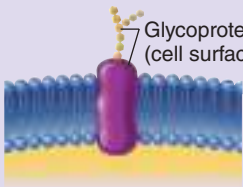

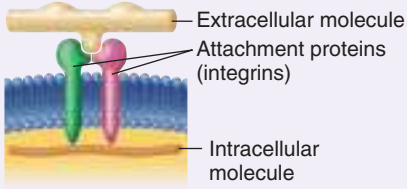

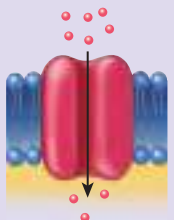

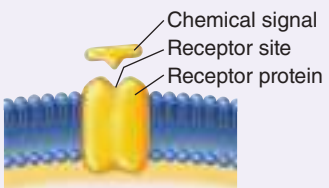

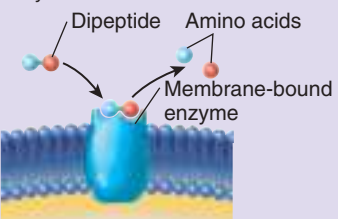

Attachment Proteins

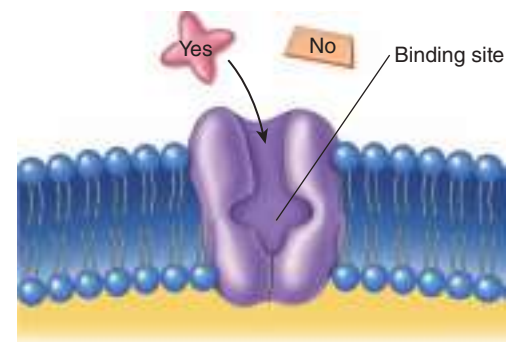

Attachment proteins are integral proteins that allow cells to attach to other cells or to extracellular molecules (table 3.2). Many attachment proteins also attach to intracellular molecules. Two examples of attachment proteins are cadherins and integrins. **Cadherins** are proteins that attach cells to other cells; **integrins** are proteins that attach cells to extracellular molecules. Integrins function in pairs of integral membrane proteins, which interact with both intracellular and extracellular molecules. Because of the interaction with intracellular molecules, integrins also function in cellular communication.

Transport Proteins

Transport proteins are integral proteins that allow ions or molecules to move from one side of the plasma membrane to the other. Transport proteins have three characteristics that are important to their function: specificity, saturation, and competition. **Specificity** means that each transport protein binds to and transports only a certain type of molecule or ion (figure 3.3a). For example, the transport protein that moves glucose does not move amino acids. The chemical structure of the binding site determines the specificity of the transport protein because only substances that are the right shape can bind to the protein (figure 3.3a). **Competition** is the result of molecules with similar shape binding to the transport protein (figure 3.3b). Although the binding sites of transport proteins exhibit specificity, closely related substances that have the same shape may bind to the same binding site. The substance in the greater concentration or the substance that binds to the binding site more readily is moved across the plasma membrane at the greater rate. **Saturation** means that the rate of movement of molecules across the membrane is limited by the number of available transport proteins (figure 3.4). As the concentration of a transported substance increases, more transport proteins have their binding sites occupied, so the rate at which the substance is moved across the plasma membrane increases.

TABLE 3.2 Functions of Membrane Proteins

Membrane Protein	Protein Function
<p>Marker molecules</p>  <p>Glycoprotein (cell surface marker)</p>	Allow cells to identify other cells or other molecules
<p>Attachment proteins</p>  <p>Extracellular molecule</p> <p>Attachment proteins (integrins)</p> <p>Intracellular molecule</p>	Anchor cells to other cells (cadherins) or to extracellular molecules (integrins)
<p>Transport Proteins</p> <p>Channel proteins</p> 	Form passageways through the plasma membrane, allowing specific ions or molecules to enter or exit the cell; may be leak or gated
<p>Carrier proteins (transporters)</p> 	Move ions or molecules across the membrane; binding of specific chemical to carrier proteins causes changes in the shape of the carrier proteins; the carrier proteins then move the specific chemical across the membrane
<p>ATP-powered pumps</p> 	Move specific ions or molecules across the membrane; require ATP molecules to function
<p>Receptor proteins</p>  <p>Chemical signal</p> <p>Receptor site</p> <p>Receptor protein</p>	Function as binding sites for chemical signals in the extracellular fluid; binding of chemical signals to receptors triggers cellular responses
<p>Enzymes</p>  <p>Dipeptide</p> <p>Amino acids</p> <p>Membrane-bound enzyme</p>	Catalyze chemical reactions either inside or outside cells

(a) Specificity. Only molecules that are the right shape to bind to the binding site are transported.

(b) Competition. Similarly shaped molecules can compete for the same binding site.

FIGURE 3.3 Transport Proteins: Specificity and Competition

However, once the concentration of the substance is increased so that all the binding sites are occupied, the rate of movement remains constant, even though the concentration of the substance increases further. There are three major classes of transport proteins: (1) channel proteins, (2) carrier proteins, and (3) ATP-powered pumps.

Channel Proteins

Channel proteins are one or more integral membrane proteins arranged so that they form a tiny channel through the plasma membrane (figure 3.5; table 3.2). The hydrophobic regions of the proteins face outward toward the hydrophobic part of the plasma membrane, and the hydrophilic regions of the protein face inward and line the channel. Ions or small molecules of the right size, charge, and shape can pass through the channel. The charges in the hydrophilic part of the channel proteins determine which types of ions can pass through the channel.

Channel proteins include leak ion channels and gated ion channels. **Leak ion channels**, or *nongated ion channels*, are always open and are responsible for the plasma membrane's permeability to ions when the plasma membrane is at rest. **Gated ion channels** open and close depending on certain conditions of the cell. Some gated ion channels open or close in response to chemical signals binding to the ion channel. **Ligand** (lig'and, lī'gand) is a generic term for any chemical signal molecule used by cells to communicate with each other, and ion channels that respond to these signals are called **ligand-gated ion channels**. Other gated ion channels open or close when there is a change in the membrane potential. These are called **voltage-gated ion channels**.

The rate of transport of molecules into a cell is plotted against the concentration of those molecules outside the cell minus the concentration of those molecules inside the cell. As the concentration difference increases, the rate of transport increases and then levels off.

1 When the concentration of molecules outside the cell is low, the transport rate is low because it is limited by the number of molecules available to be transported.

2 When more molecules are present outside the cell, as long as enough transport proteins are available, more molecules can be transported, and therefore the transport rate increases.

3 The transport rate is limited by the number of transport proteins and the rate at which each transport protein can transport solutes. When the number of molecules outside the cell is so large that the transport proteins are all occupied, the system is saturated and the transport rate cannot increase.

PROCESS FIGURE 3.4 Saturation of a Transport Protein

FIGURE 3.5 Leak and Gated Membrane Channels

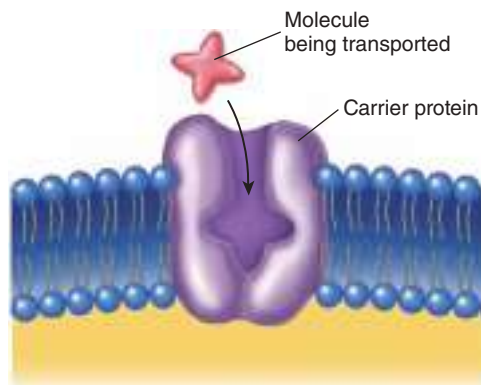

The functioning of membrane ion channels is so vital to homeostasis that serious disease can occur if a type of channel does not function properly. **Cystic fibrosis** is a genetic disorder that affects chloride ion channels. The failure of these ion channels to function causes the affected cells to produce thick, viscous secretions. Although cystic fibrosis affects many cell types, its most profound effects are in the pancreas and the lungs. In the pancreas, the thick secretions block the release of digestive enzymes, resulting in an inability to digest certain types of food and sometimes leading to serious cases of pancreatitis (inflammation of the pancreas). In the lungs, the thick secretions block airways and make breathing difficult.

Channel proteins were once thought of as simple tubes, with or without gates, through which ions pass. Many channel proteins, however, are more complex than that. It now appears that ions briefly bind to specific sites inside channels and that the shapes of those channels change as ions are transported through them. The size and charge within a channel determine the channel's specificity. For example, Na^+ channels do not transport K^+ , and vice versa. In addition, similar ions moving into and binding within a channel protein are in competition with each other. Furthermore,

the number of ions moving into a channel protein can exceed the capacity of the channel, thus saturating the channel. Therefore, channel proteins exhibit specificity, competition, and saturation.

Carrier Proteins

Carrier proteins, or *transporters*, are integral membrane proteins that move ions or molecules from one side of the plasma membrane to the other. Specific ions or molecules attach to binding sites within the carrier protein. The binding of the specific ion or molecule causes the carrier proteins to change shape and release the bound ion or molecule to the other side of the plasma membrane (figure 3.6). The carrier protein then resumes its original shape and is available to transport more ions or molecules.

- 1 A molecule enters the carrier protein from one side of the plasma membrane.

- 2 The carrier protein briefly binds the transported molecule.

- 3 The carrier protein changes shape and releases the transported molecule on the other side of the plasma membrane. The carrier protein then changes back to its original shape (go to step 1).

PROCESS FIGURE 3.6 Transport by a Carrier Protein

Some carrier proteins transport one ion or molecule at a time, but other carrier proteins can transport more than one type of substance at a time. Because of this difference, the movement of ions or molecules by carrier proteins can be classified as uniport, symport, or antiport. **Uniport** is the movement of one specific ion or molecule across the membrane. **Symport** (*cotransport*) is the movement of two different ions or molecules in the same direction across the plasma membrane, whereas **antiport** (*countertransport*) is the movement of two different ions or molecules in opposite directions across the plasma membrane. Carrier proteins involved in these types of movement are called **uniporters**, **symporters**, and **antiporters**, respectively.

ATP-Powered Pumps

ATP-powered pumps are transport proteins that require cellular energy to move specific ions or molecules from one side of the plasma membrane to the other. The activity of ATP-powered pumps is fueled by the breakdown of adenosine triphosphate (ATP). Recall from chapter 2 that energy stored in ATP molecules is used to power many cellular activities. ATP-powered pumps have binding sites, to which specific ions or molecules can bind, as well as a binding site for ATP. The breakdown of ATP to adenosine diphosphate (ADP) releases energy, changing the shape of the protein, which moves the ion or molecule across the membrane (figure 3.7).

Receptor Proteins

Receptor proteins are membrane proteins or glycoproteins that have an exposed **receptor site** on the outer cell surface. Specific substances, such as chemical signals, can attach to the receptor site. Many receptors and the chemical signals they bind are part of an intercellular communication system that coordinates cell activities. One cell can release a chemical signal that diffuses to another cell and binds to its receptor. The binding acts as a signal that triggers a response. The same chemical signal would have no effect on other cells that lacked the specific receptor molecule.

Receptors Linked to Channel Proteins

Some membrane-bound receptors also help form ligand-gated ion channels. The ion channels are composed of proteins that span the plasma membrane. Parts of one or more of the channel proteins form receptors on the cell surface. When chemical signals, or ligands, bind to these receptors, the combination alters the three-dimensional structure of the proteins of the ion channels, causing the channels either to open or to close. The result is a change in the permeability of the plasma membrane to the specific ions passing through the ion channels (figure 3.8). For example, acetylcholine released from nerve cells is a chemical signal that combines with membrane-bound receptors of skeletal muscle cells. The combination of acetylcholine molecules with the receptor sites opens Na^+ channels in the plasma membrane. Consequently, the Na^+ diffuse into the skeletal muscle cells and trigger events that cause the cells to contract.

Receptors Linked to G Protein Complexes

Some membrane-bound receptor proteins function by altering the activity of a **G protein complex** located on the inner surface of the

- 1 ATP and ion bind to the ATP-powered pump.

- 2 The ATP breaks down to adenosine diphosphate (ADP) and a phosphate (P_i) and releases energy, which powers the shape change in the ATP-powered pump. As a result, the ion moves across the membrane.

- 3 The ion and phosphate are released from the ATP-powered pump. The pump resumes its original shape (go to step 1).

PROCESS FIGURE 3.7 Transport by an ATP-Powered Pump

plasma membrane (figure 3.9). The G protein complex acts as an intermediary between a receptor and other cellular proteins. The G protein complex consists of three proteins: alpha (α), beta (β), and gamma (γ) proteins. The G protein complex interacts with a receptor protein when a chemical signal is bound to it. When the G protein complex is not interacting with a receptor protein, the α subunit of the G protein complex has guanosine diphosphate (GDP) attached to it (figure 3.9, *step 1*). When a chemical signal binds to the receptor, the receptor becomes associated with the G protein complex. The α subunit releases the GDP and attaches to guanosine triphosphate (GTP; figure 3.9, *step 2*). At this point the α subunit is considered activated. The G protein complex separates from the receptor, and the activated α subunit separates from the β and γ subunits (figure 3.9, *step 3*). The activated α subunit

- 1 The Na^+ channel has receptor sites for the chemical signal, acetylcholine. When the receptor sites are not occupied by acetylcholine, the Na^+ channel remains closed.

- 2 When two acetylcholine molecules bind to their receptor sites on the Na^+ channel, the channel opens to allow Na^+ to diffuse through the channel into the cell.

PROCESS FIGURE 3.8 Opening and Closing of a Ligand-Channel Protein

can stimulate a cell response in at least three ways: (1) by means of intracellular chemical signals, (2) by the opening of ion channels in the plasma membrane, and (3) by the activation of enzymes associated with the plasma membrane.

Drugs with structures similar to those of specific chemical signals may compete with those chemical signals for their receptor sites. Depending on the exact characteristics of a drug, it binds to a receptor site and either activates or inhibits the action of the receptor. For example, some drugs compete with the chemical signal epinephrine for its receptor sites. Some of these drugs activate epinephrine receptors; others inhibit them.

Predict 2

A research scientist is developing a new drug that blocks muscle cell receptors that, when activated, stimulate a muscle contraction. In her first experiment, she used 250 mg of the new drug but saw no effect. In her second experiment, she increased the dosage to 750 mg. This dosage was successful in blocking the muscle stimulation. Explain why increasing the dosage would affect the outcome of the experiment.

- 1 A G protein complex will only interact with a receptor protein that has a chemical signal bound to it. In its unassociated state, the α subunit of the G protein complex has guanosine diphosphate (GDP) attached to it.

- 2 When a chemical signal binds to the receptor, the receptor becomes associated with the G protein complex. GDP is released from the α subunit and a guanosine triphosphate (GTP) is attached to it. The α subunit is now activated.

- 3 The G protein complex separates from the receptor and the activated α subunit separates from the other subunits. The activated α subunit stimulates a cell response.

PROCESS FIGURE 3.9 Receptor Linked to a G Protein Complex

Enzymes

Some membrane proteins function as **enzymes**, which can catalyze chemical reactions on either the inner or the outer surface of the plasma membrane. For example, some enzymes on the surface of

cells in the small intestine break the peptide bonds of dipeptides to form two single amino acids (table 3.2). Some membrane-associated enzymes are always active; others are activated by membrane-bound receptors or G protein complexes.

ASSESS YOUR PROGRESS

- What are the three classes of transport proteins?
- Describe specificity, competition, and saturation as characteristics of transport proteins.
- What are the three types of channel proteins, and what signal causes each to open or close?
- Define uniport, symport, and antiport.
- Compare and contrast how carrier proteins and ATP-powered pumps move ions or molecules across the plasma membrane.
- To what part of a receptor molecule does a chemical signal attach? Explain how a chemical signal can bind to a receptor on a channel protein and cause a change in membrane permeability.
- Describe how receptors alter the activity of G protein complexes. List three ways in which activated α subunits can stimulate a cell response.
- Give an example of the action of a plasma membrane enzyme.

3.6 Movement Through the Plasma Membrane

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the nature of the plasma membrane in reference to the passage of materials through it.
- List and explain the three ways that molecules and ions can pass through the plasma membrane.
- Discuss the process of diffusion and relate it to a concentration gradient.
- Explain the role of osmosis and osmotic pressure in controlling the movement of water across the plasma membrane. Illustrate the differences among hypotonic, isotonic, and hypertonic solutions in terms of water movement.
- Describe mediated transport.
- Compare and contrast facilitated diffusion, active transport, and secondary active transport.
- Describe the processes of endocytosis and exocytosis.

The plasma membrane separates extracellular material from intracellular material and is **selectively permeable**—that is, it allows only certain substances to pass through it. The intracellular material has a different composition than the extracellular material, and the cell's survival depends on the maintenance of these differences. Enzymes, other proteins, glycogen, and potassium ions are present in higher concentrations intracellularly; sodium, calcium, and chloride ions exist in higher concentrations extracellularly. In addition,

even though nutrients must continually enter the cell and waste products must exit, the cell's volume remains unchanged. Because of the plasma membrane's permeability and its ability to transport molecules selectively, the cell is able to maintain homeostasis. Rupture of the membrane, alteration of its permeability characteristics, or inhibition of transport processes can disrupt the normal concentration differences across the plasma membrane and lead to cell death.

Molecules and ions can move across the plasma membrane in different ways, depending on the chemical characteristics of the molecules and ions and the structure and function of the cell. Molecules that are soluble in lipids, such as oxygen, carbon dioxide, and steroids, pass through the plasma membrane readily by dissolving in the lipid bilayer. Some small, non-lipid-soluble molecules, such as urea, can diffuse between the phospholipid molecules of the plasma membrane. Large, non-lipid-soluble molecules and ions that

cannot diffuse across the phospholipid bilayer may move across the plasma membrane with the help of transport proteins. Finally, large, non-lipid-soluble molecules, as well as small pieces of matter and even whole cells, can be transported across the plasma membrane in a **vesicle**, a small, membrane-bound sac. Table 3.3 lists the specific types of movement across plasma membranes, and each of these methods is described in detail in the following sections.

Passive Membrane Transport

Membrane transport mechanisms are classified as either passive or active based on whether or not the cell expends metabolic energy during the transport process. During passive membrane transport, the cell does not expend metabolic energy. Active membrane transport does require the cell to expend metabolic energy. Passive membrane transport includes diffusion, osmosis, and

TABLE 3.3 Comparison of Membrane Transport Mechanisms

Transport Mechanism	Description	Substances Transported	Example
Passive Transport Mechanisms			
Diffusion	Random movement of molecules results in net movement from areas of higher to lower concentration.	Lipid-soluble molecules dissolve in the lipid bilayer and diffuse through it; ions and small molecules diffuse through membrane channels.	Oxygen, carbon dioxide, and lipids, such as steroid hormones, dissolve in the lipid bilayer; Cl^- and urea move through membrane channels.
Osmosis	Water diffuses across a selectively permeable membrane.	Water diffuses through the lipid bilayer.	Water moves from the intestines into the blood.
Facilitated diffusion	Carrier proteins combine with substances and move them across the plasma membrane; no ATP is used; substances are always moved from areas of higher to lower concentration; it exhibits the characteristics of specificity, saturation, and competition.	Some substances too large to pass through membrane channels and too polar to dissolve in the lipid bilayer are transported.	Glucose moves by facilitated diffusion into muscle cells and adipocytes.
Active Transport Mechanisms			
Active transport	ATP-powered pumps combine with substances and move them across the plasma membrane; ATP is used; substances can be moved from areas of lower to higher concentration; it exhibits the characteristics of specificity, saturation, and competition.	Substances too large to pass through channels and too polar to dissolve in the lipid bilayer are transported; substances that are accumulated in concentrations higher on one side of the membrane than on the other are transported.	Ions, such as Na^+ , K^+ , and Ca^{2+} , are actively transported.
Secondary active transport	Ions are moved across the plasma membrane by active transport, which establishes an ion concentration gradient; ATP is required; ions then move back down their concentration gradient by facilitated diffusion, and another ion or molecule moves with the diffusion ion (symport) or in the opposite direction (antiport).	Some sugars, amino acids, and ions are transported.	There is a concentration gradient for Na^+ into intestinal epithelial cells. This gradient provides the energy for the symport of glucose. As Na^+ enter the cell, down their concentration gradient, glucose also enters the cell. In many cells, H^+ are moved in the opposite direction of Na^+ (antiport).
Vesicular Transport			
Endocytosis	The plasma membrane forms a vesicle around the substances to be transported, and the vesicle is taken into the cell; this requires ATP; in receptor-mediated endocytosis, specific substances are ingested.	Phagocytosis takes in cells and solid particles; pinocytosis takes in molecules dissolved in liquid.	Immune system cells called phagocytes ingest bacteria and cellular debris; most cells take in substances through pinocytosis.
Exocytosis	Materials manufactured by the cell are packaged in secretory vesicles that fuse with the plasma membrane and release their contents to the outside of the cell; this requires ATP.	Proteins and other water-soluble molecules are transported out of cells.	Digestive enzymes, hormones, neurotransmitters, and glandular secretions are transported, and cell waste products are eliminated.

facilitated diffusion. Active membrane transport will be discussed later in the chapter.

Diffusion

A solution consists of one or more substances dissolved in the predominant liquid or gas. The liquid or gas is called the **solvent** and the substances dissolved in it are called **solutes**. When solutes are first added to a solvent, the molecules of the solute are concentrated in one area, but eventually they will spread out through the solvent in a process called diffusion. **Diffusion** is the movement of solutes from an area of higher solute concentration to an area of lower solute concentration (figure 3.10). Diffusion is a product of the constant random motion of all atoms, molecules, or ions in a solution. Because there are more solute particles in an area of higher concentration than in an area of lower concentration and because the particles move randomly, the chances are greater that solute particles will move from the higher to the lower concentration than in the opposite direction. Thus, the overall, or net, movement is from the area of higher solute concentration to that of lower solute concentration. Eventually, the solutes will become evenly distributed throughout the solution. The solutes and solvent molecules will continue to move randomly, but an equilibrium will exist because no net movement of solutes will occur. Examples of diffusion include the movement and distribution of smoke or perfume throughout a room without air currents and the dispersion of a dye throughout a beaker of still water.

A concentration difference occurs when the solutes are not evenly distributed in a solvent. The concentration difference between two points, divided by the distance between the two points, is called the **concentration gradient**. Solute particles diffuse *down* their concentration gradients (from a higher to a lower solute concentration) until an equilibrium is achieved. The greater the concentration gradient, the greater the rate of diffusion of a solute down that gradient. Adjusting the concentration difference or distance between the two points changes the concentration gradient. Increasing the concentration difference between the two points or decreasing the distance between the two points causes the concentration gradient to increase, whereas decreasing the concentration difference between the two points or increasing the distance between the two points causes the concentration gradient to decrease.

The rate of diffusion is influenced by several factors, including the magnitude of the concentration gradient, the temperature of the solution, the size of the diffusing molecules, and the viscosity of the solvent. The rate of diffusion increases as the concentration gradient increases. The greater the concentration gradient, the greater the number of solute particles moving from a higher to a lower solute concentration. As the temperature of a solution increases, the speed at which all molecules move increases, resulting in a greater diffusion rate. Small molecules diffuse through a solution more readily than do large ones, so smaller molecules diffuse faster than larger molecules. **Viscosity** is a measure of a fluid's resistance to flow. A fluid with a low viscosity flows more easily, and a fluid with a high viscosity flows less easily. Thick solutions, such as syrup, are more viscous than water. Diffusion occurs more slowly in viscous solvents than in thin, watery solvents.

Diffusion of molecules is an important means by which substances move between the extracellular and intracellular fluids in the body. Substances that can diffuse through either the lipid bilayer or the membrane channels can pass through the plasma membrane (figure 3.11). Some nutrients enter and some waste products leave the cell by diffusion, and maintenance of the appropriate intracellular concentration of these substances depends to a large degree on diffusion. For example, if the extracellular concentration of oxygen is reduced, the concentration gradient decreases, inadequate oxygen diffuses into the cell, and the cell cannot function normally.

ASSESS YOUR PROGRESS

21. Explain why the plasma membrane is selectively permeable.
22. List three ways that substances can move across the plasma membrane.
23. Describe how the amount of solute in a solvent creates a concentration gradient. Do solutes diffuse with (down) or against their concentration gradient?
24. How is the rate of diffusion affected by an increased concentration gradient? By increased temperature of a solution? By increased viscosity of the solvent?

PROCESS FIGURE 3.10 Diffusion 

- 1 Certain specific non-lipid-soluble molecules or ions diffuse through membrane channels.
- 2 Other non-lipid-soluble molecules or ions, for which membrane channels are not present in the cell, cannot enter the cell.
- 3 Lipid-soluble molecules diffuse directly through the plasma membrane.

PROCESS FIGURE 3.11 Diffusion Through the Plasma Membrane

Predict 3

Mr. Smith is suffering from chronic renal failure, characterized by a gradual decrease in his kidneys' ability to perform their normal functions. Over the past few months, blood tests have indicated an increasing concentration of urea in his blood, which is a sign that the concentration of urea in the extracellular fluid is also increasing. Urea, a toxic waste produced inside cells, diffuses across the plasma membrane into the extracellular fluid. The kidneys eliminate excess urea in the urine. Explain why the extracellular concentration of urea is increasing, and predict how the intracellular concentration of urea is changing.

Osmosis

Osmosis (os-mō'sis) is the diffusion of water (solvent) across a selectively permeable membrane, such as a plasma membrane (figure 3.12). *Selectively permeable* means that the membrane allows water but not all the solutes dissolved in the water to diffuse through it. Interestingly, the permeability of some kidney cells to water can be regulated. Researchers found that the cells of kidneys have **aquaporins**, or water channel proteins, that open and close to adjust membrane permeability to water. Water diffuses from a solution with proportionately more water, across a selectively permeable membrane, and into a solution with proportionately less water. Because solution concentrations are defined in terms of solute concentrations, not in terms of water content (see chapter 2), water diffuses from the less concentrated solution (fewer solutes, more water) into the more concentrated solution (more solutes, less water). Osmosis is important to cells because large volume changes caused by water movement disrupt normal cell function.

Osmotic pressure is the force required to prevent water from moving by osmosis across a selectively permeable membrane. The

osmotic pressure of a solution can be determined by placing the solution into a tube that is closed at one end by a selectively permeable membrane (figure 3.12). The tube is then immersed in distilled water. Water molecules move by osmosis through the membrane into the tube, forcing the solution to move up the tube. As the solution rises into the tube, its weight produces hydrostatic pressure, which moves water out of the tube back into the distilled water surrounding the tube. At equilibrium, net movement of water stops, which means that the movement of water into the tube by osmosis is equal to the movement of water out of the tube caused by hydrostatic pressure. The osmotic pressure of the solution in the tube is equal to the hydrostatic pressure that prevents net movement of water into the tube.

The osmotic pressure of a solution provides information about the tendency for water to move by osmosis across a selectively permeable membrane. Because water moves from less concentrated solutions (fewer solutes, more water) into more concentrated solutions (more solutes, less water), the greater the concentration of a solution (the less water it has), the greater the tendency for water to move into the solution, and the greater the osmotic pressure to prevent that movement.

Predict 4

Given the demonstration in figure 3.12, what happens to osmotic pressure if the membrane is not selectively permeable but instead allows all solutes and water to pass through it?

Three terms describe the osmotic pressure of solutions. Solutions with the same concentration of solute particles (see chapter 2) have the same osmotic pressure and are referred to as **isosmotic** (ī'sos-mot'ik). The solutions are isosmotic even if the types of solute particles in the two solutions differ from each other. If one solution has a greater concentration of solute particles, and therefore a greater osmotic pressure than another solution, the first solution is said to be **hyperosmotic** (hī'per-oz-mot'ik) compared with the more dilute solution. The more dilute solution, with the lower osmotic pressure, is **hyposmotic** (hī-pos-mot'ik) compared with the more concentrated solution.

Three additional terms describe the tendency of cells to shrink or swell when placed into a solution (figure 3.13). If a cell placed into a solution neither shrinks nor swells, the solution is said to be **isotonic** (ī-sō-ton'ik). In an isotonic solution, the shape of the cell remains constant, maintaining its internal tension or tone, a condition called **tonicity** (tō-nis'i-tē). If a cell is placed into a solution and water moves out of the cell by osmosis, causing the cell to shrink, the solution is called **hypertonic** (hī-per-ton'ik). If a cell is placed into a solution and water moves into the cell by osmosis, causing the cell to swell, the solution is called **hypotonic** (hī-pō-ton'ik).

An isotonic solution may be isosmotic to the cytoplasm. Because isosmotic solutions have the same concentration of solutes and water as the cytoplasm of the cell, no net movement of water occurs, and the cell neither swells nor shrinks (figure 3.13b). Hypertonic solutions can be hyperosmotic and have a greater concentration of solute molecules and a lower concentration of water than the cytoplasm of the cell. Therefore, water moves by osmosis from the cell into the hypertonic solution, causing the cell to shrink, a process called **crenation** (krē-nā'shŭn) in red blood cells

PROCESS FIGURE 3.12 Osmosis

(figure 3.13c). Hypotonic solutions can be hyposmotic and have a smaller concentration of solute molecules and a greater concentration of water than the cytoplasm of the cell. Therefore, water moves by osmosis into the cell, causing it to swell. If the cell swells enough, it can rupture, a process called **lysis** (lī'sis; figure 3.13a). Solutions injected into the bloodstream or the tissues must be isotonic because shrinkage or swelling of cells disrupts their normal function and can lead to cell death.

The *-osmotic* terms refer to the concentration of the solutions, and the *-tonic* terms refer to the tendency of cells to swell or

shrink. These terms should not be used interchangeably. Not all isosmotic solutions are isotonic. For example, it is possible to prepare a solution of glycerol and a solution of mannitol that are isosmotic to the cytoplasm of the cell. Because the solutions are isosmotic, they have the same concentration of solutes and water as the cytoplasm. However, glycerol can diffuse across the plasma membrane, whereas mannitol cannot. When glycerol diffuses into the cell, the solute concentration of the cytoplasm increases, and its water concentration decreases. Therefore, water moves by osmosis into the cell, causing it to swell, and the glycerol solution

(a) When a red blood cell is placed in a hypotonic solution (one having a low solute concentration), water enters the cell by osmosis (*black arrows*), causing the cell to swell or even burst (*lyse; puff of red in lower part of cell*).

(b) When a red blood cell is placed in an isotonic solution (one having a concentration of solutes equal to that inside the cell), water moves into and out of the cell at the same rate (*black arrows*). No net water movement occurs, and the cell shape remains normal.

(c) When a red blood cell is placed in a hypertonic solution (one having a high solute concentration), water moves by osmosis out of the cell and into the solution (*black arrows*), resulting in shrinkage (*crenation*).

FIGURE 3.13 Effects of Hypotonic, Isotonic, and Hypertonic Solutions on Red Blood Cells

is both isosmotic and hypotonic. In contrast, mannitol cannot enter the cell, and the isosmotic mannitol solution is also isotonic.

Facilitated Diffusion

Because of their chemical structure or size, many essential molecules, such as amino acids and glucose, cannot enter or exit the cell by diffusing directly through the plasma membrane. Instead, these molecules and ions cross the membrane by **mediated transport**, a membrane transport process by which membrane transport proteins mediate, or assist, the movement of large, water-soluble molecules or electrically charged molecules or ions across the plasma membrane.

Facilitated diffusion is a mediated transport process that moves substances into or out of cells from a higher to a lower concentration

(figure 3.14). Carrier proteins and channel proteins carry out facilitated diffusion. Facilitated diffusion does not require metabolic energy to transport substances across the plasma membrane. The rate at which molecules or ions are transported is directly proportional to their concentration gradient up to the point of saturation, when all the carrier proteins or channels are occupied. Then the rate of transport remains constant at its maximum rate (see figure 3.4).

► Predict 5

The transport of glucose into and out of most cells, such as muscle cells and adipocytes, occurs by facilitated diffusion. Once glucose enters a cell, it is rapidly converted to another molecule, such as glucose-6-phosphate or glycogen. What effect does this conversion have on the cell's ability to acquire glucose? Explain.

1 The carrier protein binds with a molecule, such as glucose, on the outside of the plasma membrane.

2 The carrier protein changes shape and releases the molecule on the inside of the plasma membrane.

Active Membrane Transport

Active Transport

Active transport is a mediated transport process that requires energy provided by ATP (figure 3.15). Movement of the transported substance to the opposite side of the membrane and its subsequent release from the ATP-powered pump are fueled by the breakdown of ATP. The maximum rate at which active transport proceeds depends on the number of ATP-powered pumps in the plasma membrane and the availability of adequate ATP. Active transport is important because it can move substances against their concentration gradients—that is, from lower concentrations to higher concentrations. Consequently, it can accumulate substances on one side of the plasma membrane at concentrations many times greater than those on the other side. Active transport can also move substances from higher to lower concentrations.

Some active-transport mechanisms exchange one substance for another. For example, the **sodium-potassium ($\text{Na}^+ - \text{K}^+$) pump** moves Na^+ out of cells and K^+ into cells (figure 3.15). The result is a higher concentration of Na^+ outside the cell and a higher concentration of K^+ inside the cell. Because ATP is broken down during the transport of Na^+ and K^+ , the pump is also called **sodium-potassium ATP-ase**. The $\text{Na}^+ - \text{K}^+$ pump is very important to a number of cell functions, as discussed in chapters 9 and 11.

Secondary Active Transport

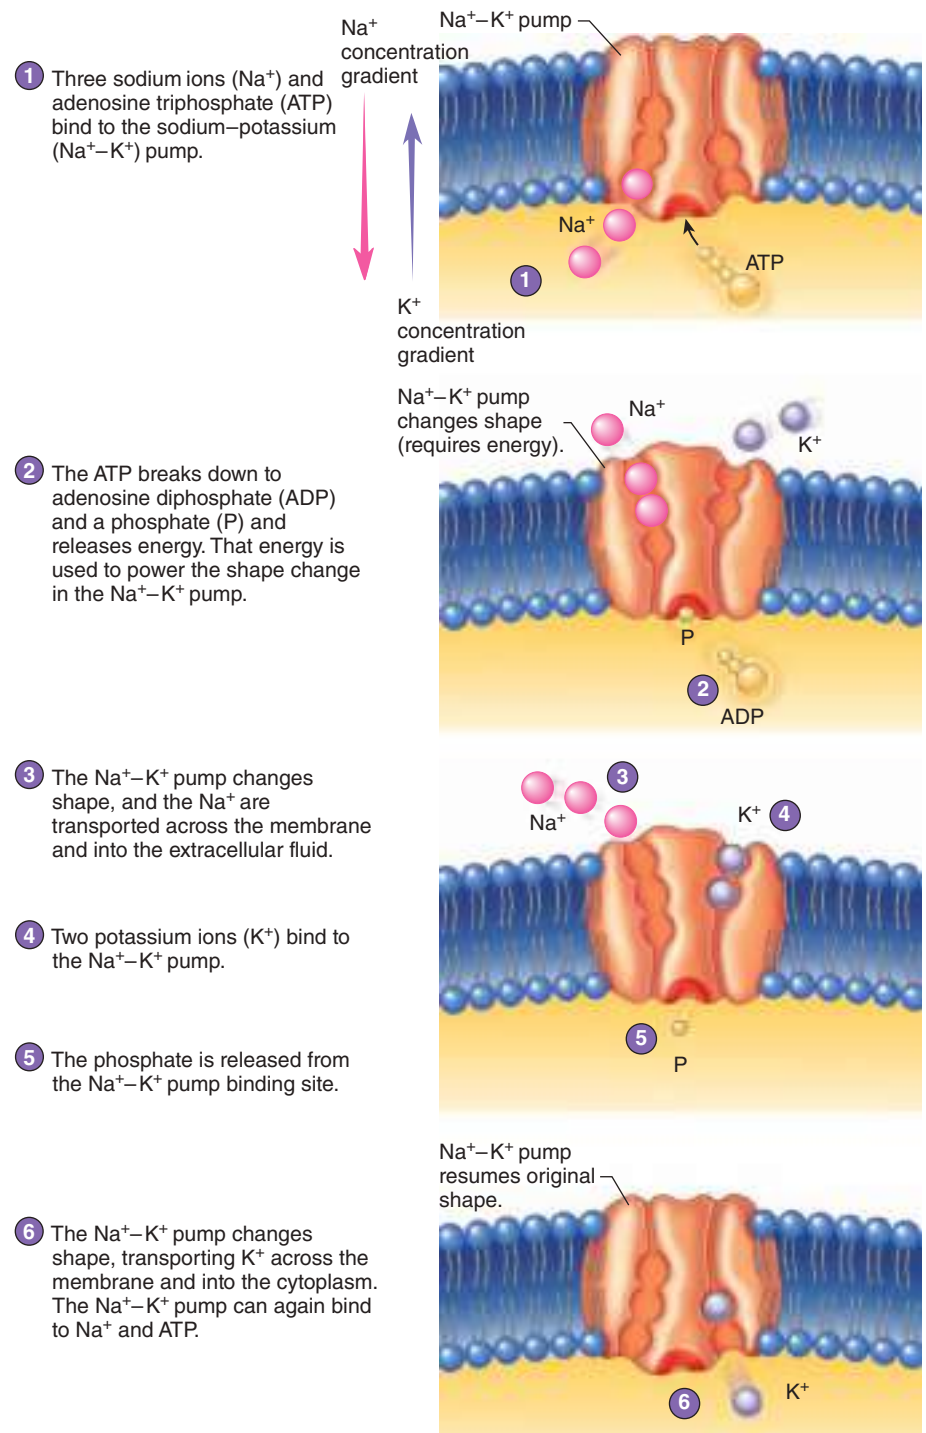

Secondary active transport involves the active transport of an ion, such as sodium, out of a cell, establishing a concentration gradient, with a higher concentration of the ions outside the cell. The tendency for the ions to move back into the cell (down their concentration gradient) provides the energy necessary to move a different ion or some other molecule into the cell. For example, glucose moves from the lumen of the intestine into epithelial cells by secondary active transport (figure 3.16). This process requires two transport proteins: (1) A $\text{Na}^+ - \text{K}^+$ pump actively moves Na^+ out of the cell, and (2) a carrier protein facilitates the movement of Na^+ and glucose into the cell. Both Na^+ and glucose are necessary for the carrier protein to function.

The movement of Na^+ down its concentration gradient provides the energy to move glucose molecules into the cell against their concentration gradient. Thus, glucose can accumulate at concentrations higher inside the cell than outside. Because the movement of glucose molecules against their concentration gradient results from the formation of a concentration gradient of Na^+ by an active-transport mechanism, the process is called secondary active transport.

Vesicular Transport

Vesicular transport is the movement of larger volumes of substances across the plasma membrane through the formation or release of vesicles, membrane-bound sacs, in the cytoplasm. Vesicular transport includes endocytosis and exocytosis.

Vesicular transport requires energy in the form of ATP and therefore is an active membrane transport process. However, because it involves the bulk movement of material into the cell, vesicular transport does not demonstrate the degree of specificity or saturation that other forms of active membrane transport exhibit.

PROCESS FIGURE 3.15 Active Transport: Sodium-Potassium Pump **APR**

- 1 A Na^+-K^+ pump maintains a concentration of Na^+ that is higher outside the cell than inside.
- 2 Sodium ions move back into the cell through a transport protein that also moves glucose. The concentration gradient for Na^+ provides energy required to move glucose against its concentration gradient.

PROCESS FIGURE 3.16 Secondary Active Transport (Symport) of Na^+ and Glucose

Endocytosis (en'dō-sī-tō'sis) occurs when material moves through the plasma membrane and into the cytoplasm by the formation of a vesicle. A portion of the plasma membrane wraps around a particle or droplet in the extracellular fluid. The portion of the plasma membrane then fuses, so that the particle or droplet is surrounded by a membrane. That portion of the membrane then “pinches off,” so that the enclosed particle or droplet is within the cytoplasm of the cell, and the plasma membrane is left intact.

There are two types of endocytosis: phagocytosis and pinocytosis. In **phagocytosis** (fāg-ō-sī-tō'sis), which means “cell-eating,” solid particles are ingested and phagocytic vesicles are formed (figure 3.17). White blood cells and some other cell types phagocytize bacteria, cell debris, and foreign particles. Phagocytosis is therefore important in eliminating harmful substances from the body.

Pinocytosis (pin'ō-sī-tō'sis), which means “cell-drinking,” is distinguished from phagocytosis in that smaller vesicles form,

(b)

FIGURE 3.17 Phagocytosis

(a) In this type of endocytosis, a solid particle is ingested, and a phagocytic vesicle forms around it. (b) Colorized scanning electron micrograph of phagocytosis of a red blood cell.

and they contain molecules dissolved in liquid rather than particles (figure 3.18). Pinocytosis often forms vesicles near the tips of deep invaginations of the plasma membrane. It is a common

FIGURE 3.18 Pinocytosis

Pinocytosis is much like phagocytosis, except that the cell processes—and therefore the vesicles formed—are much smaller and the material inside the vesicle is liquid rather than particulate. Pinocytotic vesicles form on the internal side of a capillary, are transported across the cell, and open by exocytosis outside the capillary.

transport phenomenon in a variety of cell types, occurring in certain cells of the kidneys, epithelial cells of the intestines, cells of the liver, and cells that line capillaries.

Endocytosis can exhibit specificity. For example, cells that phagocytize bacteria and necrotic tissue do not phagocytize healthy cells. The plasma membrane may contain specific receptor molecules that recognize certain substances and allow them to be transported into the cell by phagocytosis or pinocytosis. This is called **receptor-mediated endocytosis**, and the receptor sites combine only with certain molecules (figure 3.19). This mechanism increases the rate at which the cells take up specific substances. Cholesterol and growth factors are examples of molecules that can be taken into a cell by receptor-mediated endocytosis.

Hypercholesterolemia is a common genetic disorder characterized by the reduction in or absence of low-density lipoprotein (LDL) receptors on cell surfaces, which interferes with the receptor-mediated endocytosis of LDL cholesterol. As a result of inadequate cholesterol uptake, cholesterol synthesis within these cells is not regulated, and too much cholesterol is produced. The excess cholesterol accumulates in blood vessels, resulting in atherosclerosis. Atherosclerosis can cause heart attacks or strokes. A more detailed description of hypercholesterolemia can be found in chapter 24.

PROCESS FIGURE 3.19 Receptor-Mediated Endocytosis

Some cells release material through a vesicular transport mechanism called **exocytosis** (ek'sō-sī-tō'sis). In these cells, secretions accumulate within vesicles. These secretory vesicles then move to the plasma membrane, where the vesicle membrane fuses with the plasma membrane and the vesicle contents are expelled from the cell (figure 3.20). The secretion of digestive enzymes by the pancreas and the secretion of mucus by the salivary glands are examples of exocytosis.

ASSESS YOUR PROGRESS

25. Define osmosis, and describe how osmotic pressure is created. As the concentration of a solution increases, what happens to its osmotic pressure and to the tendency for water to move into the solution?
26. Compare isosmotic, hyperosmotic, and hyposmotic solutions with isotonic, hypertonic, and hypotonic solutions.

27. What is mediated transport? What types of particles move through the plasma membrane by mediated transport?
28. Contrast facilitated diffusion and active transport in relation to energy expenditure and direction of movement with respect to the concentration gradient.
29. What is secondary active transport? Describe how it functions.
30. What occurs during endocytosis? What role do vesicles play?
31. How do phagocytosis and pinocytosis differ from each other?
32. What is receptor-mediated endocytosis?
33. Describe and give examples of exocytosis.

3.7 Cytoplasm

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the composition and functions of the cytoplasm.
- B. Describe the composition and functions of the cytoskeleton.

(a)

Cytoplasm, the cellular material outside the nucleus but inside the plasma membrane, is about half cytosol and half organelles.

Cytosol

The fluid portion of the cytoplasm is **cytosol** (sī'tō-sol). The cytosol is a colloid, a viscous solution containing dissolved ions and molecules as well as suspended molecules, especially proteins. Many of these proteins are enzymes that catalyze the breakdown of molecules for energy or the synthesis of sugars, fatty acids, nucleotides, amino acids, and other molecules. Other proteins in the cytosol make up the cytoskeleton and cytoplasmic inclusions.

Cytoskeleton

Just as our skeleton supports many of the structures of our bodies, the **cytoskeleton** supports the cell and holds the nucleus and other organelles in place. In addition, some components of the cytoskeleton are responsible for changes in cell shape and the movement of cell organelles. The cytoskeleton consists of three groups of proteins: microtubules, actin filaments, and intermediate filaments (figure 3.21).

Microtubules are hollow tubes composed primarily of protein units called **tubulin**. The microtubules are about 25 nanometers (nm) in diameter, with walls about 5 nm thick. They vary in length but

Intermediate filament (b)

FIGURE 3.21 Cytoskeleton

(a) Diagram of the cytoskeleton. (b) Scanning electron micrograph of the cytoskeleton.

are normally several micrometers (μm) long. Microtubule length can change as tubulin subunits are added or removed. Microtubules play a variety of roles within cells. They help provide support and structure to the cytoplasm of the cell, much like an internal scaffolding. Microtubules are involved in cell division and in the transport of intracellular materials. Microtubules also form essential components of certain cell organelles, such as centrioles, spindle fibers, cilia, and flagella.

Actin filaments, also called *microfilaments*, are small fibrils, about 8 nm in diameter, that form bundles, sheets, or networks in the cytoplasm. Actin filaments provide structure to the cytoplasm and mechanical support for microvilli. Actin filaments also support the plasma membrane and define the shape of the cell. Changes in cell shape involve the breakdown and reconstruction of actin filaments. These changes in shape allow some cells to move about. Muscle cells contain a large number of highly organized actin filaments, which are responsible for the muscle's contractile capabilities (see chapter 9).

Intermediate filaments are protein fibers about 10 nm in diameter that provide mechanical strength to cells. For example, intermediate filaments support the extensions of nerve cells, which have a very small diameter but can be up to a meter in length.

Cytoplasmic Inclusions

The cytosol also contains **cytoplasmic inclusions**, which are aggregates of chemicals either produced or taken in by the cell. For example, lipid droplets or glycogen granules store energy-rich molecules; hemoglobin in red blood cells transports oxygen; the pigment melanin colors the skin, hair, and eyes; and **lipochromes** (lip'ō-krōmz) are pigments that increase in amount with age. Dust, minerals, and dyes can also accumulate in the cytoplasm.

ASSESS YOUR PROGRESS

34. Differentiate between the cytoplasm and the cytosol.
35. What are the general functions of the cytoskeleton?
36. List and describe the functions of microtubules, actin filaments, and intermediate filaments.
37. What are cytoplasmic inclusions? Give several examples.

3.8 The Nucleus and Cytoplasmic Organelles

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Define *organelle*.
- B. Describe the structure and function of the nucleus and nucleoli.
- C. Explain the structure and function of ribosomes.
- D. Compare the structure and functions of rough and smooth endoplasmic reticula.
- E. Discuss the structure and function of the Golgi apparatus.

- F. Describe the role of secretory vesicles in the cell.
- G. Compare the structure and roles of lysosomes and peroxisomes in digesting material within the cell.
- H. Relate the structure and function of proteasomes.
- I. Describe the structure and function of mitochondria.
- J. Explain the structure and function of the centrosome.
- K. Compare the structure and function of cilia, flagella, and microvilli.

Organelles are structures within cells that are specialized for particular functions, such as manufacturing proteins or producing ATP. Organelles can be thought of as individual workstations within the cell, each responsible for performing specific tasks. One class of organelles has membranes that are similar to the plasma membrane, whereas other organelles are clusters of proteins and other molecules not surrounded by a membrane. The interior of the membrane-bound organelles is separated from the cytoplasm, creating subcellular compartments having their own enzymes capable of carrying out unique chemical reactions. The nucleus is the largest organelle of the cell. The remaining organelles are considered cytoplasmic organelles (see table 3.1).

The number and type of cytoplasmic organelles within each cell are related to the specific structure and function of the cell. Cells secreting large amounts of protein contain well-developed organelles that synthesize and secrete protein, whereas cells actively transporting substances, such as sodium ions, across their plasma membrane contain highly developed organelles that produce ATP. The following sections describe the structure and main functions of the nucleus and major cytoplasmic organelles in cells.

The Nucleus

The **nucleus** is a large, membrane-bound structure usually located near the center of the cell. It may be spherical, elongated, or lobed, depending on the cell type. All body cells have a nucleus at some point in their life cycle (see section 3.10), although some cells, such as red blood cells, lose their nuclei as they develop. Other cells, such as skeletal muscle cells and osteoclasts, a type of bone cell, contain more than one nucleus.

The nucleus consists of **nucleoplasm** surrounded by a **nuclear envelope** (figure 3.22). The nuclear envelope is composed of two membranes separated by a space. At many points on the surface of the nuclear envelope, the inner and outer membranes fuse to form porelike structures called **nuclear pores**. Molecules move between the nucleus and the cytoplasm through these openings.

Deoxyribonucleic acid (DNA) is mostly found within the nucleus (see figure 2.27), although small amounts of DNA are also found within mitochondria (described later in this section). The DNA and associated proteins are organized into discrete structures called **chromosomes** (krō'mō-sōmz; figure 3.23). The associated proteins include **histones** (his'tōnz), which are important for the structural organization of DNA, as well as other proteins that regulate DNA function. During most of the cell's life cycle, the chromosomes are dispersed throughout the nucleus as delicate filaments collectively referred to as **chromatin** (krō'ma-tin; figures 3.22 and 3.23).

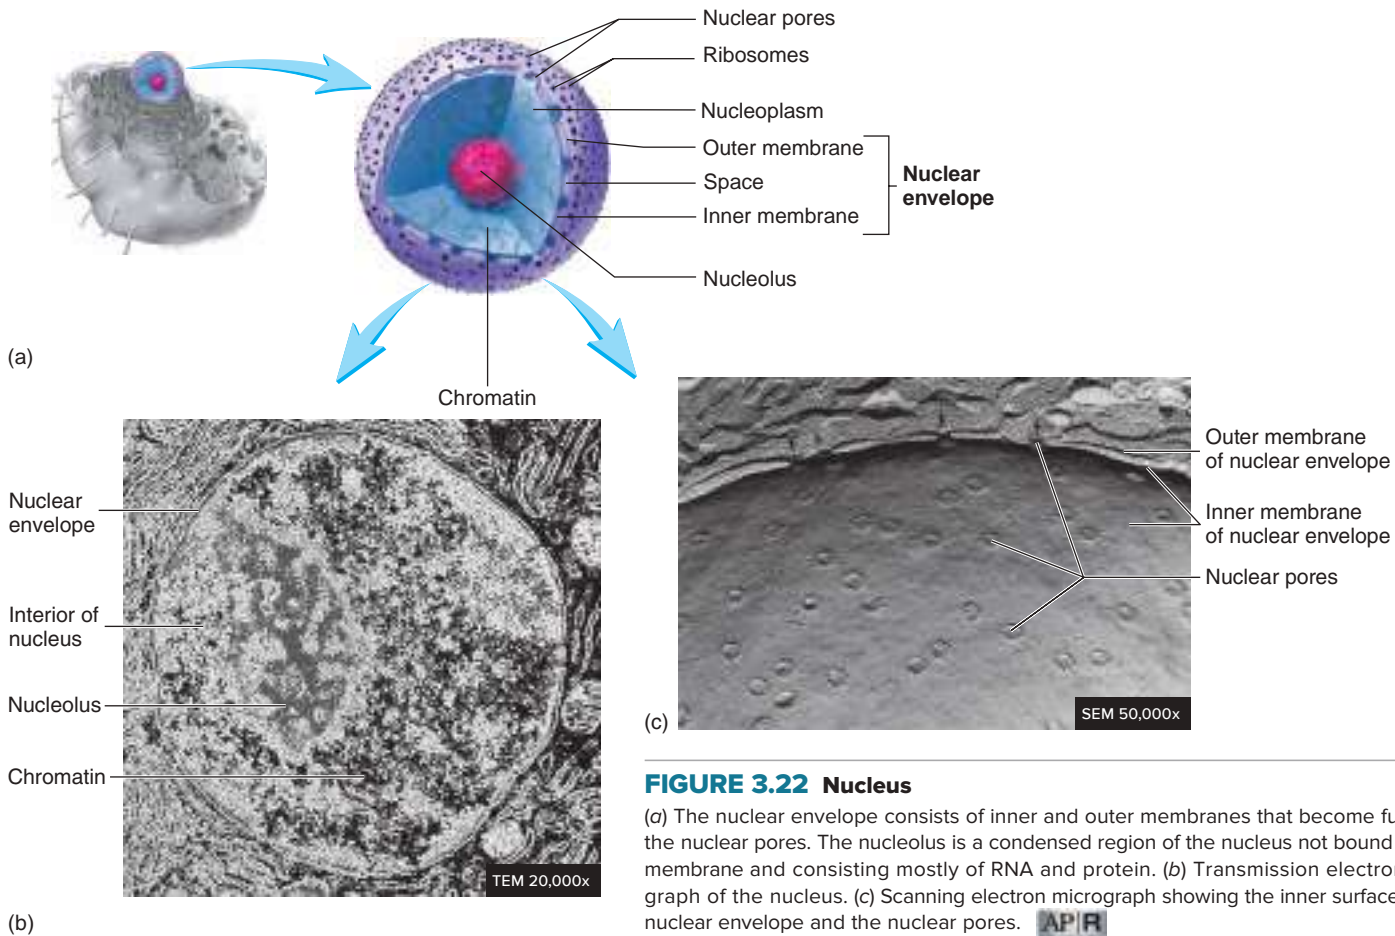

FIGURE 3.22 Nucleus

(a) The nuclear envelope consists of inner and outer membranes that become fused at the nuclear pores. The nucleolus is a condensed region of the nucleus not bound by a membrane and consisting mostly of RNA and protein. (b) Transmission electron micrograph of the nucleus. (c) Scanning electron micrograph showing the inner surface of the nuclear envelope and the nuclear pores.

During cell division (see “Cell Division,” section 3.10), the chromatin filaments become densely coiled, forming compact chromosomes.

DNA determines the structural and functional characteristics of the cell by specifying the structure of proteins. Proteins form many of a cell’s structural components, as well as all the enzymes that regulate most of the chemical reactions in the cell. DNA establishes the structure of proteins by specifying the sequence of their amino acids (see figure 2.23a). DNA is a large molecule that does not leave the nucleus but functions by means of an intermediate, **ribonucleic acid (RNA)**, which can leave the nucleus through nuclear pores. DNA determines the structure of messenger RNA (mRNA), ribosomal RNA (rRNA), and transfer RNA (tRNA; all described in more detail in section 3.9). A **gene** is a region of a DNA molecule that specifies an RNA molecule.

Because mRNA synthesis occurs within the nucleus, cells without nuclei accomplish protein synthesis only as long as the mRNA produced before the nucleus degenerates remains functional. For example, red blood cells lack nuclei—the nuclei of developing red blood cells are expelled from the cells before the red blood cells enter the blood. Red blood cells survive without a nucleus for about 120 days and must be continually replaced. In comparison, many cells with nuclei, such as nerve and skeletal muscle cells, potentially survive as long as the person is alive.

A **nucleolus** (noo-klē’ō-lūs) is a dense region within the nucleus. A nucleolus lacks a surrounding membrane (see figure 3.1). Usually, one nucleolus exists per nucleus, but several nucleoli may be seen in the nuclei of rapidly dividing cells. The subunits for ribosomes are manufactured in the nucleolus, so the portions of chromosomes that contain DNA from which rRNA is produced are located in the nucleolus.

Ribosomes

Ribosomes (rī’bō-sōmz) are the sites of protein synthesis. Each ribosome is composed of a large subunit and a small subunit. The ribosomal subunits consist of **ribosomal RNA (rRNA)** produced in the nucleolus of the nucleus and proteins produced in the cytoplasm. The ribosomal subunits are assembled separately in the nucleolus of the nucleus (figure 3.24). The ribosomal subunits then move through the nuclear pores into the cytoplasm, where the ribosomal subunits assemble with mRNA to form the functional ribosome during protein synthesis. Ribosomes can be found free in the cytoplasm or attached to an intracellular membrane complex called the endoplasmic reticulum. **Free ribosomes** primarily synthesize proteins used inside the cell, whereas ribosomes attached to the endoplasmic reticulum produce integral membrane proteins and proteins that are secreted from the cell.

FIGURE 3.23 Chromosome Structure

DNA is associated with globular histone proteins and other DNA-binding proteins. DNA molecules and bound proteins are called chromatin. During cell division, the chromatin condenses, so that individual structures, called chromosomes, become visible.

ASSESS YOUR PROGRESS

38. Define organelles. Are all organelles found in all cells?
39. Describe the structure of the nucleus and the nuclear envelope. What is the function of the nuclear pores?
40. Distinguish between chromatin and a chromosome. What molecule is found in chromatin? What are histones?
41. How can DNA control the structural and functional characteristics of the cell without leaving the nucleus? List the types of RNA.
42. What is the function of the nucleolus?
43. What molecules combine to form ribosomes? Where are ribosomal subunits formed? And assembled?
44. Compare the functions of free ribosomes and ribosomes attached to the endoplasmic reticulum.

Endoplasmic Reticulum

The outer membrane of the nuclear envelope is continuous with a series of membranes distributed throughout the cytoplasm of the cell (see figure 3.1), collectively referred to as the **endoplasmic reticulum** (en'dō-plas'mik re-tik'ū-lŭm; network inside the cytoplasm). The endoplasmic reticulum consists of broad, flattened, interconnecting sacs and tubules (figure 3.25). The interior spaces of those sacs and tubules are called **cisternae** (sis-ter'nē) and are isolated from the rest of the cytoplasm.

The **rough endoplasmic reticulum** is called “rough” because ribosomes are attached to it. The ribosomes of the rough endoplasmic reticulum are sites where proteins are produced and modified for use as integral membrane proteins and for secretion into the extracellular space. The amount and configuration of the endoplasmic reticulum within the cytoplasm depend on the type and function of the particular cell. Cells with abundant rough endoplasmic reticulum synthesize large amounts of protein, which are secreted for use outside the cell.

Smooth endoplasmic reticulum, which is endoplasmic reticulum without attached ribosomes, manufactures lipids, such as phospholipids, cholesterol, and steroid hormones, as well as carbohydrates. Enzymes required for lipid synthesis are associated with the membranes of the smooth endoplasmic reticulum, and cells that synthesize large amounts of lipids contain dense accumulations of smooth endoplasmic reticulum. Many phospholipids produced in the smooth endoplasmic reticulum help form vesicles within the cell and contribute to the plasma membrane. Smooth endoplasmic reticulum also participates in **detoxification**, the processes by which enzymes act on chemicals and drugs to change their structure and reduce their toxicity. The smooth endoplasmic reticulum of skeletal muscle stores the calcium ions that function in muscle contraction.

Golgi Apparatus

The **Golgi** (gōl'jē) **apparatus** is composed of flattened, membranous sacs, containing cisternae, stacked on each other like dinner plates (figure 3.26). The Golgi apparatus can be thought of as a packaging and distribution center because it modifies, packages, and distributes proteins and lipids manufactured by the rough and smooth endoplasmic reticula (figure 3.27). Proteins produced at the ribosomes attached to the rough endoplasmic reticulum move into the endoplasmic reticulum. These proteins are later packaged into **transport vesicles** that then move to the Golgi apparatus. These transport vesicles fuse with the Golgi apparatus membrane and release the proteins into the Golgi apparatus cisterna. The Golgi apparatus concentrates and, in some cases, chemically modifies the proteins by synthesizing and attaching carbohydrate molecules to the proteins to form glycoproteins or by attaching lipids to the proteins to form lipoproteins. The proteins are then packaged into vesicles that pinch off from the margins of the Golgi apparatus and are distributed to various locations. Some vesicles carry proteins to the plasma membrane, where the proteins are secreted from the cell by exocytosis; other vesicles contain proteins that become part of the

- 1 Ribosomal proteins, produced in the cytoplasm, are transported through nuclear pores into the nucleolus.
- 2 rRNA, most of which is produced in the nucleolus, is assembled with ribosomal proteins to form small and large ribosomal subunits.
- 3 The small and large ribosomal subunits leave the nucleolus and the nucleus through nuclear pores.
- 4 The small and large subunits, now in the cytoplasm, combine with each other and with mRNA during protein synthesis.

PROCESS FIGURE 3.24 Production of Ribosomes

 (b) Transmission electron micrograph of the Golgi apparatus. **APR**

47. Explain the functions of the smooth endoplasmic reticulum.
48. Relate the structure and function of the Golgi apparatus.
49. Name three ways in which proteins are distributed from the Golgi apparatus.

Secretory Vesicles

The membrane-bound **secretory vesicles** (see figure 3.26) that pinch off from the Golgi apparatus move to the surface of the cell, their membranes fuse with the plasma membrane, and the contents of the vesicles are released to the exterior by exocytosis. The membranes of the vesicles are then incorporated into the plasma membrane.

Secretory vesicles accumulate in some cells, but their contents frequently are not released to the exterior until the cell receives a signal. For example, secretory vesicles that contain the hormone insulin do not release it until the concentration of glucose in the blood increases and acts as a signal for the secretion of insulin from the cells.

Lysosomes

Lysosomes (lī'sō-sōmz) are membrane-bound vesicles that form at the Golgi apparatus (figure 3.27). They contain a variety of hydrolytic enzymes that function as intracellular digestive systems. Vesicles taken into the cell fuse with the lysosomes to form one vesicle and to expose the endocytized materials to hydrolytic enzymes (figure 3.28). Various enzymes within lysosomes digest nucleic acids, proteins, polysaccharides, and lipids. Certain white blood cells have large numbers of lysosomes that contain enzymes to digest phagocytized bacteria. Lysosomes also digest the organelles of the cell that are no longer functional, a process called **autophagy** (aw-tō-fā'jē; self-eating). In other cells, the lysosomes move to the plasma membrane, and the enzymes are secreted by exocytosis. For example, the normal process of bone remodeling involves the breakdown of bone tissue by specialized bone cells. Lysosomes produced by those cells release the enzymes responsible for that degradation into the extracellular fluid.

Peroxisomes

Peroxisomes (per-ok'si-sōmz) are membrane-bound vesicles that are smaller than lysosomes. Peroxisomes contain enzymes that break down fatty acids and amino acids. The breakdown of these molecules can produce hydrogen peroxide (H_2O_2) as a toxic by-product. Peroxisomes also contain the enzyme **catalase**, which breaks down hydrogen peroxide to water and oxygen thereby eliminating the toxic substance. Cells that are active in detoxification, such as liver and kidney cells, have many peroxisomes.

Proteasomes

Proteasomes (prō'tē-ă-sōmz) are large protein complexes containing enzymes that break down and recycle other proteins within the cell. Proteasomes are not surrounded by membranes but instead

Clinical IMPACT

Tay-Sachs Disease

Some diseases result from nonfunctional lysosomal enzymes. For example, **Tay-Sachs disease** is a rare genetic disorder caused by the inability of lysosomal enzymes to break down **gangliosides**, specialized membrane lipids of neurons. These lipids accumulate in the cells and damage them. The common symptoms of Tay-Sachs disease include paralysis, blindness, and death, usually before age 5. Damage to the central nervous system begins in the fetus, but other symptoms do not become apparent until several months after birth. The infant appears to develop normally but then begins to regress, losing motor function and vision, experiencing seizures, and exhibiting delayed mental development. As a result of the destruction of cells of the nervous system, the individual usually dies by the age of 4 or 5.

Unfortunately, there is no known cure or treatment for Tay-Sachs disease. However, genetic counseling of high-risk couples accompanied by prenatal screening has greatly reduced the incidence of the disease.

- 1 Some proteins are produced at ribosomes on the surface of the rough endoplasmic reticulum and are transferred into the cisterna of the endoplasmic reticulum as they are produced.
- 2 The proteins are surrounded by a vesicle that forms from the membrane of the endoplasmic reticulum.
- 3 This transport vesicle moves from the endoplasmic reticulum to the Golgi apparatus, fuses with its membrane, and releases the proteins into its cisterna.
- 4 The Golgi apparatus concentrates and, in some cases, modifies the proteins into glycoproteins or lipoproteins.
- 5 The proteins are packaged into vesicles that form from the membrane of the Golgi apparatus.
- 6 Some vesicles, such as lysosomes, contain enzymes that are used within the cell.
- 7 Secretory vesicles carry proteins to the plasma membrane, where the proteins are secreted from the cell by exocytosis.
- 8 Some vesicles contain proteins that become part of the plasma membrane.

PROCESS FIGURE 3.27 Function of the Golgi Apparatus

PROCESS FIGURE 3.28 Action of Lysosomes

are a collection of specific proteins forming barrel-like structures. The inner surfaces of the barrel have enzymatic regions that break down the proteins. Other proteins at the ends of the barrel regulate which proteins are taken in for breakdown and recycling.

Mitochondria

Mitochondria (mī-tō-kon'drē-ă) are the organelles that provide the majority of the energy for the cell. Consequently, they are often called the cell's power plants. Mitochondria are usually depicted as small, rod-shaped structures (figure 3.29). However, in living cells, mitochondria are very dynamic and constantly change shape and number as they split and fuse with each other. Mitochondria are the major sites for the production of ATP, which is the primary energy source for most energy-requiring chemical reactions within the cell. Each mitochondrion has an inner and an outer membrane, separated by an intermembrane space. The outer membrane has a smooth contour, but the inner membrane has numerous infoldings called **cristae** (kris'tē; sing. *crista*) that project like shelves into the interior of the mitochondrion. The material located inside the inner membrane is called the **matrix**.

Complex series of mitochondrial enzymes form the two major enzyme systems responsible for most ATP synthesis (see chapter 25). The enzymes of the citric acid (Krebs) cycle are in the matrix. The enzymes of the electron-transport chain are embedded within the inner membrane. Cells with a greater energy requirement have more mitochondria with more cristae than do cells with lower energy requirements. Within the cytoplasm of a cell, the mitochondria are more numerous in areas where ATP is used. For example, mitochondria are numerous in cells that perform active transport and are packed near the membrane where active transport occurs.

Increases in the number of mitochondria result from the division of preexisting mitochondria. When muscles enlarge as a result of

exercise, the number of mitochondria within the muscle cells increases to provide the additional ATP required for muscle contraction.

Mitochondria also contain DNA and ribosomes. The information for making some mitochondrial proteins is stored in mitochondrial DNA, and those proteins are synthesized on mitochondrial ribosomes. Though mitochondria have the materials for manufacturing proteins separate from the rest of the cell, researchers have found that the structure of most mitochondrial proteins is determined by nuclear DNA, and these proteins are synthesized on ribosomes within the cytoplasm and then transported into the mitochondria. Both mitochondrial DNA and mitochondrial ribosomes are very different from those within the cell's nucleus and cytoplasm, respectively. Mitochondrial DNA is a closed circle of about 16,500 base pairs (bp) coding for 37 genes, compared with the open strands of nuclear DNA, which is composed of 3 billion bp coding for about 20,000 genes. In addition, unlike nuclear DNA, mitochondrial DNA does not have associated histone proteins. Mitochondrial ribosomes are more similar in size and structure to bacterial ribosomes than to cytoplasmic ribosomes.

Predict 6

Describe the structural characteristics of cells that are highly specialized to do the following: (a) synthesize and secrete proteins, (b) actively transport substances into the cell, (c) synthesize lipids, and (d) phagocytize foreign substances.

Centrioles and Spindle Fibers

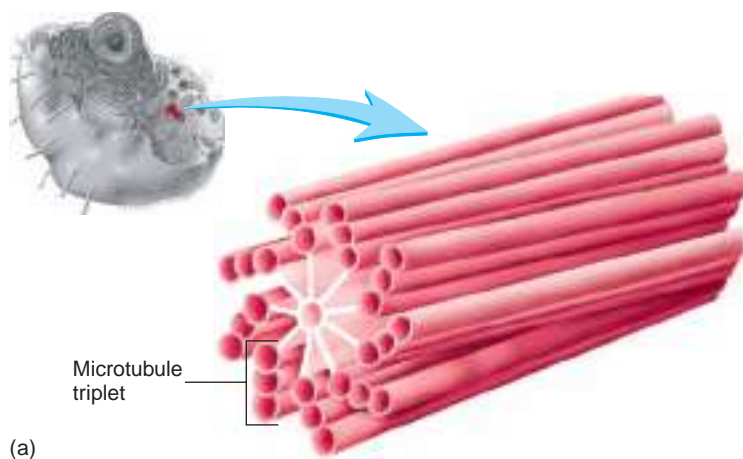

The **centrosome** (sen'trō-sōm), a specialized zone of cytoplasm close to the nucleus, is the center of microtubule formation in the cell. Within the centrosome are two **centrioles** (sen'trē-ōlz). Each centriole is a small, cylindrical organelle about 0.3–0.5 μm in length and 0.15 μm in diameter, and the two centrioles are normally oriented perpendicular to each other within the centrosome (see figure 3.1). The wall of the centriole is composed of nine evenly spaced, longitudinally oriented, parallel units, or triplets. Each unit consists of three parallel microtubules joined together (figure 3.30).

Microtubules appear to influence the distribution of actin and intermediate filaments. Through its control of microtubule formation, the centrosome is closely involved in determining cell shape and movement. The microtubules extending from the centrosomes are very dynamic—constantly growing and shrinking.

Before cell division, the two centrioles double in number; the centrosome divides into two; and one centrosome, containing two centrioles, moves to each end of the cell. Microtubules called **spindle fibers** extend out in all directions from the centrosome. These microtubules grow and shrink even more rapidly than those of non-dividing cells. If the extended end of a spindle fiber comes in contact with a chromosome, the spindle fiber attaches to the chromosome and stops growing or shrinking. Eventually, spindle fibers from each centrosome bind to all the chromosomes. During cell division, the spindle microtubules facilitate the movement of chromosomes toward the two centrosomes (see “Cell Division” in section 3.10).

Cilia and Flagella

Cilia (sil'ē-ă) are structures that project from the surface of cells and are capable of movement. They vary in number from one to

Mitochondrial Diseases

Mitochondria play a major role in the synthesis of ATP. Each mitochondrion contains a single DNA molecule with at least 37 genes, 13 of which code for proteins that are important for ATP synthesis. The other 24 genes are important for the expression of mitochondrial genes. Therefore, mutations, or changes, in mitochondrial genes can lead to disruptions in normal ATP synthesis, reducing the amount of ATP produced by the cells. Disorders that result from such mutations are collectively called **mitochondrial diseases**. The effects of these diseases are most obvious in tissues that require large amounts of ATP, particularly nervous and muscle tissues. As a consequence, the common symptoms of mitochondrial diseases are loss of neurological function and defects in muscular activity. For example, **Leber hereditary optic neuropathy** results in sudden vision loss due to optic nerve degeneration. Mutations associated with this disorder have been found in the genes that function in ATP synthesis, especially in the cells of the optic nerve. Because of their high energy demands, the cells of the optic nerve are damaged or die due to the lack of ATP.

In humans, mitochondria are passed only from the mother to her offspring because the mitochondria of sperm cells do not enter the oocyte during fertilization (see chapter 29). Therefore, mitochondrial diseases, involving the mitochondrial genes, show a pattern of maternal inheritance—that is, a mother afflicted with a mitochondrial disease passes it to all her offspring, but a father suffering from the same disorder passes it to none of his offspring.

thousands per cell. Cilia are cylindrical in shape, measuring about 10 μm in length and 0.2 μm in diameter. The shaft of each cilium is enclosed by the plasma membrane. Each cilium contains two centrally located microtubules and nine peripheral pairs of fused microtubules (the so-called 9 + 2 arrangement) that extend from the base to the tip of the cilium (figure 3.31). Movement of the cilium results when the microtubules move past each other, a process that requires energy from ATP. **Dynein arms**, proteins

FIGURE 3.30 Centriole

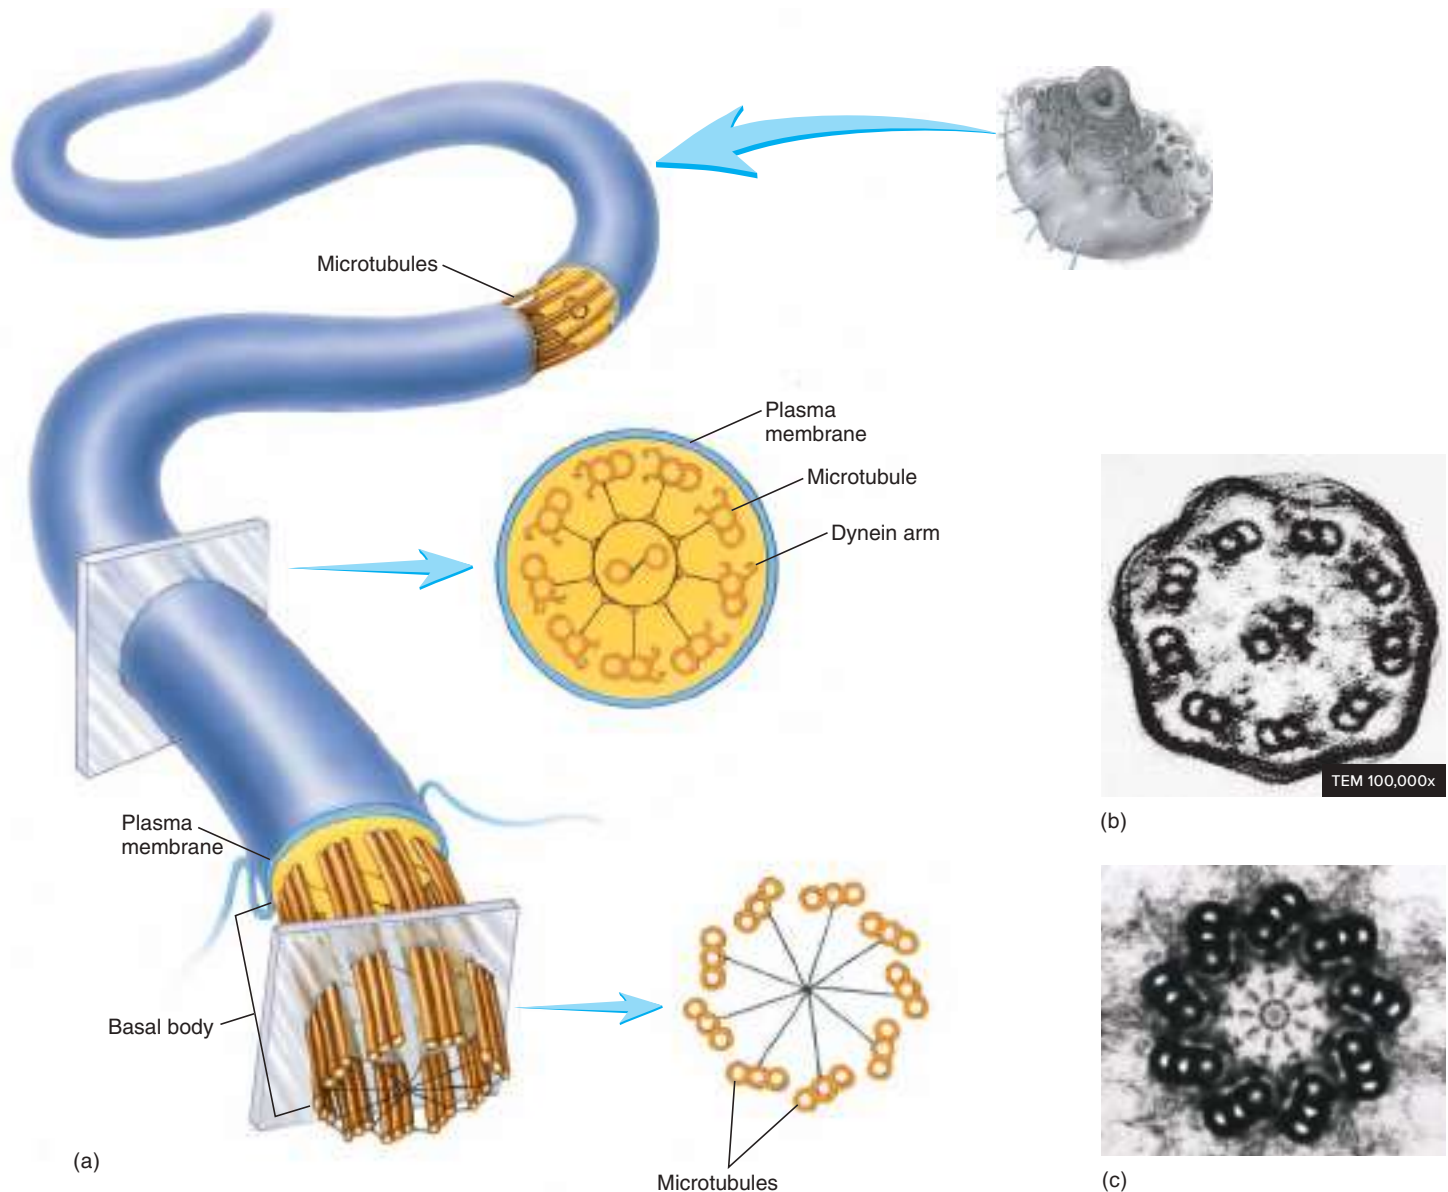

FIGURE 3.31 Structure of Cilia and Flagella

(a) The shaft of a cilium or flagellum has nine microtubule doublets around its periphery and two in the center. Dynein arms are proteins that connect one pair of microtubules to another pair. Dynein arm movement, which requires ATP, causes the microtubules to slide past each other, resulting in bending or movement of the cilium or flagellum. A basal body attaches the cilium or flagellum to the plasma membrane. (b) Transmission electron micrograph through a cilium. (c) Transmission electron micrograph through the basal body of a cilium.

connecting adjacent pairs of microtubules, push the microtubules past each other. A **basal body** (a modified centriole) is located in the cytoplasm at the base of the cilium.

Cilia are numerous on surface cells that line the respiratory tract and the female reproductive tract. In these regions, cilia move in a coordinated fashion, with a power stroke in one direction and a recovery stroke in the opposite direction (figure 3.32). Their motion moves materials over the surface of the cells. For example, cilia in the trachea move mucus containing trapped dust particles upward and away from the lungs, thus helping keep the lungs clear of debris.

Flagella (flă-jel'ă) have a structure similar to that of cilia, but they are longer (45 μm). Sperm cells are the only human cells that possess flagella, and usually only one flagellum exists per cell.

Furthermore, whereas cilia move small particles across the cell surface, flagella move the entire cell. For example, each sperm cell is propelled by a single flagellum. In contrast to cilia, which have a power stroke and a recovery stroke, flagella move in a wavelike fashion.

Microvilli

Microvilli (mī-krō-vil'ī; figure 3.33) are cylindrically shaped extensions of the plasma membrane about 0.5–1.0 μm in length and 90 nm in diameter. Normally, each cell has many microvilli. The presence of microvilli increases the cell surface area. A student looking at photographs may confuse microvilli with cilia, but

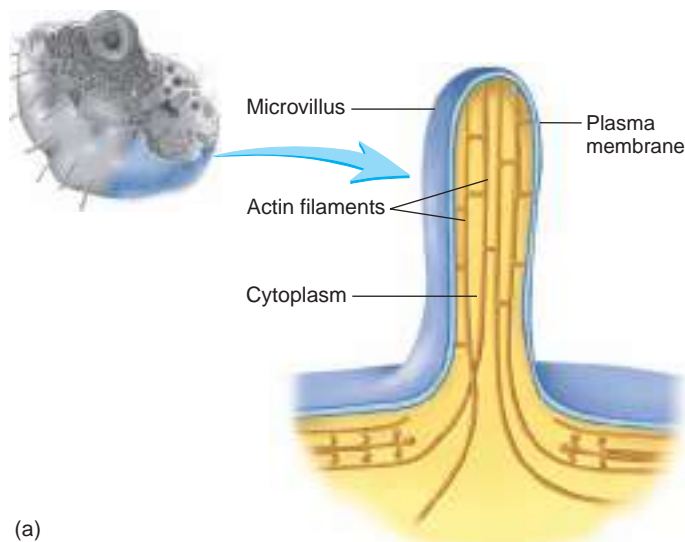

FIGURE 3.32 Ciliary Movement

(a)

(b)

FIGURE 3.33 Microvillus

(a) A microvillus is a tiny, tubular extension of the cell; it contains cytoplasm and some actin filaments (microfilaments). (b) Transmission electron micrograph of microvilli.

microvilli are only one-tenth to one-twentieth the size of cilia. Individual microvilli can usually be seen only with an electron microscope, whereas cilia can be seen with a light microscope. Microvilli do not move, and they are supported with actin filaments, not microtubules. Microvilli are found on the cells of the intestine, kidney, and other areas where absorption is an important function. In certain locations of the body, microvilli are highly modified to function as sensory receptors. For example, elongated microvilli in hair cells of the inner ear respond to sound.

ASSESS YOUR PROGRESS

56. What is the centrosome? Relate the structure of centrioles.
57. What are spindle fibers? Explain the relationship among centrosomes, spindle fibers, and chromosomes during cell division.
58. Contrast the structure and function of cilia with those of flagella.
59. Describe the structure and function of microvilli. How are microvilli different from cilia?

3.9 Genes and Gene Expression

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the two-step process that results in gene expression.
- B. Explain the roles of DNA, mRNA, tRNA, and rRNA in the production of a protein.
- C. Explain what the genetic code is and what it is coding for.
- D. Describe what occurs during posttranscriptional processing and posttranslational processing.
- E. Describe the regulation of gene expression.

Genes are the functional units of heredity. **Heredity** is the transmission of genetic traits from parent to offspring. Each gene is a segment of a DNA molecule that specifies the structure of an RNA molecule. This RNA can be functional on its own, or it can produce a protein. The production of RNA and/or proteins from the information stored in DNA is called **gene expression** (figure 3.34). Gene expression that produces proteins involves two steps: transcription and translation. This process can be illustrated with an analogy. Suppose a cook wants a cake recipe that is found only in a reference book in the library. Because the book cannot be checked out, the cook makes a copy, or **transcription**, of the recipe. Later, in the kitchen, the information contained in the copied recipe is used to make the cake. The changing of something from one form to another (from recipe to cake) is called **translation**. In this analogy, DNA is the reference book that contains many recipes (genes) for making different proteins. DNA, however, is too large a molecule to pass through the nuclear envelope to go to the cytoplasm (the kitchen), where the proteins are synthesized. Just as the reference book stays in the library, DNA remains in the nucleus. Therefore, through transcription, the cell makes a copy of the gene (the recipe) necessary to make

MICROBES In Your Body

Differences Between Prokaryotic and Eukaryotic Cells

Recall from chapter 1, *Microbes In Your Body*, “Getting to Know Your Bacteria,” that for every human cell in your body, there are 10 bacterial cells. But what are the major differences between those cells and human cells?

All living organisms can be grouped into two classes based on their cell structure: eukaryotes and prokaryotes. Human cells and some microbes in our bodies are eukaryotes. However, all bacteria cells are prokaryotes. It is this fundamental distinction that explains many facets of our biology.

Breaking down the term *prokaryotic* sheds light on the nature of this cell type: *pro* means pre, or before, and *karyon* means kernel, or nucleus—in other words, *before nuclei*. True to their name, prokaryotic cells do not have a formed, membrane-bound nucleus. Prokaryotes are also very ancient, appearing on earth at least 3 billion years ago.

Prokaryotic cells are ubiquitous—they are found in almost every location on earth and live many places other organisms cannot. Though we often associate bacteria with

diseases, most prokaryotes are harmless; it is a small minority that is pathogenic. Second, prokaryotes comprise a majority of the total mass of living organisms on earth, despite their small size. Most prokaryotic cells are much smaller than most eukaryotic cells, which are, in general, 10 times longer and 1000 times larger in volume than prokaryotic cells. Prokaryotic cells are usually single-celled organisms, although some can be found living in groups with other prokaryotic cells.

Although prokaryotic cells do not have a formed nucleus, their DNA is clustered together among other cellular materials in a region termed the nucleoid. Prokaryotic cells also lack membrane-bound organelles or internal membranes. Their DNA is located in a single chromosome, which is circular in shape. Generally, most prokaryotes have between 1000 and 4000 genes, compared with eukaryotes, which have more genes—approximately 20,000 in humans. However, despite what some humans might view as limitations (small cell size, fewer genes), prokaryotes are impressively varied in their biochemical capabilities.

Bacterial cells are fundamentally different from human cells in their structure and their biology. Bacteria have molecules and mechanisms that humans do not, which allow for pathogenic bacteria to be targeted by antibiotics without harm to human cells. On the other hand, the immense population of bacteria in and on our bodies, referred to as commensal bacteria, are critical to our health. Commensal bacteria provide humans with materials and processes our cells are incapable of performing. For example, *E. coli* in our intestine produce a significant amount of required vitamin K. Throughout the rest of this book, we will highlight the importance of bacteria to homeostasis.

Predict 7

Viruses are also a type of microbe, yet they are not cells. Viruses consist of a molecule of nucleic acid (RNA or DNA) surrounded by protein. They must enter other organisms' cells and use their molecules and machinery to replicate themselves. Why aren't antibiotics prescribed for viral infections?

a particular protein (the cake). The copy, which is called mRNA, travels from the nucleus to ribosomes (the kitchen) in the cytoplasm, where the information in the copy is used to construct a protein (i.e., translation). Of course, to turn a recipe into a cake, ingredients are needed. The ingredients necessary to synthesize a protein are amino acids. Specialized transport molecules, called **transfer RNA (tRNA)**, carry the amino acids to the ribosomes (figure 3.34).

In summary, gene expression involves transcription (making a copy of a small part of the stored information in DNA) and translation (converting that copied information into a protein). The details of transcription and translation are considered next.

Transcription

Transcription is the synthesis of mRNA, tRNA, and rRNA molecules based on the nucleotide sequence in DNA (figure 3.35). Transcription occurs when a section of a DNA molecule unwinds and its complementary strands separate. One of the DNA strands serves as the template strand for the process of transcription. Nucleotides that form RNA align with the DNA nucleotides in the template strand by complementary base pairing. For example, suppose the DNA base sequence TGCA is to be transcribed. An adenine aligns with the thymine of DNA, cytosine aligns with guanine, and guanine aligns with cytosine. Instead of thymine, uracil of RNA (see figure 2.26) aligns with adenine of DNA. Thus, the sequence of bases that aligns with the TGCA sequence of DNA is

ACGU. This pairing relationship between nucleotides ensures that the information in DNA is transcribed correctly into RNA.

Predict 8

Given the following sequence of nucleotides of a template DNA strand, predict the sequence of mRNA that is transcribed from it. What is the nucleotide sequence of the complementary strand of the DNA molecule? How does it differ from the nucleotide sequence of RNA?

DNA nucleotide sequence: CGTACGCCGAGACGTCAAC

RNA polymerase is an enzyme that synthesizes the complementary RNA molecule from DNA. RNA polymerase must attach to the DNA molecule near the beginning of the gene. A DNA nucleotide sequence called a **promoter** signals the beginning of the gene and is the site for initial RNA polymerase binding; however, RNA polymerase does not attach to the promoter by itself. It must first associate with other proteins called **transcription factors** in order to interact with the DNA. The attachment of RNA polymerase to the promoter causes a portion of the DNA molecule to unwind, exposing the DNA nucleotide sequence for that region of the template strand. Complementary RNA nucleotides then align with the DNA nucleotides of the template strand. The RNA nucleotides are combined by dehydration reactions, catalyzed by RNA polymerase, to form RNA. Only a small portion of the DNA molecule unwinds at any one time. As complementary nucleotides are added to the

FUNDAMENTAL Figure

- 1 DNA contains the information necessary to produce proteins.
- 2 Transcription of a region of one DNA strand results in mRNA, which is a complementary copy of the information in the DNA strand needed to make a protein.
- 3 The mRNA leaves the nucleus and goes to a ribosome.
- 4 Amino acids, the building blocks of proteins, are carried to the ribosome by tRNAs.
- 5 In the process of translation, the information contained in mRNA is used to determine the number, kinds, and arrangement of amino acids in the polypeptide chain.

PROCESS FIGURE 3.34 Overview of Gene Expression

RNA, RNA polymerase moves along the DNA, unwinding the next portion, while the previously unwound section of DNA strands winds back together. The termination of transcription in eukaryotic cells is not completely understood. When the RNA polymerase encounters the end of the gene sequence, interactions with other proteins cause the release of the newly formed RNA. The type of RNA that will make proteins is called messenger RNA (mRNA).

The region of a DNA molecule between the promoter and termination of transcription is a gene. The structure of a gene is more complex than just the nucleotides that code for a protein; some regions that are transcribed as part of the mRNA do not code for parts of a protein. Regions of the mRNA that do code for proteins are called **exons**, whereas the regions that do not code for a protein are called **introns**. An mRNA that contains introns is called a **pre-mRNA** (figure 3.36). The introns are removed from the pre-mRNA, and the exons are spliced together. After intron removal and splicing, the functional mRNA will then consist only of exons.

Before a pre-mRNA leaves the nucleus, it undergoes several modifications called **posttranscriptional processing**, which produces the functional mRNA that is used in translation to produce a protein (figure 3.36). A **7-methylguanosine cap** is added to one end of mRNA, and a series of adenine nucleotides, called a **poly-A tail**, is added to the other end. These modifications to the ends of the mRNA ensure that mRNA travels from the nucleus to the cytoplasm and interacts with ribosomes during translation.

In a process called **alternative splicing**, various combinations of exons are incorporated into mRNA. Which exons—and how many—are used to make mRNA can vary between cells of different tissues, resulting in different mRNAs transcribed from the same gene. Alternative splicing allows a single gene to produce more than one specific protein; however, the various proteins usually have similar functions in different tissues. In humans, nearly all mRNAs undergo alternative RNA splicing.

- 1 The strands of the DNA molecule separate from each other. One DNA strand serves as a template for mRNA synthesis.
- 2 Nucleotides that will form mRNA pair with DNA nucleotides according to the base-pair combinations shown in the key at the top of the figure. Thus, the sequence of nucleotides in the template DNA strand (*purple*) determines the sequence of nucleotides in mRNA (*gray*). RNA polymerase (the enzyme is not shown) joins the nucleotides of mRNA together.
- 3 As nucleotides are added, an mRNA molecule is formed.

PROCESS FIGURE 3.35 Formation of mRNA by Transcription of DNA

Genetic Code

The **genetic code** is the information contained in mRNA and it relates the nucleotide sequence of mRNA to the amino acid sequence of a protein. The mRNA is organized into **codons**, three nucleotide sequences, each of which specifies an amino acid during translation. For example, the codon GAU specifies the amino acid aspartic acid, and the codon CGA specifies arginine. Although there are only 20 different amino acids commonly found in proteins, 64 possible

codons exist. Therefore, an amino acid can have more than 1 codon. The codons for arginine include CGA, CGG, CGU, and CGC. Furthermore, some codons act as signals during translation. AUG, which specifies methionine, also acts as a **start codon**, which signals the beginning of translation. UAA, UGA, and UAG act as **stop codons**, which signal the end of translation. Unlike the start codon, stop codons do not specify amino acids. If you think of the mRNA as a sentence describing the structure of a protein, the start codon is the capital letter at the beginning of the sentence and the stop codon is the period at the end. Therefore, the protein-coding region of an mRNA begins at the start codon and ends at a stop codon.

Translation

Translation is the synthesis of a protein at the ribosome based on the sequence of the codons of mRNA (figure 3.37). In addition to mRNA, translation requires ribosomes and tRNA. Ribosomes consist of **ribosomal RNA (rRNA)** and proteins. Like mRNA, tRNA and rRNA are produced in the nucleus by transcription.

The function of tRNA is to match a specific amino acid to a specific codon of mRNA. There are multiple types of tRNA, each specific to one amino acid. The amino acid binds to one end of its specific tRNA molecule. Another part of the tRNA, called the **anticodon**, consists of three nucleotides and is complementary to a particular codon of mRNA. On the basis of the pairing relationships between nucleotides, the anticodon can combine only with its matched codon. For example, the tRNA that has the anticodon CUA combines with the codon GAU of mRNA. The codon GAU codes for aspartic acid, so the matching tRNA will have aspartic acid attached to it.

Ribosomes align the codons of the mRNA with the anticodons of tRNA and then enzymatically join the amino acids of adjacent tRNA molecules. The mRNA moves through the ribosome one codon at a time. With each move, a new tRNA enters the ribosome and the amino acid is linked to the growing chain, forming a polypeptide. The step-by-step process of translation at the ribosome is described in detail in figure 3.37.

After a ribosome uses the initial part of mRNA, another ribosome can attach to the mRNA and begin to make a protein. The resulting cluster of ribosomes attached to the same mRNA is called a **polyribosome** (figure 3.37). Each ribosome in a polyribosome produces an identical protein, and polyribosomes are an efficient way to produce many copies of the same protein using a single mRNA molecule.

Many proteins are longer when they are first made than in their final, functional state. These proteins are called **proproteins**, and the extra piece of the molecule is cleaved off by enzymes to make the proprotein into a functional protein. Many proteins are enzymes, and the proproteins of those enzymes are called **proenzymes**. If many proenzymes were made within cells

PROCESS FIGURE 3.36 Posttranscriptional Change in mRNA

as functional enzymes, they could digest the cell that made them. Instead, they are made as proenzymes and are not converted to active enzymes until they reach a protected region of the body, such as inside the small intestine, where they are functional. Many proteins are modified through **posttranslational processing** before they are functional in the cell. An example of posttranslational processing is the addition of side chains, such as polysaccharides, following translation. Another example is the assembly of complex proteins, where two or more amino acid chains are joined after each chain is produced on separate ribosomes.

Regulation of Gene Expression

Most of the cells in the body have the same DNA. However, the transcription of mRNA in cells is regulated so that only the necessary genes are transcribed. The proteins associated with DNA in the nucleus play a role in regulating transcription. As cells differentiate and acquire specialized functions during development, part of the DNA is no longer transcribed, whereas other segments of DNA become more active. For example, the DNA coding for hemoglobin is not expressed in most cells, and little, if any, hemoglobin is synthesized. But in developing red blood cells, the DNA coding for hemoglobin is transcribed, and hemoglobin synthesis occurs rapidly.

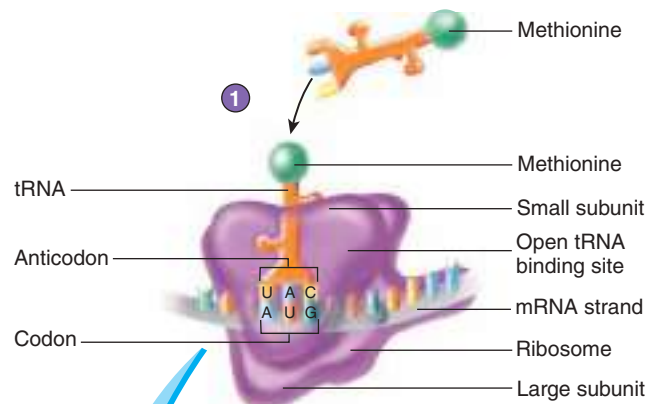

Gene expression in a single cell is not normally constant but fluctuates in response to changes in signals from within and outside the cell. Regulatory molecules that interact with nuclear proteins can either increase or decrease the transcription rate of

specific DNA segments. For example, triiodothyronine (T_3), a hormone released by cells of the thyroid gland, enters cells, such as skeletal muscle cells; interacts with specific nuclear proteins; and increases transcription of mRNAs from specific genes. Consequently, the production of certain proteins increases. As a further result, an increase in the number of mitochondria and an increase in metabolism occur in these cells.

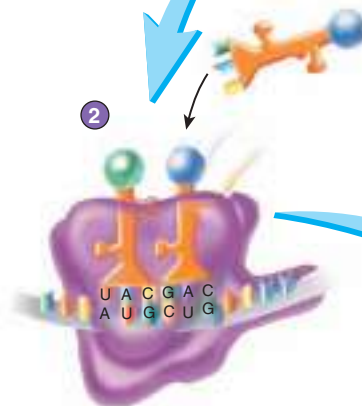

ASSESS YOUR PROGRESS

60. What is gene expression, and what two processes result in gene expression?
61. What type of molecule results from transcription? Where do the events of transcription occur?
62. Place the events of transcription in sequence.
63. What are exons and introns? How do they relate to pre-mRNA and posttranscriptional processing?
64. What is the role of alternative splicing in variation?
65. What is the genetic code?
66. What are start and stop codons? How is a start codon different from a promoter?
67. Place the steps of translation in sequence. In what molecules are codons and anticodons found? What is a polyribosome?
68. What occurs in posttranslational processing? How does it relate to proproteins and proenzymes?
69. State two ways the cell controls what part of DNA is transcribed.

- 1 To start protein synthesis, a ribosome binds to mRNA. The ribosome also has two binding sites for tRNA, one of which is occupied by a tRNA with its amino acid. Note that the first codon to associate with a tRNA is AUG, the start codon, which codes for methionine. The codon of mRNA and the anticodon of tRNA are aligned and joined. The other tRNA binding site is open.

- 2 By occupying the open tRNA binding site, the next tRNA is properly aligned with mRNA and with the other tRNA.

- 3 An enzyme within the ribosome catalyzes a synthesis reaction to form a peptide bond between the amino acids. Note that the amino acids are now associated with only one of the tRNAs.

- 4 The ribosome shifts position by three nucleotides. The tRNA without the amino acid is released from the ribosome, and the tRNA with the amino acids takes its position. A tRNA binding site is left open by the shift. Additional amino acids can be added by repeating steps 2 through 4.

- 5 Eventually, a stop codon in the mRNA, such as UAA, ends the process of translation. At this point, the mRNA and polypeptide chain are released from the ribosome.

- 6 Multiple ribosomes attach to a single mRNA to form a polyribosome. As the ribosomes move down the mRNA, proteins attached to the ribosomes lengthen and eventually detach from the mRNA.

PROCESS FIGURE 3.37 Translation of mRNA to Produce a Protein 

3.10 Cell Life Cycle

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the stages of the cell life cycle.
- Give the details of DNA replication.
- Explain what occurs during mitosis and cytokinesis.
- Define *apoptosis*.

The **cell life cycle** includes the changes a cell undergoes from the time it is formed until it divides to produce two new cells. The life cycle of a cell has two stages: interphase and cell division (figure 3.38). Cell division includes mitosis, the division of the nucleus, and cytokinesis, the division of the cytoplasm.

Interphase

Interphase is the phase between cell divisions; nearly all of the life cycle of a typical cell is spent in interphase. During this time,

FIGURE 3.38 Cell Cycle

The cell cycle is divided into interphase (blue) and cell division (mitosis and cytokinesis). Interphase is divided into G₁, S, and G₂ subphases. During G₁, the cell carries out routine metabolic activities. During the S phase, DNA is replicated. During the G₂ phase, the cell prepares for division. (a) Following mitosis, two cells are formed by the process of cytokinesis. Each new cell begins a new cell cycle. (b) Many cells exit the cell cycle and enter the G₀ phase, where they remain until stimulated to divide, at which point they reenter the cell cycle.

the cell carries out the metabolic activities necessary for life and performs its specialized functions—for example, secreting digestive enzymes. In addition, the cell prepares to divide. This preparation includes both an increase in cell size as many cell components double in quantity and a doubling of the DNA content during DNA replication. The centrioles within the centrosome are also duplicated. Consequently, when the cell divides, each new cell receives the organelles and DNA necessary for continued functioning.

Interphase can be divided into three subphases, called G₁, S, and G₂. During G₁ (the first *gap* phase), the cell carries out routine metabolic activities. During the S phase (the *synthesis* phase), the DNA is replicated (new DNA is synthesized). During the G₂ phase (the second *gap* phase), the cell prepares for cell division. Many body cells do not divide for days, months, or even years. These “resting” cells do not follow the normal pattern of the cell cycle but instead enter what is called the G₀ phase, in which they remain unless stimulated to divide.

DNA Replication

DNA replication is the process in which the two strands of a DNA molecule each serve as the template for making complementary new strands of nucleotides. The two old strands combine with their respective complementary new strand, thereby producing two molecules of DNA (figure 3.39). During interphase, DNA and its associated proteins appear as dispersed chromatin threads within the nucleus. When DNA replication begins, the two strands of each DNA molecule separate from each other for some distance (figure 3.39). Each strand then functions as a template, or pattern, for the production of a new, complementary strand of DNA. Each new strand forms as complementary nucleotides pair with the nucleotides of each template strand of the original DNA molecule. The production of the new nucleotide strands is catalyzed by **DNA polymerase**, an enzyme that adds new nucleotides to the 3' end of the growing strands. Because of the antiparallel orientation of the two DNA strands, the strands form differently. One strand, called the **leading strand**, forms as a continuous strand, whereas the other strand, called the **lagging strand**, forms in short segments called *Okazaki fragments*. The Okazaki fragments are then spliced by **DNA ligase**. DNA replication results in two identical DNA molecules. Each of the two new DNA molecules has one strand of nucleotides derived from the original DNA molecule and one newly synthesized strand.

Cell Division

Cell division produces the new cells necessary for growth and tissue repair. A parent cell divides to form two daughter cells, each having the same amount and type of DNA as the parent cell. The daughter cells also tend to have the same structure and perform the same functions as the parent cell. However, during development and cell differentiation, the functions of daughter cells may differ from each other and from that of the parent cell.

Cell division involves two major events: division of the chromosomes into two new nuclei and division of the cytoplasm to form two new cells, each of which contains one of the newly formed nuclei. The nuclear events are called mitosis, and the cytoplasmic division is called cytokinesis.

- 1 The strands of the DNA molecule separate from each other.
- 2 Each old strand (dark purple) functions as a template on which a new, complementary strand (light purple) is formed. The base-pairing relationship between nucleotides determines the sequence of nucleotides in the newly formed strands.
- 3 Two identical DNA molecules are produced.

PROCESS FIGURE 3.39 Replication of DNA

Replication during the S phase of interphase produces two identical molecules of DNA. **AP®**

Mitosis

Mitosis (mī-to'is) is the division of a cell's nucleus into two new nuclei, each containing the same amount and type of DNA as the original nucleus. During mitosis, the chromatin becomes very densely coiled to form compact chromosomes called **mitotic chromosomes**. Mitotic chromosomes are discrete bodies that can be stained and easily seen with a light microscope. Recall that the DNA has been replicated during interphase of the cell cycle. As a result, each mitotic chromosome consists of two copies of the original chromosome. Each copy is called a **chromatid** (krō'ma-tid). The chromatids are attached at the **centromere** (sen'trō-mēr) (figure 3.40; see figure 3.23). The **kinetochore** (ki-nē'tō-kōr, ki-net'ō-kōr) is a protein structure that binds the centromere and provides a point of

- 1 The DNA of a chromosome is dispersed as chromatin.
- 2 The DNA molecule unwinds, and each strand of the molecule is replicated.
- 3 During mitosis, the chromatin from each replicated DNA strand condenses to form a chromatid. The chromatids are joined at the centromere to form a single mitotic chromosome.
- 4 The chromatids separate to form two new, identical individual chromosomes. The chromosomes will unwind to form chromatin in the nuclei of the two daughter cells.

PROCESS FIGURE 3.40 Replication of a Chromosome

attachment for microtubules that will separate and move the chromatids during mitosis. As two daughter cells form, a nucleus is re-formed around the chromatids. After the chromatids have separated, each is considered a chromosome. Each daughter cell receives

a copy of the chromosomes. Thus, the daughter cells receive the same complement of chromosomes and are genetically identical.

Mitosis is divided into four phases: prophase, metaphase, anaphase, and telophase (tel'ō-fāz):

- During **prophase** (figure 3.41, *step 2*), the chromatin condenses to form mitotic chromosomes. The chromosomes are visible with a light microscope, and it is evident that each has replicated. Also, the centrioles in the cytoplasm divide and migrate to each pole of the cell. Microtubules called spindle fibers extend from the centrioles to the centromeres of the chromosomes. In late prophase, the nucleolus and nuclear envelope disappear.
- In **metaphase** (figure 3.41, *step 3*), the chromosomes align near the center of the cell.
- At the beginning of **anaphase** (figure 3.41, *step 4*), the chromatids separate. At this point, one of the two identical sets of chromosomes is moved by the spindle fibers toward the centrioles at each of the poles of the cell. At the end of anaphase, each set of chromosomes has reached an opposite pole of the cell, and the cytoplasm begins to divide.
- During **telophase** (figure 3.41, *step 5*), nuclear envelopes form around each set of chromosomes to form two separate nuclei. The chromosomes begin to uncoil and resemble the genetic material characteristic of interphase.

Cytokinesis

Cytokinesis (sī'tō-ki-nē'sis) is the division of the cell's cytoplasm to produce two new cells. Cytokinesis begins in anaphase and continues through telophase (figure 3.41). The first sign of cytokinesis is the formation of a **cleavage furrow**, an indentation of the plasma membrane that forms midway between the centrioles. A contractile ring composed primarily of actin filaments pulls the plasma membrane inward, dividing the cell into halves. Cytokinesis is complete when the membranes of the halves separate at the cleavage furrow to form two separate cells.

Apoptosis

Apoptosis (ăp'op-tō'sis), or programmed cell death, is a normal process by which cell number within various tissues is adjusted and controlled. In the developing fetus, apoptosis removes extra tissue, such as cells between the developing fingers and toes. In some adult tissues, apoptosis eliminates excess cells to maintain a constant number of cells within the tissue. Damaged or potentially dangerous cells, virus-infected cells, and potential cancer cells are also eliminated by apoptosis induced by immune cells.

Apoptosis is regulated by specific genes. The proteins coded for by those genes initiate events within the cell that ultimately lead to the cell's death. As apoptosis begins, the chromatin within the nucleus condenses and fragments. This is followed by fragmentation of the nucleus and finally by death and fragmentation of the cell. Specialized cells called macrophages phagocytize the cell fragments.

71. Describe the cell's activities during the G_1 , S , and G_2 phases of interphase.
72. Describe the process of DNA replication. What are the functions of DNA polymerase and DNA ligase?
73. What are the two major events of cell division? What happens in each?
74. Differentiate among chromatin, chromatids, and chromosomes.
75. List the events that occur during prophase, metaphase, anaphase, and telophase of mitosis.
76. What is the end result of mitosis and cytokinesis?
77. What is apoptosis? How is it beneficial to the body?

3.11 Cellular Aspects of Aging

LEARNING OUTCOME

After reading this section, you should be able to

A. List the major hypotheses of aging.

We are all familiar with the outward signs of aging, such as wrinkled skin, gray hair, and reduced vision. A number of cellular structures or events appear to be involved in causing these effects. The major hypotheses that attempt to explain how aging occurs concentrate on molecules within the cell, such as lipids, proteins, and nucleic acids. It is estimated that at least 35% of the factors affecting aging are genetic.

1. **Cellular clock.** One hypothesis of aging suggests the existence of a cellular clock that, after a certain passage of time or a certain number of cell divisions, results in the death of a given cell line.
2. **Death genes.** Another hypothesis suggests that there are “death genes,” which turn on late in life, or sometimes prematurely, causing cells to deteriorate and die.
3. **DNA damage.** Other hypotheses suggest that, through time, DNA is damaged, resulting in cell degeneration and death.
4. **Free radicals.** DNA is also susceptible to direct damage, resulting in mutations that may result in cellular dysfunction and, ultimately, cell death. One of the major sources of DNA damage is apparently **free radicals**, which are atoms or molecules with an unpaired electron.
5. **Mitochondrial damage.** Mitochondrial DNA may be more sensitive to free-radical damage than is nuclear DNA. Mitochondrial DNA damage may result in loss of proteins critical to mitochondrial function. Because the mitochondria are the primary source of ATP, loss of mitochondrial function could lead to the loss of energy critical to cell function and, ultimately, to cell death. One proposal suggests that reduced caloric intake may reduce free-radical damage to mitochondria.

ASSESS YOUR PROGRESS

70. What are the two stages of the cell life cycle? Which stage is the longest?

ASSESS YOUR PROGRESS

78. List and describe the five hypotheses that explain the process of aging.

FUNDAMENTAL Figure

1 **Interphase** is the time between cell divisions. DNA is present as thin threads of chromatin in the nucleus. DNA replication occurs during the S phase of interphase. Organelles, other than the nucleus, and centrioles duplicate during interphase.

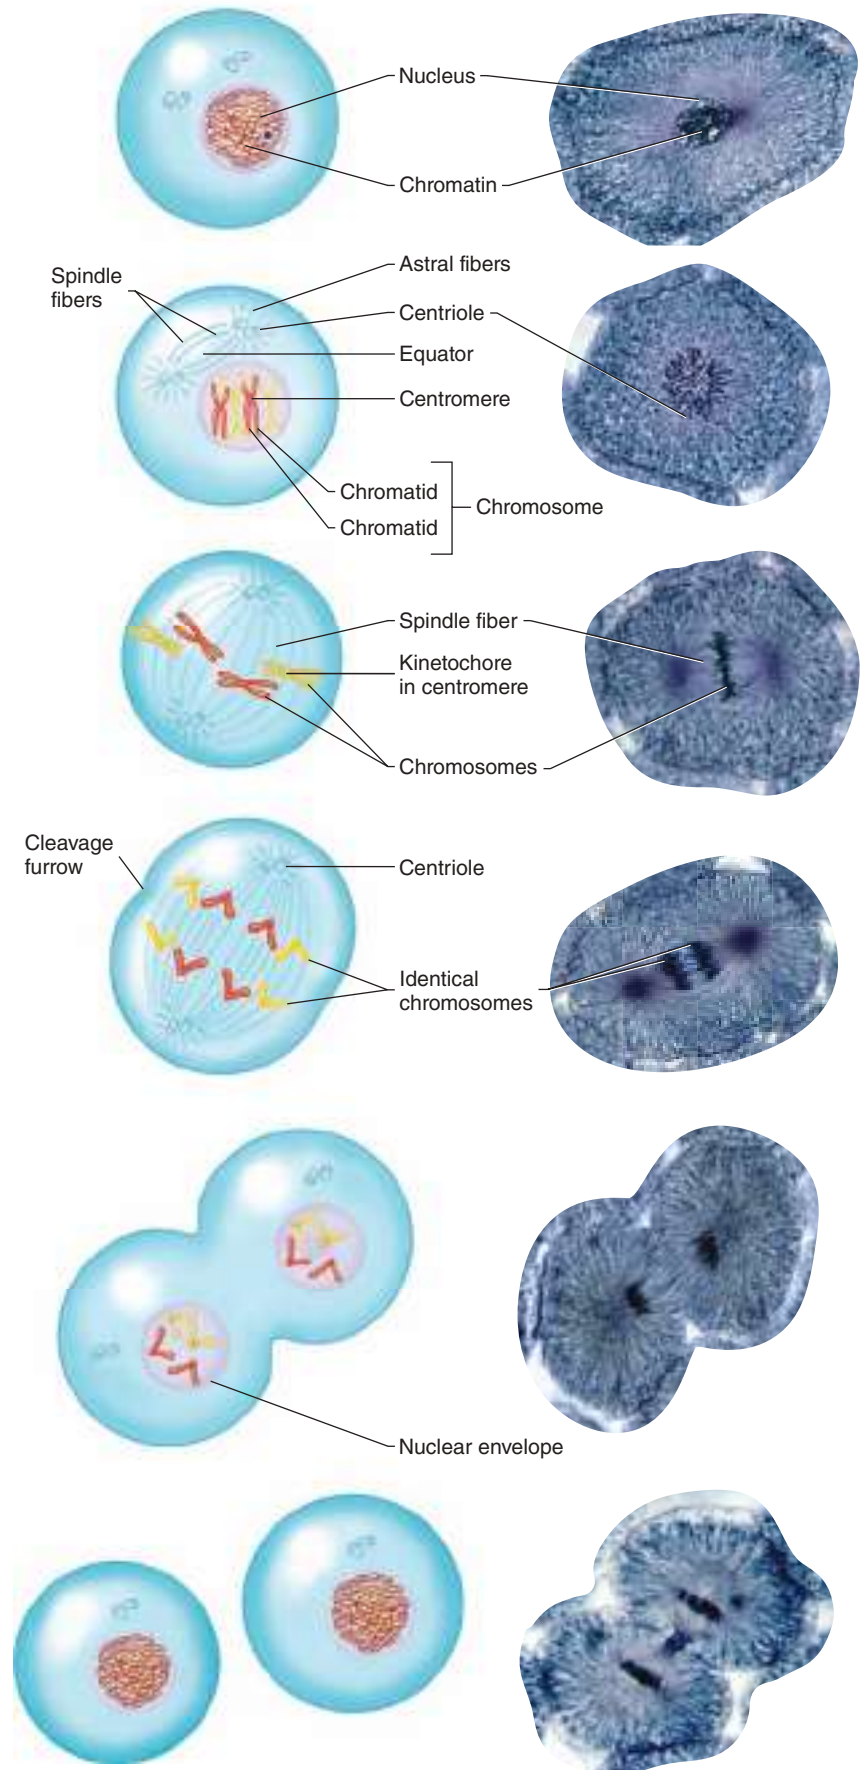

2 In **prophase**, the chromatin condenses into chromosomes. Each chromosome consists of two chromatids joined at the centromere. The centrioles move to the opposite ends of the cell, and the nucleolus and the nuclear envelope disappear. Microtubules form near the centrioles and project in all directions. Some of the microtubules end blindly and are called astral fibers. Others, known as spindle fibers, project toward an invisible line called the equator and overlap with fibers from opposite centrioles.

3 In **metaphase**, the chromosomes align in the center of the cell in association with the spindle fibers. Some spindle fibers are attached to kinetochores in the centromere of each chromosome.

4 In **anaphase**, the chromatids separate, and each chromatid is then referred to as a chromosome. Thus, when the centromeres divide, the chromosome number is double, and there are two identical sets of chromosomes. The chromosomes, assisted by the spindle fibers, move toward the centrioles at each end of the cell. Separation of the chromatids signals the beginning of anaphase, and by the time anaphase has ended, the chromosomes have reached the poles of the cell. Cytokinesis begins during anaphase as a cleavage furrow forms around the cell.

5 In **telophase**, migration of each set of chromosomes is complete. The chromosomes unravel to become less distinct chromatin threads. The nuclear envelope forms from the endoplasmic reticulum. The nucleoli form, and cytokinesis continues to produce two cells.

6 Mitosis is complete, and a new interphase begins. The chromosomes have unraveled to become chromatin. Cell division has produced two daughter cells, each with DNA that is identical to the DNA of the parent cell.

Cancer (kan'ser) refers to a malignant, spreading tumor. A tumor (too'mör) is a growth of neoplastic tissue. The term **neoplasm** (nē'ō-plazm; new growth) refers to abnormal tissue growth from rapid cell proliferation that continues after normal growth would have stopped. **Oncology** (ong-kol'ō-jē) is the study of tumors and the problems they cause. A neoplasm can be either **benign** (bē-nīn'; L. kind), unlikely to spread or to become worse, or **malignant** (ma-lig'nānt; with malice or intent to cause harm), able to spread and become worse. Although benign tumors are usually less dangerous than malignant tumors, they can cause problems if they compress surrounding tissues and impair their functions.

Cells of malignant neoplasms, or cancer cells, differ from cells of normal tissues in two fundamental ways: (1) Cancer cells have unregulated growth and altered morphology. They tend to be more spherical than normal cells. They appear more embryonic, or less mature, than the normal tissue from which they arise. For example, a skin cancer cell is more spherical and softer than the stratified squamous epithelial cells of the skin. (2) Cancer cells are invasive. They have the ability to squeeze into spaces and enter surrounding tissues. They secrete enzymes that cut paths through healthy tissue. Cancer cells can dislodge; enter blood vessels, lymphatic vessels, or body cavities; and travel to distant sites, where they invade tissues. The process by which cancer spreads to distant sites is called **metastasis** (me-tas'ta-sis).

Most cancers are caused by mutations of genes within somatic cells. It is estimated that less than 10% of cancers are inherited. Cancer develops in somatic cells because

of mutations that occur during cell division. When DNA is replicated prior to cell division, a small number of replication errors occur. A DNA sequence with replication errors in it is a mutation. Other factors that cause mutations by damaging or altering DNA include radiation, certain chemicals and toxins, and some viruses. Because mutations are most likely to occur during DNA replication, cancer usually develops in tissues that are undergoing frequent cell divisions, such as epithelial cells (see chapter 4). Cancer requires multiple mutations that accumulate over many cell generations. This is one reason that cancer becomes more common in older people.

Two major mechanisms help prevent the development of cancer: (1) DNA repair enzymes detect and correct errors that occur during replication. The likelihood that cancer will develop is increased if the genes controlling DNA repair enzymes undergo mutations and become defective, so that mutated genes persist in cells. (2) A self-destruction mechanism called apoptosis destroys cells with abnormal DNA. Apoptosis is a normal process involved in the self-destruction of cells that have a limited life span, but it can also cause self-destruction in cells with damaged DNA. Thus, apoptosis can cause mutated cells to self-destruct and thereby remove cells with mutations before cancer develops. Mutation of the genes responsible for apoptosis can also result in the persistence of cells with mutations, and these cells can continue to divide.

Some genes promote cell division, whereas others suppress it. Genes that promote cell division are called **proto-oncogenes**. Mutations in proto-oncogenes can give rise to

abnormal regulatory genes, called **oncogenes** (ong'ko-jēnz), which increase the rate of cell division. Oncogenes often code for proteins that control cell division. **Tumor suppressor genes** are normal genes that slow or stop cell division. Mutations that delete or inactivate tumor suppressor genes can also increase the rate of cell division by taking off the brakes, so to speak, of the processes that promote cell division. Many types of oncogenes and altered tumor suppressor genes have been identified in human cancer cells.

Additional mutations cause the structure and functions of the cancer cells to differ from those of normal cells. For example, these mutations increase the ability of cancer cells to invade and destroy surrounding tissues and to metastasize. The continued accumulation of mutations in cancer cells is also responsible for changes in the characteristics of the cancer cells over time. These changes can cause the cancer cells in a tumor to become less sensitive to treatments designed to kill them, such as chemotherapeutic drugs.

Cancer therapy concentrates primarily on confining and then killing the malignant cells. This goal is currently accomplished by killing the tissue with x-rays or lasers, by removing the tumor surgically, or by treating the patient with drugs that kill rapidly dividing cells. The major problem with current therapy is that many cancers cannot be completely eliminated. Also, these treatments often kill normal cells in rapidly growing tissues, such as bone marrow, where new blood cells are produced, and the lining of the intestinal tract. Loss of these tissues can result in anemia, caused by the lack of red blood cells, and nausea, caused by the loss of the intestinal lining.

Answer

Learn to Predict ◀ From page 58

Consider first the important points made in the question itself. First, Carlos suffers from a genetic disease (diabetes insipidus) and, second, this disease results in excessive water loss at the kidneys. In this chapter, we learned that genes determine the structure of cellular proteins. But the question is, what type of protein? There are two possibilities. We also learned that cellular proteins have many functions, including membrane receptors and transport proteins. Mutations in the gene for either type can lead to disruption in water homeostasis. ADH is a hormone, or chemical signal, that regulates water loss from the kidneys. A

mutation in the membrane receptor gene specific for ADH can, therefore, disrupt ADH regulation, since the kidney cells cannot respond to ADH. On the other hand, aquaporins are membrane proteins that regulate osmosis or diffusion of water across the membrane. A mutation in an aquaporin gene can also lead to the disruption of water homeostasis.

Answers to the rest of this chapter's Predict questions are in appendix G.

Summary

3.1 Functions of the Cell (p. 59)

1. The plasma membrane forms the outer boundary of the cell.
2. The nucleus directs the cell's activities.
3. The cytoplasm, between the nucleus and the plasma membrane, is where most cell activities take place.
4. Cells perform the following functions:
 - Cells metabolize and release energy.
 - Cells synthesize molecules.
 - Cells provide a means of communication.
 - Cells reproduce and provide for inheritance.

3.2 How We See Cells (p. 61)

1. Light microscopes allow us to visualize the general features of cells.
2. Electron microscopes allow us to visualize the fine structure of cells.

3.3 Plasma Membrane (p. 61)

1. The plasma membrane passively or actively regulates what enters or leaves the cell.
2. The plasma membrane is composed of a phospholipid bilayer, in which proteins are suspended (commonly depicted by the fluid-mosaic model).

3.4 Membrane Lipids (p. 63)

Lipids give the plasma membrane most of its structure and some of its function.

3.5 Membrane Proteins (p. 64)

1. Membrane proteins function as marker molecules, attachment proteins, transport proteins, receptor proteins, and enzymes.
2. Transport proteins include channel proteins, carrier proteins, and ATP-powered pumps.
3. Some receptor proteins are linked to and control channel proteins.
4. Some receptor molecules are linked to G protein complexes, which control numerous cellular activities.

3.6 Movement Through the Plasma Membrane (p. 69)

1. Lipid-soluble molecules pass through the plasma membrane readily by dissolving in the lipid bilayer. Small molecules diffuse between the phospholipid molecules of the plasma membrane.
2. Large, non-lipid-soluble molecules and ions (e.g., glucose and amino acids) are transported through the membrane by transport proteins.
3. Large, non-lipid-soluble molecules, as well as very large molecules and even whole cells, can be transported across the membrane in vesicles.

Passive Membrane Transport

1. Diffusion is the movement of a substance from an area of higher solute concentration to one of lower solute concentration (down a concentration gradient).
2. The concentration gradient is the difference in solute concentration between two points divided by the distance separating the points.
3. The rate of diffusion increases with an increase in the concentration gradient, an increase in temperature, a decrease in molecular size, and a decrease in viscosity.
4. The end result of diffusion is uniform distribution of molecules.
5. Diffusion requires no expenditure of energy.

6. Osmosis is the diffusion of water (solvent) across a selectively permeable membrane.
7. Osmotic pressure is the force required to prevent the movement of water across a selectively permeable membrane.
8. Isosmotic solutions have the same concentration of solute particles, hyperosmotic solutions have a greater concentration of solute particles, and hyposmotic solutions have a lower concentration of solute particles.
9. Cells placed in an isotonic solution neither swell nor shrink. In a hypertonic solution, they shrink (crenate); in a hypotonic solution, they swell and may burst (lyse).
10. Mediated transport is the movement of a substance across a membrane by means of a transport protein. The substances transported tend to be large, water-soluble molecules.
11. Facilitated diffusion moves substances down their concentration gradient and does not require energy (ATP).

Active Membrane Transport

1. Active transport can move substances against their concentration gradient and requires ATP. An exchange pump is an active-transport mechanism that simultaneously moves two substances in opposite directions across the plasma membrane.
2. In secondary active transport, an ion is moved across the plasma membrane by active transport, and the energy produced by the ion diffusing back down its concentration gradient can transport another molecule, such as glucose, against its concentration gradient.
3. Vesicular transport is the movement of large volumes of substances across the plasma membrane through the formation or release of vesicles.
4. Endocytosis is the bulk movement of materials into cells.
 - Phagocytosis is the bulk movement of solid material into cells by the formation of a vesicle.
 - Pinocytosis is similar to phagocytosis, except that the ingested material is much smaller and is in solution.
5. Receptor-mediated endocytosis allows for endocytosis of specific molecules.
6. Exocytosis is the secretion of materials from cells by vesicle formation.
7. Both endocytosis and exocytosis require energy.

3.7 Cytoplasm (p. 77)

The cytoplasm is the material outside the nucleus and inside the plasma membrane.

Cytosol

1. Cytosol consists of a fluid part (the site of chemical reactions), the cytoskeleton, and cytoplasmic inclusions.
2. The cytoskeleton supports the cell and is responsible for cell movements. It consists of protein fibers.
 - Microtubules are hollow tubes composed of the protein tubulin. They form spindle fibers and are components of centrioles, cilia, and flagella.
 - Actin filaments are small protein fibrils that provide structure to the cytoplasm or cause cell movements.
 - Intermediate filaments are protein fibers that provide structural strength to cells.
3. Cytoplasmic inclusions, such as lipochromes, are not surrounded by membranes.

3.8 The Nucleus and Cytoplasmic Organelles (p. 78)

Organelles are subcellular structures specialized for specific functions.

The Nucleus

1. The nuclear envelope consists of a double membrane with nuclear pores.
2. DNA and associated proteins are found inside the nucleus as chromatin.
3. DNA is the hereditary material of the cell. It controls cell activities by producing proteins through RNA.
4. A gene is a portion of a DNA molecule. Genes determine the proteins in a cell.
5. Nucleoli consist of RNA and proteins and are the sites of ribosomal subunit assembly.

Ribosomes

1. Ribosomes consist of small and large subunits manufactured in the nucleolus and assembled in the cytoplasm.
2. Ribosomes are the sites of protein synthesis.
3. Ribosomes can be free or associated with the endoplasmic reticulum.

Endoplasmic Reticulum

1. The endoplasmic reticulum is an extension of the outer membrane of the nuclear envelope; it forms tubules or sacs (cisternae) throughout the cell.
2. The rough endoplasmic reticulum has ribosomes and is a site of protein synthesis and modification.
3. The smooth endoplasmic reticulum lacks ribosomes and is involved in lipid production, detoxification, and calcium storage.

Golgi Apparatus

The Golgi apparatus is a series of closely packed, modified cisternae that modify, package, and distribute lipids and proteins produced by the endoplasmic reticulum.

Secretory Vesicles

Secretory vesicles are membrane-bound sacs that carry substances from the Golgi apparatus to the plasma membrane, where the contents of the vesicles are released by exocytosis.

Lysosomes

1. Lysosomes are membrane-bound sacs containing hydrolytic enzymes. Within the cell, the enzymes break down phagocytized material and nonfunctional organelles (autophagy).
2. Enzymes released from the cell by lysis or enzymes secreted from the cell can digest extracellular material.

Peroxisomes

Peroxisomes are membrane-bound sacs containing enzymes that digest fatty acids and amino acids, as well as enzymes that catalyze the breakdown of hydrogen peroxide.

Proteasomes

Proteasomes are large, multienzyme complexes, not bound by membranes, that digest selected proteins within the cell.

Mitochondria

1. Mitochondria are the major sites for the production of ATP, which cells use as an energy source.
2. The mitochondria have a smooth outer membrane and an inner membrane that is infolded to form cristae.
3. Mitochondria contain their own DNA, can produce some of their own proteins, and can replicate independently of the cell.

Centrioles and Spindle Fibers

1. Centrioles are cylindrical organelles located in the centrosome, a specialized zone of the cytoplasm that serves as the site of microtubule formation.

2. Spindle fibers are involved in the separation of chromosomes during cell division.

Cilia and Flagella

1. Cilia facilitate the movement of materials over the surface of the cell.
2. Flagella, which are much longer than cilia, propel sperm cells.

Microvilli

Microvilli increase the surface area of the plasma membrane for absorption or secretion.

3.9 Genes and Gene Expression (p. 88)

1. During transcription, information stored in DNA is copied to form mRNA.
2. During translation, the mRNA goes to ribosomes, where it directs the synthesis of proteins.

Transcription

1. DNA unwinds and, through nucleotide pairing, produces pre-mRNA (transcription).
2. Introns are removed and exons are spliced together during post-transcriptional processing.
3. Modifications to the ends of mRNA also occur during posttranscriptional processing.

Genetic Code

The genetic code specifies amino acids and consists of codons, which are sequences of three nucleotides in mRNA.

Translation

1. mRNA moves through the nuclear pores to ribosomes.
2. Transfer RNA (tRNA), which carries amino acids, interacts at the ribosome with mRNA. The anticodons of tRNA bind to the codons of mRNA, and the amino acids join to form a protein (translation).
3. During posttranslational processing, proproteins, some of which are proenzymes, are modified into proteins, some of which are enzymes.

Regulation of Gene Expression

1. Cells become specialized because certain parts of the DNA molecule are activated but other parts are not.
2. The level of DNA activity and thus protein production can be controlled internally or can be affected by regulatory substances secreted by other cells.

3.10 Cell Life Cycle (p. 94)

The cell life cycle has two stages: interphase and cell division.

Interphase

1. Interphase, the period between cell divisions, is the time of DNA replication.
2. During replication, DNA unwinds, and each strand produces a new DNA molecule.

Cell Division

1. Cell division includes nuclear division and cytoplasmic division.
2. Mitosis is the replication of the cell's nucleus, and cytokinesis is division of the cell's cytoplasm.
3. Mitosis is a continuous process divided into four phases.
 - *Prophase*. Chromatin condenses to become visible as chromosomes. Each chromosome consists of two chromatids joined at the centromere. Centrioles move to opposite poles of the cell, and astral fibers and spindle fibers form. Nucleoli disappear, and the nuclear envelope degenerates.
 - *Metaphase*. Chromosomes align at the center of the cell.

- *Anaphase*. The chromatids of each chromosome separate at the centromere. Each chromatid is then called a chromosome. The chromosomes migrate to opposite poles.
 - *Telophase*. Chromosomes unravel to become chromatin. The nuclear envelope and nucleoli reappear.
4. Cytokinesis begins with the formation of the cleavage furrow during anaphase. It is complete when the plasma membrane comes together at the equator, producing two new daughter cells.

Apoptosis

Apoptosis, or programmed cell death, is a normal process by which cell number within various tissues is adjusted and controlled.

3.11 Cellular Aspects of Aging (p. 96)

Aging may be due to the presence of “cellular clocks,” the function of “death genes,” DNA damage, free radicals, or mitochondrial damage.

REVIEW AND COMPREHENSION

- In the plasma membrane, _____ form(s) the lipid bilayer, _____ determine(s) the fluid nature of the membrane, and _____ mainly determine(s) the function of the membrane.
 - phospholipids, cholesterol, proteins
 - phospholipids, proteins, cholesterol
 - proteins, cholesterol, phospholipids
 - cholesterol, phospholipids, proteins
 - cholesterol, proteins, phospholipids
- Which of the following functioning proteins are found in the plasma membrane?
 - channel proteins
 - marker molecules
 - receptor molecules
 - enzymes
 - All of these are correct.
- In general, lipid-soluble molecules diffuse through the _____; small, water-soluble molecules diffuse through the _____.
 - membrane channels, membrane channels
 - membrane channels, lipid bilayer
 - lipid bilayer, carrier proteins
 - membrane channels, carrier proteins
 - carrier proteins, membrane channels
- Small pieces of matter, and even whole cells, can be transported across the plasma membrane in
 - membrane channels.
 - carrier molecules.
 - receptor molecules.
 - marker molecules.
 - vesicles.
- The rate of diffusion increases if the
 - concentration gradient decreases.
 - temperature of a solution decreases.
 - viscosity of a solution decreases.
 - All of these are correct.
- Concerning the process of diffusion, at equilibrium
 - the net movement of solutes stops.
 - random molecular motion continues.
 - there is an equal movement of solute in opposite directions.
 - the concentration of solute is equal throughout the solution.
 - All of these are correct.
- If a cell is placed in a(n) _____ solution, lysis of the cell may occur.
 - hypertonic
 - isotonic
 - hypotonic
 - isosmotic
- Suppose that a woman runs a long-distance race in the summer. During the race, she loses a large amount of hyposmotic sweat. You would expect her cells to
 - shrink.
 - swell.
 - stay the same.
- Which of these statements about facilitated diffusion is true?
 - In facilitated diffusion, net movement is down the concentration gradient.
 - Facilitated diffusion requires the expenditure of energy.
 - Facilitated diffusion does not require a carrier protein.
 - Facilitated diffusion moves materials through membrane channels.
 - Facilitated diffusion moves materials in vesicles.
- Which of these statements concerning the symport of glucose into cells is true?
 - The sodium-potassium exchange pump moves Na^+ into cells.
 - The concentration of Na^+ outside cells is less than inside cells.
 - A carrier protein moves Na^+ into cells and glucose out of cells.
 - The concentration of glucose can be greater inside cells than outside cells.
 - As Na^+ are actively transported into the cell, glucose is carried along.
- A white blood cell ingests solid particles by forming vesicles. This describes the process of
 - exocytosis.
 - facilitated diffusion.
 - secondary active transport.
 - phagocytosis.
 - pinocytosis.
- Given these characteristics:
 - requires energy
 - requires carrier proteins
 - requires membrane channels
 - requires vesicles
 Choose the characteristics that apply to exocytosis.
 - 1,2
 - 1,4
 - 1,3,4
 - 1,2,3
 - 1,2,3,4
- Cytoplasm is found
 - in the nucleus.
 - outside the nucleus and inside the plasma membrane.
 - outside the plasma membrane.
 - inside mitochondria.
 - everywhere in the cell.
- Which of these elements of the cytoskeleton is composed of tubulin and forms essential components of centrioles, spindle fibers, cilia, and flagella?
 - actin filaments
 - intermediate filaments
 - microtubules
- A large structure, normally visible in the nucleus of a cell, where ribosomal subunits are produced is called a(n)
 - endoplasmic reticulum.
 - mitochondrion.
 - nucleolus.
 - lysosome.
- A cell that synthesizes large amounts of protein for use outside the cell has a large
 - number of cytoplasmic inclusions.
 - number of mitochondria.
 - amount of rough endoplasmic reticulum.
 - amount of smooth endoplasmic reticulum.
 - number of lysosomes.
- Which of these organelles produces large amounts of ATP?
 - nucleus
 - mitochondria
 - ribosomes
 - endoplasmic reticulum
 - lysosomes

18. Cylindrically shaped extensions of the plasma membrane that do not move, are supported by actin filaments, and may function in absorption or as sensory receptors are
 a. centrioles. c. cilia. e. microvilli.
 b. spindle fibers. d. flagella.
19. A portion of an mRNA molecule that determines one amino acid in a polypeptide chain is called a(n)
 a. nucleotide. b. gene. c. codon. d. exon. e. intron.
20. In which of these organelles is mRNA synthesized?
 a. nucleus d. nuclear envelope
 b. ribosome e. peroxisome
 c. endoplasmic reticulum
21. During the cell life cycle, DNA replication occurs during the
 a. G₁ phase. b. G₂ phase. c. M phase. d. S phase.
22. Given the following activities:
 (1) repair (3) gamete production
 (2) growth (4) differentiation
 Which of the activities is (are) the result of mitosis?
 a. 2 b. 3 c. 1,2 d. 3,4 e. 1,2,4
23. Apoptosis
 a. is a programmed cell death.
 b. removes excess cells between the developing fingers and toes of a fetus.
 c. eliminates virally infected cells and cancer cells from the body.
 d. All of these are correct.

Answers in appendix E

CRITICAL THINKING

1. Why does a surgeon use sterile distilled water rather than sterile isotonic saline to irrigate a surgical wound from which a tumor has been removed?
2. Solution A is hyperosmotic to solution B. If solution A is separated from solution B by a selectively permeable membrane, does water move from solution A into solution B, or vice versa? Explain.
3. A researcher wants to determine the nature of the transport mechanism that moved substance X into a cell. She could measure the concentration of substance X in the extracellular fluid and within the cell, as well as the rate of movement of substance X into the cell. She does a series of experiments and gathers the data shown in the accompanying graph. Choose the transport process that is consistent with the data.
 a. diffusion
 b. active transport
 c. facilitated diffusion
 d. There is not enough information to make a judgment.
4. A dialysis membrane is selectively permeable, and substances smaller than proteins are able to pass through it. If you wanted to use a dialysis machine to remove only urea (a small molecule) from blood, what could you use for the dialysis fluid?
 a. a solution that is isotonic and contains only large molecules, such as protein
 b. a solution that is isotonic and contains the same concentration of all substances except that it has no urea
 c. distilled water, which contains no ions or dissolved molecules
 d. blood, which is isotonic and contains the same concentration of all substances, including urea
5. Luke started a training program at the beginning of the summer. For the first week, he jogged 1 mile. Each week after that, he increased the distance he jogged by about 0.5 mile and increased his speed. At the end of 2 months, he was able to jog 4.5 miles each day at a faster pace than he had been able to jog at the beginning of the summer. During the 2-month period, the muscle cells in his heart and his legs increased in size. Identify a critical membrane-bound organelle that increased in number and made it possible for Luke to run the longer distance. Also, explain how these organelles increased in number, and describe the location of the genetic code for the proteins in the organelles.
6. If you had the ability to inhibit mRNA synthesis with a drug, explain how you could distinguish between proteins released from secretory vesicles in which they had been stored and proteins released from cells in which they had been newly synthesized.

Answers in appendix F

Graph depicting the rate of movement of substance X from a fluid into a cell (y axis) versus the concentration of substance X within the cell minus the concentration outside the cell (x axis). At point A, the extracellular concentration of substance X is equal to the intracellular concentration of substance X (designated 0 on the x axis).

4

Tissues

In some ways, the human body is like a car. Both consist of many parts that are made of materials consistent with their specialized functions. For example, car tires are made of synthetic rubber reinforced with a variety of fibers, the engine is composed of various metal parts, and the windows are transparent glass. Similarly, the many parts of the human body are made of groups of specialized cells and the materials surrounding them. Muscle cells, which contract to produce body movements, differ both structurally and functionally from epithelial cells, which protect, secrete, or absorb. Conversely, cells in the retina of the eye, which are specialized to detect light and enable us to see, do not contract as muscle cells do—nor do they exhibit the functions of epithelial cells.

The structure and the function of tissues are so closely related that we can often predict the function of a tissue when given its structure, and vice versa. Knowledge of tissue structure and function is important in understanding organs, organ systems, and the complete organism.

Learn to Predict

It is Matt's birthday, but he will not be eating any cake. Matt has gluten enteropathy, also called celiac disease, which results from an inappropriate immune response to gluten, a group of proteins found in wheat and various other grains. After eating food containing gluten, such as most breads and cereals, Matt has bouts of diarrhea because his intestinal lining is unable to properly absorb water and nutrients. The poor absorption is due to a reduced number of villi, or fingerlike protrusions of the intestinal lining, and reduced transport capacity of the remaining cells within the villi. In chapter 3 we learned that water and nutrients enter and exit the body's cells by osmosis and other transport processes. Chapter 4 describes how tissues are specialized to allow this flow of water and nutrients. **After reading this chapter, identify the type of tissue affected by Matt's disease and which parts of the cells in this tissue are damaged, thus reducing their ability to absorb water and nutrients. Then explain why Matt has diarrhea after eating food containing gluten.**

Photo: Fluorescent image of intestinal tissue. A section of small intestine has been immunolabeled to detect actin (*red*) and laminin (*green*), structural proteins that help support the villi, which protrude into the lumen of the intestine. Nuclei are shown in *blue*.

4.1 Tissues and Histology

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the general make-up of a tissue.
- B. List the four primary tissue types.
- C. Explain how histology relates to biopsies and autopsies.

Tissues (tish'ūz) are collections of specialized cells and the extracellular substances surrounding them. Body tissues are classified into four types, based on the structure of the cells, the composition of the noncellular substances surrounding the cells (called the **extracellular matrix**), and the functions of the cells. The four primary tissue types, from which all organs of the body are formed, are epithelial tissue, connective tissue, muscle tissue, and nervous tissue.

Epithelial and connective tissues are the most diverse in form. The different types of epithelial and connective tissues are classified by structure, including cell shape, relationship of cells to one another, and composition of the extracellular matrix. Muscle and nervous tissues are also classified by structure as well as by functional characteristics and location.

The relationship between the function and the structure of body parts is an important concept in anatomy and physiology. The function of a body structure can often be determined by its specific type of tissue. For example, the lungs have a thin layer of specialized epithelial tissue that enhances the exchange of gases between air and blood. In contrast, the outer layer of the skin is composed of a different type of epithelial tissue, which provides protection to underlying tissues.

The tissues of the body are interdependent. For example, muscle tissue cannot produce movement unless it receives oxygen carried by red blood cells, and new bone tissue cannot form unless epithelial tissue absorbs calcium and other nutrients from the digestive tract. Also, the loss of one vital tissue through disease or injury can lead to organ failure and death.

Histology (his-tol'ō-jē) is the microscopic study of tissues. Much information about a person's health can be gained by examining tissues. A **biopsy** (bī'op-sē) is the process of removing tissue samples from patients surgically or with a needle for diagnostic purposes. Examining tissue samples can distinguish various disorders. For example, some red blood cells have an abnormal shape in people suffering from sickle-cell disease, and red blood cells are smaller than normal in people with iron-deficiency anemia. Cancer is identified and classified based on characteristic changes in tissues. For example, changes in the structure of epithelial cells can indicate cancer of the uterine cervix, and changes in white blood cells identify people who have leukemia. Also, a greatly increased number of white blood cells can be a sign of infection. Epithelial cells from respiratory airways have an abnormal structure in people with chronic bronchitis, as well as in people with lung cancer.

Tissue samples can be sent to a laboratory for examination. In some cases, tissues are removed surgically and examined quickly, so that the results can be reported while the patient is still anesthetized. These results help determine the appropriate therapy—for example, the amount of tissue removed as part of breast or other types of cancer treatment.

An **autopsy** (aw'top-sē) is an examination of the organs of a dead body to determine the cause of death or to study the changes caused by a disease. Microscopic examination of tissue is often part of an autopsy.

ASSESS YOUR PROGRESS

1. What components are found in a tissue?
2. Name the four primary tissue types and the characteristics that are used to classify them.
3. Define histology. Explain how the histology of tissues taken by biopsy or autopsy can be used to diagnose some diseases.

4.2 Embryonic Tissue

LEARNING OUTCOME

After reading this section, you should be able to

- A. Identify the three embryonic germ layers and name the adult structures that are derived from each.

Approximately 13 or 14 days after fertilization, the embryonic stem cells that give rise to a new individual form a slightly elongated disk consisting of two layers, the epiblast and the hypoblast (the suffix *-blast* means bud or germ). Cells of the epiblast then migrate between the two layers to form the three embryonic germ layers: the ectoderm, the mesoderm, and the endoderm. The ectoderm, mesoderm, and endoderm are called germ layers because the beginning of all adult structures can be traced back to one of them. The germ layers give rise to all the tissues of the body (see chapter 29).

The **endoderm** (en'dō-derm), the inner layer, forms the lining of the digestive tract and its derivatives. The **mesoderm** (mez'ō-derm), the middle layer, forms tissues such as muscle, bone, and blood vessels. The **ectoderm** (ek'tō-derm), the outer layer, forms the skin; a portion of the ectoderm called **neuroectoderm** (noor-ō-ek'tō-derm) becomes the nervous system (see chapter 29). Groups of cells that break away from the neuroectoderm during development, called **neural crest cells**, give rise to parts of the peripheral nerves (see chapter 29), skin pigment (see chapter 5), the medulla of the adrenal gland (see chapter 18), and many tissues of the face.

ASSESS YOUR PROGRESS

4. Name the three embryonic germ layers.
5. What adult structures are derived from each layer?
6. What is formed from neural crest cells?

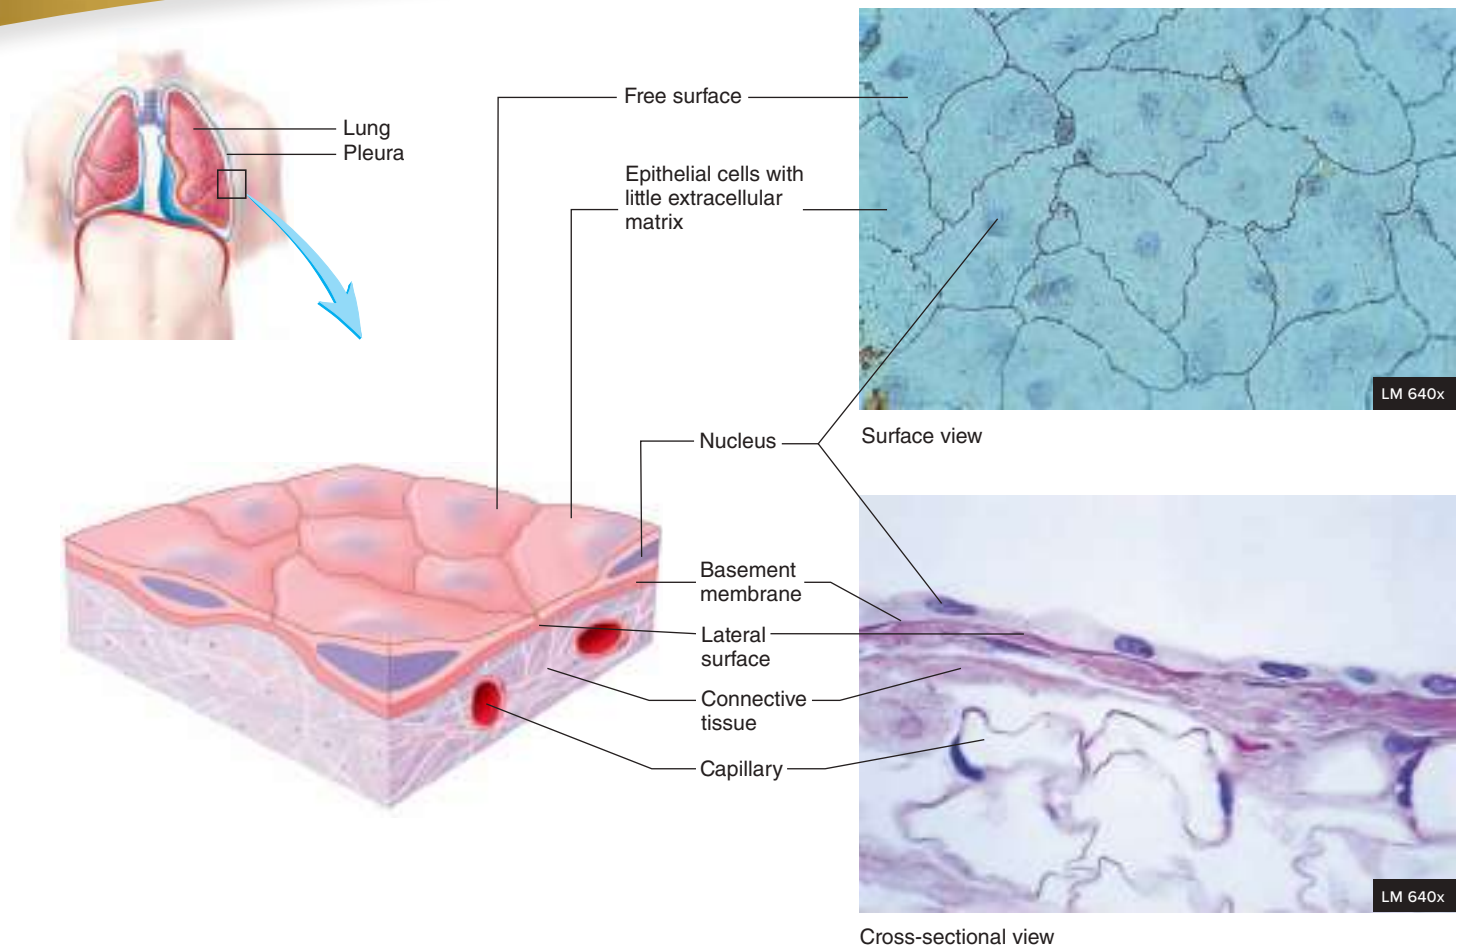

FIGURE 4.1 Characteristics of Epithelial Tissue

Surface and cross-sectional views of epithelial tissue illustrate the following characteristics: little extracellular material between cells, a free surface, and a basement membrane attaching epithelial cells to underlying tissues. Capillaries in connective tissue do not penetrate the basement membrane. Nutrients, oxygen, and waste products must diffuse across the basement membrane between the capillaries and the epithelial cells.

4.3 Epithelial Tissue

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List and explain the general characteristics of epithelial tissue.**
- B. Describe the major functions of epithelial tissue.**
- C. Classify epithelial tissues based on the number of cell layers and the shape of the cells.**
- D. Name and describe the various types of epithelial tissue, including their chief functions and locations.**
- E. Relate the structural specializations of epithelial tissue with the functions they perform.**
- F. Differentiate between exocrine and endocrine glands, and unicellular and multicellular glands.**
- G. Categorize glands based on their structure and function.**

Epithelial (ep-i-thē'lē-ăl) **tissue**, or *epithelium* (ep-i-thē'lē-ŭm), covers and protects surfaces, both outside and inside the body. The characteristics common to most types of epithelial tissue are shown in figure 4.1 and listed here:

1. *Mostly composed of cells.* Epithelial tissue consists almost entirely of cells, with very little extracellular matrix between them.
2. *Covers body surfaces.* Epithelial tissue covers body surfaces and forms glands that are derived developmentally from body surfaces. The body surfaces include the exterior surface, the lining of the digestive and respiratory tracts, the heart and blood vessels, and the linings of many body cavities.
3. *Distinct cell surfaces.* Most epithelial tissues have one **free**, or **apical** (ap'i-kāl), **surface** where cells are exposed and not attached to other cells. The cells have a **lateral surface** where cells are attached to other epithelial cells. At the base of the cells is **basal surface** attached to a basement membrane. The free surface often lines the lumen of ducts, vessels, and cavities. The **basement membrane** is a specialized type of extracellular material secreted by epithelial and connective tissue cells. The basement membrane helps attach the epithelial cells to the underlying

tissues, like the adhesive on Scotch™ tape. It plays an important role in supporting and guiding cell migration during tissue repair. The basement membrane is typically porous, which allows substances to move to and from the epithelial tissue above it. A few epithelial tissues, such as those in lymphatic capillaries and liver sinusoids, do not have basement membranes, and some epithelial tissues, such as those in some endocrine glands, do not have a free surface or a basal surface with a basement membrane.

4. **Cell and matrix connections.** Specialized cell contacts bind adjacent epithelial cells together and to the extracellular matrix of the basement membrane.
5. **Nonvascular.** Blood vessels in the underlying connective tissue do not penetrate the basement membrane to reach the epithelium; thus, all gases and nutrients carried in the blood must reach the epithelium by diffusing from blood vessels across the basement membrane. In epithelial tissues with many layers of cells, diffusion must also occur across cells, and the most metabolically active cells are close to the basement membrane.
6. **Capable of regeneration.** Epithelial tissue has the ability to replace damaged cells with new epithelial cells. Undifferentiated cells (stem cells) continuously divide and produce new cells. In some types of epithelial tissues, such as those in the skin and the digestive tract, new cells continuously replace cells that die.

Functions of Epithelial Tissues

The major functions of epithelial tissue are

1. **Protecting underlying structures.** For example, the outer layer of the skin and the epithelium of the oral cavity protect the underlying structures from abrasion.
2. **Acting as a barrier.** Epithelium prevents many substances from moving through it. For example, the skin acts as a barrier to water and reduces water loss from the body. The skin also prevents many toxic molecules and microorganisms from entering the body.
3. **Permitting the passage of substances.** Though epithelium acts as a barrier for some substances, it also permits many other substances to move through it. For example, oxygen and carbon dioxide are exchanged between the air and blood by diffusion through the epithelium in the lungs. Epithelium acts as a filter in the kidney, allowing many substances to pass from the blood into the urine but retaining other substances, such as blood cells and proteins, in the blood.
4. **Secreting substances.** Mucous glands, sweat glands, and the enzyme-secreting portions of the pancreas are all composed of epithelial cells that secrete their products onto surfaces or into ducts that carry them to other areas of the body.
5. **Absorbing substances.** The plasma membranes of certain epithelial tissues contain carrier proteins (see chapter 3), which regulate the absorption of materials.

ASSESS YOUR PROGRESS

7. List six characteristics common to most types of epithelial tissue.
8. What are the distinct cell surfaces found in epithelial tissue? Describe them.
9. List and describe the major functions of epithelial tissue.

Classification of Epithelial Tissues

Epithelial tissues are classified primarily according to the number of cell layers and the shape of the superficial cells. There are three major types of epithelium based on the number of cell layers in each:

1. **Simple epithelium** consists of a single layer of cells, with each cell extending from the basement membrane to the free surface.
2. **Stratified epithelium** consists of more than one layer of cells, but only the basal layer attaches the deepest layer to the basement membrane.
3. **Pseudostratified columnar epithelium** is a special type of simple epithelium. The prefix *pseudo-* means false, so this type of epithelium appears to be stratified but is not. It consists of one layer of cells, with all the cells attached to the basement membrane. There appear to be two or more layers of cells because some of the cells are tall and extend to the free surface, whereas others are shorter and do not extend to the free surface.

There are three types of epithelium based on idealized shapes of the epithelial cells:

1. **Squamous** (skwā'mūs) cells are flat or scalelike.
2. **Cuboidal** (cubelike) cells are cube-shaped—about as wide as they are tall.
3. **Columnar** (tall and thin, similar to a column) cells tend to be taller than they are wide.

In most cases, an epithelium is given two names, such as simple squamous, stratified squamous, simple columnar, or pseudostratified columnar. The first name indicates the number of layers, and the second indicates the shape of the cells at the free surface (table 4.1). Tables 4.2–4.4 provide an overview of the major types of epithelial tissues and their distribution.

Simple squamous epithelium consists of one layer of flat, or scalelike, cells that rest on a basement membrane (table 4.2a). Stratified squamous epithelium consists of several layers of cells. Near the basement membrane, the cells are more cube-shaped, but at the free surface the cells are flat or scalelike (table 4.3a). Pseudostratified columnar epithelial cells are columnar in shape (taller than they are wide) and, although they appear to consist of more than one layer, all the cells rest on the basement membrane (table 4.4a).

TABLE 4.1

Classification of Epithelium

Number of Layers or Category	Shape of Cells
Simple (single layer of cells)	Squamous Cuboidal Columnar
Stratified (more than one layer of cells)	Squamous Nonkeratinized (moist) Keratinized Cuboidal (very rare) Columnar (very rare)
Pseudostratified (modification of simple epithelium)	Columnar
Transitional (modification of stratified epithelium)	Roughly cuboidal to columnar when not stretched and squamouslike when stretched

TABLE 4.2 Simple Epithelium

(a) Simple Squamous Epithelium **APR**

Structure: Single layer of flat, often hexagonal cells; the nuclei appear as bumps when viewed as a cross section because the cells are so flat

Function: Diffusion, filtration, some secretion, and some protection against friction

Location: Lining of blood vessels and the heart, lymphatic vessels (endothelium) and small ducts, alveoli of the lungs, portions of the kidney tubules, lining of serous membranes (mesothelium) of the body cavities (pleural, pericardial, peritoneal), and inner surface of the tympanic membranes

(b) Simple Cuboidal Epithelium **APR**

Structure: Single layer of cube-shaped cells; some cells have microvilli (kidney tubules) or cilia (terminal bronchioles of the lungs)

Function: Secretion and absorption by cells of the kidney tubules; secretion by cells of glands and choroid plexuses; movement of particles embedded in mucus out of the terminal bronchioles by ciliated cells

Location: Kidney tubules, glands and their ducts, choroid plexuses of the brain, lining of terminal bronchioles of the lungs, surfaces of the ovaries

TABLE 4.2 Simple Epithelium—Continued

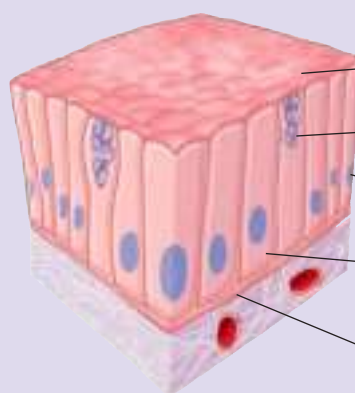

(c) Simple Columnar Epithelium **APR**

Structure: Single layer of tall, narrow cells; some cells have cilia (bronchioles of lungs, auditory tubes, uterine tubes, and uterus) or microvilli (intestines)

Function: Movement of particles out of the bronchioles of the lungs by ciliated cells; partially responsible for the movement of oocytes through the uterine tubes by ciliated cells; secretion by cells of the glands, the stomach, and the intestines; absorption by cells of the small and large intestines

Location: Glands and some ducts, bronchioles of the lungs, auditory tubes, uterus, uterine tubes, stomach, intestines, gallbladder, bile ducts, ventricles of the brain

Lining of stomach and intestines

Free surface

Goblet cell containing mucus

Nucleus

Simple columnar epithelial cell

Basement membrane

LM 640x

TABLE 4.3 Stratified Epithelium

(a) Stratified Squamous Epithelium **APR**

Structure: Multiple layers of cells that are cube-shaped in the basal layer and progressively flattened toward the surface; the epithelium can be nonkeratinized (moist) or keratinized; in nonkeratinized stratified squamous epithelium, the surface cells retain a nucleus and cytoplasm; in keratinized stratified epithelium, the cytoplasm of cells at the surface is replaced by a protein called keratin, and the cells are dead

Function: Protection against abrasion, a barrier against infection, reduction of water loss from the body

Location: Keratinized—primarily in the skin; nonkeratinized—mouth, throat, larynx, esophagus, anus, vagina, inferior urethra, cornea

Skin

Cornea

Mouth

Esophagus

Free surface

Nonkeratinized stratified squamous epithelial cell

Nuclei

Basement membrane

LM 72x

TABLE 4.3 Stratified Epithelium—Continued

(b) Stratified Cuboidal Epithelium

Structure: Multiple layers of somewhat cube-shaped cells

Function: Secretion, absorption, protection against infection

Location: Sweat gland ducts, ovarian follicular cells, salivary gland ducts

**(c) Stratified Columnar Epithelium**

Structure: Multiple layers of cells with tall, thin cells resting on layers of more cube-shaped cells; the cells are ciliated in the larynx

Function: Protection, secretion

Location: Mammary gland ducts, larynx, a portion of the male urethra

TABLE 4.4 Pseudostratified Columnar Epithelium and Transitional Epithelium

(a) Pseudostratified Columnar Epithelium **APR**

Structure: Single layer of cells; some cells are tall and thin and reach the free surface, and others do not; the nuclei of these cells are at different levels and appear stratified; the cells are almost always ciliated and are associated with goblet cells that secrete mucus onto the free surface

Function: Synthesize and secrete mucus onto the free surface; move mucus (or fluid) that contains foreign particles over the surface of the free surface and from passages

Location: Lining of the nasal cavity, nasal sinuses, auditory tubes, pharynx, trachea, bronchi of the lungs

(b) Transitional Epithelium **APR**

Structure: Stratified cells that appear cube-shaped when the organ or tube is not stretched and squamous when the organ or tube is stretched by fluid; the number of layers also decreases on stretch

Function: Accommodate fluctuations in the volume of fluid in organs or tubes; protect against the caustic effects of urine

Location: Lining of the urinary bladder, ureters, superior urethra

Tissue not stretched

Tissue stretched

Stratified squamous epithelium can be classified further as either nonkeratinized or keratinized, according to the condition of the outermost layer of cells. **Nonkeratinized (moist) stratified squamous epithelium** (table 4.3a), found in areas such as the mouth, esophagus, rectum, and vagina, consists of living cells in the deepest and outermost layers. A layer of fluid covers the outermost layers of cells, which makes them moist. In contrast, **keratinized (ker'ă-ti-nīzd) stratified squamous epithelium**, found in the skin (see chapter 5), consists of living cells in the deepest layers, and the outer layers are composed of dead cells containing the protein keratin. The dead, keratinized cells give the tissue a dry, durable, moisture-resistant character. In addition to the skin, keratinized stratified squamous epithelium is also found in the gums and hard palate of the mouth.

A unique type of stratified epithelium called **transitional epithelium** (table 4.4b) lines the urinary bladder, ureters, pelvis of the kidney (including the major and minor calyces; kal'-i-sēz), and superior part of the urethra (see chapter 26). These are structures where considerable expansion can occur. The shape of the cells and the number of cell layers vary, depending on the degree to which transitional epithelium is stretched. The surface cells and the underlying cells are roughly cuboidal or columnar when the epithelium is not stretched, and they become more flattened or squamouslike as the epithelium is stretched. Also, as the epithelium is stretched, the epithelial cells can shift on one another, so that the number of layers decreases from five or six to two or three.

Functional Characteristics

Epithelial tissues have many functions, including forming a barrier between a free surface and the underlying tissues and secreting, transporting, and absorbing selected molecules (table 4.5). The structure and organization of cells within each epithelial type reflect these functions.

Cell Layers and Cell Shapes

Simple epithelium, with its single layer of cells, covers surfaces. In the lungs it facilitates the diffusion of gases; in the kidneys it filters blood; in glands it secretes cellular products; and in the intestines it absorbs nutrients. Stratified epithelium is found in areas where protection is a major function because it is able to hinder the selective movement of materials through the epithelium. The multiple layers of cells in stratified epithelium are well adapted for a protective role. As the outer cells are damaged, they are replaced by cells from deeper layers; thus, a continuous barrier of epithelial cells is maintained in the tissue. Stratified squamous epithelium is found in areas of the body where abrasion can occur, such as the skin, mouth, throat, esophagus, anus, and vagina.

Differing functions are also reflected in cell shape. Cells that filter substances and allow diffusion are normally flat and thin. For example, simple squamous epithelium forms blood and lymphatic capillaries, alveoli (air sacs) of the lungs, and parts of the kidney tubules. Cells that secrete or absorb are usually cuboidal or columnar. They have greater cytoplasmic volume relative to surface area than seen with squamous cells. This greater volume results from the presence of organelles responsible for the tissues' functions. For example, pseudostratified columnar epithelium,

which secretes large amounts of mucus, lines the respiratory tract (see chapter 23) and contains large **goblet cells**, which are specialized columnar epithelial cells. The goblet cells are responsible for synthesizing and secreting mucus.

Predict 2

Explain the consequences of having (a) nonkeratinized stratified epithelium rather than simple columnar epithelium lining the digestive tract, (b) nonkeratinized stratified squamous epithelium rather than keratinized stratified squamous epithelium in the skin, and (c) simple columnar epithelium rather than stratified squamous epithelium lining the mouth.

ASSESS YOUR PROGRESS

- Describe simple, stratified, and pseudostratified epithelial tissues. Distinguish among squamous, cuboidal, and columnar epithelial cells.
- How do nonkeratinized stratified squamous epithelium and keratinized stratified squamous epithelium differ? Where is each type found?
- Describe the changes in cell shape and number of cell layers in transitional epithelium as it is stretched. Where is transitional epithelium found?
- List the types of epithelial tissue, giving the structure, functions, and major locations of each.
- What functions would a single layer of epithelial cells be expected to perform? A stratified layer?
- Why are cuboidal or columnar cells found where secretion or absorption is occurring?

Free Surfaces

The free surfaces of epithelial tissues can be smooth or folded; they may have microvilli or cilia. Smooth surfaces reduce friction. For example, the lining of blood vessels is a simple squamous epithelium that reduces friction as blood flows through the vessels (see chapter 21).

Microvilli and cilia were described in chapter 3. Microvilli are extensions of the cell that greatly increase free surface area. They occur in cells that absorb or secrete, such as serous membranes and the lining of the small intestine (see chapter 24). Microvilli are nonmotile and contain microfilaments. Stereocilia are a specialized, elongated form of microvilli found in sensory structures, such as the inner ear (see chapter 15), where they play a role in sound detection. Stereocilia are also found in some places where absorption is important, such as in the epithelium of the epididymis. In contrast, motile cilia contain microtubules, which allow them to move materials across the free surface of the cell (see chapter 3). Three types of ciliated epithelium line the respiratory tract (see chapter 23), where cilia move mucus containing foreign particles out of the respiratory airways. Cilia are also found on the apical surface of the simple columnar epithelial cells of the uterus and uterine tubes, where the cilia help move mucus and oocytes.

Transitional epithelium has a rather unusual plasma membrane specialization: rigid sections of membrane separated by very

TABLE 4.5 Functions and Locations of Epithelial Tissue

Function	LOCATION				
	Simple Squamous Epithelium	Simple Cuboidal Epithelium	Simple Columnar Epithelium	Stratified Squamous Epithelium	Stratified Cuboidal Epithelium
Diffusion	Blood and lymphatic capillaries, alveoli of lungs, thin segments of loops of Henle				
Filtration	Bowman capsules of kidneys				
Secretion or absorption	Mesothelium (serous fluid)	Choroid plexus (produces cerebrospinal fluid), part of kidney tubules, many glands and their ducts	Stomach, small intestine, large intestine, uterus, many glands		
Protection (against friction and abrasion)	Endothelium (e.g., epithelium of blood vessels) Mesothelium (e.g., epithelium of body cavities)			Skin (epidermis), corneas, mouth and throat, epiglottis, larynx, esophagus, anus, vagina	
Movement of mucus (ciliated)		Terminal bronchioles of lungs	Bronchioles of lungs, auditory tubes, uterine tubes, uterus		
Capable of great stretching					
Miscellaneous	Inner part of tympanic membranes, smallest ducts of glands	Surface of ovaries, inside lining of eyes (pigmented epithelium of retina), ducts of glands	Bile duct, gallbladder, ependyma (lining of brain ventricles and central canal of spinal cord), ducts of glands	Lower part of urethra, sebaceous gland ducts	Sweat gland ducts

flexible regions in which the plasma membrane is folded. When transitional epithelium is stretched, the folded regions of the plasma membrane can unfold. Transitional epithelium is specialized to expand in tissues such as the urinary bladder.

Cell Connections

Cells have structures that hold them to one another or to the basement membrane. These structures do three things: (1) mechanically bind the cells together, (2) help form a permeability barrier, and (3) provide a mechanism for intercellular communication.

Epithelial cells have cell surface glycoproteins, which attach to other glycoproteins located on adjacent cells and in the basement membrane. Among the glycoprotein connections between cells, there are some relatively strong adhesive structures called **desmosomes** (dez/mō-sōmz). Desmosomes consist of adhesive glycoproteins that bind cells together and intracellular proteins attached to intermediate filaments that extend into the cytoplasm of the cells (figure 4.2). Many desmosomes are found in

epithelial tissues that are subjected to stress, such as the stratified squamous epithelium of the skin. **Hemidesmosomes**, similar to one-half of a desmosome, attach epithelial cells to the basement membrane.

Tight junctions hold cells together and form a permeability barrier (figure 4.2). Tight junctions are formed by proteins in the plasma membranes of adjacent cells that join one another to make a very tight seal. Near the free surface of simple epithelial cells, the tight junctions form a ring that completely surrounds each cell and binds adjacent cells together to prevent the passage of materials between cells. For example, in the stomach and the urinary bladder, chemicals cannot pass between cells. Thus, water and other substances must pass through the epithelial cells, which can actively regulate what is absorbed or secreted. Tight junctions are found in areas where a layer of simple epithelium forms a permeability barrier. For example, water can diffuse through epithelial cells, and active transport, symport, and facilitated diffusion move most nutrients through the epithelial cells of the small intestine.

Stratified Columnar Epithelium	Pseudostratified Columnar Epithelium	Transitional Epithelium
	Larynx, nasal cavity, paranasal sinuses, nasopharynx, auditory tubes, trachea, bronchi of lungs	
		Urinary bladder, ureter, superior part of urethra
Part of male urethra, epididymides, ductus deferens, mammary gland ducts	Part of male urethra, salivary gland ducts	

An **adhesion belt** of glycoproteins is found just below the tight junction. It is located between the plasma membranes of adjacent cells and acts as a weak glue that holds cells together. These connections are not as strong as those of desmosomes.

A **gap junction** is a small, specialized contact region between cells containing protein channels that aid intercellular communication by allowing ions and small molecules to pass from one cell to another (figure 4.2). In epithelium, the function of gap junctions is not entirely clear; gap junctions between ciliated epithelial cells may coordinate the movements of cilia. In cardiac and smooth muscle tissues, gap junctions are important in coordinating important functions. Because ions can pass through the gap junctions from one cell to the next, electrical signals can pass from cell to cell to coordinate the contraction of cardiac and smooth muscle cells. Thus, electrical signals that originate in one cell of the heart can spread from cell to cell and cause the entire heart to contract. In the heart, the gap junctions between cardiac muscle cells are found in specialized cell-to-cell connections called **intercalated disks** (see chapter 20). Intercalated disks

FUNDAMENTAL Figure

FIGURE 4.2 Cell Connections

Desmosomes, adhesion belts, and tight junctions anchor cells to one another, and hemidesmosomes anchor cells to the basement membrane. Gap junctions allow adjacent cells to communicate with each other. Few cells have all of these different connections.

contain both gap junctions and desmosomes that help hold adjacent cells in close contact.

Predict 3

If a simple epithelium has well-developed tight junctions, explain how NaCl can move from one side of the epithelial layer to the other, what type of epithelium it is likely to be, and how the movement of NaCl causes water to move in the same direction.

ASSESS YOUR PROGRESS

16. What is the function of each of the following characteristics of an epithelial free surface: is smooth, has cilia, has microvilli, is folded? Give an example of where each surface type is found in the body.
17. Name the possible ways by which epithelial cells are bound to one another and to the basement membrane.
18. What role do desmosomes play in the skin?
19. What is the general function of gap junctions?

Glands

Glands are secretory organs. Glands are composed primarily of epithelium, with a supporting network of connective tissue. These glands develop from an infolding or outfolding of epithelium in the embryo. If the gland maintains an open contact with the epithelium from which it developed, a duct is present. Glands with ducts are called **exocrine** (ek'sō-krin) **glands**. Both the glands and their ducts are lined with epithelium. Alternatively, some glands become separated from the epithelium of their origin and have no ducts; these are called **endocrine** (en'dō-krin) **glands**. Endocrine glands have extensive blood vessels. The cellular products of endocrine glands, which are called **hormones** (hōr'mōnz), are secreted into the bloodstream and carried throughout the body.

Most exocrine glands are composed of many cells and are called **multicellular glands**, but some exocrine glands are composed of a single cell and are called **unicellular glands** (figure 4.3a). For example, **goblet cells** (see table 4.2c) are unicellular glands that secrete mucus.

Multicellular exocrine glands can be classified according to the structure of their ducts and secretory regions (figure 4.3). **Simple glands** have a single, nonbranched duct. If there are multiple secretory regions that branch off the duct, then the gland is called branched. **Compound glands** have multiple, branched ducts. For both simple and compound glands, the shape of the secretory regions further defines the gland. Glands with secretory regions shaped as tubules (small tubes) are called **tubular**, whereas those

(a) **Simple glands (single, nonbranched ducts)**

(b) **Compound glands (multiple, branched ducts)**

FIGURE 4.3 Structure of Exocrine Glands

The names of exocrine glands are based on the structure of their ducts (simple or compound) and the structure of their secretory regions (tubular, acinar or alveolar, or tubuloacinar).

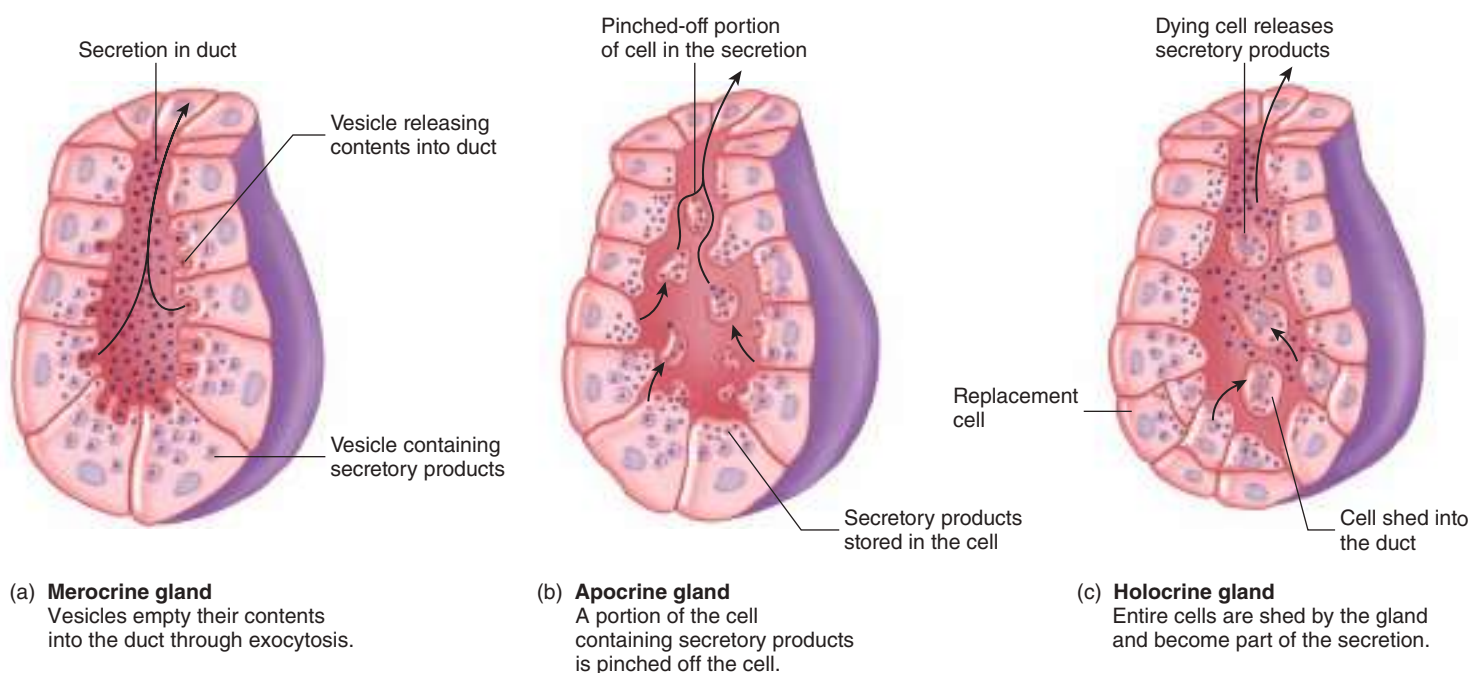

FIGURE 4.4 Exocrine Glands and Secretion Types

Exocrine glands are classified by type of secretion.

shaped in saclike structures are called **acinar** (as'i-nar) or **alveolar** (al-vē'ō-lar). Tubular glands can be straight or coiled. Glands with a combination of the two are called tubuloacinar or tubuloalveolar.

Exocrine glands can also be classified according to how products leave the cell. The most common type of secretion is **merocrine** (mer'ō-krin) **secretion**. Merocrine secretion involves the release of secretory products by exocytosis (figure 4.4a). Merocrine secretion is used by water-producing sweat glands and the exocrine portion of the pancreas. **Apocrine** (ap'ō-krin) **secretion** involves the release of secretory products as pinched-off fragments of the gland cells (figure 4.4b). The milk-producing mammary glands release milk by a combination of apocrine and mostly merocrine secretion. **Holocrine** (hol'ō-krin) **secretion** involves the shedding of entire cells (figure 4.4c). Products accumulate in the cytoplasm of each epithelial cell, the cell ruptures and dies, and the entire cell becomes part of the secretion. The lost cells are replaced by other cells deeper in the gland. Holocrine secretion is used by the sebaceous (oil) glands of the skin.

ASSESS YOUR PROGRESS

20. Distinguish between exocrine and endocrine glands. How are multicellular exocrine glands classified on the basis of their duct system? Their secretory portion shape?
21. Give an example of a unicellular exocrine gland. What does it secrete?
22. Describe three ways in which exocrine glands release secretions. Give an example of each method.

4.4 Connective Tissue

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List and describe the major functions of connective tissue.**
- B. Identify the specialized cells found in connective tissue.**
- C. Describe the three main components of the extracellular matrix of connective tissue.**
- D. Discuss the types and functions of embryonic connective tissue.**
- E. Explain how adult connective tissue is classified.**
- F. Give an example of each type of connective tissue, describe its characteristic functions, and state its location in the body.**

Connective tissue is a diverse primary tissue type that makes up part of every organ in the body. Connective tissue differs from the other three tissue types in that it consists of cells separated from each other by abundant extracellular matrix. Connective tissue is diverse in both structure and function.

Functions of Connective Tissue

Connective tissue performs the following major functions:

1. **Enclosing and separating other tissues.** Sheets of connective tissue form capsules around organs, such as the liver and kidneys. Connective tissue also forms layers that separate tissues and organs. For example, connective tissues separate muscles, arteries, veins, and nerves from one another.

2. *Connecting tissues to one another.* Strong cables, or bands, of connective tissue called tendons attach muscles to bone, whereas connective tissue bands called ligaments hold bones together.
3. *Supporting and moving parts of the body.* Bones of the skeletal system provide rigid support for the body, and the semi-rigid cartilage supports structures such as the nose, ears, and joint surfaces. Joints between bones allow one part of the body to move relative to other parts.
4. *Storing compounds.* Adipose tissue (fat) stores high-energy molecules, and bones store minerals, such as calcium and phosphate.
5. *Cushioning and insulating.* Adipose tissue cushions and protects the tissue it surrounds and provides an insulating layer beneath the skin that helps conserve heat.
6. *Transporting.* Blood transports the gases, nutrients, enzymes, hormones, and cells of the immune system throughout the body.
7. *Protecting.* Cells of the immune system and blood protect against toxins and tissue injury, as well as against microorganisms. Bones protect underlying structures from injury.

Cells of Connective Tissue

The specialized cells of the various connective tissues produce the extracellular matrix. The name of the cell identifies the cell functions by means of one of the following suffixes: *-blast*, *-cyte*, or *-clast*. **Blasts** create the matrix, **cytes** maintain it, and **clasts** break it down for remodeling. Osteoblasts form bone (*osteo-*, bone), osteocytes maintain it, and osteoclasts break it down (see chapter 6). **Fibroblasts** are cells that form fibrous connective tissue, and **fibrocytes** maintain it. **Chondroblasts** form cartilage (*chondro-*, cartilage), and **chondrocytes** maintain it.

Adipocytes (ad'i-pōs-sītz), also called adipose (ad'i-pōs; fat) cells, contain large amounts of lipid. The lipid pushes the rest of the cell contents to the periphery, so that each cell appears to contain a large, centrally located lipid droplet with a thin layer of cytoplasm around it. Adipocytes are rare in some connective tissue types, such as cartilage, but abundant in others, such as loose connective tissue.

Mast cells play important roles in inflammation. They contain chemicals, such as heparin, histamine, and proteolytic enzymes, that are released in response to injury, such as trauma and infection. Mast cells commonly lie beneath membranes in loose connective tissue and along small blood vessels of organs.

White blood cells, or *leukocytes* (see chapter 19), continuously move from blood vessels into connective tissues. The rate of movement increases dramatically in response to injury or infection. In addition, accumulations of lymphocytes, a type of white blood cell, are common in some connective tissues, such as that beneath the epithelial lining of certain parts of the digestive system.

Macrophages are large, phagocytic cells found in some connective tissue types. They are derived from monocytes, a type of white blood cell. Macrophages are either fixed, meaning that they do not move through the connective tissue, or wandering, moving in ameboid fashion through the connective tissue. Macrophages phagocytize foreign and injured cells, and they play a major role in protecting against infections. **Platelets** are fragments of hemopoietic cells containing enzymes and special proteins that function in the clotting process to reduce bleeding from a wound.

Undifferentiated mesenchymal cells are a type of **adult stem cell** that persist in connective tissue. They have the potential to form multiple cell types, such as fibroblasts or smooth muscle cells, in response to injury.

Extracellular Matrix

The extracellular matrix of connective tissue has three major components: (1) protein fibers, (2) ground substance, and (3) fluid. Ground substance consists of nonfibrous protein and other molecules. The structure of the matrix gives connective tissue types most of their functional characteristics—for example, they enable bones and cartilage to bear weight, tendons and ligaments to withstand tension, and the skin's dermis to withstand punctures, abrasions, and other abuse.

Protein Fibers of the Matrix

Three types of protein fibers—collagen, reticular, and elastic—help form connective tissue.

Collagen (kol'a-jen) **fibers** consist the protein of collagen. Collagen is the most abundant protein in the body. It accounts for one-fourth to one-third of total body protein and 6% of total body weight. Collagen is synthesized within fibroblasts and secreted into the extracellular space. After collagen molecules are secreted, they are linked together to make long collagen fibrils. The collagen fibrils are then joined together in bundles to form collagen fibers (figure 4.5a). Collagen fibers are very strong and flexible, like microscopic ropes, but are not very elastic. There are at least 20 types of collagen fibers, many of which are specific to certain tissues. Type I collagen is the most abundant in the body. The flexible, ropelike strength of type I collagen fibers makes them well suited for tendons, ligaments, skin, and bone. These body structures need to resist being pulled yet have some flexibility. Type II collagen is found in cartilage, and type III is found in reticular fibers.

Reticular (re-tik'ū-lār; netlike) **fibers** are very fine collagen fibers and therefore not a chemically distinct category of fibers. However, reticular fibers are very different from collagen fibers. They are not as strong as most collagen fibers. They are very short, thin fibers that branch to form a network. Networks of reticular fibers fill spaces between tissues and organs.

Elastic fibers consist of the protein **elastin** (e-las'tin). As the name suggests, this protein has the ability to return to its original shape after being stretched or compressed, giving tissue an elastic quality. Fibroblasts secrete elastin polypeptide chains, which are linked together to form a network. The elastin network stretches like a rubber band in response to force and recoils when relaxed (figure 4.5b). Elastic fibers provide the elasticity of skin, lungs, and arteries.

Ground Substance of the Matrix

The **ground substance** consists of nonfibrous molecules. It is the “shapeless” background against which the collagen fibers are seen through the microscope. The two major components are hyaluronic acid and proteoglycans. **Hyaluronic** (hī'ā-loo-ron'ik; glassy appearance) **acid** is a long, unbranched polysaccharide chain composed of repeating disaccharide units. It gives a very slippery

(b) Elastic fibers

(c) Proteoglycan aggregates

FIGURE 4.5 Molecules of the Connective Tissue Matrix

quality to the fluids that contain it; for that reason, it is a good lubricant for joint cavities (see chapter 8). Hyaluronic acid is also present in large quantities in connective tissue and is the major component of the vitreous humor of the eye (see chapter 15).

A **proteoglycan** (prō'tē-ō-glī'kan) **monomer** is a large molecule that consists of a protein core attached to many long polysaccharides called **glycosaminoglycans** (glī-kōs-am-i-nō-glī'kanz). A common glycosaminoglycan is **chondroitin sulfate**. The protein cores of many proteoglycan monomers can attach through link proteins to a long molecule of hyaluronic acid to form a **proteoglycan aggregate** (figure 4.5c). Proteoglycan aggregates trap large quantities of water, which allows them to return to their original shape when compressed or deformed. There are several types of glycosaminoglycans, and their abundance varies with each connective tissue type.

Adhesive molecules in the ground substance hold the proteoglycan aggregates together, as well as attach them to cells of the tissue. Specific adhesive molecules predominate in certain types of ground substance. For example, **chondronectin** is in the ground substance of cartilage, **osteonectin** is in the ground substance of bone, and **fibronectin** is in the ground substance of fibrous connective tissue.

ASSESS YOUR PROGRESS

23. What is the main characteristic that distinguishes connective tissue from other tissues?
24. List the major functions of connective tissue, and give an example of a type of connective tissue that performs each function.
25. Explain the differences among -blast, -cyte, and -clast cells of connective tissue.
26. What are the three components of the extracellular matrix of connective tissue?
27. Contrast the structure and characteristics of collagen fibers, reticular fibers, and elastic fibers.
28. Describe the structure and functions of hyaluronic acid and proteoglycan aggregates.
29. What is the function of adhesive molecules? Give some specific examples.

Connective Tissue Classifications

Connective tissue types blend into one another, and the transition points cannot be identified precisely. As a result, connective tissue is somewhat arbitrarily classified by the type and proportions of cells and extracellular matrix components. Table 4.6 presents the classification of connective tissue used in this text.

TABLE 4.6**Classification of Connective Tissue**

Embryonic Connective Tissue

Red marrow	
Yellow marrow	

Two major categories of connective tissue are embryonic and adult. Embryonic connective tissue is called **mesenchyme** (mez'en-kīm). It is composed of fibroblasts surrounded by semi-fluid extracellular matrix containing delicate reticular fibers (table 4.7a). It forms in the embryo during the third and fourth weeks of development from mesoderm and neural crest cells (see

chapter 29), and all adult connective tissue types develop from it. By 8 weeks of development, most of the mesenchyme has become specialized to form the types of connective tissue seen in adults. The major source of remaining embryonic connective tissue in the newborn is in the umbilical cord, where it is called **mucous connective tissue**, or *Wharton's jelly* (table 4.7b). The structure of

TABLE 4.7 Embryonic Connective Tissue

(a) Mesenchyme

Structure: The mesenchymal cells are irregularly shaped; the extracellular matrix is abundant and contains scattered reticular fibers

Location: Mesenchyme is the embryonic tissue from which connective tissues, as well as other tissues, arise

(b) Mucous Connective Tissue

Structure: Mucous tissue is mesenchymal tissue that remains unspecialized; the cells are irregularly shaped; the extracellular matrix is abundant and contains scattered reticular fibers

Location: Umbilical cord of newborn

mucous connective tissue is similar to that of mesenchyme. The mucous connective tissue helps support the umbilical cord blood vessels between the mother and the child. After birth, the mucous connective tissue can also be a rich source of stem cells.

Adult connective tissue consists of three types: connective tissue proper (loose and dense), supporting connective tissue (cartilage and bone), and fluid connective tissue (blood).

Connective Tissue Proper

Loose Connective Tissue

Loose connective tissue (table 4.8) consists of relatively few protein fibers that form a lacy network, with numerous spaces filled with ground substance and fluid. Three subdivisions of loose connective tissue are areolar, adipose, and reticular.

Areolar (ă-r ē'ō-lăr) **tissue** is the “loose packing” material of most organs and other tissues; it attaches the skin to underlying tissues (table 4.8a). It contains collagen, reticular, and elastic fibers and a variety of cells. For example, fibroblasts produce the fibrous matrix; macrophages move through the tissue, engulfing bacteria and cell debris; mast cells contain chemicals that help mediate inflammation; and lymphocytes are involved in immunity. The loose packing of areolar tissue is often associated with the other loose connective tissue types, adipose and reticular tissue.

Adipose tissue and reticular tissue are connective tissues with special properties. **Adipose tissue** (table 4.8b) consists of adipocytes, which contain large amounts of lipid. Unlike other connective tissue types, adipose tissue is composed of large cells and a small amount of extracellular matrix, which consists of loosely arranged collagen and reticular fibers with some scattered elastic fibers. Blood vessels form a network in the extracellular matrix. The adipocytes are usually arranged in clusters, or lobules, separated from one another by loose connective tissue. Adipose tissue functions as an insulator, a protective tissue, and a site of energy storage. Lipids take up less space per calorie than either carbohydrates or proteins and therefore are well adapted for energy storage.

Adipose tissue exists in both yellow and brown forms. **Yellow adipose tissue** is by far the most abundant. Yellow adipose tissue appears white at birth, but it turns yellow with age because of the accumulation of pigments, such as carotene, a plant pigment that humans can metabolize as a source of vitamin A. In humans, **brown adipose tissue** is found in specific areas of the body, such as the axillae (armpits), the neck, and near the kidneys. The brown color results from the cytochrome pigments in the tissue's numerous mitochondria and its abundant blood supply. It is difficult to distinguish brown adipose from yellow adipose in babies because the color difference is not great. Brown adipose tissue is specialized to generate heat as a result of oxidative metabolism of lipid molecules in mitochondria. It can play a significant role in regulating body temperature in newborns and is now recognized to also play a role in adult metabolism (see chapter 25).

Reticular tissue forms the framework of lymphatic tissue (table 4.8c), such as in the spleen and lymph nodes, as well as in bone marrow and the liver. It is characterized by a network of reticular fibers and reticular cells. **Reticular cells** produce the reticular fibers and remain closely attached to them. The spaces between the reticular fibers can contain a wide variety of other

cells, such as macrophages, blood cells, and dendritic cells, which look very much like reticular cells but are cells of the immune system (see chapter 22).

Dense Connective Tissue

Dense connective tissue has a relatively large number of protein fibers, which form thick bundles and fill nearly all of the extracellular space. Most of the cells of developing dense connective tissue are spindle-shaped fibroblasts. Once the fibroblasts become completely surrounded by matrix, they are fibrocytes. Dense connective tissue can be subdivided into two major groups: regular and irregular.

Dense regular connective tissue has protein fibers in the extracellular matrix that are oriented predominantly in one direction. **Dense regular collagenous connective tissue** (table 4.9a) has abundant collagen fibers, which give this tissue a white appearance. Dense regular collagenous connective tissue forms structures such as tendons, which connect muscles to bones (see chapter 9), and most ligaments, which connect bones to bones (see chapter 8). The collagen fibers of dense connective tissue resist stretching and give the tissue considerable strength in the direction of the fiber orientation. Tendons and most ligaments consist almost entirely of thick bundles of densely packed, parallel collagen fibers with the orientation of the collagen fibers in one direction, which makes the tendons and ligaments very strong, cablelike structures.

The general structures of tendons and ligaments are similar, but they differ in the following respects: (1) The collagen fibers of ligaments are often less compact, (2) some fibers of many ligaments are not parallel, and (3) ligaments are usually more flattened than tendons and form sheets or bands of tissues.

Dense regular elastic connective tissue (table 4.9b) consists of parallel bundles of collagen fibers and abundant elastic fibers. The elastin in elastic ligaments gives them a slightly yellow color. Dense regular elastic connective tissue forms some elastic ligaments, such as those in the vocal folds and the **nuchal** (noo'käl; back of the neck) **ligament**, which lies along the posterior of the neck, helping hold the head upright. When elastic ligaments are stretched, they tend to shorten to their original length, much as an elastic band does.

► Predict 4

Explain the advantages of having elastic ligaments that extend from vertebra to vertebra in the vertebral column and why it would be a disadvantage if tendons, which connect skeletal muscles to bone, were elastic.

Dense irregular connective tissue contains protein fibers arranged as a meshwork of randomly oriented fibers. Alternatively, the fibers within a given layer of dense irregular connective tissue can be oriented in one direction, whereas the fibers of adjacent layers are oriented at nearly right angles to that layer. Dense irregular connective tissue forms sheets of connective tissue that have strength in many directions but less strength in any single direction than does regular connective tissue.

► Predict 5

Scars consist of dense irregular connective tissue made of collagen fibers. Vitamin C is required for collagen synthesis. Predict the effect of scurvy, which is a nutritional disease caused by vitamin C deficiency, on wound healing.

TABLE 4.8 **Connective Tissue Proper: Loose Connective Tissue**
(a) Areolar Connective Tissue **AP|R**

Structure: Cells (e.g., fibroblasts, macrophages, and lymphocytes) within a fine network of mostly collagen fibers; often merges with denser connective tissue

Function: Loose packing, support, and nourishment for the structures with which it is associated

Location: Widely distributed throughout the body; substance on which epithelial basement membranes rest; packing between glands, muscles, and nerves; attaches the skin to underlying tissues

(b) Adipose Tissue **AP|R**

Structure: Little extracellular matrix surrounding cells; the adipocytes are so full of lipid that the cytoplasm is pushed to the periphery of the cell

Function: Packing material, thermal insulation, energy storage, and protection of organs against injury from being bumped or jarred

Location: Predominantly in subcutaneous areas, in mesenteries, in renal pelvis, around kidneys, attached to the surface of the colon, in mammary glands, in loose connective tissue that penetrates spaces and crevices

(c) Reticular Tissue

Structure: Fine network of reticular fibers irregularly arranged

Function: Provides a superstructure for lymphatic and hemopoietic tissues

Location: Within the lymph nodes, spleen, bone marrow

TABLE 4.9 **Connective Tissue Proper: Dense Connective Tissue**
(a) Dense Regular Collagenous Connective Tissue **APR**

Structure: Matrix composed of collagen fibers running in somewhat the same direction

Function: Able to withstand great pulling forces exerted in the direction of fiber orientation; great tensile strength and stretch resistance

Dense irregular collagenous connective tissue (table 4.9c) forms most of the dermis, which is the tough, inner portion of the skin (see chapter 5), as well as the connective tissue capsules that surround organs such as the kidney and spleen.

Dense irregular elastic connective tissue (table 4.9d) is found in the walls of elastic arteries. In addition to collagen fibers, oriented in many directions, the layers of this tissue contain abundant elastic fibers.

TABLE 4.9 **Connective Tissue Proper: Dense Connective Tissue—Continued**
(c) Dense Irregular Collagenous Connective Tissue

Structure: Matrix composed of collagen fibers that run in all directions or in alternating planes of fibers oriented in a somewhat single direction

Function: Tensile strength capable of withstanding stretching in all directions

Location: Sheaths; most of the dermis of the skin; organ capsules and septa; outer covering of body tubes

ASSESS YOUR PROGRESS

30. List the two types of embryonic tissue. What does mesenchyme give rise to in the adult? What is the purpose of mucous connective tissue?
31. What are the three classifications of adult connective tissue, and what tissue types are included in each?
32. Describe the fiber arrangement in loose (areolar) connective tissue. What are the functions of this tissue type, and where is it found in the body?
33. What structural features distinguish adipose tissue from other types of connective tissue? What is an adipocyte?
34. Name the two types of adipose tissue, and give the functions of each. Which type is primarily found in infants?
35. What is the function of reticular tissue? Where is it found?

36. Structurally and functionally, what is the difference between dense regular connective tissue and dense irregular connective tissue?
37. Name the two kinds of dense regular connective tissue, and give an example of each. Do the same for dense irregular connective tissue.

Supporting Connective Tissue
Cartilage

Cartilage (kar'ti-lij) is composed of cartilage cells within an extensive and relatively rigid matrix. The surface of nearly all cartilage is surrounded by a layer of dense irregular connective tissue called the **perichondrium** (per-i-kon'drē-ŭm), described in more detail in chapter 6. Cartilage cells arise from the

perichondrium and secrete cartilage matrix. Once completely surrounded by matrix, the cartilage cells are called **chondrocytes** (kon'drō-sītz), and the spaces in which they are located are called **lacunae** (lă-koo'nē). The matrix contains protein fibers, ground substance, and fluid. The protein fibers are collagen fibers or a mixture of collagen and elastic fibers. The ground substance consists of proteoglycans and other organic molecules. Most of the proteoglycans in the matrix form aggregates with hyaluronic acid. Within the cartilage matrix, proteoglycan aggregates function as minute sponges capable of trapping large quantities of water. This trapped water allows cartilage to spring back after being compressed. The collagen fibers give cartilage considerable strength. Next to bone, cartilage is the firmest structure in the body.

Cartilage has no blood vessels or nerves, except those of the perichondrium; it therefore heals very slowly after an injury because the cells and nutrients necessary for tissue repair cannot reach the damaged area easily.

There are three types of cartilage:

1. **Hyaline** (hī'ă-lin) **cartilage** has large amounts of both collagen fibers and proteoglycans (table 4.10*a*). Collagen fibers are evenly dispersed throughout the ground substance, and hyaline cartilage in joints has a very smooth surface. Specimens appear to have a glassy, translucent matrix when viewed through a microscope. Hyaline cartilage is found where strong support and some flexibility are needed, such as in the rib cage and within the trachea and bronchi (see chapter 23). It also covers the surfaces of bones that move smoothly against each other in joints. Hyaline cartilage forms most of the skeleton before it is replaced by bone in the embryo, and it is involved in growth that increases the length of bones (see chapter 6).

2. **Fibrocartilage** has more collagen fibers than proteoglycans (table 4.10*b*). Compared with hyaline cartilage, fibrocartilage has much thicker bundles of collagen fibers dispersed through its matrix. Fibrocartilage is slightly compressible and very tough. It is found in areas of the body where a great deal of pressure is applied to joints, such as in the knee, in the jaw, and between the vertebrae. Some joints, such as the knee, have both hyaline and fibrocartilage connective tissue. In these joints, pads of fibrocartilage help absorb shocks and prevent bone-to-bone abrasion. Fibrocartilage injuries of the knee joint (meniscus tears) are common sports-related injuries.
3. **Elastic cartilage** has numerous elastic fibers in addition to collagen and proteoglycans dispersed throughout its matrix (table 4.10*c*). It is found in areas that have rigid but elastic properties, such as the external ears.

► Predict 6

One of several changes caused by rheumatoid arthritis in joints is the replacement of hyaline cartilage with dense irregular collagenous connective tissue. Predict the effect of replacing hyaline cartilage with fibrous connective tissue.

Bone

Bone is a hard connective tissue that consists of living cells and mineralized matrix. Bone matrix has organic and inorganic portions. The organic portion consists of protein fibers, primarily collagen, and other organic molecules. The mineral, or inorganic, portion consists of specialized crystals called **hydroxyapatite** (hī-drok'sē-ap-ă-tīt), which contains calcium and phosphate. The strength and

TABLE 4.10 Supporting Connective Tissue: Cartilage

(a) Hyaline Cartilage APR

Structure: Collagen fibers are small and evenly dispersed in the matrix, making the matrix appear transparent; the chondrocytes are found in spaces, or lacunae, within the firm but flexible matrix

Function: Allows the growth of long bones; provides rigidity with some flexibility in the trachea, bronchi, ribs, and nose; forms strong, smooth, yet somewhat flexible articulating surfaces; forms the embryonic skeleton

Location: Growing long bones, cartilage rings of the respiratory system, costal cartilage of ribs, nasal cartilages, articulating surface of bones, embryonic skeleton

Chondrocyte
in a lacuna

Nucleus

Matrix

TABLE 4.10 Supporting Connective Tissue: Cartilage—Continued

(b) Fibrocartilage **AP|R**

Structure: Collagen fibers similar to those in hyaline cartilage; the fibers are more numerous than in other cartilages and are arranged in thick bundles

Function: Somewhat flexible and capable of withstanding considerable pressure; connects structures subjected to great pressure

Location: Intervertebral disks, symphysis pubis, articular disks (e.g., knee and temporomandibular [jaw] joints)

**(c) Elastic Cartilage** **AP|R**

Structure: Similar to hyaline cartilage, but matrix also contains elastic fibers

Function: Provides rigidity with even more flexibility than hyaline cartilage because elastic fibers return to their original shape after being stretched

Location: External ears, epiglottis, auditory tubes

rigidity of the mineralized matrix allow bones to support and protect other tissues and organs. **Osteocytes** (os'tē-ō-sītz), or bone cells, are located within holes in the matrix, which are called lacunae and are similar to the lacunae of cartilage.

Two types of bone exist:

1. **Spongy bone** has spaces between **trabeculae** (tră-bek'ū-lē; beams), or plates, of bone and therefore resembles a sponge (table 4.11a).
2. **Compact bone** is more solid, with almost no space between many thin layers, or **lamellae** (lă-mel'ē; sing. lă-mel'ă) of bone (table 4.11b).

Bone, unlike cartilage, has a rich blood supply. For this reason, bone can repair itself much more readily than can cartilage. Bone and bone cells are described more fully in chapter 6.

Fluid Connective Tissue**Blood**

Blood is unusual among the connective tissues because the matrix between the cells is liquid (table 4.12a). The cells of most other connective tissues are more or less stationary within a relatively rigid matrix, but blood cells move freely within a fluid matrix. Blood's liquid matrix allows it to flow rapidly through the body,

TABLE 4.11 Supporting Connective Tissue: Bone

(a) Spongy Bone

Structure: Latticelike network of scaffolding characterized by trabeculae with large spaces between them filled with hemopoietic tissue; the osteocytes, or bone cells, are located within lacunae in the trabeculae

Function: Acts as scaffolding to provide strength and support without the greater weight of compact bone

Location: In the interior of the bones of the skull, vertebrae, sternum, and pelvis; in the ends of the long bones

**(b) Compact Bone**

Structure: Hard, bony matrix predominates; many osteocytes (not seen in this bone preparation) are located within lacunae that are distributed in a circular fashion around the central canals; small passageways connect adjacent lacunae

Function: Provides great strength and support; forms a solid outer shell on bones that keeps them from being easily broken or punctured

Location: Outer portions of all bones, the shafts of long bones

carrying nutrients, oxygen, waste products, and other materials. The matrix of blood is also unusual in that most of it is produced by cells contained in other tissues, rather than by blood cells. There are three types of cellular structures: red blood cells, white blood cells, and cell fragments called platelets. White blood cells sometimes leave the bloodstream and wander through other tissues. Blood is discussed more fully in chapter 19.

Hemopoietic tissue

Hemopoietic (hē'mō-poy-et'ik) **tissue** forms blood cells. In adults, hemopoietic tissue is found in **bone marrow** (mar'ō;

table 4.12b), which is the soft connective tissue in the cavities of bones. There are two types of bone marrow: **red marrow** and **yellow marrow** (see chapter 6). Red marrow is hemopoietic tissue surrounded by a framework of reticular fibers. Hemopoietic tissue produces red and white blood cells and platelets; it is described in detail in chapter 19. In children, the marrow of most bones is red marrow. Yellow marrow consists of yellow adipose tissue and does not produce blood cells. As children grow, yellow marrow replaces much of the red marrow in bones.

TABLE 4.12 Fluid Connective Tissue: Blood and Hemopoietic Tissue

(a) Blood **AP|R**
Structure: Blood cells and a fluid matrix

Function: Transports oxygen, carbon dioxide, hormones, nutrients, waste products, and other substances; protects the body from infections and is involved in temperature regulation

Location: Within the blood vessels; white blood cells frequently leave the blood vessels and enter the interstitial spaces

(b) Bone Marrow **AP|R**
Structure: Reticular framework with numerous blood-forming cells (red marrow)

Function: Produces new blood cells (red marrow); stores lipids (yellow marrow)

Location: Within marrow cavities of bone; two types: (1) red marrow (hemopoietic, or blood-forming, tissue) in the ends of long bones and in short, flat, and irregularly shaped bones and (2) yellow marrow, mostly adipose tissue, in the shafts of long bones

ASSESS YOUR PROGRESS

38. Describe the cells and matrix of cartilage. What are lacunae? What is the perichondrium? Why does cartilage heal slowly?
39. What are the three types of cartilage? How do they differ in structure and function? Where would each type be found in the body?
40. Describe the cells and matrix of bone. Differentiate between spongy and compact bone.
41. What characteristic separates blood from other connective tissues? What are the three formed elements in blood?
42. Describe the function of hemopoietic tissue. Explain the difference between red marrow and yellow marrow.

4.5 Muscle Tissue

LEARNING OUTCOME

After reading this section, you should be able to

- A. Discuss the three types of muscle tissue by describing their general structures, locations in the body, and functions.**

The main characteristic of **muscle tissue** is that it contracts, or shortens, with a force and therefore is responsible for movement. Muscle contraction is accomplished by the interaction of

Clinical GENETICS

Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder that affects approximately 1 in 5000 people. The gene for Marfan syndrome codes for a protein called fibrillin-1, which is necessary for the normal structure of the elastic fibers of connective tissue. Children of a person with Marfan syndrome have a 50% chance of inheriting the disorder because it is an autosomal dominant trait (see chapter 29). However, about 25% of the cases of Marfan syndrome occur in children whose parents do not have the disorder. In these cases, a mutation of the gene

occurs during the formation of sperm cells or oocytes.

Many people with Marfan syndrome have limbs, fingers, and toes that are disproportionately long in relation to the rest of the body. Connective tissues are weakened; as a consequence, the heart valves, which are composed largely of connective tissue, do not function normally, resulting in heart murmurs (abnormal heart sounds). Poor vision is common because the lenses of the eyes, which are normally held in place by elastic fibers, are positioned abnormally. The lungs are prone to

collapse, and dilation of large arteries, such as the aorta, can occur. A common cause of death in people with Marfan syndrome is rupture of the aorta. There is no cure for the condition, but treatments can reduce the danger of the symptoms. For example, drugs that lower blood pressure reduce the vascular risks.

It has been speculated that President Lincoln may have had Marfan syndrome, but some geneticists now think it more likely that he had a rare inherited form of endocrine cancer that includes physical features of Marfan syndrome.

contractile proteins, which are described in chapter 9. Muscles contract to move the entire body, to pump blood through the heart and blood vessels, and to decrease the size of hollow organs, such as the stomach and urinary bladder. The three types of muscle tissue—skeletal, cardiac, and smooth muscle—are grouped according to both structure and function (table 4.13).

Skeletal muscle is what we normally think of as “muscle” (table 4.14*a*). It is the meat of animals and constitutes about 40% of a person’s body weight. As the name implies, skeletal muscle attaches to the skeleton and enables the body to move. Skeletal muscle is under voluntary (conscious) control because a person can

purposefully cause skeletal muscle contraction to achieve specific body movements. However, the nervous system can cause skeletal muscles to contract without conscious involvement, as occurs during reflex movements and the maintenance of muscle tone. Skeletal muscle cells are long, cylindrical cells, each containing many nuclei located at the periphery of the cell. Some skeletal muscle cells extend the entire length of a muscle. Skeletal muscle cells are **striated** (strī’āt-ed), or banded, because of the arrangement of contractile proteins within the cells (see chapter 9).

Cardiac muscle is the muscle of the heart; it is responsible for pumping blood (table 4.14*b*). Cardiac muscle is under

TABLE 4.13 Comparison of Muscle Types

	Skeletal Muscle	Cardiac Muscle	Smooth Muscle
Location	Attached to bones	In the heart	In the walls of hollow organs, blood vessels, eyes, glands, skin
Cell Shape	Very long, cylindrical cells (1–4 cm and may extend the entire length of the muscle, 10–100 μm in diameter)	Cylindrical cells that branch (100–500 μm in length, 12–20 μm in diameter)	Spindle-shaped cells (15–200 μm in length, 5–8 μm in diameter)
Nucleus	Multinucleated, peripherally located	Single, centrally located	Single, centrally located
Striations	Yes	Yes	No
Control	Voluntary (conscious)	Involuntary (unconscious)	Involuntary (unconscious)
Ability to Contract Spontaneously	No	Yes	Yes
Function	Moves the body	Provides the major force for moving blood through the blood vessels	Moves food through the digestive tract, empties the urinary bladder, regulates blood vessel diameter, changes pupil size, contracts many gland ducts, moves hair, performs many other functions
Special Features	None	Branching fibers, intercalated disks containing gap junctions joining the cells to each other	Gap junctions

TABLE 4.14 Muscle Tissue

(a) Skeletal Muscle **APR**

Structure: Skeletal muscle cells or fibers appear striated (banded); cells are large, long, and cylindrical, with many nuclei located at the periphery

Function: Moves the body; is under voluntary (conscious) control

Location: Attached to bone or other connective tissue

(b) Cardiac Muscle **APR**

Structure: Cardiac muscle cells are cylindrical and striated and have a single, centrally located nucleus; they are branched and connected to one another by intercalated disks, which contain gap junctions

Function: Pumps the blood; is under involuntary (unconscious) control

Location: In the heart

TABLE 4.14 Muscle Tissue—Continued

(c) Smooth Muscle 

Structure: Smooth muscle cells are tapered at each end, are not striated, and have a single nucleus

Function: Regulates the size of organs, forces fluid through tubes, controls the amount of light entering the eye, and produces “goose bumps” in the skin; is under involuntary (unconscious) control

Location: In hollow organs, such as the stomach and small and large intestines

involuntary (unconscious) control, although a person can learn to influence the heart rate by using techniques such as meditation and biofeedback. Cardiac muscle cells are cylindrical but much shorter than skeletal muscle cells. Cardiac muscle cells are striated and usually have one nucleus per cell. They are often branched and connected to one another by **intercalated** (in-ter'kă-lā-ted; inserted between) **disks**, which contain specialized gap junctions and are important in coordinating cardiac muscle cell contractions (see chapter 20).

Smooth muscle forms the walls of hollow organs (except the heart); it is also found in the skin and eyes (table 4.14c). Smooth muscle is responsible for a number of functions, such as moving food through the digestive tract and emptying the urinary bladder. Like cardiac muscle, smooth muscle is controlled involuntarily. Smooth muscle cells are tapered at each end, have a single nucleus, and are not striated.

ASSESS YOUR PROGRESS

43. Functionally, what is unique about muscle tissue?
44. Compare the structure of skeletal, cardiac, and smooth muscle cells.
45. Which type of muscle is under voluntary control?
46. Where is each type of muscle tissue found, and what tasks does each perform?

4.6 Nervous Tissue

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe the structural and functional roles of neurons and glia in the nervous tissue.

Nervous tissue is found in the brain, spinal cord, and nerves and is characterized by the ability to conduct electrical signals called **action potentials**. Nervous tissue consists of neurons, which are responsible for its conductive ability, and support cells called **glia**.

Neurons, or *nerve cells*, are the conducting cells of nervous tissue. Just as an electrical wiring system transports electricity throughout a house, neurons transport electrical signals throughout the body. A neuron is composed of three major parts: a cell body, dendrites, and an axon. The **cell body** contains the nucleus and is the site of general cell functions. Dendrites and axons consist of projections of cytoplasm surrounded by membrane. **Dendrites** (den'drītz) usually receive action potentials. They are much shorter than axons and have multiple branches at their ends. The **axon** (ak'son) usually conducts action potentials away from the cell body. Axons can be much longer than dendrites, and they have a constant diameter along their entire length.

Neurons can be grouped based on their structure. **Multipolar neurons** have multiple dendrites and a single axon (table 4.15a). **Bipolar neurons** have a single dendrite and an axon. **Pseudo-unipolar neurons** have only a single, short process that extends from the cell body and then divides into two branches, which extend to the periphery and to the central nervous system (table 4.15b). The two branches function as a single axon,

although there are dendritelike receptors on the peripheral branch. Within each of these subgroups are many shapes and sizes of neurons, especially in the brain and spinal cord.

Glia (g'lē-ă; glue) are the support cells of the brain, spinal cord, and peripheral nerves (table 4.15). Glia nourish, protect, and insulate neurons. Neurons and glia cells are described in greater detail in chapter 11.

TABLE 4.15 Types of Neurons

(a) Multipolar Neuron 

Structure: The neuron consists of dendrites, a cell body, and a long axon; glia, or support cells, surround the neurons

Function: Neurons transmit information in the form of action potentials, store “information,” and integrate and evaluate data; glia support, protect, and form specialized sheaths around axons

Location: In the brain, spinal cord, ganglia

(b) Pseudo-Unipolar Neuron

Structure: The neuron consists of a cell body with one axon

Function: Conducts action potentials from the periphery to the brain or spinal cord

Location: In ganglia outside the brain and spinal cord

ASSESS YOUR PROGRESS

47. What is the characteristic function of nervous tissue?
48. Define and list the functions of the cell body, dendrites, and axon of a neuron.
49. Differentiate among multipolar, bipolar, and pseudo-unipolar neurons.
50. What are the functions of glia?

4.7 Tissue Membranes

LEARNING OUTCOME

After reading this section, you should be able to

- A. List the structural and functional characteristics of mucous, serous, and synovial membranes.

A tissue membrane is a thin sheet of tissue that covers a structure or lines a cavity. Most membranes are formed from a superficial epithelial tissue and the connective tissue on which it rests. There are four tissue membranes in the body, one external and three internal. The external membrane is the skin, or cutaneous membrane (see chapter 5). The three major categories of internal membranes are mucous, serous, and synovial membranes.

Mucous Membranes

A **mucous** (mū'kūs) **membrane** lines cavities and canals that open to the outside of the body, such as the digestive, respiratory, excretory, and reproductive passages (figure 4.6a). Mucous membranes consist of epithelial cells, their basement membrane, and a thick layer of loose connective tissue called the **lamina propria** (lam'i-nă prō'prē-ă). Some mucous membranes also contain a layer of smooth muscle cells. Many, but not all, mucous membranes contain goblet cells or multicellular mucous glands that secrete **mucus** (mū'kūs), a viscous protein substance. The functions of the mucous membranes vary, depending on their location, and include protection, absorption, and secretion. For example, the stratified squamous epithelium of the oral cavity performs a protective function, whereas the simple columnar epithelium of the small intestine absorbs nutrients and secretes digestive enzymes and mucus. Mucous membrane also lines the nasal passages. When that membrane becomes inflamed, we experience the “runny nose” characteristic of the common cold or an allergy.

Serous Membranes

A **serous** (sēr'ūs) **membrane** lines cavities that do not open to the exterior of the body (figure 4.6b), such as the pericardial, pleural, and peritoneal cavities. Serous membranes consist of three components: a layer of simple squamous epithelium called **mesothelium** (mez-ō-thē'lē-ŭm), its basement membrane, and a delicate layer of loose connective tissue. Serous membranes do not contain glands, but they secrete a small amount of fluid called **serous fluid**, which lubricates the serous membranes, making their surfaces slippery. Serous membranes protect the internal organs from friction, help hold them

FUNDAMENTAL Figure

FIGURE 4.6 Internal Tissue Membranes

(a) Mucous membranes line cavities that open to the outside and often contain mucous glands, which secrete mucus. (b) Serous membranes line cavities that do not open to the exterior; they do not contain glands but do secrete serous fluid. (c) Synovial membranes line cavities that surround synovial joints.

in place, and act as selectively permeable barriers to prevent large amounts of fluid from accumulating within the serous cavities.

Synovial Membranes

Synovial (si-nō'vē-ăl) **membranes** line freely movable joints (figure 4.6c). Synovial membranes are made up of only connective tissue. They consist of modified connective tissue cells,

either intermixed with part of the dense connective tissue of the joint capsule or separated from the capsule by areolar or adipose tissue. They produce **synovial fluid**, which is rich in hyaluronic acid, making the joint fluid very slippery, thus facilitating smooth movement within the joint. Synovial and other connective tissue membranes are discussed in chapter 8.

ASSESS YOUR PROGRESS

51. Compare mucous, serous, and synovial membranes according to the types of cavities they line and their secretions.
52. What are the functions of mucous, serous, and synovial membranes?

4.8 Tissue Damage and Inflammation

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the process of inflammation in response to tissue damage and explain how inflammation protects the body.
- B. Relate the five major signs of inflammation and how they are produced.

Inflammation (*flamma*, flame) is the response that occurs when tissues are damaged. Although many agents cause injury, such as microorganisms, cold, heat, radiant energy, chemicals, electricity, and mechanical trauma, the inflammatory response to all of them is similar. The **inflammatory response** mobilizes the body's defenses, isolates and destroys microorganisms and other injurious agents, and removes foreign materials and damaged cells, so that tissue repair can proceed (see chapter 22). Figure 4.7 illustrates the stages of the inflammatory response.

Inflammation has five major manifestations: redness, heat, swelling, pain, and disturbed function. Although unpleasant, these processes usually aid recovery, and each of the symptoms can be understood in terms of events that occur during the inflammatory response.

After a person is injured, chemical substances called **chemical mediators** are released or activated in the tissues and the adjacent blood vessels. The mediators are histamine, kinins, prostaglandins, leukotrienes, and others. Some mediators induce dilation of blood vessels and produce redness and heat. Dilation of blood vessels is beneficial because it speeds the arrival of white blood cells and other substances important for fighting infections and repairing the injury.

Chemical mediators also stimulate pain receptors and increase the permeability of blood vessels. The increased permeability allows materials such as clotting proteins and white blood cells to move out of the blood vessels and into the tissue, where they can deal directly with the injury. As proteins from the blood move into the tissue, they change the osmotic relationship between the blood and the tissue. Water follows the proteins by osmosis, and the tissue swells, producing **edema** (e-dē'mă). Edema increases the pressure in the tissue, which can also stimulate neurons and cause pain.

Clotting proteins present in blood diffuse into the interstitial spaces and form a clot. Clotting also occurs by platelet aggregation in the injured blood vessels. Clotting isolates the injurious agent and separates it from the rest of the body. Foreign particles and microorganisms at the site of injury are “walled off” from tissues by the clotting process. Pain, limitation of movement resulting from edema, and tissue destruction all contribute to the disturbed function. This disturbance can be valuable because it warns the person to protect the injured structure from further damage. Sometimes the inflammatory response lasts longer or is more intense than is desirable, and the patient is given drugs to suppress the symptoms. Antihistamines block the effects of histamine, aspirin prevents the synthesis of prostaglandins, and cortisone reduces the release of several chemical mediators that cause inflammation. Still, the inflammatory response by itself may not be enough to combat the effects of injury or fight off an infection, and the patient may require antibiotics.

Predict 7

In some injuries, tissues are so severely damaged that some cells die and blood vessels are destroyed. For such injuries, where do the signs of inflammation, such as redness, heat, edema, and pain, occur?

ASSESS YOUR PROGRESS

53. What is the function of the inflammatory response?
54. Name the five manifestations of inflammation; explain how each is produced and the benefits of each.

4.9 Tissue Repair

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the three groups of cells based on their ability to regenerate.
- B. Explain the major events involved in tissue repair.

Tissue repair is the substitution of viable cells for dead cells by regeneration or replacement. In **regeneration** (rē'jen-er-ā'shŭn), the new cells are the same type as those that were destroyed, and normal function is usually restored. In **replacement**, a new type of tissue develops, which eventually produces a scar and causes the loss of some tissue function. Most wounds heal through regeneration and replacement; which process dominates depends on the tissues involved and the nature and extent of the wound.

Cells are classified into three groups according to their ability to regenerate—labile, stable, or permanent cells. **Labile cells** continue to divide throughout life. Labile cells include adult stem cells and other cells of the skin, mucous membranes, and hemopoietic and lymphatic tissues. Damage to these cells can be repaired completely by regeneration. **Stable cells**, such as those of connective tissues and glands, including the liver, pancreas, and endocrine glands, do not normally divide after

- 1 A splinter in the skin causes damage and introduces bacteria. Chemical mediators of inflammation are released or activated in injured tissues and adjacent blood vessels. Some blood vessels rupture, causing bleeding.
- 2 Chemical mediators cause capillaries to dilate and the skin to become red. Chemical mediators also increase capillary permeability, and fluid leaves the capillaries, producing swelling (arrows).

- 3 White blood cells (e.g., neutrophils) leave the dilated blood vessels and move to the site of bacterial infection, where they begin to phagocytize bacteria and other debris.

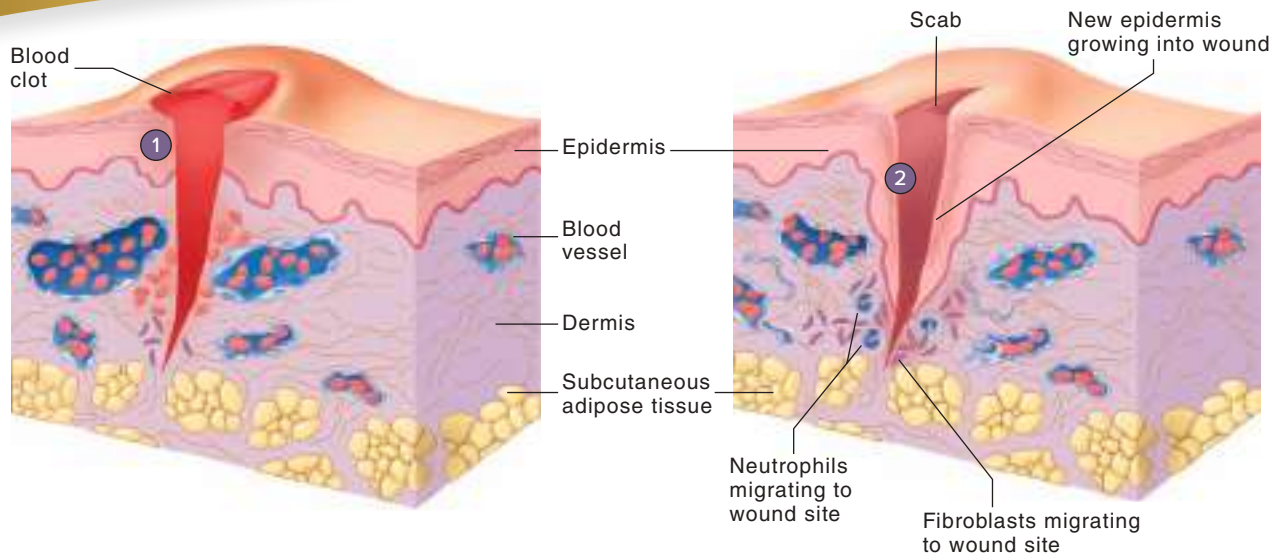

PROCESS FIGURE 4.7 Stages of the Inflammatory Response

growth ceases, but they retain the ability to divide and are capable of regeneration in response to injury. **Permanent cells** have a very limited ability to replicate and, if killed, are usually replaced by a different type of cell. Some permanent cells, such as neurons, are postmitotic. If damaged, neurons may recover if the cell body is not destroyed; however, if the neuron cell body is destroyed, the remainder of the neuron dies. Some undifferentiated cells of the central nervous system are stem cells that can undergo mitosis and form functional neurons in the adult. This has raised hope that damaged areas of the brain

may be regenerated. Undifferentiated cells of skeletal and cardiac muscle also have a very limited ability to regenerate in response to injury, although individual skeletal and cardiac muscle cells can repair themselves. In contrast, smooth muscle readily regenerates following injury.

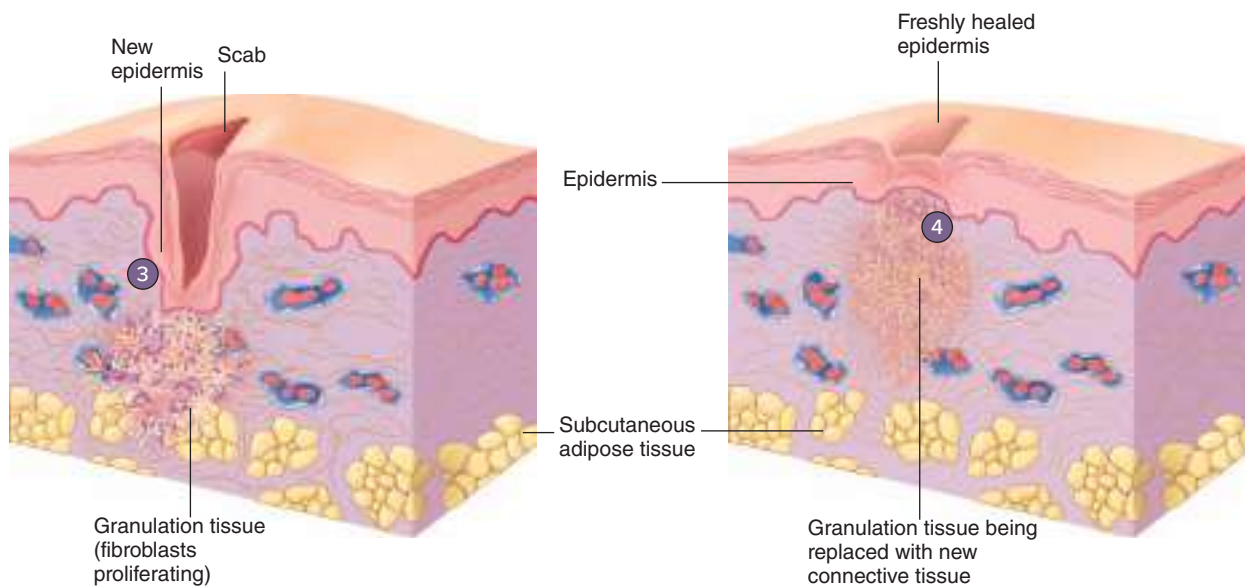

Skin repair is a good example of tissue repair (figure 4.8). The basic pattern of repair is the same as for other tissues, especially those covered by epithelium. If the edges of the wound are close together, as in a surgical incision, the wound heals by a process called **primary union**, or *primary intention*. If the edges are not

FUNDAMENTAL Figure

1 Fresh wound cuts through the epithelium (epidermis) and underlying connective tissue (dermis), and a clot forms.

2 Approximately 1 week after the injury, a scab is present, and epithelium (new epidermis) is growing into the wound.

3 Approximately 2 weeks after the injury, the epithelium has grown completely into the wound, and fibroblasts have formed granulation tissue.

4 Approximately 1 month after the injury, the wound has completely closed, the scab has been sloughed, and the granulation tissue is being replaced by new connective tissue.

PROCESS FIGURE 4.8 Tissue Repair

close together, or if tissue loss has been extensive, the process is called **secondary union**, or *secondary intention*.

In primary union, the wound fills with blood and a clot forms (see chapter 19). The clot contains the threadlike protein **fibrin** (fī'brin), which binds the edges of the wound together. The surface of the clot dries to form a **scab**, which seals the wound and helps prevent infection. An inflammatory response induces

vasodilation and takes more blood cells and other substances to the area. Blood vessel permeability increases, resulting in edema (swelling). Fibrin and blood cells move into the wounded tissues because of the increased vascular permeability. Fibrin isolates and walls off microorganisms and other foreign matter. Phagocytic white blood cells called neutrophils (noo'trō-filz) then move into the tissue to help fight the infection (figure 4.8). They ingest

bacteria and tissue debris to clear the area for repair. Neutrophils are killed in this process and can accumulate as a mixture of dead cells and fluid called **pus** (pŭs).

Fibroblasts from surrounding connective tissue migrate into the clot and produce collagen and other extracellular matrix components. Capillaries grow from blood vessels at the edge of the wound and revascularize the area, and fibrin in the clot is broken down and removed. **Granulation tissue**, a delicate, granular-appearing connective tissue that consists of fibroblasts, collagen, and capillaries, replaces the clot. A large amount of granulation tissue is converted to a **scar**, which consists of dense irregular collagenous connective tissue. At first, a scar is bright red because numerous blood vessels are present. Later, the scar becomes white as collagen accumulates and the vascular channels are compressed.

Repair by secondary union proceeds in a similar fashion, but with some differences. Because the wound edges are far apart, the clot may not close the gap completely, and it takes the epithelial cells much longer to regenerate and cover the wound. Also, the increased tissue damage means that both the degree of inflammation and the risk of infection are greater and there is more cell debris for the phagocytes to remove. Much more granulation tissue forms, and the contraction of fibroblasts in the granulation tissue leads to **wound contracture**, resulting in disfiguring and debilitating scars. Thus, it is advisable to suture a large wound, so that it can heal by primary rather than secondary union. Healing is faster, with a lowered risk of infection and a reduced degree of scarring.

ASSESS YOUR PROGRESS

55. Define tissue repair. Differentiate between repair by regeneration and repair by replacement.
56. Compare labile, stable, and permanent cells according to their ability to regenerate. Give examples of each type.
57. Describe the process of wound repair. Contrast healing by primary union and healing by secondary healing. Which process is better, and why?
58. What is granulation tissue? How does granulation tissue contribute to scars and wound contracture?

4.10 Effects of Aging on Tissues

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe the age-related changes that occur in cells and in extracellular matrix.

Age-related changes—for example, reduced visual acuity and reduced smell, taste, and touch sensations—are well documented. A clear decline in many types of athletic performance can be measured after approximately age 30–35. With advanced age, the number of neurons and muscle cells decreases substantially. The functional capacity of body systems, such as the respiratory and cardiovascular

systems, declines. The rates of healing and scarring in the elderly are very different from those in the very young, and major changes in skin structure develop. Characteristic alterations in brain function also develop in the elderly. All these changes result in the differences among young, middle-aged, and older people.

At the tissue level, age-related changes affect cells and the extracellular materials they produce. In general, cells divide more slowly in older people. Collagen fibers become more irregular in structure, even though their number may increase. As a consequence, connective tissues with abundant collagen, such as tendons and ligaments, become less flexible and more fragile. Elastic fibers fragment, bind to calcium ions, and become less elastic. Consequently, elastic connective tissues become less elastic. Reduced flexibility and elasticity of connective tissue are responsible for increased wrinkling of the skin, as well as the increased tendency for bones to break in older people.

Arterial walls also become less elastic due to changes in the structure of elastic and collagen fibers. Atherosclerosis results as plaques form in the walls of blood vessels, which contain collagen fibers, lipids, and calcium deposits (see chapter 21). These changes result in a reduced blood supply to tissues and an

Clinical IMPACT

Molecular Tissue Profiles of Cancer Tissue

There are many types of cancer and special names for them based on their tissue of origin. The most common types of cancer are those from epithelial tissue. A **carcinoma** (kar-si-nō'ma) is a cancer derived from epithelial tissue. Carcinomas include nearly all lung, breast, colon, prostate, and skin cancers. Basal cell and squamous cell carcinomas are types of skin cancer derived from epithelial tissue. **Adenocarcinomas** (ad'ē-nō-kar-si-nō'maz) are types of carcinomas derived from glandular epithelium. Most breast cancers are adenocarcinomas. A **sarcoma** (sar-kō'mă) is a relatively rare type of cancer derived from mesodermal tissue (muscle and connective tissue). For example, an osteosarcoma (os'tē-ō-sar-kō'mă) is cancer of bone, and a chondrosarcoma (kon'drō-sar-kō'mă) is cancer of cartilage.

Identifying the tissue of origin is useful for the diagnosis and treatment of cancer. Since tumor cells have altered shapes compared with their morphology in tissues (see Clinical Genetics, “Genetic Changes in Cancer Cells,” in chapter 3), molecular markers are commonly used to identify the type of tumor. For example, specific types of carcinomas express keratin filaments that are characteristic of different types of epithelial tissue. Other intermediate filaments are diagnostic of sarcomas and other types of cancers. Advances in nucleic acid technologies have opened the door for even more extensive gene expression profiling of cancers. In the future, it is likely that distinct molecular profiles of cancer will allow a more definitive diagnosis and prognosis, which may lead to targeted therapies tailored for individual patients.

increased susceptibility to blockage and rupture. The rate of red blood cell synthesis declines in the elderly as well.

Injuries in the very young heal more rapidly and more completely than in older people. A fracture in an infant's femur is likely to heal quickly and eventually leave no evidence in the bone. A similar fracture in an adult heals more slowly, and a scar, seen in x-rays of the bone, is likely to persist throughout life.

However, there is good news. It is increasingly evident that many of the cell losses and functional declines of aging can be slowed by physical and mental exercise. Staying active, both

physically and mentally, is often a good prescription for better health.

ASSESS YOUR PROGRESS

59. How do cells respond to the effects of aging?
60. Describe the age-related changes in tissues with abundant collagen and elastic fibers.
61. How does healing of injuries change in older people?

Answer

Learn to Predict ◀ From page 103

The question tells us that gluten enteropathy affects the intestinal lining, reducing its ability to absorb nutrients and water. It also reminds us that nutrient and water absorption occurs at the cellular level via several different transport processes.

Let us first identify the tissue type affected by gluten enteropathy. In chapter 4 we learned that epithelial tissue covers body surfaces, including the lining of the intestines. Further reading showed that the intestinal lining is composed of simple columnar epithelial tissue. Therefore, the tissue type affected by Matt's gluten enteropathy is simple columnar epithelium.

We are then asked to identify the specific cell parts affected by this disease. As stated in the question, the intestinal lining is organized into fingerlike projections called villi, which are covered by the simple columnar epithelium. Chapter 4 stated that the epithelial cells of this tissue have microvilli. In chapter 3, we learned that microvilli are extensions of the plasma membrane that increase the surface area for absorption. Matt's gluten

enteropathy reduced his ability to absorb nutrients and water, so we can conclude that the cell parts affected by the disease are the microvilli.

Finally, the question asks us to explain why Matt suffers from bouts of diarrhea after eating gluten. We know that gluten damages the intestinal lining by decreasing the number of villi and microvilli. This reduces the surface area for absorption. If the surface area decreases, fewer nutrients are absorbed. Chapter 3 showed us that water moves by osmosis to areas of higher solute concentration. The nutrient molecules are solutes in the intestines. Since the solutes are not being absorbed, the solute concentration remains high in the intestines, and water absorption decreases. As a result, the nutrients and water accumulate in the intestines, resulting in the watery feces of diarrhea.

Answers to the rest of this chapter's Predict questions are in appendix G.

4.1 Tissues and Histology (p. 104)

1. Tissues are collections of similar cells and the extracellular substances surrounding them.
2. The four primary tissue types are epithelial, connective, muscle, and nervous tissues.
3. Histology is the microscopic study of tissues.

4.2 Embryonic Tissue (p. 104)

All four of the primary tissue types are derived from each of the three germ layers (mesoderm, ectoderm, and endoderm).

4.3 Epithelial Tissue (p. 105)

1. Epithelium consists of cells with little extracellular matrix. It covers surfaces, usually has a basement membrane, and does not have blood vessels.
2. The basement membrane is secreted by the epithelial cells and attaches the epithelium to the underlying tissues.

Summary

Functions of Epithelial Tissues

Epithelial tissues protect underlying structures, act as barriers, permit some substances to pass through epithelial layers, secrete substances, and absorb substances.

Classification of Epithelial Tissues

1. Simple epithelium has a single layer of cells, stratified epithelium has two or more layers, and pseudostratified epithelium has a single layer that appears stratified.
2. Cells can be squamous (flat), cuboidal, or columnar.
3. Stratified squamous epithelium can be nonkeratinized or keratinized.
4. Transitional epithelium is stratified, with cells that can change shape from cuboidal to flattened.

Functional Characteristics

1. Simple epithelium is usually involved in diffusion, filtration, secretion, or absorption. Stratified epithelium serves a protective role. Squamous cells function in diffusion and filtration. Cuboidal or columnar cells, with a larger cell volume that contains many organelles, secrete or absorb.
2. A smooth free surface reduces friction (mesothelium and endothelium), microvilli increase absorption (intestines), and cilia move materials across the free surface (respiratory tract and uterine tubes). Transitional epithelium has a folded surface that allows the cell to change shape, and the number of cells making up the epithelial layers changes.
3. Cells are bound together mechanically by glycoproteins, desmosomes, and adhesion belts and to the basement membrane by hemidesmosomes. Tight junctions form a permeability barrier, and gap junctions allow intercellular communication.

Glands

1. Glands are organs that secrete. Exocrine glands secrete through ducts, and endocrine glands release hormones that are absorbed directly into the blood.
2. Glands are classified as unicellular or multicellular. Goblet cells are unicellular glands. Multicellular exocrine glands have ducts, which are simple or compound. The ducts can be tubular or end in small sacs (acini or alveoli). Tubular glands can be straight or coiled.
3. Glands are classified according to their mode of secretion. Merocrine glands (pancreas) secrete substances as they are produced, apocrine glands (mammary glands) accumulate secretions that are released when a portion of the cell pinches off, and holocrine glands (sebaceous glands) accumulate secretions that are released when the cell ruptures and dies.

4.4 Connective Tissue (p. 115)

Connective tissue is distinguished by its extracellular matrix.

Functions of Connective Tissue

Connective tissues enclose and separate organs and tissues; connect tissues to one another; help support and move body parts; store compounds; cushion and insulate the body; transport substances; and protect against toxins and injury.

Cells of Connective Tissue

1. The extracellular matrix results from the activity of specialized connective tissue cells; in general, -blast cells form the matrix, -cyte cells maintain it, and -clast cells break it down. Fibroblasts form protein fibers of many connective tissues, osteoblasts form bone, and chondroblasts form cartilage.
2. Connective tissue commonly contains adipocytes, mast cells, white blood cells, macrophages, and mesenchymal cells (stem cells).

Extracellular Matrix

1. The major components of the extracellular matrix of connective tissue are protein fibers, ground substance, and fluid.
2. Protein fibers of the matrix have the following characteristics:
 - Collagen fibrils are joined to form collagen fibers. The collagen fibers resemble ropes. They are strong and flexible but resist stretching.
 - Reticular fibers are fine collagen fibers that form a branching network that supports other cells and tissues.
 - Elastic fibers have a structure similar to that of a spring. After being stretched, they tend to return to their original shape.

3. Ground substance has the following major components:
 - Hyaluronic acid makes fluids slippery.
 - Proteoglycan aggregates trap water, which gives tissues the capacity to return to their original shape when compressed or deformed.
 - Adhesive molecules hold proteoglycans together and to plasma membranes.

Connective Tissue Classifications

Connective tissue is classified according to the type and proportions of cells and extracellular matrix fibers, ground substance, and fluid.

1. Embryonic connective tissue is called mesenchyme, consists of irregularly shaped cells and abundant matrix, and gives rise to adult connective tissue.
2. Adult connective tissue consists of connective tissue proper, supporting connective tissue, and fluid connective tissue.

Connective Tissue Proper

1. Loose connective tissue
 - Areolar connective tissue has many different cell types and a random arrangement of protein fibers with space between the fibers. This tissue fills spaces around the organs and attaches the skin to underlying tissues.
 - Adipose tissue has adipocytes filled with lipid and very little extracellular matrix (a few reticular fibers). It functions in energy storage, insulation, and protection. Adipose tissue can be yellow or brown. Brown adipose tissue is specialized for generating heat.
 - Reticular tissue is a network of reticular fibers; it forms the framework of lymphatic tissue, bone marrow, and the liver.
2. Dense connective tissue
 - Dense regular connective tissue is composed of fibers arranged in one direction, which provides strength in a direction parallel to the fiber orientation. Two types of dense regular connective tissue exist: collagenous (tendons and most ligaments) and elastic (ligaments of vertebrae).
 - Dense irregular connective tissue has fibers organized in many directions, which produces strength in different directions. Two types of dense irregular connective tissue exist: collagenous (capsules of organs and dermis of skin) and elastic (large arteries).

Supporting Connective Tissue

1. Cartilage
 - Cartilage has a relatively rigid matrix composed of protein fibers and proteoglycan aggregates. The major cell type is the chondrocyte, which is located within lacunae.
 - Hyaline cartilage has evenly dispersed collagen fibers that provide rigidity with some flexibility. Examples include the costal cartilage, the covering over the ends of bones in joints, the growing portion of long bones, and the embryonic skeleton.
 - Fibrocartilage has collagen fibers arranged in thick bundles; it can withstand great pressure, and it is found between vertebrae, in the jaw, and in the knee.
 - Elastic cartilage is similar to hyaline cartilage, but it contains elastin. It is more flexible than hyaline cartilage and is found in the external ear.
2. Bone
 - Bone cells, or osteocytes, are located in lacunae surrounded by a mineralized matrix (hydroxyapatite) that makes bone very hard. Spongy bone has spaces between bony trabeculae; compact bone is more solid.

Fluid Connective Tissue

1. Blood
 - Blood cells are suspended in a fluid matrix.
2. Hemopoietic tissue
 - Hemopoietic tissue forms blood cells.

4.5 Muscle Tissue (p. 126)

1. Muscle tissue has the ability to contract.
2. Skeletal (striated voluntary) muscle attaches to bone and is responsible for body movement. Skeletal muscle cells are long and cylindrically shaped with many peripherally located nuclei.
3. Cardiac (striated involuntary) muscle cells are cylindrical, branching cells with a single, central nucleus. Cardiac muscle is found in the heart and is responsible for pumping blood through the circulatory system.
4. Smooth (nonstriated involuntary) muscle forms the walls of hollow organs, the iris of the eye, and other structures. Its cells are spindle-shaped with a single, central nucleus.

4.6 Nervous Tissue (p. 129)

1. Nervous tissue is able to conduct electrical impulses and is composed of neurons (conductive cells) and glia (support cells).
2. Neurons have cell processes called dendrites and axons. Dendrites receive electrical impulses, and axons conduct them. Neurons can be multipolar (several dendrites and an axon), bipolar (one dendrite and one axon), or pseudo-unipolar (one axon).

4.7 Tissue Membranes (p. 131)

1. There are four tissue membranes in the body, one external (skin) and three internal (mucous, serous, synovial).
2. Mucous membranes consist of epithelial cells, their basement membrane, the lamina propria, and sometimes smooth muscle cells;

they line cavities that open to the outside and often contain mucous glands, which secrete mucus.

3. Serous membranes line cavities that do not open to the exterior and do not contain glands but do secrete serous fluid.
4. Synovial membranes are formed by connective tissue, line joint cavities, and secrete a lubricating fluid.

4.8 Tissue Damage and Inflammation (p. 132)

1. Inflammation involves a response that isolates injurious agents from the rest of the body and destroys the injurious agent.
2. Inflammation produces five symptoms: redness, heat, swelling, pain, and disturbed function.

4.9 Tissue Repair (p. 132)

1. Tissue repair is the substitution of viable cells for dead ones. Tissue repair occurs by regeneration or replacement.
 - Labile cells divide throughout life and can undergo regeneration.
 - Stable cells do not ordinarily divide after growth is complete but can regenerate if necessary.
 - Permanent cells cannot replicate. If killed, permanent tissue is repaired by replacement.
2. Tissue repair by primary union occurs when the edges of the wound are close together. Secondary union occurs when the edges are far apart.

4.10 Effects of Aging on Tissues (p. 135)

1. Age-related changes in tissues result from reduced rates of cell division and changes in the extracellular fibers.
2. Collagen fibers become less flexible and have reduced strength.
3. Elastic fibers become fragmented and less elastic.

REVIEW AND COMPREHENSION

1. Given these characteristics:
 - (1) capable of contraction
 - (2) covers free body surfaces
 - (3) lacks blood vessels
 - (4) composes various glands
 - (5) anchored to connective tissue by a basement membrane
 Which of these are characteristics of epithelial tissue?
 - a. 1,2,3
 - b. 2,3,5
 - c. 3,4,5
 - d. 1,2,3,4
 - e. 2,3,4,5
2. Which of these embryonic germ layers gives rise to muscle, bone, and blood vessels?
 - a. ectoderm
 - b. endoderm
 - c. mesoderm
3. A tissue that covers a surface, is one cell layer thick, and is composed of flat cells is
 - a. simple squamous epithelium.
 - b. simple cuboidal epithelium.
 - c. simple columnar epithelium.
 - d. stratified squamous epithelium.
 - e. transitional epithelium.
4. Stratified epithelium is usually found in areas of the body where the principal activity is
 - a. filtration.
 - b. protection.
 - c. absorption.
 - d. diffusion.
 - e. secretion.
5. Which of these characteristics do *not* describe nonkeratinized stratified squamous epithelium?
 - a. many layers of cells
 - b. flat surface cells
 - c. living surface cells
 - d. found in the skin
 - e. outer layers covered by fluid
6. In parts of the body where considerable expansion occurs, such as the urinary bladder, which type of epithelium would you expect to find?
 - a. cuboidal
 - b. pseudostratified
 - c. transitional
 - d. squamous
 - e. columnar
7. Epithelial cells with microvilli are most likely found
 - a. lining blood vessels.
 - b. lining the lungs.
 - c. lining the uterine tube.
 - d. lining the small intestine.
 - e. in the skin.

8. Pseudostratified ciliated columnar epithelium can be found lining the
 - a. digestive tract.
 - b. trachea.
 - c. thyroid gland.
 - d. kidney tubules.
 - e. urinary bladder.
9. A type of cell connection whose *only* function is to prevent the cells from coming apart is a
 - a. desmosome.
 - b. gap junction.
 - c. tight junction.
10. The glands that lose their connection with epithelium during embryonic development and secrete their cellular products into the bloodstream are called _____ glands.
 - a. apocrine
 - b. endocrine
 - c. exocrine
 - d. holocrine
 - e. merocrine
11. A _____ gland has a duct that branches repeatedly, and the ducts end in saclike structures.
 - a. simple tubular
 - b. compound tubular
 - c. simple coiled tubular
 - d. simple acinar
 - e. compound acinar
12. The fibers in dense connective tissue are produced by
 - a. fibroblasts.
 - b. adipocytes.
 - c. osteoblasts.
 - d. osteoclasts.
 - e. macrophages.
13. Mesenchymal cells
 - a. form embryonic connective tissue.
 - b. give rise to all adult connective tissues.
 - c. in adults produce new connective tissue cells in response to injury.
 - d. All of these are correct.
14. A tissue with a large number of collagen fibers organized parallel to each other would most likely be found in
 - a. a muscle.
 - b. a tendon.
 - c. adipose tissue.
 - d. a bone.
 - e. cartilage.
15. Extremely delicate fibers that make up the framework for organs such as the liver, spleen, and lymph nodes are
 - a. elastic fibers.
 - b. reticular fibers.
 - c. microvilli.
 - d. cilia.
 - e. collagen fibers.
16. In which of these locations is dense irregular elastic connective tissue found?
 - a. ligaments
 - b. nuchal ligament
 - c. dermis of the skin
 - d. large arteries
 - e. adipose tissue
17. Which of these is *not* true of adipose tissue?
 - a. It is the site of energy storage.
 - b. It is a type of connective tissue.
 - c. It acts as a protective cushion.
 - d. Brown adipose is found only in older adults.
 - e. It functions as a heat insulator.
18. Which of these types of connective tissue has the smallest amount of extracellular matrix?
 - a. adipose
 - b. bone
 - c. cartilage
 - d. loose connective tissue
 - e. blood
19. Fibrocartilage is found
 - a. in the cartilage of the trachea.
 - b. in the rib cage.
 - c. in the external ear.
 - d. on the surface of bones in movable joints.
 - e. between vertebrae.
20. A tissue composed of cells located in lacunae surrounded by a hard matrix of hydroxyapatite is
 - a. hyaline cartilage.
 - b. bone.
 - c. nervous tissue.
 - d. dense regular collagenous connective tissue.
 - e. fibrocartilage.
21. Which of these characteristics apply to smooth muscle?
 - a. striated, involuntary
 - b. striated, voluntary
 - c. unstriated, involuntary
 - d. unstriated, voluntary
22. Which of these statements about nervous tissue is *not* true?
 - a. Neurons have cytoplasmic extensions called axons.
 - b. Electrical signals (action potentials) are conducted along axons.
 - c. Bipolar neurons have two axons.
 - d. Neurons are nourished and protected by glia.
 - e. Dendrites receive electrical signals and conduct them toward the cell body.
23. The linings of the digestive, respiratory, excretory, and reproductive passages are composed of
 - a. serous membranes.
 - b. mucous membranes.
 - c. mesothelium.
 - d. synovial membranes.
 - e. endothelium.
24. Chemical mediators
 - a. cause blood vessels to constrict.
 - b. decrease the permeability of blood vessels.
 - c. initiate processes that lead to edema.
 - d. help prevent clotting.
 - e. decrease pain.
25. Which of these types of cells is labile?
 - a. neuron
 - b. skin
 - c. liver
 - d. pancreas
26. Permanent cells
 - a. divide and replace damaged cells in replacement tissue repair.
 - b. form granulation tissue.
 - c. are responsible for removing scar tissue.
 - d. are usually replaced by a different cell type if they are destroyed.
 - e. are replaced during regeneration tissue repair.

Answers in appendix E

CRITICAL THINKING

1. Given the observation that a tissue has more than one layer of cells lining a free surface, (1) list the possible tissue types that exhibit those characteristics, and (2) explain what additional observations are needed to identify the tissue type.
2. A patient suffered from kidney failure a few days after being exposed to a toxic chemical. A biopsy of his kidney indicated that many of the thousands of epithelium-lined tubules making up the kidney had lost their simple cuboidal epithelial cells, although the basement

- membranes appeared mostly intact. How likely is a full recovery for this person?
- Willie B. Coffin has smoked for years. In the past few months, mucus has accumulated in his lungs and he coughs often. A tissue sample (biopsy) taken from the lower portion of his trachea indicated that stratified squamous epithelium has replaced the normal pseudostratified columnar epithelium lining the trachea. Willie's physician explained that he has bronchitis, inflammation of the respiratory airways, caused by smoking. As a result, some of the normal epithelium of the large respiratory passageways has been converted to stratified squamous epithelium. Explain why mucus has accumulated in Willie's lungs to a greater degree than normal.
 - How can you distinguish between a gland that produces a merocrine secretion and a gland that produces a holocrine secretion? Assume that you have the ability to chemically analyze the composition of the secretions.
 - Name a tissue that has the following characteristics: abundant extracellular matrix consisting almost entirely of collagen fibers that are parallel to each other. Then state which of the following injuries results from damage to this kind of tissue: dislocated neck vertebrae, torn tendon, or ruptured intervertebral disk.
 - Antihistamines block the effect of a chemical mediator called histamine, which is released during the inflammatory response. What effect does administering antihistamines have on the inflammatory response, and is the use of an antihistamine beneficial?

Answers in appendix F

Integumentary System

It is the morning of “the big day.” You look in the mirror and, much to your dismay, there is a big, red bump on your chin. Just when you needed to look your best, this had to happen! For most people, blemish-free skin is highly desirable, and any sign of acne is cause for embarrassment. Hair loss and crows’ feet also cause consternation in some people. It goes without saying that much time, effort, and money are spent on changing the appearance of the integumentary system. Think about the amount of counter space dedicated to skin care products, hair care products, and cosmetics in a typical discount store. People apply lotion to their skin, color their hair, and trim their nails. They try to prevent sweating by using antiperspirants and reduce or even mask body odor by washing or using deodorants and perfumes.

The **integumentary** (in-teg-ū-men’tā-rē) **system** consists of the skin and accessory structures, such as hair, glands, and nails. Although people are concerned about the appearance of their integumentary system for vanity’s sake, its appearance can also indicate physiological imbalances. Some disorders, such as acne or warts, affect only the integumentary system. Other disorders affect different body parts but are reflected in the integumentary system, which provides useful signs for diagnosis. For example, reduced blood flow through the skin during a heart attack can cause a person to look pale, whereas increased blood flow as a result of fever can cause a flushed appearance. Some diseases cause skin rashes, such as those characteristic of measles, chickenpox, and allergic reactions.

Learn to Predict

It was a dream job—summer days spent poolside, soaking up the sun. Following her freshman year, Laura worked as a lifeguard at the country club in her hometown. By the end of summer, she had a golden tan and was anxious to show off her hot new look on campus. However, after returning to school in the fall, she was disappointed to see that her skin kept getting lighter, and in only a few weeks it had returned to its normal pale tone. **By combining your understanding of epithelial tissue from chapter 4 with further information about skin structure and pigmentation in this chapter, explain how and why Laura’s tan faded in the fall.**

Photo: The number of skin care products is amazing. The woman in this photo is shopping at a retail store that specializes in products primarily dedicated to improving the appearance of the integumentary system.

Module 4
Integumentary System

5.1 Functions of the Integumentary System

LEARNING OUTCOME

After reading this section, you should be able to

A. Describe the general functions of the integumentary system.

Although we are often concerned with how the integumentary system looks, it has many important functions that go beyond appearance. The integumentary system forms the boundary between the body and the external environment, thereby separating us from the external environment while allowing us to interact with it. Following are the major functions of the integumentary system:

1. **Protection.** The skin is the covering of the body. Though exposed to the external environment, the skin's structure reduces the negative and harmful effects of ultraviolet light. The skin also keeps microorganisms from entering the body and reduces water loss from the body, preventing dehydration.
2. **Sensation.** The integumentary system has sensory receptors that can detect heat, cold, touch, pressure, and pain.
3. **Temperature regulation.** The skin plays a major role in regulating body temperature through the modulation of blood flow through the skin and the activity of sweat glands.
4. **Vitamin D production.** When exposed to ultraviolet light, the skin produces a molecule that can be transformed into vitamin D, an important regulator of calcium homeostasis.
5. **Excretion.** Small amounts of waste products are excreted through the skin and glands.

ASSESS YOUR PROGRESS

1. Provide an example for each function of the integumentary system.

5.2 Skin

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the structure and function of the epidermis.
- B. Discuss the epidermal strata and relate them to the process of keratinization.
- C. Differentiate between thick and thin skin as to the layers present and their locations.
- D. Explain the major factors affecting skin color.
- E. Describe the structure and functions of the dermis.

The skin is made up of two major tissue layers, the epidermis and the dermis (figure 5.1). The **epidermis** (ep-i-der'mis; upon the dermis) is the superficial layer of the skin, consisting of stratified squamous epithelial tissue. The multiple cell layers of the epidermis resists abrasion on the skin's surface and reduces water loss

through the skin. The epidermis rests on the **dermis** (der'mis; skin), a layer of connective tissue. The structure of the dermis is responsible for most of the strength of the skin. The strength of the dermis is seen in leather, which is produced from the hide (skin) of an animal by removing the epidermis and preserving the dermis in a process called tanning.

The skin rests on the **subcutaneous tissue**, or *hypodermis* (hi-pō-der'mis), a layer of loose connective tissue (figure 5.1). The subcutaneous tissue is not part of the skin or the integumentary system, but it does connect the skin to underlying muscle or bone. Table 5.1 summarizes the structures and functions of the skin and subcutaneous tissue.

Epidermis

The epidermis is stratified squamous epithelium. It is separated from the underlying dermis by a basement membrane. The epidermis is not as thick as the dermis and contains no blood vessels. The living cells of the epidermis receive nutrients and excrete waste products by the diffusion of substances between the epidermis and the capillaries of the dermis (figure 5.2).

The epidermis is composed of several types of cells. Most cells of the epidermis are called **keratinocytes** (ke-rat'i-nō-sītz) because they produce a protein mixture called **keratin** (ker'ă-tin), which makes the cells more durable. Because of their durability, keratinocytes give the epidermis its ability to resist abrasion and reduce water loss. Other cells of the epidermis include melanocytes, Langerhans cells, and Merkel cells. **Melanocytes** (mel'ă-nō-sītz), produce the pigment melanin, which contributes to skin color. **Langerhans cells** are part of the immune system (see chapter 22) and **Merkel cells** are specialized epidermal cells associated with the nerve endings responsible for detecting light touch and superficial pressure (see chapter 14).

The keratinocytes of the epidermis are constantly lost at its surface but are also constantly replaced by other cells moving from deeper layers. New keratinocytes are produced when keratinocyte stem cells undergo mitosis in the deepest layer of the epidermis. As new cells form, they push older cells to the surface, where they slough off. The outermost cells in this stratified arrangement protect the cells underneath, and the deeper, replicating cells replace cells lost from the surface. As they move from the deeper epidermal layers to the surface, the keratinocytes change shape and chemical composition, through the process called **keratinization** (ker'ă-tin-i-ză'shūn), where the cells accumulate keratin. During keratinization, the cells eventually die and produce an outer layer of dead, hard cells that resists abrasion and forms a permeability barrier. The study of keratinization is important because many skin diseases result from malfunctions in this process. For example, large scales of epidermal tissue are sloughed off in **psoriasis** (sō-rī'ă-sis). By comparing normal and abnormal keratinization, scientists may be able to develop effective therapies for psoriasis.

Although keratinization is a continual process, distinct transitional stages can be recognized as the cells change. On the basis of these stages, the many layers of cells in the epidermis are divided into regions, or **strata** (sing. stratum; figures 5.2b and 5.3). From the deepest to the most superficial, the five strata are the stratum

FIGURE 5.1 Skin and Subcutaneous Tissue

The skin, consisting of the epidermis and the dermis, is connected by the subcutaneous tissue to underlying structures. Note the accessory structures (hairs, glands, and arrector pili), some of which project into the subcutaneous tissue, as well as the large amount of adipose tissue in the subcutaneous tissue. **APR**

basale, stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum. The number of cell layers in each stratum and even the number of strata in the skin vary, depending on their location in the body.

Stratum Basale

The deepest portion of the epidermis is a single layer of cuboidal or columnar cells called the **stratum basale** (bā'sā-lē), or *stratum germinativum* (jer'mi-nā-tīv'um; figure 5.3, *stratum 1*). The epidermis is anchored to the basement membrane by hemidesmosomes. In addition, desmosomes hold the keratinocytes together (see chapter 4). The connections formed by the hemidesmosomes and desmosomes provide structural strength to the epidermis. Keratinocytes are strengthened internally by keratin fibers (intermediate filaments) that insert into the desmosomes. Keratinocyte stem cells of the stratum basale undergo mitotic divisions approximately every 19 days. One daughter cell remains a stem cell in the stratum basale and divides again, but the other daughter cell is pushed toward the surface and becomes keratinized. It takes approximately 40–56 days for the cell to reach the epidermal surface and slough off.

Stratum Spinosum

Superficial to the stratum basale is the **stratum spinosum** (spī-nō'sūm), consisting of 8–10 layers of many-sided cells

(figure 5.3, *stratum 2*). As the cells in this stratum are pushed to the surface, they flatten; desmosomes break apart, and new desmosomes form. During preparation for microscopic observation, the cells usually shrink from one another, except where they are attached by desmosomes, causing the cells to appear spiny—hence the name stratum spinosum. Additional keratin fibers and lipid-filled, membrane-bound organelles called **lamellar** (lam'ē-lār, lā-mel'ar) **bodies** form inside the keratinocytes.

Stratum Granulosum

The **stratum granulosum** (gran-ū-lō'sūm) consists of two to five layers of somewhat flattened, diamond-shaped cells. The long axes of these cells are oriented parallel to the surface of the skin (figure 5.3, *stratum 3*). This stratum derives its name from the presence of protein granules of **keratohyalin** (ker'ā-tō-hī'ā-lin), which accumulate in the cytoplasm of the cell. The lamellar bodies, formed as the cells pass through the stratum spinosum, move to the plasma membrane and release their lipid contents into the extracellular space. Inside the cell, a protein envelope forms beneath the plasma membrane. In the most superficial layers of the stratum granulosum, the nucleus and other organelles degenerate, and the cell dies. Unlike the other organelles and the nucleus, however, the keratin fibers and keratohyalin granules within the cytoplasm do not degenerate.

TABLE 5.1 Comparison of the Skin (Epidermis and Dermis) and Subcutaneous Tissue

Part	Structure	Function
Epidermis	Superficial part of skin; stratified squamous epithelium; composed of four or five strata	Prevents water loss and the entry of chemicals and microorganisms; protects against abrasion and harmful effects of ultraviolet light; produces vitamin D; gives rise to hair, nails, and glands
Stratum corneum	Most superficial stratum of the epidermis; 25 or more layers of dead squamous cells	Provides structural strength due to keratin within cells; prevents water loss due to lipids surrounding cells; sloughing off of most superficial cells resists abrasion
Stratum lucidum	Three to five layers of dead cells; appears transparent; present in thick skin, absent in most thin skin	Disperses keratohyalin around keratin fibers
Stratum granulosum	Two to five layers of flattened, diamond-shaped cells	Produces keratohyalin granules; lamellar bodies release lipids from cells; cells die
Stratum spinosum	A total of 8–10 layers of many-sided cells	Produces keratin fibers; lamellar bodies form inside keratinocytes
Stratum basale	Deepest stratum of the epidermis; single layer of cuboidal or columnar cells; basement membrane of the epidermis attaches to the dermis	Produces cells of the most superficial strata; melanocytes produce and contribute melanin, which protects against ultraviolet light
Dermis	Deep part of skin; connective tissue composed of two layers	Is responsible for the structural strength and flexibility of the skin; the epidermis exchanges gases, nutrients, and waste products with blood vessels in the dermis
Papillary layer	Papillae project toward the epidermis; loose connective tissue	Brings blood vessels close to the epidermis; dermal papillae form fingerprints and footprints
Reticular layer	Mat of collagen and elastic fibers; dense irregular connective tissue	Is the main fibrous layer of the dermis; strong in many directions; forms cleavage lines
Subcutaneous tissue	Not part of the skin; loose connective tissue with abundant deposits of adipose tissue	Attaches the dermis to underlying structures; adipose tissue provides energy storage, insulation, and padding; blood vessels and nerves from the subcutaneous tissue supply the dermis

Stratum Lucidum

The **stratum lucidum** (loo'si-dŭm) is a thin, clear zone above the stratum granulosum (figure 5.3, *stratum 4*). It consists of several layers of dead cells with indistinct boundaries. Keratin fibers are present, but the keratohyalin, which was evident as granules in the stratum granulosum, has dispersed around the keratin fibers, and the cells appear somewhat transparent. The stratum lucidum is present in only a few areas of the body (see the section “Thick and Thin Skin”).

Stratum Corneum

The last, and most superficial, stratum of the epidermis is the **stratum corneum** (kōr'nē-ŭm; figure 5.3, *stratum 5*). This stratum is composed of 25 or more layers of dead, overlapping squamous cells joined by desmosomes. Eventually, the desmosomes break apart, and the cells are shed from the surface of the skin. Excessive shedding of the stratum corneum of the scalp results in dandruff. Less noticeably, skin cells are continually shed from other areas as clothes rub against the body or as the skin is washed.

The stratum corneum consists of **cornified cells**, which are dead cells, with a hard protein envelope, filled with the protein keratin. Keratin is a mixture of keratin fibers and keratohyalin. The envelope and the keratin are responsible for the structural strength of the stratum corneum. The type of keratin found in the skin is soft keratin. Another type of keratin, hard keratin, is found in nails and the external parts of hair. Cells containing hard keratin are more durable than cells with soft keratin, and they are not shed.

Lipids are released from lamellar bodies surrounding the skin cells. The lipids are responsible for many of the skin's permeability characteristics.

➤ Predict 2

Some drugs are administered by applying them to the skin (e.g., a nicotine skin patch to help a person stop smoking). The drug diffuses through the epidermis to blood vessels in the dermis. What kind of substances can pass easily through the skin by diffusion? What kinds of substances have difficulty diffusing through the skin?

Thick and Thin Skin

When we say a person has thick or thin skin, we are usually referring metaphorically to the person's ability to take criticism. However, in a literal sense all of us have both thick and thin skin. Skin is classified as thick or thin based on the structure of the epidermis. **Thick skin** has all five epithelial strata, and the stratum corneum has many layers of cells. Thick skin is found in areas subject to pressure or friction, such as the palms of the hands, the soles of the feet, and the fingertips.

Thin skin covers the rest of the body and is more flexible than thick skin. Each of its strata contains fewer layers of cells than are found in thick skin; the stratum granulosum frequently consists of only one or two layers of cells, and the stratum lucidum is generally absent. Hair is found only in thin skin.

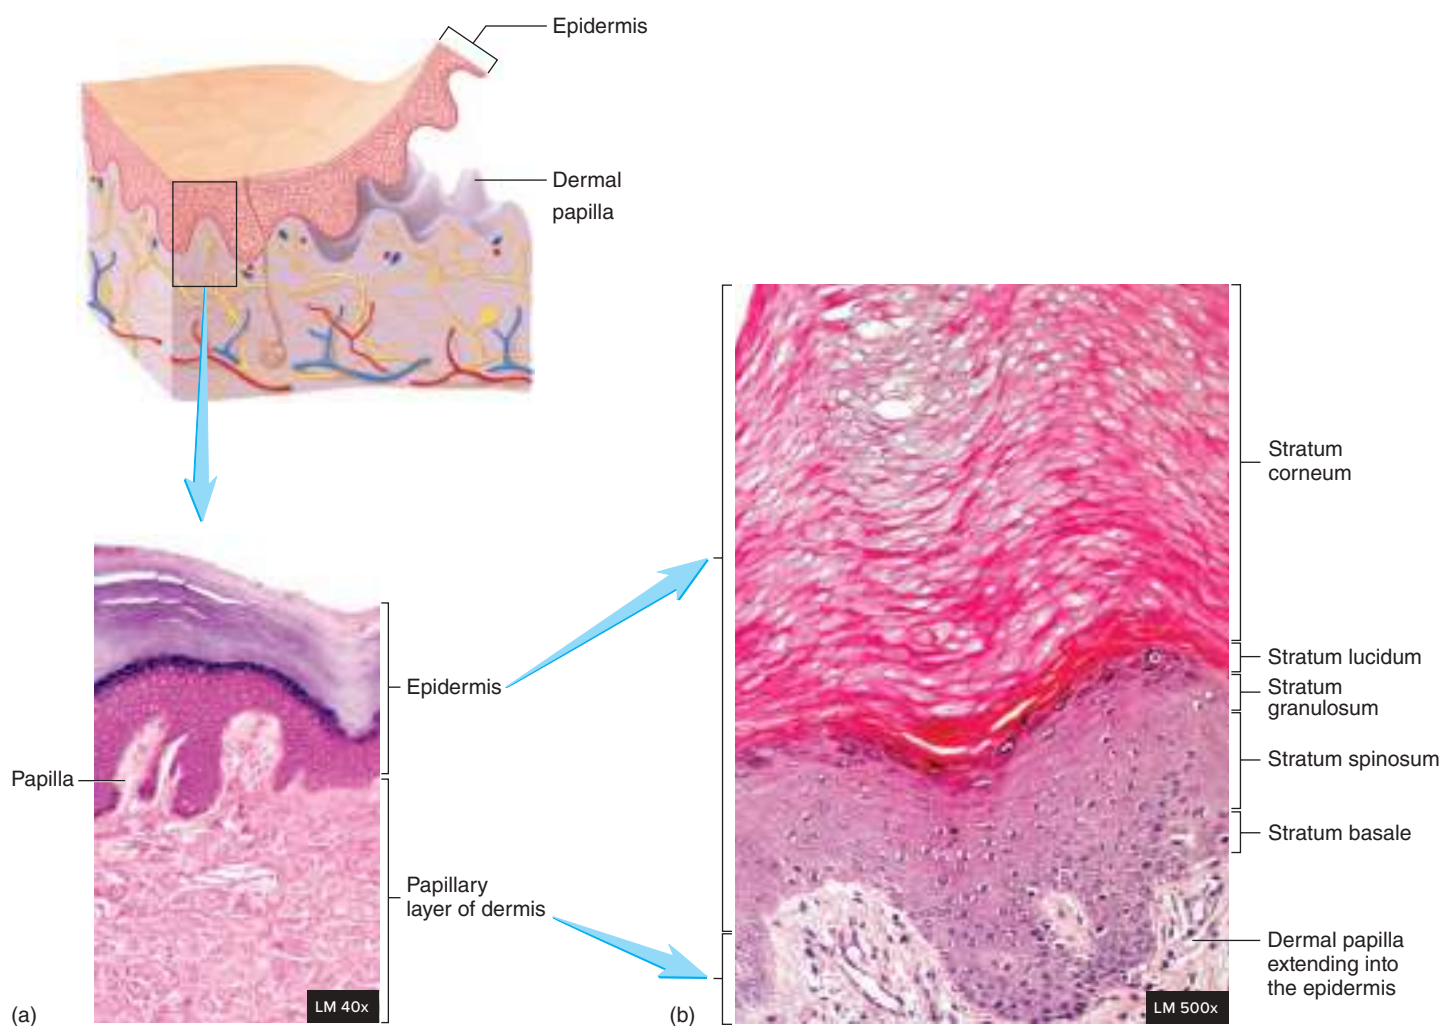

FIGURE 5.2 Dermis and Epidermis

(a) Photomicrograph of the dermis covered by the epidermis. The dermis consists of the papillary and reticular layers. The papillary layer has projections, called papillae, that extend into the epidermis. (b) Higher-magnification photomicrograph of the epidermis resting on the papillary layer of the dermis. Note the strata of the epidermis. **AP|R**

The entire skin, including both the epidermis and the dermis, varies in thickness from 0.5 mm in the eyelids to 5.0 mm on the back and shoulders. The terms *thin* and *thick*, which refer to the epidermis only, should not be used when total skin thickness is considered. Variation in the thickness of the dermis accounts for most of the difference in total skin thickness. For example, the skin of the back is thin skin, whereas that of the palm of the hand is thick skin; however, because the dermis of the skin of the back is thicker, the total skin thickness of the back is greater than that of the palm.

In skin subjected to friction or pressure, an area called a **callus** (kal'ŭs) often forms when the stratum corneum of the epidermis increases in thickness. The increased number of cell layers provides added protection in the area that experiences more mechanical stress. The skin over bony prominences develop a cone-shaped structure called a **corn**. The base of the cone is at the surface, but the apex extends deep into the epidermis, and pressure on the corn may be quite painful. Calluses and corns can develop in both thin and thick skin.

Skin Color

The factors that determine skin color include pigments in the skin, blood circulating through the skin, and the thickness of the stratum corneum. **Melanin** (mel'ă-nin) is the group of pigments primarily responsible for skin, hair, and eye color. Melanin also provides protection against ultraviolet light from the sun. Large amounts of melanin are found in certain regions of the skin, such as freckles, moles, the nipples, the areolae of the breasts, the axillae, and the genitalia. Other areas of the body, such as the lips, palms of the hands, and soles of the feet, contain less melanin.

Melanin is produced by **melanocytes** (mel'ă-nō-sītz), irregularly shaped cells with many long processes that extend between the keratinocytes of the stratum basale and the stratum spinosum (figure 5.4). Melanocytes produce and package melanin into vesicles called **melanosomes** (mel'ă-nō-sōmz), which move into cell processes of the melanocytes. Keratinocytes phagocytize (see chapter 3) the tips of the melanocyte cell processes, thereby acquiring melanosomes. Although all keratinocytes can contain melanin, the only cells that produce it are melanocytes.

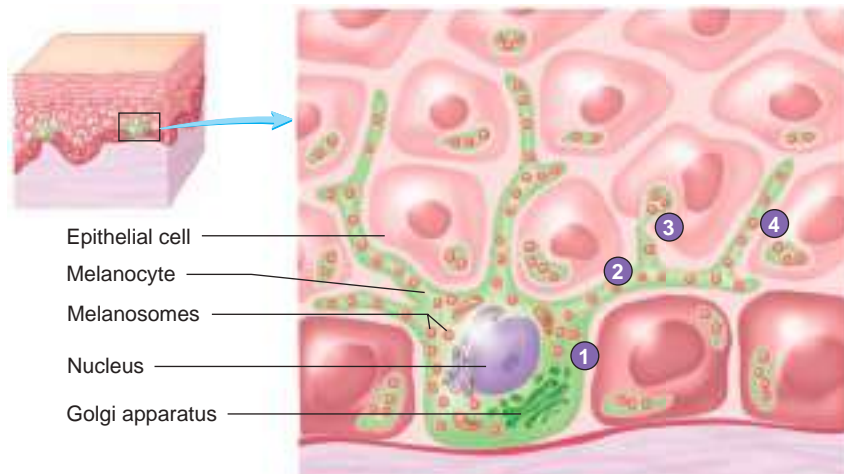

PROCESS FIGURE 5.3 Epidermal Layers and Keratinization

To produce melanin, the enzyme tyrosinase (tī'rō-si-nās, tīr'ō-si-nās) converts the amino acid tyrosine to dopaquinone (dō'pā-kwīn'ōn, dō'pā-kwī-nōn). Dopaquinone can be converted to a variety of related molecules, most of which are brown to black pigments but some of which are yellowish or reddish.

Melanin production is determined by genetic factors, exposure to light, and hormones. Genetic factors are primarily responsible for the variations in skin color among different races and among people of the same race. It is interesting to note that the number of melanocytes in the skin is relatively the same for all humans, regardless of

race. Racial variations in skin color are determined by several major factors: the amount and types of melanin produced by the melanocytes and the size, number, and distribution of the melanosomes. Although many genes are responsible for skin color, a single mutation (see chapter 29) can prevent the manufacture of melanin. **Albinism** (al'bi-nizm) is usually a recessive genetic trait that results from an inability to produce tyrosinase. The result is a deficiency or an absence of pigment in the skin, the hair, and the irises of the eyes. Exposure to ultraviolet light darkens the melanin already present in the skin and stimulates melanin production, resulting in tanning.

- 1 Melanosomes are produced by the Golgi apparatus of the melanocyte.
- 2 Melanosomes move into melanocyte cell processes.
- 3 Epithelial cells phagocytize the tips of the melanocyte cell processes.
- 4 The melanosomes, which were produced inside the melanocytes, have been transferred to epithelial cells and are now inside them.

PROCESS FIGURE 5.4 Melanin Transfer to Keratinocytes

Melanocytes make melanin, which is packaged into melanosomes and transferred to many keratinocytes. **AP|R**

Clinical GENETICS

Skin Cancer

Skin cancer is the most common type of cancer. Most skin cancers result from damage caused by the ultraviolet (UV) radiation in sunlight. Some skin cancers are induced by chemicals, x-rays, depression of the immune system, or inflammation, whereas others are inherited.

UV radiation damages the genes (DNA) in epidermal cells, producing mutations. If a mutation is not repaired, the mutation is passed to one of the two daughter cells when a cell divides by mitosis. If mutations affecting oncogenes and tumor suppressor genes in epidermal cells accumulate, uncontrolled cell division and skin cancer can result (see Clinical Genetics, “Genetic Changes in Cancer Cells,” in chapter 3).

The amount of protective melanin in the skin affects the likelihood of developing skin cancer. Fair-skinned individuals, who have less melanin, are at an increased risk of developing skin cancer compared with dark-skinned individuals, who have more melanin. Long-term or intense exposure to UV radiation also increases the risk. Thus, individuals who are older than 50, who have engaged in repeated recreational or occupational exposure to the sun, or who have experienced sunburn are at increased risk. Most skin cancers develop on the parts of the body that are frequently exposed to sunlight, such as the face, neck, ears, and dorsum of the forearm and hand. A physician should be consulted if skin cancer is suspected.

There are three types of skin cancer: basal cell carcinoma, squamous cell carcinoma, and melanoma (figure 5A). **Basal cell carcinoma**, the most common type, affects cells in the stratum basale. Basal cell carcinomas have a

varied appearance. Some are open sores that bleed, ooze, or crust for several weeks. Others are reddish patches; shiny, pearly, or translucent bumps; or scarlike areas of shiny, taut skin. Removal or destruction of the tumor cures most cases.

Squamous cell carcinoma is the second most common type of skin cancer. Squamous cell carcinoma affects cells in the stratum spinosum and can appear as a wartlike growth; a persistent, scaly red patch; an open sore; or an elevated growth with a central depression. These lesions may bleed. Removal or destruction of the tumor cures most cases.

Melanoma (mel’ă-nō’mă) is the least common, but most deadly, type of skin cancer, accounting for over 77% of the skin cancer deaths in the United States. Because they arise from melanocytes, most melanomas are black or brown, but occasionally a melanoma stops producing melanin and appears skin-colored, pink, red, or purple. About 40% of melanomas develop in preexisting moles. Treatment of melanomas when they are confined to the epidermis is almost always successful. However, if a melanoma invades the dermis and metastasizes to other parts of the body, it is difficult to treat and can be deadly.

Early detection and treatment of melanoma before it metastasizes can prevent death. Melanoma can be detected by routine examination of the skin and application of the **ABCDE rule**, which states the signs of melanoma: *A* stands for asymmetry (one side of the lesion does not match the other side), *B* is for border irregularity (the edges are ragged, notched, or blurred), *C* is for color (pigmentation is not uniform), *D* is for diameter (greater than 6 mm), and *E* is for evolving (lesion changes over time).

Evolving lesions change size, shape, elevation, or color; they may bleed, crust, itch, or become tender.

In order for cancer cells to metastasize, they must leave their site of origin, enter the circulation, and become established in a new location. For example, melanoma cells first spread within the epidermis. Some of those cells may then break through the basement membrane and invade the dermis; from there, they may enter lymphatic or blood vessels and spread to other parts of the body. The ability of cancer cells to metastasize requires an accumulation of mutations that enables the cells to detach from similar cells, recognize and digest the basement membrane, and become established elsewhere when surrounded by different cell types.

Basal cell carcinomas very rarely metastasize, and only 2–6% of squamous cell carcinomas metastasize. Compared with keratinocytes, melanocytes are more likely to give rise to tumors that metastasize because, in their developmental past, they had the ability to migrate and become established in new locations. In the embryo, melanocytes are derived from a population of cells called neural crest cells (see chapter 13). A gene called *Slug* regulates neural crest cell migration. In normal melanocytes, the *Slug* gene is inactive, but in metastasizing melanoma cells it is reactivated. The reactivation of embryonic genes, such as *Slug*, may also play a role in other metastasizing cancers.

Most skin cancers result from a series of genetic changes in somatic cells. Some people, however, have a genetic susceptibility to developing skin cancer. **Xeroderma pigmentosum** (zēr’ō-der’mă pig’men-tō’sūm) is a rare, inherited disorder in which a DNA

(a) Basal cell carcinoma

(b) Squamous cell carcinoma

(c) Melanoma

FIGURE 5A Cancer of the Skin

repair gene is defective. Because damage to genes by UV radiation is not repaired, exposure to UV radiation results in the development of fatal skin cancers in childhood. Limiting exposure to the sun and using sunscreens can reduce everyone's likelihood of developing skin cancer, especially those who have a genetic

susceptibility. Two types of UV radiation play a role. Ultraviolet-B (UVB; 290–320 nm) radiation is the most potent for causing sunburn; it is also the main cause of basal and squamous cell carcinomas and a significant cause of melanoma. Ultraviolet-A (UVA; 320–400 nm) also contributes to skin cancer

development, especially melanoma. It, too, penetrates the dermis, causing wrinkling and leathering of the skin. The Skin Cancer Foundation recommends using a broad-spectrum sunscreen that protects against both UVB and UVA, with a sun protection factor (SPF) of at least 15.

During pregnancy, certain hormones, such as estrogen and melanocyte-stimulating hormone, cause the mother's body to increase melanin production, which causes darkening of the nipples, areolae, and genitalia. The cheekbones, forehead, and chest also may darken, resulting in the “mask of pregnancy,” and a dark line of pigmentation may appear on the midline of the abdomen. Diseases that cause increased secretion of adrenocorticotropic hormone and melanocyte-stimulating hormone, such as Addison disease, also cause increased pigmentation.

Erythema (er-ī-thē'mă) is a condition in which the skin turns a reddish hue when the amount of blood flowing through the skin increases. An inflammatory response (see chapter 4) stimulated by infection, sunburn, allergic reactions, insect bites, or other causes can produce erythema, as can exposure to the cold and blushing or flushing when angry or hot. A decrease in blood flow, as occurs in shock, can make the skin appear pale, and a decrease in the blood oxygen content produces **cyanosis** (sī-ă-nō'sis), a bluish skin color (see Clinical Impact, “The Integumentary System as a Diagnostic Aid,” later in this chapter).

Carotene (kar'ō-tēn) is a yellow pigment found in plants, such as carrots and corn. Humans normally ingest carotene and use it as a source of vitamin A. Carotene is lipid-soluble and, when large amounts of carotene are consumed, the excess accumulates in the stratum corneum and in adipocytes of the dermis and subcutaneous tissue, causing the skin to develop a yellowish tint. The yellowish tint slowly disappears once carotene intake is reduced.

The location of pigments and other substances in the skin affects the color produced. For example, light reflected off dark pigment in the dermis or subcutaneous tissue can be scattered by collagen fibers of the dermis to produce a blue color. The same effect produces the blue color of the sky as light is reflected from dust particles in the air. The deeper within the dermis or subcutaneous tissue any dark pigment is located, the bluer the pigment appears because of the light-scattering effect of the overlying tissue. This effect causes the blue color of tattoos, bruises, and some superficial blood vessels.

ASSESS YOUR PROGRESS

- From deepest to most superficial, name and describe the five strata of the epidermis. In which stratum are new cells formed by mitosis? Which strata have live cells, and which strata have dead cells?
- Describe the structural features resulting from keratinization that make the epidermis structurally strong and resistant to water loss.

- Compare the structure and location of thick and thin skin. Is hair in thick or thin skin?
- Which cells of the epidermis produce melanin? What happens to the melanin once it is produced?
- How do genetic factors, exposure to sunlight, and hormones determine the amount of melanin in the skin?
- How do carotene, blood flow, oxygen content, and collagen affect skin color?

Dermis

The dermis is connective tissue. Recall from chapter 4 that connective tissue consists of cells distributed widely in an extensive extracellular matrix, which includes protein fibers. The cells of the dermis include fibroblasts, a few adipocytes, and macrophages. Collagen is the main type of protein fiber of the extracellular matrix, but elastic and reticular fibers are also present. The dermis contains blood vessels that allow for nutrient and waste exchange to the cells of the dermis and the living cells of the epidermis. The dermis also contains nerve endings, hair follicles, smooth muscles, glands, and lymphatic vessels (see figure 5.1). The nerve endings are varied in structure and function. They include free nerve endings for pain, itch, tickle, and temperature sensations; hair follicle receptors for light touch; Pacinian corpuscles for deep pressure; Meissner corpuscles for detecting simultaneous stimulation at two points on the skin; and Ruffini end organs for sensing continuous touch or pressure (see figure 14.1).

The dermis is composed of two tissue layers (see figure 5.2a): the superficial **papillary** (pap'i-lār-ē) **layer** and the deeper **reticular** (re-tik'ū-lār) **layer**. The papillary layer derives its name from projections, called **dermal papillae** (pă-pil'ē), that extend toward the epidermis. The papillary layer is loose connective tissue with thin fibers that are somewhat loosely arranged. The papillary layer also contains blood vessels that supply the overlying epidermis with oxygen and nutrients, remove waste products, and aid in regulating body temperature.

The dermal papillae under the thick skin of the palms of the hands and soles of the feet lie in parallel, curving ridges that shape the overlying epidermis into fingerprints and footprints. The ridges increase friction and improve the grip of the hands and feet. Everyone has unique fingerprints and footprints, even identical twins.

The reticular layer, which is composed of dense irregular connective tissue, is the main layer of the dermis. It is continuous with the subcutaneous tissue and forms a mat of irregularly arranged fibers that are resistant to stretching in many directions.

The elastic and collagen fibers are oriented more in some directions than in others and produce **cleavage lines**, or *tension lines*, in the skin (figure 5.5). It is important for health professionals to understand cleavage line directions because an incision made parallel to the cleavage lines is less likely to gap than an incision made across them. The development of infections and the formation of scar tissue are reduced in wounds where the edges are closer together.

If the skin is overstretched, the dermis may rupture and leave lines that are visible through the epidermis. These lines of scar tissue, called **stretch marks**, can develop on the abdomen and breasts of a woman during pregnancy or on the skin of athletes who have quickly increased muscle size by intense weight training.

ASSESS YOUR PROGRESS

8. Name and compare the two layers of the dermis. Which layer is responsible for most of the structural strength of the skin?
9. What are formed by the dermal papillae in thick skin? What roles do they have?
10. What are cleavage lines, and how are they related to the healing of a cut?

FIGURE 5.5 Cleavage Lines

The orientation of collagen fibers produces cleavage lines, or tension lines, in the skin.

5.3 Subcutaneous Tissue

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe the structure and functions of the subcutaneous tissue underlying the skin.

Deep to the skin is the subcutaneous tissue. The subcutaneous tissue attaches the skin to underlying bone and muscle and supplies the skin with blood vessels and nerves (see figure 5.1). The subcutaneous tissue consists of loose connective tissue with collagen and elastic fibers. The main types of cells within the subcutaneous tissue are fibroblasts, adipocytes, and macrophages. The subcutaneous tissue, which is not part of the skin, is sometimes called the *hypodermis*.

Approximately half the body's stored lipids are in the subcutaneous tissue, where they function in insulation and padding and as a source of energy. The subcutaneous tissue can be used to estimate total body fat by pinching the skin at selected locations and measuring the thickness of the skin fold and underlying subcutaneous tissue. The thicker the fold, the greater the amount of total body fat.

The amount of adipose tissue in the subcutaneous tissue varies with age, sex, and diet. Most babies have a chubby appearance because they have proportionately more adipose tissue than adults. Women have proportionately more adipose tissue than men, especially over the thighs, buttocks, and breasts, which accounts for some of the differences in body shape between women and men. The amount of adipose tissue in the subcutaneous tissue is also responsible for some of the differences in body shape between individuals of the same sex.

Clinical IMPACT

Injections

Injections are used to introduce certain substances, such as medication and vaccines, into the body. There are three types of injections. An **intradermal injection**, as is used for the tuberculin skin test, goes into the dermis. It is administered by drawing the skin taut and inserting a small needle at a shallow angle into the skin. A **subcutaneous injection** extends into the subcutaneous tissue; an insulin injection is one example. A subcutaneous injection is achieved by pinching the skin to form a "tent," into which a short needle is inserted. An **intramuscular injection** reaches a muscle deep to the subcutaneous tissue. It is accomplished by inserting a long needle at a 90-degree angle to the skin. Intramuscular injections are used for injecting most vaccines and certain antibiotics.

ASSESS YOUR PROGRESS

11. Name the types of tissue forming the subcutaneous tissue layer.
12. How is the subcutaneous tissue related to the skin?
13. List the functions of the adipose tissue within the subcutaneous tissue.

5.4 Accessory Skin Structures

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the structure of a hair and discuss the phases of hair growth.
- B. Explain the function of the arrector pili muscle.
- C. Name the glands of the skin and describe the secretions they produce.
- D. Describe the parts of a nail and explain how nails grow.

The accessory skin structures include the hair, glands, and nails.

Hair

The presence of **hair** is one of the characteristics of all mammals; if the hair is dense and covers most of the body surface, it is called fur. In humans, hair is found everywhere on the skin except the palms, the soles, the lips, the nipples, parts of the external genitalia, and the distal segments of the fingers and toes.

Hair structure and coloration change as a person ages. By the fifth or sixth month of fetal development, delicate, unpigmented hair called **lanugo** (lă-noo'gō) has developed and covered the fetus. Near the time of birth, long, coarse, and pigmented hairs called **terminal hairs** replace the lanugo of the scalp, eyelids, and eyebrows. **Vellus** (vel'ūs) **hairs**, which are short, fine, and usually unpigmented, replace the lanugo on the rest of the body. At puberty, terminal hair, especially in the pubic and axillary regions, replaces much of the vellus hair. The hair of the chest, legs, and arms is approximately 90% terminal hair in males and approximately 35% in females. In males, terminal hairs replace the vellus hairs of the face to form the beard. The beard, pubic, and axillary hair are signs of sexual maturity. In addition, pubic and axillary hair may function as wicks for dispersing odors produced by secretions from specialized glands in the pubic and axillary regions. It also has been suggested that pubic hair protects against abrasion during intercourse and axillary hair reduces friction when the arms move.

Hair Structure

A hair is divided into the **shaft**, which protrudes above the surface of the skin, and the **root**, located below the surface (figure 5.6a). The base of the root is expanded to form the **hair bulb**. Most of the root and the shaft are composed of columns of dead, keratinized epithelial cells arranged in three concentric layers: the medulla, the cortex, and the cuticle (figure 5.6c). The **medulla** (me-dool'ă) is the central axis of the hair, and it consists of two or three layers

of cells containing soft keratin. The **cortex** surrounds the medulla and forms the bulk of the hair. The cells of the cortex contain hard keratin. The cortex is covered by the **cuticle** (kū'ti-kl), a single layer of cells also containing hard keratin. The edges of the cuticle cells overlap like shingles on a roof.

The **hair follicle** is a tubelike invagination of the epidermis that extends into the dermis. A hair develops and grows within each hair follicle. A hair follicle consists of a **dermal root sheath** and an **epithelial root sheath**. The dermal root sheath is the portion of the dermis that surrounds the epithelial root sheath. The epithelial root sheath is divided into external and internal parts (figure 5.6b). At the opening of the follicle, the external epithelial root sheath has all the strata found in thin skin. Deeper in the hair follicle, the number of cells decreases until, at the hair bulb, only the stratum basale is present. This has important consequences for skin repair. If the epidermis and the superficial part of the dermis

Clinical
IMPACTThe Integumentary System
as a Diagnostic Aid

The integumentary system can be used in diagnosis because it is easily observed and often reflects events occurring in other parts of the body. For example, **cyanosis** (sī-ā-nō'sis), a bluish color to the skin that results from decreased blood oxygen content, is an indication of impaired cardiovascular or respiratory function. When red blood cells wear out, they are broken down, and the liver excretes part of their contents as bile pigments into the small intestine. **Jaundice** (jawn'dis), a yellowish skin color, occurs when excess bile pigments accumulate in the blood. If a disease, such as viral hepatitis, damages the liver, bile pigments are not excreted and accumulate in the blood.

Rashes and lesions in the skin can be symptomatic of problems elsewhere in the body. For example, scarlet fever results from a bacterial infection in the throat. The bacteria release a toxin into the blood that causes the pink-red rash for which this disease was named. In allergic reactions (see chapter 22), histamine released into the tissues produces swelling and reddening. Development of the skin rash called hives can indicate an allergy to foods or drugs, such as penicillin.

The condition of the skin, hair, and nails is affected by nutritional status. Vitamin A deficiency causes the skin to produce excess keratin and assume a characteristic sandpaper texture, whereas iron-deficiency anemia causes the nails to lose their normal contour and become flat or concave (spoon-shaped).

Hair concentrates many substances, which can be detected by laboratory analysis, and comparing a patient's hair with "normal" hair can be useful in certain diagnoses. For example, lead poisoning results in high levels of lead in the hair. Forensic analyses can also be conducted on hair samples to test for drug use and poisoning. However, hair analyses are not reliable for determining a person's general health or nutritional status.

FIGURE 5.6 Hair Follicle

(a) The hair follicle contains the hair and consists of a dermal and an epithelial root sheath. (b) Enlargement of the hair follicle wall and hair bulb. (c) Cross section of a hair within a hair follicle. **APR**

are damaged, the keratinocyte stem cells located in the stratum basale of the undamaged part of the hair follicle can be a source of new epithelium. The internal epithelial root sheath has raised edges that mesh closely with the raised edges of the hair cuticle and hold the hair in place. When a hair is pulled out, the internal epithelial root sheath usually comes out as well and is plainly visible as whitish tissue around the root of the hair.

The hair bulb is an expanded knob at the base of the hair root (figure 5.6a,b). Inside the hair bulb is a mass of undifferentiated

epithelial cells called the **matrix**. The matrix produces the hair and the internal epithelial root sheath. The dermis of the skin projects into the hair bulb as a **hair papilla**. Within the hair papilla are blood vessels that provide nourishment to the cells of the matrix.

Hair Growth

Hair is produced in cycles that involve a **growth stage** and a **resting stage**. During the growth stage, a hair increases in length as

new matrix cells are produced, differentiate, become keratinized, and die. The hair grows longer as cells are added at the base of the hair root. Eventually, hair growth stops; the hair follicle shortens and holds the hair in place. A resting period follows, after which a new cycle begins and a new hair replaces the old hair, which falls out of the hair follicle. Thus, losing a hair normally means that the hair is being replaced. The length of each stage depends on the hair—eyelashes grow for approximately 30 days and rest for 105 days, whereas scalp hairs grow for 3 years and rest for 1–2 years. At any given time, an estimated 90% of the scalp hairs are in the growing stage, and loss of approximately 100 scalp hairs per day is normal.

The most common kind of permanent hair loss is “pattern baldness.” Hair follicles shrink and revert to producing vellus hair, which is very short, transparent, and for practical purposes invisible. Eventually, hair production in these smaller follicles may completely cease. Although baldness is more common and more pronounced in certain men, it can also occur in women. Genetic factors and the hormone testosterone are involved in causing pattern baldness.

The average rate of hair growth is approximately 0.3 mm per day, although hairs grow at different rates, even in the same approximate location. Cutting, shaving, or plucking hair does not alter the growth rate or the character of the hair, but hair can feel coarse and bristly shortly after shaving because the short hairs are less flexible. Maximum hair length is determined by the rate of hair growth and the length of the growing phase. For example, scalp hair can become very long, but eyelashes are short.

Hair Color

Similar to how melanocytes of the epidermis produce melanin and pass it to the keratinocytes of the skin, melanocytes within the hair bulb matrix produce melanin and pass it to keratinocytes in the hair cortex and medulla. As with the skin, varying amounts and types of melanin cause different shades of hair color. Blonde hair has little black-brown melanin, whereas jet black hair has the most. Intermediate amounts of melanin account for different shades of brown. Red hair is caused by varying amounts of a red type of melanin. Hair sometimes contains both black-brown and red melanin. With age, the amount of melanin in hair can decrease, causing hair color to fade or become white (i.e., no melanin). Gray hair is usually a mixture of unfaded, faded, and white hairs. Hair color is controlled by several genes, and dark hair color is not necessarily dominant over light.

Muscles

Associated with each hair follicle are smooth muscle cells called the **arrector pili** (ă-rek'tōr pī'lī). The arrector pili extend from the dermal root sheath of the hair follicle to the papillary layer of the dermis (figure 5.6a). Normally, the hair follicle and the hair inside it are at an oblique angle to the surface of the skin. When the arrector pili muscles contract, however, they pull the follicle into a more perpendicular position, causing the hair to “stand on end.” Movement of the hair follicles produces raised areas called “goose bumps.”

ASSESS YOUR PROGRESS

- When and where are lanugo, vellus, and terminal hairs found in the skin?
- What are the regions of a hair? What type of cells make up most of a hair?
- Describe the three layers of a hair seen in cross section.
- Describe the parts of a hair follicle. How is the epithelial root sheath important in skin repair?
- In what part of a hair does growth take place? What are the stages of hair growth? Do all hairs grow at the same rate?
- What determines the different shades of hair color?
- Explain the location and action of arrector pili muscles.

Glands

The major glands of the skin are the sebaceous glands and the sweat glands (figure 5.7).

Sebaceous Glands

Sebaceous (sē-bā'shūs) **glands**, located in the dermis, are simple or compound alveolar glands that produce **sebum** (sē'būm), an oily, white substance rich in lipids. Because sebum is released by the lysis and death of secretory cells, sebaceous glands are classified as holocrine glands (see chapter 4). Most sebaceous glands are connected by a duct to the upper part of the hair follicles, from which the sebum oils the hair and the skin surface. The secretion of sebum onto the hair and surrounding skin prevents drying and protects against some bacteria. A few sebaceous glands located in

FIGURE 5.7 Glands of the Skin

Sebaceous glands and apocrine sweat glands empty into a hair follicle. Eccrine sweat glands empty onto the surface of the skin.

MICROBES In Your Body

Using Bacteria to Fight Bacteria

Acne (acne vulgaris) is the most common skin condition in the United States. Though 80% of all American adolescents develop acne, adults can also be affected by it. When considering all age groups, approximately 40 to 50 million Americans suffer from acne. Unfortunately, there is not a tried-and-true cure for acne; however, new research examining the skin microbiome may have found a natural and effective treatment to get healthy, clear skin.

Unique species of bacteria, *Propionibacterium acnes* (*P. acnes*), are found in sebum-rich areas of the skin, such as the forehead, side of the nose, and back. There, these bacteria feed on lipids found in sebum. Although it has been difficult to study these bacteria, the inception of the Human Microbiome Project (see “Getting to Know Your Bacteria” in chapter 1) allowed scientists to determine specific genetic traits

of skin microbiome bacteria. Using this technique, scientists have identified three unique strains of *P. acnes*. Of the three strains, one is more dominant in people with acne-free skin. Research has shown that this strain of *P. acnes* does not adversely affect the host. However, the other two strains *P. acnes* are pathogenic to humans. So how does this information help scientists learn how to prevent acne? It seems that the “good” *P. acnes* prevents invasion of the skin by certain bacteria through a natural metabolic process. When *P. acnes* breaks down lipids, the skin pH is lowered to a level not tolerated by the invading bacteria. Scientists have proposed that the strain of *P. acnes* in healthy skin (“good” *P. acnes*) kills off the pathogenic strains of *P. acnes* (“bad” *P. acnes*) in a similar fashion. Since acne-affected people do not host the “good” strain, the “bad” strain can take over and cause the annoying skin eruptions of

acne. Thus, perhaps in the future, to prevent acne, affected people can apply the “good” *P. acnes* or similar bacteria to their skin to prevent the “bad” *P. acnes* from taking over.

► Predict 3

You just learned that acne-causing bacteria tend to live in areas of the skin with many sebaceous glands. However, in the section “Glands,” it states that sebum protects against certain bacteria.

- Based on what you’ve learned about bacteria in the “Microbes in Your Body” boxes in chapters 1 and 3, why do you think *P. acnes* are able to survive the antibacterial effects of sebum?
- Why do you think certain acne medications are so effective simply by inhibiting sebum production?

the lips, the eyelids (meibomian glands), and the genitalia are not associated with hairs but open directly onto the skin surface.

Sweat Glands

There are two types of **sweat**, or *sudoriferous* (soo-dō-rif’er-ūs) **glands**: eccrine glands and apocrine glands. At one time, physiologists believed that secretions were released in a merocrine fashion from eccrine glands and in an apocrine fashion from apocrine glands (see chapter 4). But we now know that apocrine sweat glands also release some of their secretions in a merocrine fashion, and possibly some in a holocrine fashion. Traditionally, they are still referred to as apocrine sweat glands.

Eccrine (ek’rin) **sweat glands** (sometimes called *merocrine* [mer’ō-krin, mer’ō-krīn, mer’ō-krēn] *sweat glands*) are the most common type of sweat gland. They are simple, coiled, tubular glands that open directly onto the surface of the skin through sweat pores (figure 5.7). Eccrine sweat glands can be divided into two parts: the deep, coiled portion, which is located mostly in the dermis, and the duct, which passes to the skin surface. The coiled part of the gland produces an isotonic fluid that is mostly water but also contains some salts (mainly sodium chloride) and small amounts of ammonia, urea, uric acid, and lactic acid. As this fluid moves through the duct, sodium chloride moves by active transport from the duct back into the body, thereby conserving salts. The resulting hypotonic fluid that leaves the duct is called **sweat**. When the body temperature starts to rise above normal, the sweat glands produce sweat, which evaporates and cools the body. Sweat also can be released in the palms, soles, and axillae as a result of emotional stress. Emotional sweating is used in lie detector

(polygraph) tests because sweat gland activity may increase when a person tells a lie. Such tests can detect the sweat produced, even in small amounts, because the salt solution conducts electricity and lowers the electrical resistance of the skin.

Eccrine sweat glands are distributed over the majority of the areas of the body but are most numerous in the palms of the hands and soles of the feet. Eccrine sweat glands are not found on the margin of the lips, the labia minora, and the tips of the penis and clitoris.

Apocrine (ap’ō-krin) **sweat glands** are simple, coiled, tubular glands that usually open into hair follicles superficial to the opening of the sebaceous glands (figure 5.7). Apocrine sweat glands are found in the axillae and genitalia (scrotum and labia majora) and around the anus. Unlike eccrine sweat glands, apocrine sweat glands do not help regulate temperature in humans. Apocrine sweat glands become active at puberty as a result of sex hormones. Their secretions contain organic substances, such as 3-methyl-2-hexenoic acid, that are essentially odorless when first released but are quickly metabolized by bacteria to cause what is commonly known as body odor. Many mammals use scent as a means of communication, and physiologists have suggested that the activity of apocrine sweat glands may signal sexual maturity.

Other Glands

Other skin glands are the ceruminous glands and the mammary glands. The **ceruminous** (sě-roo’mi-nūs) **glands** are modified eccrine sweat glands located in the ear canal (external auditory canal). **Cerumen**, or earwax, is composed of the combined secretions of ceruminous glands and sebaceous glands. Cerumen and hairs in

the ear canal protect the tympanic membrane by preventing dirt and small insects from moving too deeply into the ear canal. However, an accumulation of cerumen can block the ear canal and make hearing more difficult.

The **mammary glands** are modified apocrine sweat glands located in the breasts. They produce milk. The structure and regulation of mammary glands are discussed in chapters 28 and 29.

Nails

A **nail** is a thin plate consisting of layers of dead stratum corneum cells that contain a very hard type of keratin. Nails are located on the distal ends of the digits (fingers and toes). A nail consists of the proximal **nail root** and the distal **nail body** (figure 5.8a). The nail root is covered by skin, and the nail body is the visible portion of the nail. The lateral and proximal edges of the nail are covered by skin called the **nail fold**, and the edges are held in place by the **nail groove** (figure 5.8b). The stratum corneum of the nail fold grows onto the nail body as the **cuticle**, or *eponychium* (ep-ō-nik'ē-ŭm). Beneath the free edge of the nail body is the **hyponychium** (hī'pō-nik'ē-ŭm), a thickened region of the stratum corneum (figure 5.8c).

The nail root extends distally from the **nail matrix**. The nail also attaches to the underlying **nail bed**, which is located between the nail matrix and the hyponychium. The nail matrix and bed are composed of epithelial tissue, with a stratum basale that gives rise to the cells that form the nail. The nail matrix is thicker than the nail bed and produces nearly all of the nail. The nail bed is visible through the clear nail and appears pink because of blood vessels in the dermis. A small part of the nail matrix, the **lunula** (loo'noo-lă), is seen through the nail body as a whitish,

crescent-shaped area at the base of the nail. The lunula, seen best on the thumb, appears white because the blood vessels do not show through the thicker nail matrix.

As the nail forms in the nail matrix and bed, it slides over the nail bed toward the distal end of the digit. Nails grow at an average rate of 0.5–1.2 mm per day, and fingernails grow more rapidly than toenails. Unlike hair, they grow continuously throughout life and do not have a resting phase.

Predict 4

While trying to fix some loose boards on his deck, Bob hit his left thumb with his hammer. The hammer struck his thumbnail distal to the lunula and proximal to the hyponychium. After a short period, a dark area appeared in the area of the nail bed. The injury was very painful until a physician drilled a small hole through Bob's nail, releasing bloody fluid. After nearly 2 months, the dark area moved to the free edge of the nail. Explain why a dark area developed in the nail. What caused Bob's pain, and why did drilling a hole in his nail relieve it? Why did the dark area move distally over time?

ASSESS YOUR PROGRESS

21. What do sebaceous glands secrete? What is the function of the secretion?
22. Which glands of the skin are responsible for cooling the body? Where are they located? Which glands are involved with producing body odor? Where are they located?
23. Name the parts of a nail. Which part produces most of the nail? What is the lunula?
24. What makes a nail hard? Do nails have growth stages?

FIGURE 5.8 Nail

5.5 Physiology of the Integumentary System

LEARNING OUTCOMES

After reading this section, you should be able to

- Relate the protective functions of the skin, hair, glands, and nails.
- Explain how the skin acts as a sense organ.
- Discuss the importance of the skin in temperature regulation.
- Describe the involvement of the skin in vitamin D production and in excretion.

Protection

The integumentary system is the body's fortress, defending it from harm:

- The skin protects underlying structures from mechanical damage. The dermis provides structural strength, preventing tearing of the skin. The stratified epithelium of the epidermis protects against abrasion. As the outer cells of the stratum corneum slough off, they are replaced by cells from the stratum basale. Calluses develop in areas subject to heavy friction or pressure.
- The skin prevents microorganisms and other foreign substances from entering the body. Secretions from skin glands produce an environment unsuitable for some microorganisms. The skin also contains components of the immune system that act against microorganisms (see chapter 22).
- Melanin absorbs ultraviolet light and protects underlying structures from its damaging effects.
- Hair provides protection in several ways. The hair on the head acts as a heat insulator and protects against ultraviolet light and abrasion. The eyebrows keep sweat out of the eyes, the eyelashes protect the eyes from foreign objects, and hair in the nose and ears prevents dust and other materials from entering. Axillary and pubic hair are a sign of sexual maturity and protect against abrasion.
- Nails protect the ends of the fingers and toes from damage and can be used in defense.
- The intact skin plays an important role in reducing water loss because its lipids act as a barrier to the diffusion of water.

Some lipid-soluble substances readily pass through the epidermis. Lipid-soluble medications can be administered by applying them to the skin, after which the medication slowly diffuses through the skin into the blood. For example, nicotine patches are applied to help reduce withdrawal symptoms in people attempting to quit smoking.

Sensation

Receptors in the skin can detect pain, heat, cold, and pressure. For example, the epidermis and dermal papillae are well supplied with touch receptors. The dermis and deeper tissues contain pain, heat, cold, touch, and pressure receptors. Hair follicles (but not the hair)

are well innervated, and sensory receptors surrounding the base of hair follicles can detect hair movement. Sensory receptors are discussed in more detail in chapter 14.

Temperature Regulation

Body temperature is affected by blood flow through the skin. When blood vessels (arterioles) in the dermis dilate, more warm blood flows from deeper structures to the skin, and heat loss increases (figure 5.9, steps 1 and 2). Body temperature tends to increase as a result of exercise, fever, or a rise in environmental temperature. In order to maintain homeostasis, this excess heat must be lost. The body accomplishes this by producing sweat. The sweat spreads over the surface of the skin; as it evaporates, the body loses heat.

When blood vessels in the dermis constrict, less warm blood flows from deeper structures to the skin, and heat loss decreases (figure 5.9, steps 3 and 4). If body temperature begins to drop

Case STUDY

Frostbite

Billy was hiking in the mountains one autumn day. Unexpectedly, a cold front moved in and the temperature dropped to well below freezing. Billy was unprepared for the temperature change, and he did not have a hat or earmuffs. As the temperature dropped, his ears and nose became pale in color. After continued exposure to the dropping temperatures, every 15–20 minutes, his ears and nose turned red for 5–10 minutes and then became pale again. After several hours, Billy managed to hike back to the trail head. By then, he was very chilled and had no sensation in his ears or nose. As he looked in the rearview mirror of his car, he could see that the skin of his ears and nose had turned white. It took Billy 2 hours to drive to the nearest emergency room, where he learned that the white skin meant he had frostbite of his ears and nose. About 2 weeks later, the frostbitten skin peeled. Despite treatment with an antibiotic, the skin of his right ear became infected. Eventually, Billy recovered, but he lost part of his right ear.

Predict 5

Frostbite is the most common type of freezing injury. When skin temperature drops below 0°C (32°F), the skin freezes and ice crystal formation damages tissues.

- Using figure 5.9, describe the mechanism that caused Billy's ears and nose to become pale. How is this mechanism beneficial when the ambient temperature is decreasing?
- Explain what happened when Billy's ears and nose periodically turned red. How is this beneficial when the ambient temperature is very cold?
- What is the significance of Billy's ears and nose turning and staying white?
- Why is a person with frostbite likely to develop an infection of the affected part of the body?

1 Blood vessel dilation results in increased blood flow toward the surface of the skin.

2 Increased blood flow beneath the epidermis results in increased heat loss (gold arrows).

(a)

3 Blood vessel constriction results in decreased blood flow toward the surface of the skin.

4 Decreased blood flow beneath the epidermis results in decreased heat loss.

(b)

PROCESS FIGURE 5.9 Heat Exchange in the Skin 

below normal, heat can be conserved by a decrease in the diameter of dermal blood vessels.

Contraction of the arrector pili muscles causes hair to stand on end, but this does not significantly reduce heat loss in humans because so little hair covers the body. However, the hair on the head is an effective insulator. We consider general temperature regulation further in chapter 25.

Vitamin D Production

Vitamin D functions as a hormone involved in the regulation of calcium homeostasis. Its primary role is to stimulate the uptake of calcium and phosphate from the intestines. Adequate levels of these minerals are necessary for normal bone metabolism (see chapter 6), and calcium is required for normal nerve and muscle function (see chapter 9).

Vitamin D synthesis begins in skin exposed to ultraviolet light, and people can produce all the vitamin D they require by this process if enough ultraviolet light is available. However, because people live indoors and wear clothing, their exposure to ultraviolet light

may not be adequate for the manufacture of sufficient vitamin D. This is especially likely for people living in cold climates because they remain indoors or are covered by warm clothing when outdoors. Fortunately, vitamin D can also be ingested and absorbed in the small intestine. Natural sources of vitamin D are liver (especially fish liver), egg yolks, and dairy products (e.g., butter, cheese, and milk). In addition, the diet can be supplemented with vitamin D in fortified milk or vitamin pills.

Vitamin D synthesis involves a precursor molecule, 7-dehydrocholesterol (7-dē-hī'drō-kō-les'ter-ol), which is stored in the skin. When exposed to ultraviolet light, the precursor molecule is converted into **cholecalciferol** (kō'lē-kal-sif'er-ol). Cholecalciferol is released into the blood and modified first by the liver and later by the kidneys to form active vitamin D₃, **calcitriol** (kal-si-trī'ol).

Excretion

Excretion is the removal of waste products from the body. In addition to water and salts, sweat contains a small amount of waste products, including urea, uric acid, and ammonia. However, even when large

amounts of sweat are lost, the quantity of waste products eliminated in the sweat is insignificant because the urinary system excretes most of the body's waste products.

ASSESS YOUR PROGRESS

25. In what ways does the skin provide protection?
26. What kinds of sensory receptors are in the skin, and why are they important?
27. How does the skin help regulate body temperature?
28. Name the locations where cholecalciferol is produced and then modified into vitamin D. What are the functions of vitamin D?
29. What substances are excreted in sweat? Is the skin an important site of excretion?

5.6 Burns

LEARNING OUTCOME

After reading this section, you should be able to

A. Classify burns on the basis of the amount of skin damage produced.

A **burn** is injury to a tissue caused by heat, cold, friction, chemicals, electricity, or radiation. Burns are classified according to the extent of surface area involved and the depth of the burn. For an adult, the surface area that is burned can be conveniently estimated by “the rule of nines,” which divides the body into areas that are approximately 9%, or multiples of 9%, of the body surface area (BSA; figure 5.10). For younger patients, surface area relationships are different. For example, in an infant, the head and neck are 21% of BSA, whereas in an adult they are 9%. For burn victims younger than age 15, a table specifically developed for them should be consulted.

On the basis of depth, burns are classified as either partial-thickness or full-thickness burns (figure 5.11). **Partial-thickness burns** are subdivided into first- and second-degree burns. **First-degree burns** involve only the epidermis and may result in redness, pain, and slight edema (swelling). They can be caused by sunburn or brief exposure to hot or cold objects, and they heal in a week or so without scarring.

Second-degree burns damage the epidermis and dermis. Minimal dermal damage causes redness, pain, edema, and blisters. Healing takes approximately 2 weeks, and no scarring results. However, if the burn goes deep into the dermis, the wound appears red, tan, or white; may take several months to heal; and might scar. In all second-degree burns, the epidermis regenerates from epithelial tissue in hair follicles and sweat glands, as well as from the edges of the wound.

Full-thickness burns are also called **third-degree burns**. The epidermis and dermis are completely destroyed, and deeper tissue may be involved. Third-degree burns are often surrounded by first- and second-degree burns. Although the areas that have first- and second-degree burns are painful, the region of third-degree burn is usually painless because the sensory receptors have been destroyed. Third-degree burns appear white, tan, brown,

FIGURE 5.10 The Rule of Nines

(a) In an adult, surface areas can be estimated using the rule of nines: Each major area of the body is 9%, or a multiple of 9%, of the total body surface area. (b) In infants and children, the head represents a larger proportion of surface area, so the rule of nines is not as accurate, as can be seen in this depiction of a 5-year-old child.

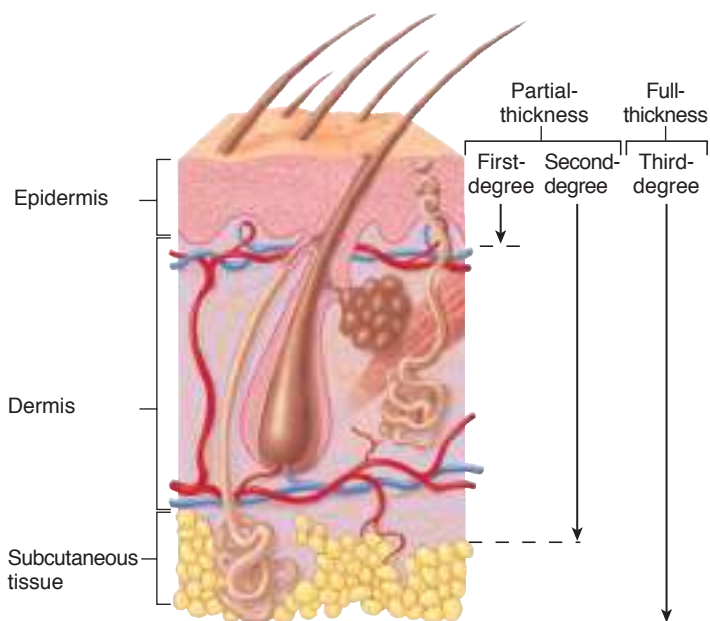

FIGURE 5.11 Burns

Partial-thickness burns are subdivided into first-degree burns (damage to only the epidermis) and second-degree burns (damage to the epidermis and part of the dermis). Full-thickness, or third-degree, burns destroy the epidermis, the dermis, and sometimes deeper tissues.

Background Information

When large areas of skin are severely burned, the resulting systemic effects can be life-threatening. Within minutes of a major burn injury, there is increased permeability of the capillaries, which are the small blood vessels in which fluid, gases, nutrients, and waste products are normally exchanged between the blood and the tissues. This increased permeability occurs at the burn site and throughout the body. As a result, fluid and electrolytes (see chapter 2) are lost from the burn wound and into tissue spaces. The loss of fluid decreases blood volume, which decreases the heart's ability to pump blood. The resulting decrease in blood delivery to tissues can cause tissue damage, shock, and even death. Treatment consists of administering intravenous fluid at a faster rate than it leaks out of the capillaries. Although this fluid replacement can reverse the shock and prevent death, fluid continues to leak into tissue spaces, causing pronounced **edema** (swelling).

Typically, after 24 hours, capillary permeability returns to normal, and the amount of intravenous fluid administered can be greatly decreased. How burns cause capillary permeability to change is not well understood; however, it is clear that, following a burn, immunological and metabolic changes affect not only capillaries but the rest of the body as well. For example, chemical mediators (see chapter 4), which are released in response to tissue damage, contribute to changes in capillary permeability throughout the body.

Substances released from the burn may also cause cells to function abnormally. Burn injuries result in an almost immediate hypermetabolic state, which persists until wound closure. Two other factors contributing to the increased metabolism are (1) a resetting of the temperature control center in the brain to a higher temperature and (2) hormones released by the endocrine system (e.g., epinephrine and norepinephrine from the adrenal glands), which can increase cell metabolism. Compared with a normal

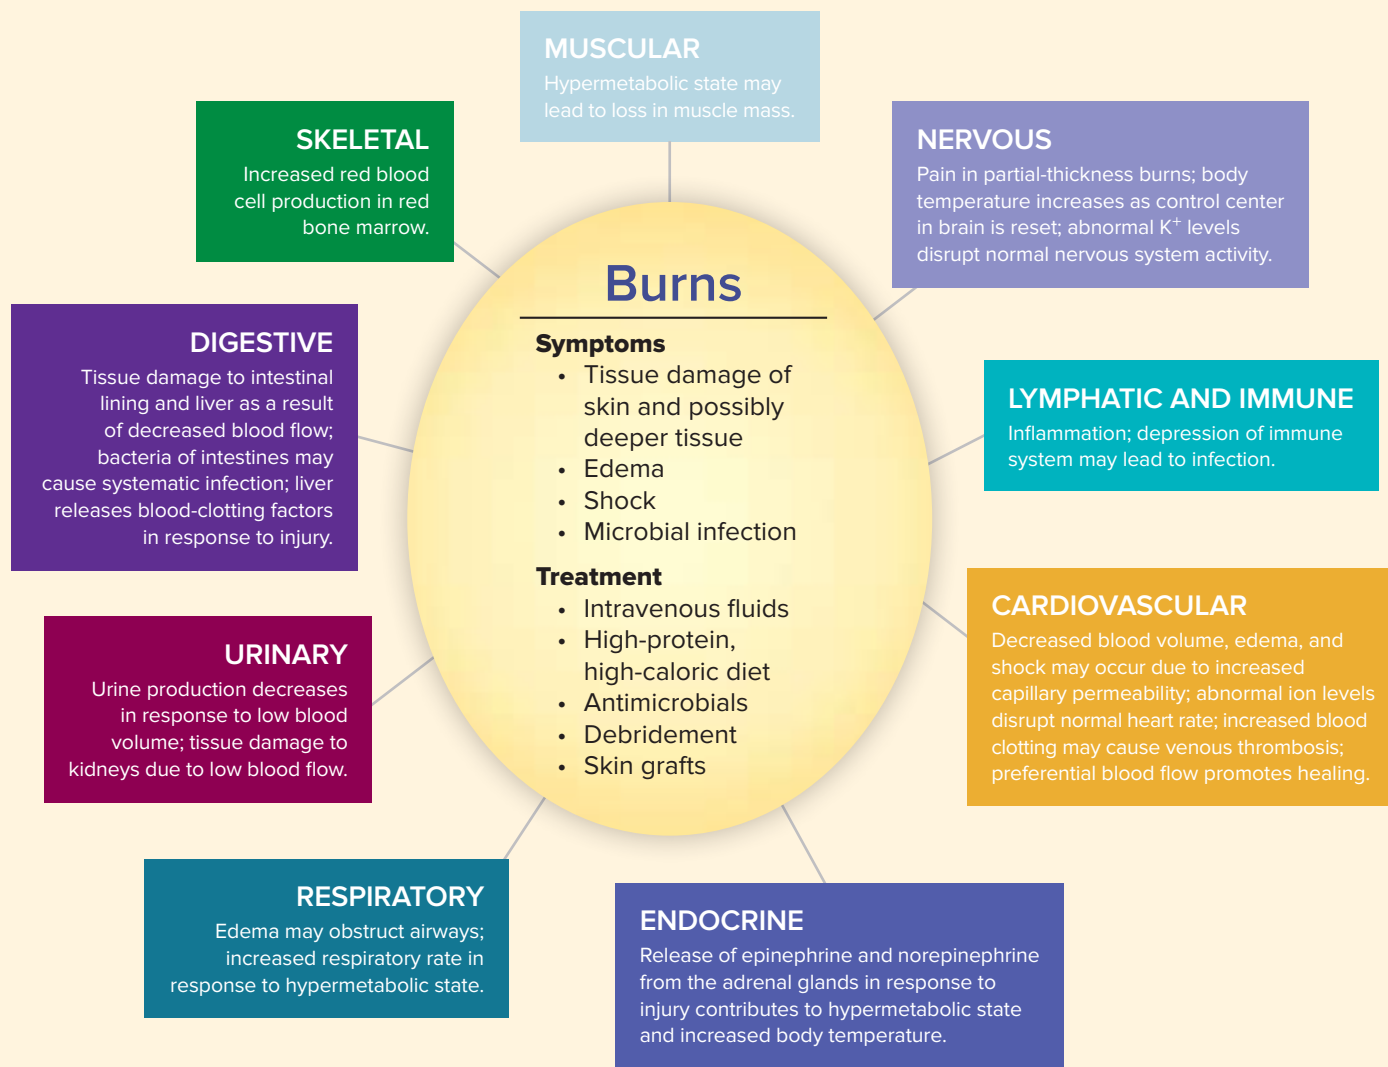

Figure 5B Partial- and Full-thickness Burns

Figure 5C Patient in a Burn Unit

body temperature of approximately 37°C (98.6°F), a typical burn patient may have a body temperature of 38.5°C (101.3°F) despite the higher loss of water by evaporation from the burn.

In severe burns, the increased metabolic rate can result in a loss of as much as 30–40% of the patient’s preburn weight. To help compensate, treatment may include doubling or tripling the patient’s caloric intake. In addition, the need for protein, which is necessary for tissue repair, is greater.

Normal skin maintains homeostasis by preventing microorganisms from entering the body. Because burns damage and sometimes completely destroy the skin, microorganisms can cause infections. For this reason, burn patients are maintained in an aseptic (sterile) environment in an attempt to prevent the entry of microorganisms into the wound. They are also given antimicrobial drugs, which kill microorganisms or suppress their growth. **Debridement** (dā-brēd-mont’), the removal of dead tissue from the burn (figure 5C), helps prevent infections by cleaning the wound and removing tissue in which infections could develop. Skin grafts, performed within a week of the injury, also help close the wound and prevent the entry of microorganisms.

Despite these efforts, however, infections are still the major cause of death for burn victims. Depression of the immune system during the first or

second week after the injury contributes to the high infection rate. First, the thermally altered tissue is recognized as a foreign substance, which stimulates the immune system. Then, the immune system is overwhelmed as immune system cells become less effective and production of the chemicals that normally provide resistance to infections decreases (see chapter 22). The greater the magnitude of the burn, the greater the depression of the immune system and the greater the risk for infection.

Venous thrombosis, the development of a clot in a vein, is another complication of burns. Blood normally forms a clot when exposed to damaged tissue, such as at a burn site, but clotting can also occur elsewhere, such as in veins, where clots can block blood flow, resulting in tissue destruction. The concentration of chemicals that cause clotting (called clotting factors) increases for two reasons: Loss of fluid from the burn patient concentrates the chemicals, and the liver releases an increased amount of clotting factors.

➤ Predict 6

When Sam was first admitted to the burn unit, the nurses carefully monitored his urine output. Why does that make sense in light of his injuries?

black, or deep cherry-red. Skin can regenerate only from the edges, and skin grafts are often necessary.

The depth and percentage of BSA affected can be combined with other criteria to classify the seriousness of a burn. The following criteria define a **major burn**: a third-degree burn over 10% or more of the BSA; a second-degree burn over 25% or more of the BSA; or a second- or third-degree burn of the hands, feet, face, genitals, or anal region. Facial burns are often associated with damage to the respiratory tract, and burns of joints often heal with scar tissue formation that limits movement. A **moderate burn** is a third-degree burn over 2–10% of the BSA or a second-degree burn over 15–25% of the BSA. A **minor burn** is a third-degree burn over less than 2% or a second-degree burn over less than 15% of the BSA.

Deep partial-thickness and full-thickness burns take a long time to heal, and they tend to form scar tissue with disfiguring and debilitating wound contracture. To prevent these complications and speed healing, skin grafts are performed. In a split skin graft, the epidermis and part of the dermis are removed from another part of the body and placed over the burn. Interstitial fluid from the burned area nourishes the graft until its dermis becomes vascularized. At the graft donation site, part of the dermis is still present. The deep parts of hair follicles and sweat gland ducts remain in this dermis, where they serve as a source of epithelial cells that form a new epidermis. This is the same process of epidermis formation that occurs following superficial second-degree burns.

When it is not possible or practical to move skin from one part of the body to a burn site, artificial skin or grafts from human cadavers or pigs are used. These techniques are often unsatisfactory because the body's immune system recognizes the graft as a foreign substance and rejects it. A solution to this problem is laboratory-grown skin. A piece of healthy skin from the burn victim is removed and placed into a flask with nutrients and hormones that stimulate rapid growth. The skin that is produced consists only of epidermis and does not contain glands or hair.

ASSESS YOUR PROGRESS

30. Define the different categories of burns. How is repair accomplished after each type?

5.7 Effects of Aging on the Integumentary System

LEARNING OUTCOME

After reading this section, you should be able to

- A. List the changes the integumentary system undergoes with age.**

As the body ages, the skin is more easily damaged because the epidermis thins and the amount of collagen in the dermis decreases. Skin infections are more likely, and skin repair occurs more slowly. A decrease in the number of elastic fibers in the dermis and a loss of adipose tissue from the subcutaneous tissue cause the skin to sag and wrinkle.

Retin-A (tretinoin; tret'i-nō-in) is a vitamin A derivative that appears to be effective in treating fine wrinkles on the face, such as those caused by long-term exposure to the sun; it is not effective in treating deep lines. One ironic side effect of Retin-A use is increased sensitivity to the sun's ultraviolet rays. Doctors prescribing this cream caution their patients to always use a sunblock when they are going to be outdoors.

The skin also becomes drier with age as sebaceous gland activity decreases. Decreases in the activity of sweat glands and the blood supply to the dermis result in a reduced ability to regulate body temperature. Elderly individuals who do not take proper precautions may experience heat exhaustion, which can even lead to death.

The number of functioning melanocytes generally decreases; however, in some localized areas, especially on the hands and face, melanocytes increase in number, producing age spots. (Age spots are different from freckles, which are caused by an increase in melanin production, not an increase in melanocyte numbers.) White or gray hairs also appear because of a decrease in or lack of melanin production.

Skin that is exposed to sunlight appears to age more rapidly than nonexposed skin. This effect is observed on areas of the body that receive sun exposure, such as the face and hands (figure 5.12). However, the effects of chronic sun exposure on the skin are different from the effects of normal aging. In skin exposed to sunlight, normal elastic fibers are replaced by an interwoven mat of thick, elastic-like material, the number of collagen fibers decreases, and the ability of keratinocytes to divide is impaired.

ASSESS YOUR PROGRESS

31. Compared with young skin, why is aged skin more likely to be damaged, wrinkled, and dry?
32. Why is heat potentially dangerous to the elderly?
33. Explain what causes age spots and white hair.
34. What effect does exposure to sunlight have on skin?

FIGURE 5.12 Effects of Sunlight on Skin

- (a) A 91-year-old Japanese monk who has spent most of his life indoors.
 (b) A 62-year-old Native American woman who has spent most of her life outdoors.

Diseases and Disorders

TABLE 5.2

Skin

Condition	Description
Birthmarks	Congenital (present at birth) disorders of the dermal capillaries
Ringworm	Fungal infection that produces patchy scaling and inflammatory response in the skin
Eczema and dermatitis	Inflammatory conditions of the skin caused by allergy, infection, poor circulation, or exposure to chemical or environmental factors
Psoriasis	Chronic skin disease characterized by thicker than normal epidermal layer (stratum corneum) that sloughs to produce large, silvery scales; bleeding may occur if the scales are scraped away
Vitiligo	Development of patches of white skin where melanocytes are destroyed, apparently by an autoimmune response
Bacterial Infections	
Impetigo	Small blisters containing pus; easily rupture to form a thick, yellowish crust; usually affects children
Erysipelas	Swollen patches in the skin caused by the bacterium <i>Streptococcus pyogenes</i>
Decubitus ulcers (bedsores, pressure sores)	Develop in people who are bedridden or confined to a wheelchair; compression of tissue and reduced circulation result in destruction of the skin and subcutaneous tissue, which later become infected by bacteria, forming ulcers
Acne	Disorder of sebaceous glands and hair follicles that occurs when sloughed cells block the hair follicle, resulting in the formation of a lesion or pimple; the lesion may become infected and result in scarring; acne appears to be affected by hormones, sebum, abnormal keratinization within hair follicles, and the bacterium <i>Propionibacterium acnes</i>
Viral Infections	
Rubeola (measles)	Skin lesions; caused by a virus contracted through the respiratory tract; may develop into pneumonia or infect the brain, causing damage
Rubella (German measles)	Skin lesions; usually mild viral disease contracted through the respiratory tract; may be dangerous if contracted during pregnancy because the virus can cross the placenta and damage the fetus
Chickenpox	Skin lesions; usually mild viral disease contracted through the respiratory tract
Shingles	Painful skin lesions; caused by the chickenpox virus after childhood infection; can recur when the dormant virus is activated by trauma, stress, or another illness
Cold sores (fever blisters)	Skin lesions; caused by herpes simplex I virus; transmitted by oral or respiratory routes; lesions recur
Genital herpes	Genital lesions; caused by herpes simplex II virus; transmitted by sexual contact

Answer

Learn to Predict ◀ From page 141

To begin, we must identify the important information provided in the question. First, we are told that Laura is spending her summer at the pool, constantly exposed to the sun, and develops a “golden tan.” Second, she returns to school in the fall, thus spending less time outside, and her tan fades.

We know that sun exposure leads to tanning of the skin, but to answer this question fully we must consider what specifically causes the skin to darken and why tanning is not permanent. We learned in this chapter that melanocytes in the epidermis produce melanin in response to sun exposure and package it in melanosomes. Keratinocytes phagocytize the tips of melanocyte processes containing the melanosomes, and the result is pigmented keratinocytes, and thus darker skin. We can therefore conclude that Laura’s skin is darker due to increased sun exposure and increased melanin production during the summer.

We also learned in this chapter that the epidermis is a stratified squamous epithelium (described in chapter 4) composed of many layers of cells. Mitosis of cells in the deepest layer (stratum basale) of the epidermis produces new cells, which gradually undergo keratinization and eventually die. At the surface of the skin, keratinized (dead) keratinocytes are sloughed off and replaced by new ones daily.

So why did Laura’s tan fade? It faded because the older, heavily pigmented keratinocytes were sloughed off each day and replaced with new cells. These new cells, produced *after* she returned to school, were less pigmented and her skin became a lighter color.

Answers to the rest of this chapter’s Predict questions are in appendix G.

Summary

The integumentary system consists of the skin, hair, glands, and nails.

5.1 Functions of the Integumentary System (p. 142)

The integumentary system separates and protects us from the external environment. Other functions include sensation, temperature regulation, vitamin D production, and excretion of small amounts of waste products.

5.2 Skin (p. 142)

Epidermis

1. The epidermis is stratified squamous epithelium divided into five strata.
2. The stratum basale consists of keratinocytes, which produce the cells of the more superficial strata.
3. The stratum spinosum consists of several layers of cells held together by many desmosomes.
4. The stratum granulosum consists of cells filled with granules of keratohyalin. Cell death occurs in this stratum.
5. The stratum lucidum consists of a layer of dead, transparent cells.
6. The stratum corneum consists of many layers of dead squamous cells. The most superficial cells slough off.
7. Keratinization is the transformation of the living cells of the stratum basale into the dead squamous cells of the stratum corneum.
 - Keratinized cells are filled with keratin and have a protein envelope, both of which contribute to structural strength. The cells are also held together by many desmosomes.
 - Intercellular spaces are filled with lipids from the lamellae that help make the epidermis impermeable to water.
8. Soft keratin is present in skin and the inside of hairs, whereas hard keratin occurs in nails and the outside of hairs. Hard keratin makes cells more durable, and these cells are not shed.

Thick and Thin Skin

1. Thick skin has all five epithelial strata.
2. Thin skin contains fewer cell layers per stratum, and the stratum lucidum is usually absent. Hair is found only in thin skin.

Skin Color

1. Melanocytes produce melanin inside melanosomes and then transfer the melanin to keratinocytes. The size and distribution of melanosomes determine skin color. Melanin production is determined genetically but can be influenced by ultraviolet light (tanning) and hormones.
2. Carotene, an ingested plant pigment, can cause the skin to appear yellowish.
3. Increased blood flow produces a red skin color, whereas decreased blood flow causes pale skin. Decreased oxygen content in the blood results in a bluish color, a condition called cyanosis.

Dermis

1. The dermis is connective tissue divided into two layers.
2. The papillary layer has projections called dermal papillae and is composed of loose connective tissue that is well supplied with capillaries.
3. The reticular layer is the main layer. It is dense irregular connective tissue consisting mostly of collagen.

5.3 Subcutaneous Tissue (p. 149)

1. Located beneath the dermis, the subcutaneous tissue is loose connective tissue that contains collagen and elastic fibers.
2. The subcutaneous tissue attaches the skin to underlying structures and is a site of lipid storage.

5.4 Accessory Skin Structures (p. 150)

Hair

1. Lanugo (fetal hair) is replaced near the time of birth by terminal hairs (scalp, eyelids, and eyebrows) and vellus hairs. At puberty, vellus hairs can be replaced with terminal hairs.
2. A hair has three parts: shaft, root, and hair bulb.
3. The root and shaft of a hair are composed of dead keratinized epithelial cells. In the center, a cortex of cells containing hard keratin surrounds a medulla composed of cells containing soft keratin. The cortex is covered by the cuticle, a single layer of cells filled with hard keratin.
4. The hair bulb produces the hair in cycles, with a growth stage and a resting stage.
5. Hair color is determined by the amount and kind of melanin present.
6. Contraction of the arrector pili muscles, which are smooth muscles, causes hair to “stand on end” and produces “goose bumps.”

Glands

1. Sebaceous glands produce sebum, which oils the hair and the surface of the skin.
2. Eccrine sweat glands produce sweat, which cools the body. Apocrine sweat glands produce an organic secretion that can be broken down by bacteria to cause body odor.
3. Other skin glands are ceruminous glands, which make cerumen (earwax), and mammary glands, which produce milk.

Nails

1. The nail root is covered by skin, and the nail body is the visible part of the nail.
2. Nearly all of the nail is formed by the nail matrix, but the nail bed contributes.
3. The lunula is the part of the nail matrix visible through the nail body.
4. The nail is stratum corneum containing hard keratin.

5.5 Physiology of the Integumentary System (p. 155)

Protection

1. The skin protects against abrasion and ultraviolet light, prevents the entry of microorganisms, helps regulate body temperature, and prevents water loss.
2. Hair protects against abrasion and ultraviolet light and is a heat insulator.
3. Nails protect the ends of the digits.

Sensation

The skin contains sensory receptors for pain, touch, hot, cold, and pressure, which allow for proper responses to the environment.

Temperature Regulation

1. Through dilation and constriction of blood vessels, the skin controls heat loss from the body.
2. Sweat glands produce sweat, which evaporates and lowers body temperature.

Vitamin D Production

1. Skin exposed to ultraviolet light produces cholecalciferol, which is modified in the liver and then in the kidneys to form active vitamin D.
2. Vitamin D increases blood calcium levels by promoting calcium uptake from the small intestine.

Excretion

Skin glands remove small amounts of waste products (e.g., urea, uric acid, and ammonia) but are not important in excretion.

5.6 Burns (p. 157)

1. Partial-thickness burns damage only the epidermis (first-degree burn) or the epidermis and the dermis (second-degree burn).
2. Full-thickness burns (third-degree burns) destroy the epidermis, the dermis, and usually underlying tissues.

5.7 Effects of Aging on the Integumentary System (p. 160)

1. As the body ages, blood flow to the skin declines, the skin becomes thinner, and elasticity is lost.
2. Sebaceous and sweat glands become less active, and the number of melanocytes decreases.

REVIEW AND COMPREHENSION

1. If a splinter penetrates the skin of the palm of the hand to the second epidermal layer from the surface, the last layer damaged is the
 - a. stratum granulosum.
 - b. stratum basale.
 - c. stratum corneum.
 - d. stratum lucidum.
 - e. stratum spinosum.

For questions 2–6, match the layer of the epidermis with the correct description or function:

- | | |
|-----------------------|---------------------|
| a. stratum basale | d. stratum lucidum |
| b. stratum corneum | e. stratum spinosum |
| c. stratum granulosum | |
2. Production of keratin fibers; formation of lamellar bodies; limited amount of cell division
 3. Sloughing occurs; 25 or more layers of dead squamous cells
 4. Production of cells; melanocytes produce and contribute melanin; hemidesmosomes present
 5. Production of keratohyalin granules; lamellar bodies release lipids; cells die
 6. Dispersion of keratohyalin around keratin fibers; layer appears transparent; cells dead
 7. The function of melanin in the skin is to
 - a. lubricate the skin.
 - b. prevent skin infections.
 - c. protect the skin from ultraviolet light.
 - d. reduce water loss.
 - e. help regulate body temperature.
 8. Concerning skin color, which pair of statements is *not* correctly matched?
 - a. skin appears yellow—carotene present
 - b. no skin pigmentation (albinism)—genetic disorder
 - c. skin tans—increased melanin production
 - d. skin appears blue (cyanosis)—oxygenated blood
 - e. African-Americans darker than Caucasians—more melanin in African-American skin

For questions 9–11, match the layer of the dermis with the correct description or function:

- | | |
|--------------------|--------------------|
| a. papillary layer | b. reticular layer |
|--------------------|--------------------|
9. Layer of dermis responsible for most of the structural strength of the skin

10. Layer of dermis responsible for fingerprints and footprints
11. Layer of dermis responsible for cleavage lines and stretch marks
12. After birth, the type of hair on the scalp, eyelids, and eyebrows is
 - a. lanugo.
 - b. terminal hair.
 - c. vellus hair.
13. Hair
 - a. is produced by the dermal root sheath.
 - b. consists of living, keratinized epithelial cells.
 - c. is colored by melanin.
 - d. contains mostly soft keratin.
 - e. grows from the tip.
14. Given these parts of a hair and hair follicle:
 - (1) cortex
 - (2) cuticle
 - (3) dermal root sheath
 - (4) epithelial root sheath
 - (5) medulla

Arrange the structures in the correct order from the outside of the hair follicle to the center of the hair.

- | | |
|--------------|--------------|
| a. 1,4,3,5,2 | d. 4,3,1,2,5 |
| b. 2,1,5,3,4 | e. 5,4,3,2,1 |
| c. 3,4,2,1,5 | |
15. Concerning hair growth,
 - a. hair falls out of the hair follicle at the end of the growth stage.
 - b. most of the hair on the body grows continuously.
 - c. cutting or plucking the hair increases its growth rate and thickness.
 - d. genetic factors and the hormone testosterone are involved in “pattern baldness.”
 - e. eyebrows have a longer growth stage and resting stage than scalp hair.
 16. Smooth muscles that are attached to hair follicles and produce “goose bumps” when they contract are called
 - a. external root sheaths.
 - b. arrector pili.
 - c. dermal papillae.
 - d. internal root sheaths.
 - e. hair bulbs.

For questions 17–19, match the type of gland with the correct description or function:

- a. apocrine sweat gland
 - b. eccrine sweat gland
 - c. sebaceous gland
17. Alveolar gland that produces a white, oily substance; usually open into hair follicles
 18. Coiled, tubular gland that secretes a hyposmotic fluid that cools the body; most numerous in the palms of the hands and soles of the feet
 19. Secretions from this coiled, tubular gland are broken down by bacteria to produce body odor; found in the axillae, in the genitalia, and around the anus
 20. The lunula of the nail appears white because
 - a. it lacks melanin.
 - b. blood vessels cannot be seen through the thick nail matrix.
 - c. the cuticle decreases blood flow to the area.
 - d. the nail root is much thicker than the nail body.
 - e. the hyponychium is thicker than the cuticle.
 21. Most of the nail is produced by the

a. cuticle.	d. nail matrix.
b. hyponychium.	e. dermis.
c. nail bed.	

22. The skin helps maintain optimum calcium and phosphate levels in the body by participating in the production of

a. vitamin A.	c. vitamin D.	e. keratin.
b. vitamin B.	d. melanin.	
23. Which of these processes increase(s) heat loss from the body?
 - a. dilation of dermal arterioles
 - b. constriction of dermal arterioles
 - c. increased sweating
 - d. Both a and c are correct.
 - e. Both b and c are correct.
24. In third-degree (full-thickness) burns, both the epidermis and the dermis are destroyed. Which of the following conditions does *not* occur as a result of a third-degree burn?
 - a. dehydration (increased water loss)
 - b. increased likelihood of infection
 - c. increased sweating
 - d. loss of sensation in the burned area
 - e. poor temperature regulation in the burned area

Answers in appendix E

CRITICAL THINKING

1. The skin of infants is more easily penetrated and injured by abrasion than is the skin of adults. Based on this fact, which stratum of the epidermis is probably much thinner in infants than in adults?
2. Melanocytes are found primarily in the stratum basale of the epidermis. In reference to their function, why does this location make sense?
3. The rate of water loss from the skin of a hand was measured. Following the measurement, the hand was soaked in alcohol for 15 minutes. After all the alcohol had been removed from the hand, the rate of water loss was again measured. Compared with the rate of water loss before soaking, what difference, if any, would you expect in the rate of water loss after soaking the hand in alcohol?
4. It has been several weeks since Goodboy Player has competed in a tennis match. After a match, he discovers that a blister has formed beneath an old callus on his foot, and the callus has fallen off. When he examines the callus, it appears yellow. Can you explain why?
5. A woman has stretch marks on her abdomen, yet she states that she has never been pregnant. Is this possible?
6. Why are your eyelashes not a foot long? Your fingernails?
7. Pulling on hair can be quite painful, yet cutting hair is not painful. Explain.
8. A patient has an ingrown toenail, in which the nail grows into the nail fold. Would cutting the nail away from the nail fold permanently correct this condition? Why or why not?
9. Defend or refute the following statement: Dark-skinned children are more susceptible to rickets (insufficient calcium in the bones) than fair-skinned children.
10. Harry, age 55, went to a health fair and had a PSA test. The test results and subsequent examinations indicated prostate cancer. Harry was given radiation treatments and chemotherapeutic drugs. These drugs adversely affect cancer cells by interrupting mitosis, but they also interrupt mitosis in normal cells. Describe the probable effect of chemotherapy on Harry's epidermis, hair, nails, skin pigmentation, and sebaceous glands.

Answers in appendix F

Skeletal System

BONES AND BONE TISSUE

Break a leg!” your friend might say just before your first job interview, but if you really broke your leg, your chances of completing the interview would be slim to none. One of the most iconic symbols of the human form, the skeleton, is essential for our day-to-day activities. Sitting, standing, walking, picking up a pencil, and taking a breath all involve the skeletal system. Besides helping the body move and breathe, the skeleton is the structural framework that gives the body its shape and protects the internal organs and soft tissues. Although the skeleton consists of the mineralized material left after the flesh and organs have been removed and is often associated with death, it is composed of dynamic, living tissues that are able to grow, adapt to stress, and undergo repair after injury.

Learn to Predict

Amir lived for football. He had played football since second grade and regularly watched every televised college and professional football game. He dreamed of the day he would be on TV, playing football. One memorable game, Amir’s favorite player broke his leg and Amir wanted to do everything he could to prevent that from happening to him. He asked his doctor to help him create a bone-healthy diet. Chapter 5 explained the anatomy and physiology of the skin, and chapter 6 explores the structure of bone tissue—how it forms and grows, as well as the nutritional requirements for normal bone growth.

After reading this chapter, explain the specific nutritional requirements of the diet Amir’s doctor advised him to consume for injury prevention.

Photo: University of Alabama wide receiver Tyrone Prothro suffered a career-ending injury in 2005 when he broke both his tibia and his fibula while attempting a touchdown reception. Unfortunately, the healed bone would never be as strong as it was before.

6.1 Functions of the Skeletal System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the components of the skeletal system.
- B. Explain the functions of the skeletal system.

The skeletal system has four components: bones, cartilage, tendons, and ligaments. The skeleton is usually thought of as the framework of the body, but the skeletal system has many other functions as well, including the following:

1. **Body support.** Rigid, strong bone is well suited for bearing weight and is the major supporting tissue of the body. Cartilage provides a firm yet flexible support within certain structures, such as the nose, external ear, thoracic cage, and trachea. **Ligaments** are strong bands of fibrous connective tissue that hold bones together.
2. **Organ protection.** Bone is hard and protects the organs it surrounds. For example, the skull encloses and protects the brain, and the vertebrae surround the spinal cord. The rib cage protects the heart, lungs, and other organs of the thorax.
3. **Body movement.** Skeletal muscles attach to bones by **tendons**, which are strong bands of connective tissue. Contraction of the skeletal muscles moves the bones, producing body movements. Joints, which are formed where two or more bones come together, allow movement between bones. Smooth cartilage covers the ends of bones within some joints, allowing the bones to move freely. Ligaments allow some movement between bones but prevent excessive movements.
4. **Mineral storage.** Some minerals in the blood are stored in bone. If blood levels of these minerals decrease, the minerals are released from bone into the blood. The principal minerals stored are calcium and phosphorus, two minerals essential for many physiological processes. Adipose tissue is also stored within bone cavities. If needed, the lipids are released into the blood and used by other tissues as a source of energy.
5. **Blood cell production.** Many bones contain cavities filled with red bone marrow, which gives rise to blood cells and platelets (see chapter 19).

ASSESS YOUR PROGRESS

1. Name the four components of the skeletal system.
2. Describe the five major functions of the skeletal system.

6.2 Cartilage

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Relate the importance of cartilage to the structure of the skeletal system.
- B. Describe the structure of hyaline cartilage.
- C. Explain the types of cartilage growth.

There are three types of cartilage: hyaline cartilage, fibrocartilage, and elastic cartilage (see chapter 4). Although each type of cartilage can provide support, hyaline cartilage is most intimately associated with bone. An understanding of hyaline cartilage structure is important because most bones in the body start out as a hyaline cartilage model. In addition, growth in bone length and bone repair often involve making hyaline cartilage first, then replacing it with bone.

Recall from chapter 1 that most human cells start out in an immature state and then undergo changes to mature into their final form. This is not too different than a baby growing and maturing into an adult. Immature cell names often end with the suffix *-blast*, which means “seed” or “bud.” Once the immature cell has grown and differentiated into its mature form, the suffix *-cyte* replaces *-blast* in the name. Hyaline cartilage **chondroblasts** (kon'drō-blasts; cartilage) produce a matrix surrounding themselves (figure 6.1). By the time the matrix has surrounded a chondroblast, the cell has differentiated into a **chondrocyte** (kon'drō-sīt), a rounded cell that occupies a space called a **lacuna** (lă-koo'nă) within the matrix. The matrix contains collagen, which provides strength, and proteoglycans, which make cartilage resilient by trapping water.

Most cartilage is covered by a protective connective tissue sheath called the **perichondrium** (per-i-kon'drē-ŭm) (figure 6.1). The perichondrium is a double-layered outer layer of dense irregular connective tissue containing fibroblasts. The inner, more delicate layer has fewer fibers and contains chondroblasts. Blood vessels and nerves penetrate the outer layer of the perichondrium but do not enter the cartilage matrix, so nutrients must diffuse through the cartilage matrix to reach the chondrocytes. **Articular** (ar-tik'ū-lār) **cartilage**, which is hyaline cartilage that covers the ends of bones where they come together to form joints, has no perichondrium, blood vessels, or nerves.

Predict 2

Explain why damaged cartilage takes a long time to heal. What are the advantages of articular cartilage having no perichondrium, blood vessels, or nerves?

There are two types of cartilage growth: appositional growth and interstitial growth. In **appositional growth**, chondroblasts in the perichondrium add new cartilage to the outside edge of the existing cartilage. The chondroblasts lay down new matrix and add new chondrocytes to the outside of the tissue. In **interstitial growth**, chondrocytes in the center of the tissue divide and add more matrix in-between the existing cells (figure 6.1).

ASSESS YOUR PROGRESS

3. What are the three types of cartilage? Which type is more closely associated with bone?
4. Describe the structure of hyaline cartilage. Name the two types of cartilage cells. What is a lacuna?
5. Differentiate between appositional and interstitial growth of cartilage.

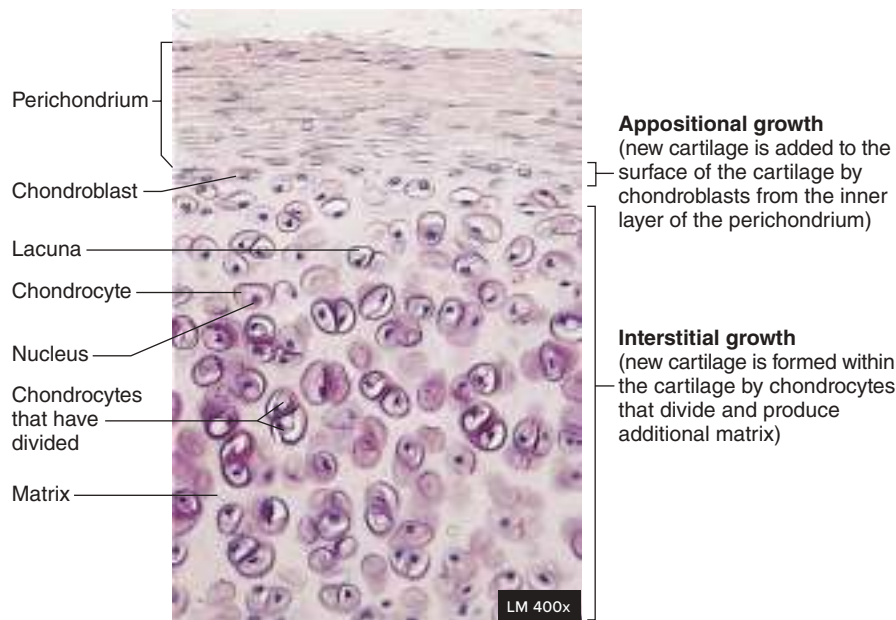

FIGURE 6.1 Hyaline Cartilage

Photomicrograph of hyaline cartilage covered by perichondrium. Chondrocytes within lacunae are surrounded by a cartilage matrix.

6.3 Bone Histology

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the components of the extracellular bone matrix and state the function of each.
- List each type of bone cell and give the function and origin of each.
- Describe the structure of woven and lamellar bone.
- Explain the structural differences between compact and spongy bone.

In chapter 4, you learned that bone is a type of connective tissue. Recall that connective tissue is characterized by having spread-out cells separated by a nonliving material called matrix. In bone, as in other connective tissues, the bone cells produce the bone matrix and become entrapped within it. The cells also break down old matrix so that new matrix can replace it. Bone matrix composition is responsible for the characteristics of bone.

Bone Matrix

By weight, mature bone matrix is normally about 35% organic and 65% inorganic material. The organic material consists primarily of collagen and proteoglycans. The inorganic material consists primarily of a calcium phosphate crystal called **hydroxyapatite** (hī-drok'sē-ap-ă-tīt), which has the molecular formula $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$.

The collagen and mineral components are responsible for the major functional characteristics of bone. Bone matrix can be compared to reinforced concrete. Like reinforcing steel bars, the collagen fibers lend flexible strength to the matrix; like concrete, the mineral components give the matrix weight-bearing strength.

If all the mineral is removed from a long bone, collagen becomes the primary constituent and the bone is overly flexible. On the other hand, if the collagen is removed from the bone, the mineral component becomes the primary constituent and the bone is very brittle (figure 6.2).

Bone Cells

There are three types of bone cells—osteoblasts, osteocytes, and osteoclasts—each with different functions and a unique origin.

Osteoblasts

Osteoblasts (os'tē-ō-blastz), bone-forming cells, have an extensive endoplasmic reticulum and numerous ribosomes. They produce collagen and proteoglycans, which are packaged into vesicles by the Golgi apparatus and released from the cell by exocytosis. Osteoblasts also release **matrix vesicles**, which contain high concentrations of Ca^{2+} and PO_4^{3-} . When the concentration reaches a critical level, needlelike hydroxyapatite crystals form. When the hydroxyapatite crystals are released from the matrix vesicles they act as templates, or seeds, which stimulate further hydroxyapatite formation and mineralization of the matrix.

The formation of new bone by osteoblasts is called **ossification** (os'i-fi-kā'shūn), or *osteogenesis* (os'tē-ō-jen' ē-sis). Ossification

FIGURE 6.2 Effects of Changing the Bone Matrix

(a) Normal bone. (b) Demineralized bone, in which collagen is the primary remaining component, can be bent without breaking. (c) When collagen is removed, mineral is the primary remaining component, making the bone so brittle that it is easily shattered.

occurs by appositional growth on the surface of previously existing material, either bone or cartilage. For example, osteoblasts beneath the periosteum cover the surface of preexisting bone (figure 6.3a). Elongated cell extensions from osteoblasts connect to the cell extensions of other osteoblasts through gap junctions (see chapter 4). Bone matrix produced by the osteoblasts covers the older bone surface and surrounds the osteoblast cell bodies and extensions. The result is a new layer of bone.

Osteocytes

Once an osteoblast has secreted enough bone matrix to become surrounded by it the cell is then referred to as an **osteocyte** (os'tē-ō-sīt; figure 6.3b). The osteocytes retain their connections to neighboring osteocytes through their cell extensions. Osteocytes become relatively inactive, compared with most osteoblasts, but it is possible for them to produce the components needed to maintain the bone matrix.

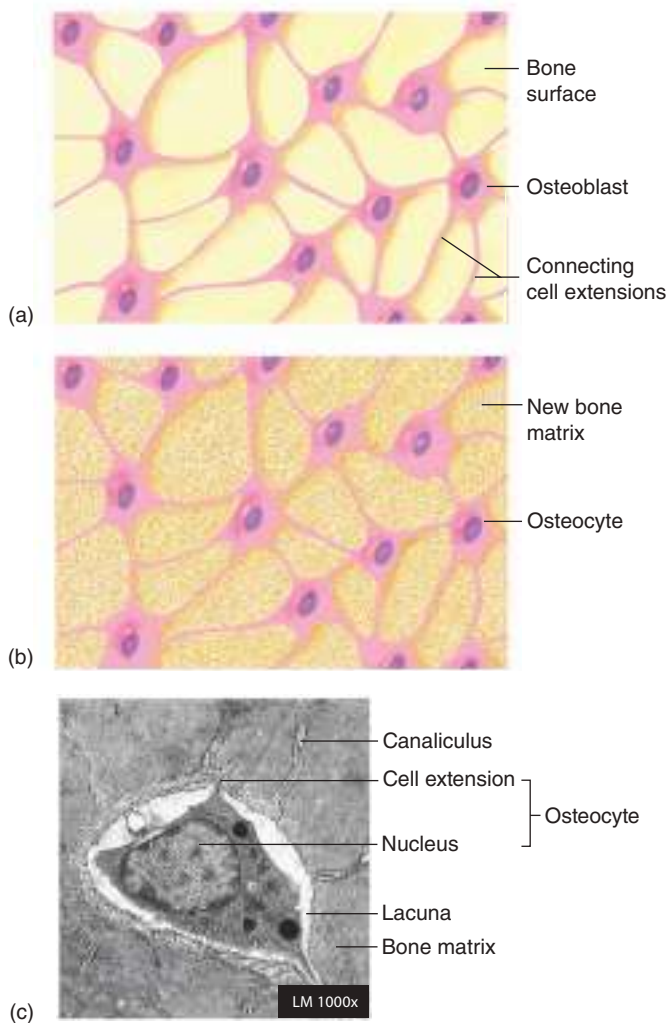

FIGURE 6.3 Ossification

(a) On a preexisting surface, such as cartilage or bone, the cell extensions of different osteoblasts join together. (b) Osteoblasts have produced bone matrix and are now osteocytes. (c) Photomicrograph of an osteocyte in a lacuna with cell extensions in the canaliculi.

The spaces without matrix but occupied by the osteocyte cell bodies are called **lacunae** (lă-koo'nē), and the spaces occupied by the osteocyte cell extensions are called **canaliculi** (kan-ă-lik'ū-lī; little canals; figure 6.3c). In a sense, the cells and their extensions form a “mold” around which the matrix is formed. Bone differs from cartilage in that the extensions of bone cells are in contact with one another through the canaliculi. Instead of diffusing through the mineralized matrix, nutrients and gases can pass through the small amount of fluid surrounding the cells in the canaliculi and lacunae or pass from cell to cell through the gap junctions connecting the cell extensions.

Osteoclasts

Osteoclasts (os'tē-ō-klastz) are bone-destroying cells (figure 6.4). These cells perform reabsorption, or breakdown, of bone that mobilizes crucial Ca^{2+} and phosphate ions for use in many metabolic processes. Note we use the term *reabsorption* here because our point of reference is the bloodstream. As bone is broken down, the Ca^{2+} goes “back” into the blood. These cells are massive, multinucleated cells whose differentiation follows a complex pathway. They are derived from the red bone marrow cells that also differentiate into monocytes (called macrophages in the tissues). These precursors attach to the bone matrix where direct contact with osteoblasts is required to allow eventual maturation into functional osteoclasts.

Mature osteoclasts carry out bone reabsorption through a multistep process. First, the osteoclasts must access the bone matrix. The current model proposes that osteoblasts lining the connective tissue around bone regulate the movement of mature osteoclasts into a bone remodeling area. Once the osteoclasts have come in contact with the bone surface, they form attachment

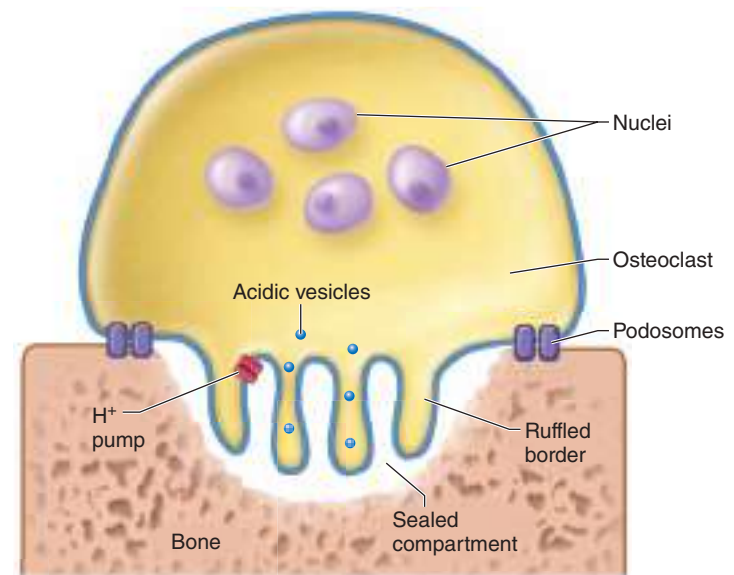

FIGURE 6.4 Osteoclast Structure

Osteoclasts are massive, multinucleated cells that secrete acid and protein-digesting enzymes, which degrade bone. These cells then transport the digested matrix from the bone into the extracellular fluid.

Clinical GENETICS

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI; os'tē-ō-jen' ē-sis im-per-fek'tā) is also known as brittle bone disorder. This connective tissue disease is caused by mutations that yield reduced or defective type I collagen. Type I collagen is the major collagen of bone, tendon, and skin. There is considerable variability in the appearance and severity of OI symptoms, which is partially explained by different types of mutations.

FIGURE 6A Osteogenesis Imperfecta

Note the abnormal shape of the upper leg bone (femur) and the excessive curve of the lower leg bones (tibia and fibula).

The mildest and most common form of OI is called type I. It is caused by too little formation of normal type I collagen. The majority of patients have a mutation in a type I collagen gene that creates a stop codon, so that the gene no longer encodes a functional protein (see chapter 3). The patient produces approximately half as much type I collagen as usual. Thus, type I OI is a collagen-deficiency disorder. Patients may exhibit any of the following characteristics: bones predisposed to fracture, especially before puberty; a tendency to develop spinal curvature; loose joints; brittle teeth; hearing loss; and a blue tint to the whites of the eyes. Unlike people who have more severe forms of OI, these patients have normal or near-normal stature and minimal or no bone deformities. The number of fractures over a lifetime can vary from a few to more than 100. Children with mild type I OI may exhibit few obvious clinical features, except for a history of broken bones. It is important for children with OI to be diagnosed properly because broken bones can be associated with child abuse.

The more severe types of OI occur when mutated collagen genes are transcribed and the resulting mRNA codes for a defective protein. The more defective the protein, the weaker the collagen fiber and the more severe the disorder. In addition, depending on the mutation, bone cells may produce less bone matrix because

they are inefficient at making matrix containing defective collagen. Thus, the most severe forms of OI are defective-collagen and collagen-deficiency disorders. Type II, the most severe OI, is usually lethal within the first week of life because of breathing failure due to rib fractures and underdeveloped lungs. Type III OI is characterized by bones that fracture very easily, even before and during birth. Fractures occurring before birth often heal in poor alignment, leaving the limbs short and bent (figure 6A). At least 12 types of OI have been described.

In the United States, 20,000 to 50,000 people may have OI. Almost all cases are caused by autosomal dominant mutations (see chapter 29). *Autosomal dominant* means that a mutation in only one copy of the gene will cause OI, even if the other gene is normal. Because OI is an autosomal dominant trait, there is a 50% chance that a child will inherit OI from an affected parent. However, the disorder's great variability may cause the child to be affected in different ways than the parent. For example, the tendency for fractures and bone deformity may be different. Approximately 25% of children with OI have parents who do not have the disorder. In these cases, a new mutation, which occurs during the formation of sperm cells or oocytes, is responsible. Unfortunately, there is no cure for OI, and treatments are primarily directed at reducing the risk for fractures.

structures via interactions with cell-surface proteins called integrins (see chapter 3). Soon after, structures called podosomes develop and form a sealed compartment under the osteoclast. The osteoclast cell membrane then further differentiates into a highly folded form called the **ruffled border** (figure 6.4).

The ruffled border is a specialized reabsorption-specific area of the membrane. Acidic vesicles fuse with the membrane of the ruffled border, while ATP-powered H^+ pumps and protein-digesting enzymes are inserted into the membrane of the ruffled border. Secretion of H^+ creates an acidic environment within the sealed compartment, which causes decalcification of the bone matrix. The protein-digestion enzymes are secreted into the sealed compartment and digest the organic, protein component of the bone matrix. After breakdown of the matrix, the degradation products are removed by a transcytosis mechanism, whereby the products enter the osteoclast and move across the cytoplasm to the other side of the osteoclast. There, the degradation products are secreted into the extracellular space, enter the blood, and are used elsewhere in the body.

Predict 3

Some patients take ATP-powered H^+ pump inhibitors, also known as proton pump inhibitors (PPIs), to control acid reflux. Predict the effect, if any, of long-term, high-dose use of PPIs on blood Ca^{2+} levels.

Origin of Bone Cells

Connective tissue develops embryologically from mesenchymal cells (see chapter 4). Some of the mesenchymal cells become **stem cells**, some of which replicate and become more specialized cell types. **Osteochondral progenitor cells** are stem cells that can become osteoblasts or chondroblasts. Osteochondral progenitor cells are located in the inner layer of the perichondrium and in layers of connective tissue that cover bone (periosteum and endosteum). From these locations, they are a potential source of new osteoblasts or chondroblasts.

Osteoblasts are derived from osteochondral progenitor cells, and osteocytes are derived from osteoblasts. Whether or not osteocytes freed from their surrounding bone matrix by reabsorption can revert

to become active osteoblasts is a debated issue. As discussed in the previous section, osteoclasts are not derived from osteochondral progenitor cells but from stem cells in red bone marrow (see chapter 19).

ASSESS YOUR PROGRESS

6. Name the components of bone matrix, and explain their contribution to bone flexibility and bones' ability to bear weight.
7. Differentiate among the characteristics and functions of osteoblasts, osteocytes, and osteoclasts.
8. Describe the formation of new bone by appositional growth. Name the spaces that are occupied by osteocyte cell bodies and cell extensions.
9. What cells give rise to osteochondral progenitor cells? What kinds of cells are derived from osteochondral progenitor cells? What types of cells give rise to osteoclasts?

Woven and Lamellar Bone

As bone formation progresses, the newly formed bone goes through several stages. Recall that ossification occurs in a few situations during life: as a fetus, when growing, and anytime in life a fracture is repaired.

The first type of bone that osteoblasts form during ossification is fairly weak bone called woven bone. In **woven bone**, the collagen fibers are randomly oriented in many directions. After woven bone formation, osteoclasts break down the woven bone and osteoblasts build new matrix. The process of removing old bone and adding new bone is called **bone remodeling** and is discussed in section 6.7. Woven bone is remodeled into a stronger, more permanent type called lamellar bone.

Lamellar bone is mature bone that is organized into thin, concentric sheets or layers approximately 3–7 micrometers (μm) thick called **lamellae** (lă-mel'ē). In general, the collagen fibers of one lamella lie parallel to one another, but at an angle to the collagen fibers in the adjacent lamellae. Osteocytes, within their lacunae, are arranged in layers sandwiched between lamellae.

Spongy and Compact Bone

As ossification continues, bone is further molded and shaped into its final form. Whether bone is woven or lamellar, it can be classified according to the amount of bone matrix relative to the amount of space within the bone. Spongy bone, which appears porous, has less bone matrix and more space than compact bone. In contrast, compact bone has more bone matrix and less space than spongy bone.

Spongy bone consists of interconnecting rods or plates of bone called **trabeculae** (tră-bek'ū-lē; beam; figure 6.5a). Between the trabeculae are spaces, which in life are filled with bone marrow and blood vessels.

Most trabeculae are thin (50–400 μm) and consist of several lamellae with osteocytes located in lacunae between the lamellae (figure 6.5b). Each osteocyte is associated with other osteocytes through canaliculi. Usually, no blood vessels penetrate the trabeculae, so osteocytes must obtain nutrients through their canaliculi. The surfaces of trabeculae are covered with a single layer of cells consisting mostly of osteoblasts with a few osteoclasts.

FIGURE 6.5 Spongy Bone

- (a) Beams of bone, the trabeculae, surround spaces in the bone. In life, the spaces are filled with red or yellow bone marrow and blood vessels.
 (b) Transverse section of a trabecula. **APR**

Trabeculae are oriented along the lines of mechanical stress within a bone (figure 6.6). If the force on a bone is changed slightly (e.g., because of a fracture that heals improperly), the trabecular pattern realigns with the new lines of stress.

Compact bone has more matrix and is denser with fewer pores than spongy bone (figure 6.7). Blood vessels enter the substance of the bone itself, and the lamellae of compact bone are primarily oriented around those blood vessels. The functional unit of a long bone is an **osteon** (os'tē-on), or *haversian* (ha-ver'shan) *system*. An osteon is composed of concentric rings of matrix, which surround a central tunnel and contain osteocytes. In cross section, an osteon resembles a circular target; the bull's-eye of the target is the **central canal**, and 4–20 concentric lamellae form the rings. Vessels that run parallel to the long axis of the bone are contained within the central canals. Central canals are lined with endosteum and contain blood vessels, nerves, and loose connective tissue. Osteocytes are located in lacunae between the lamellar rings, and canaliculi radiate between lacunae across the lamellae, looking like minute cracks across the rings of the target. **Concentric lamellae** are circular layers of bone matrix that surround the central canal.

FIGURE 6.6 Trabeculae Oriented Along Lines of Stress

The proximal end of a long bone (femur) showing trabeculae oriented along lines of stress (red lines). The trabeculae bear weight and help bones resist bending and twisting.

The outer surfaces of compact bone are formed by **circumferential lamellae**, which are thin plates that extend around the bone (figure 6.7b). In some bones, such as certain bones of the face, the layer of compact bone can be so thin that no osteons exist and the compact bone is composed of only circumferential lamellae. Between the osteons are **interstitial lamellae**, which are remnants of concentric or circumferential lamellae that were partially removed during bone remodeling.

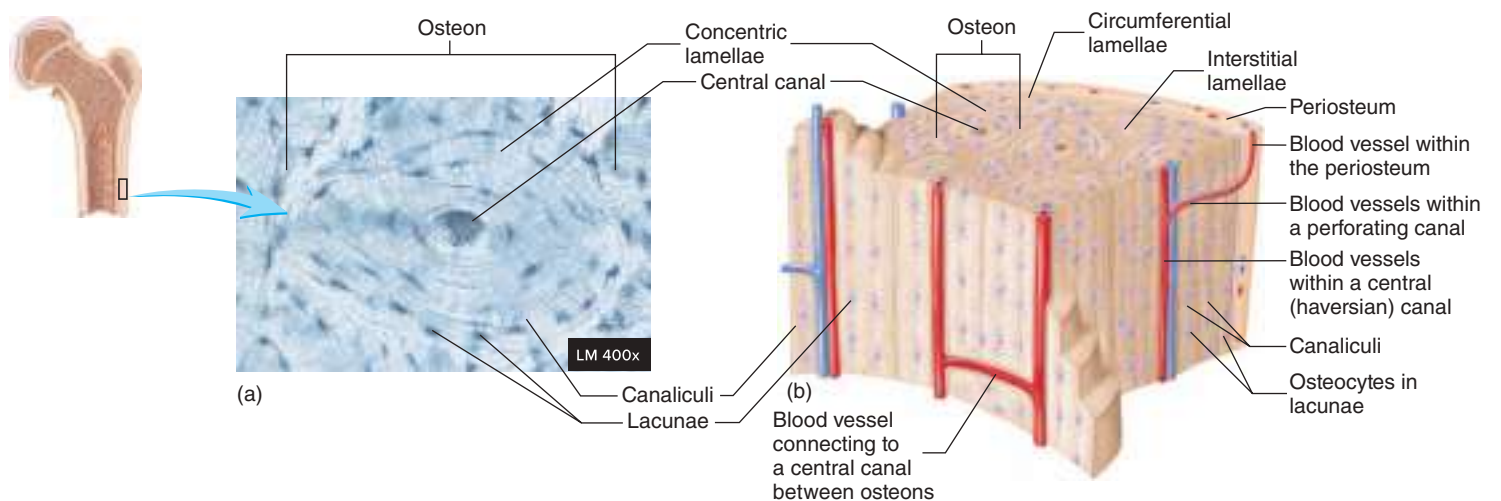

FIGURE 6.7 Compact Bone

(a) Photomicrograph of an osteon. (b) Compact bone consists mainly of osteons, which are concentric lamellae surrounding blood vessels within central canals. The outer surface of the bone is formed by circumferential lamellae, and bone between the osteons consists of interstitial lamellae. **APIA**

Osteocytes receive nutrients and eliminate waste products through the canal system within compact bone. Blood vessels from the periosteum or medullary cavity enter the bone through **perforating canals** (*Volkman canals*), which run perpendicular to the length of the bone (figure 6.7b). Perforating canals are not surrounded by concentric lamellae but, instead, pass through the concentric lamellae of osteons. The central canals receive blood vessels from perforating canals. Nutrients in the blood vessels enter the central canals, pass into the canaliculi, and move through the cytoplasm of the osteocytes that occupy the canaliculi and lacunae to the most peripheral cells at the edge of each osteon. Waste products are removed in the reverse direction.

ASSESS YOUR PROGRESS

- How is the organization of collagen fibers different in woven and lamellar bone? What process produces woven bone?
- Describe the structure of spongy bone. What are trabeculae, and what is their function? How do osteocytes within trabeculae obtain nutrients?
- Describe the structure of compact bone. What is an osteon? Name three types of lamellae found in compact bone.
- Trace the pathway nutrients must follow from blood vessels in the periosteum to osteocytes within lacunae in osteons.

6.4 Bone Anatomy

LEARNING OUTCOMES

After reading this section, you should be able to

- Classify bones according to their shape.
- Label the parts of a typical long bone.
- Explain the differences in structure between long bones and flat, short, and irregular bones.

Bone Shapes

Individual bones are classified according to shape: long, flat, short, or irregular (figure 6.8). **Long bones** are longer than they are wide. Most of the bones of the upper and lower limbs are long bones. **Flat bones** have a relatively thin, flattened shape and are usually curved. Examples of flat bones include certain skull bones, the ribs, the breastbone (sternum), and the shoulder blades (scapulae). **Short bones** are round or nearly cube-shaped, as exemplified by the bones of the wrist (carpal bones) and ankle (tarsal bones). **Irregular bones**, such as the vertebrae and facial bones, have shapes that do not readily fit into the other three categories.

Structure of a Long Bone

A long bone is the traditional model for overall bone structure (figure 6.9). Table 6.1 lists the major parts of a long bone. The **diaphysis** (dī-af'i-sis), or shaft, is composed primarily of compact bone, but it can also contain some spongy bone. The end of a long bone is mostly spongy bone, with an outer layer of compact bone. Within joints, the end of a long bone is covered with hyaline cartilage called **articular cartilage** (figure 6.9a,b).

During bone formation and growth, bones develop from centers of ossification (see section 6.5). The primary ossification center is in the diaphysis. An **epiphysis** (e-pif'i-sis; pl. -sēz) is the part of a long bone that develops from a center of ossification distinct from that of the diaphysis. Each long bone of the arm, forearm, thigh (figure 6.9a,b), and leg has one or more epiphyses on each end of the bone. Each long bone of the hand and foot has one epiphysis, which is located on the proximal or distal end of the bone.

The **epiphyseal** (ep-i-fiz'ē-āl) **plate**, or *growth plate*, is located between the epiphysis and the diaphysis (figure 6.9a). Growth in bone length (discussed in section 6.6) occurs at the epiphyseal plate. Consequently, growth in length of the long bones of the arm, forearm, thigh, and leg occurs at both ends of the diaphysis, whereas growth in length of the hand and foot bones occurs at one end of the diaphysis. When bone stops growing in length, the epiphyseal plate becomes ossified and is called the **epiphyseal line** (figure 6.9b).

FIGURE 6.8 Bone Shapes

In addition to the small spaces within spongy bone and compact bone, the diaphyses of long bones tend to have a hollow center called the **medullary cavity**. The cavities of spongy bone and the medullary cavity are filled with marrow. **Red marrow** is the site of blood cell formation, and **yellow marrow** is mostly adipose tissue. In the fetus, the spaces within bones are filled with red marrow. The conversion of red marrow to yellow marrow begins just before birth and continues well into adulthood. Yellow

TABLE 6.1 Gross Anatomy of a Long Bone

Part	Description	Part	Description
Diaphysis	Shaft of the bone	Epiphyseal plate	Area of hyaline cartilage between the diaphysis and epiphysis; cartilage growth followed by endochondral ossification results in growth in bone length
Epiphysis	Part of the bone that develops from a center of ossification distinct from the diaphysis	Spongy bone	Bone having many small spaces; found mainly in the epiphysis; arranged into trabeculae
Periosteum	Double-layered connective tissue membrane covering the outer surface of bone except where articular cartilage is present; ligaments and tendons attach to bone through the periosteum; blood vessels and nerves from the periosteum supply the bone; the periosteum is where bone grows in diameter	Compact bone	Dense bone with few internal spaces organized into osteons; forms the diaphysis and covers the spongy bone of the epiphyses
Endosteum	Thin connective tissue membrane lining the inner cavities of bone	Medullary cavity	Large cavity within the diaphysis
Articular cartilage	Thin layer of hyaline cartilage covering a bone where it forms a joint (articulation) with another bone	Red marrow	Connective tissue in the spaces of spongy bone or in the medullary cavity; the site of blood cell production
		Yellow marrow	Fat stored within the medullary cavity or in the spaces of spongy bone

FIGURE 6.9 Long Bone

The femur (thighbone) serves as a model of the parts of a long bone. (a) The presence of epiphyseal plates, as well as the condition of the diaphysis and epiphyses, shows that this is a young bone. The femur is unusual in that it has two epiphyses at its proximal end. (b) Adult long bone with epiphyseal lines. (c) Internal features of a portion of the diaphysis in (a).

marrow completely replaces the red marrow in the long bones of the limbs, except for some red marrow in the proximal part of the arm bones and thighbones. Elsewhere, varying proportions of yellow and red marrow are found. For example, part of the hipbone (ilium) may contain 50% red marrow and 50% yellow marrow. The hipbone is used as a source of donated red bone marrow because it is a large bone with more marrow than smaller bones and it can be accessed relatively easily.

The **periosteum** (per-ē-os'tē-ŭm) is a connective tissue membrane covering the outer surface of a bone (figure 6.9c). The outer fibrous layer is dense irregular collagenous connective tissue that contains blood vessels and nerves. The inner layer is a single layer of bone cells, including osteoblasts, osteoclasts, and osteochondral progenitor cells (see “Bone Cells” in section 6.3). Where tendons and ligaments attach to bone, the collagen fibers of the tendon or ligament become continuous with those of the periosteum. In addition, some of the collagen fibers of the tendons or ligaments penetrate the periosteum into the outer part of the bone. These bundles of collagen fibers are called **perforating fibers**, or *Sharpey fibers*, and they strengthen the attachment of the tendons or ligaments to the bone.

The **endosteum** (en-dos'tē-ŭm) is a single cell layer of connective tissue that lines the internal surfaces of all cavities within bones, such as the medullary cavity of the diaphysis and the smaller cavities in spongy and compact bone (figure 6.9c). The endosteum includes osteoblasts, osteoclasts, and osteochondral progenitor cells.

Structure of Flat, Short, and Irregular Bones

Flat bones contain an interior framework of spongy bone sandwiched between two layers of compact bone (figure 6.10). Short and irregular bones have a composition similar to the epiphyses of long bones—compact bone surfaces surrounding a spongy bone center with small spaces that are usually filled with marrow. Short and irregular bones are not elongated and have no diaphyses. However, certain regions of these bones, such as the processes (projections), have epiphyseal growth plates and therefore small epiphyses.

Some of the flat and irregular bones of the skull have air-filled spaces called **sinuses** (sī'nūs-ēz; see chapter 7), which are lined by mucous membranes.

FIGURE 6.10 Structure of a Flat Bone

Outer layers of compact bone surround spongy bone.

ASSESS YOUR PROGRESS

14. List the four basic shapes of bones, and give an example of each.
15. Sketch and label the parts of a typical long bone.
16. Where are the periosteum and endosteum located, and what types of cells are found in each? What is the function of perforating (Sharpey) fibers?
17. What are red and yellow bone marrows? Where are they located in a child and in an adult?
18. Compare the structure of a long bone with those of flat, short, and irregular bones. Explain where compact and spongy bones are found in each type.

6.5 Bone Development

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Outline the process of intramembranous ossification.
- B. Describe the steps of endochondral ossification.
- C. List the bones, or parts of bones, that develop from each type of ossification.

During fetal development, bone forms in two patterns—**intramembranous ossification** and **endochondral ossification**. In intramembranous ossification, bone forms from preexisting connective tissue membranes, and in endochondral ossification, bone forms from a preexisting cartilage model. Both methods initially produce woven bone, which is then remodeled into lamellar bone. After remodeling, bone formed by intramembranous ossification cannot be distinguished from bone formed by endochondral ossification. Table 6.2 compares the two types of ossification.

Intramembranous Ossification

At approximately the fifth week of development in an embryo, embryonic mesenchyme condenses around the developing brain to form a membrane of connective tissue with delicate, randomly oriented collagen fibers. Intramembranous ossification of the membrane begins at approximately the eighth week of embryonic development and is completed by approximately 2 years of age. Many skull bones, part of the mandible (lower jaw), and the diaphyses of the clavicles (collarbones) develop by intramembranous ossification (figure 6.11).

The locations in the membrane where ossification begins are called **centers of ossification**. The centers of ossification expand to form a bone by gradually ossifying the membrane. Thus, the centers have the oldest bone, and the expanding edges the youngest bone. The larger, membrane-covered spaces between the developing skull bones that have not yet been ossified are called **fontanels**, or soft spots (figure 6.12; see chapter 8). The bones eventually grow together, and all the fontanels have usually

1 A cross section of a newly formed trabecula shows the youngest bone in this series of photomicrographs. Osteocytes are surrounded by bone matrix, and osteoblasts are forming a ring on the outer surface of the trabecula. As the osteoblasts lay down bone, the trabeculae increase in size.

2 A lower magnification shows older bone than in step 1. Spongy bone has formed as a result of the enlargement and interconnections of many trabeculae.

3 A different stain that makes the bone appear blue, shows the oldest bone in this series. Within the spongy bone are trabeculae (blue) and developing red bone marrow (pink). Beneath the periosteum is an outer layer of developing compact bone.

PROCESS FIGURE 6.11 Intramembranous Ossification

The inset (lower left) shows a 12-week-old fetus. Bones formed by intramembranous ossification are yellow, and bones formed by endochondral ossification are blue. Intramembranous ossification starts at a center of ossification and expands outward. Therefore, the youngest bone is at the edge of the expanding bone and the oldest bone is at the center of ossification.

closed by 2 years of age. The steps in intramembranous ossification are as follows:

1. Intramembranous ossification begins when some of the embryonic mesenchymal cells in the membrane differentiate into osteochondral progenitor cells, which then specialize to become osteoblasts. The osteoblasts produce bone matrix that surrounds the collagen fibers of the connective tissue membrane, and the osteoblasts become osteocytes. As a result of this process, many tiny trabeculae of woven bone develop (figure 6.11, step 1).

2. Additional osteoblasts gather on the surfaces of the trabeculae and produce more bone, thereby causing the trabeculae to become larger and longer (figure 6.11, step 2). Spongy bone forms as the trabeculae join together, resulting in an interconnected network of trabeculae separated by spaces.
3. Cells within the spaces of the spongy bone specialize to form red bone marrow, and cells surrounding the developing bone specialize to form the periosteum. Osteoblasts from the periosteum lay down bone matrix to form an outer surface of compact bone (figure 6.11, step 3).

TABLE 6.2 Comparison of Intramembranous and Endochondral Ossification

Intramembranous Ossification	Endochondral Ossification
Embryonic mesenchyme forms a collagen membrane containing osteochondral progenitor cells.	Embryonic mesenchymal cells become chondroblasts, which produce a cartilage model surrounded by the perichondrium.
No stage is comparable.	Chondrocytes hypertrophy, the cartilage matrix becomes calcified, and the chondrocytes die.
Embryonic mesenchyme forms the periosteum, which contains osteoblasts.	The perichondrium becomes the periosteum when osteochondral progenitor cells within the periosteum become osteoblasts.
Osteochondral progenitor cells become osteoblasts at centers of ossification; internally, the osteoblasts form spongy bone; externally, the periosteal osteoblasts form compact bone.	Blood vessels and osteoblasts from the periosteum invade the calcified cartilage template; internally, these osteoblasts form spongy bone at primary ossification centers (and later at secondary ossification centers); externally, the periosteal osteoblasts form compact bone.
Intramembranous bone is remodeled and becomes indistinguishable from endochondral bone.	Endochondral bone is remodeled and becomes indistinguishable from intramembranous bone.

Thus, the end products of intramembranous bone formation are bones with outer compact bone surfaces and spongy centers (see figure 6.10). Remodeling converts woven bone to lamellar bone and contributes to the final shape of the bone.

Endochondral Ossification

The formation of cartilage begins at approximately the end of the fourth week of embryonic development. Endochondral ossification of some of this cartilage starts at approximately the eighth week of embryonic development, but this process might not begin in other cartilage until as late as 18–20 years of age. Bones of the base of the skull, part of the mandible, the epiphyses of the

clavicles, and most of the remaining skeletal system develop through endochondral ossification (figures 6.11 and 6.12). The steps in endochondral ossification are as follows:

1. Endochondral ossification begins as embryonic mesenchymal cells aggregate in regions of future bone formation. The mesenchymal cells differentiate into osteochondral progenitor cells that become chondroblasts. The chondroblasts produce a hyaline **cartilage model** having the approximate shape of the bone that will later be formed (figure 6.13, *step 1*). As the chondroblasts are surrounded by cartilage matrix, they become chondrocytes. The cartilage model is surrounded by perichondrium, except where a joint will form connecting one bone to another bone. The perichondrium is continuous with tissue that will become the joint capsule later in development (see chapter 8).
2. When blood vessels invade the perichondrium surrounding the cartilage model (figure 6.13, *step 2*), osteochondral progenitor cells within the perichondrium become osteoblasts. Once the osteoblasts begin to produce bone, the perichondrium becomes the periosteum. The osteoblasts produce compact bone on the surface of the cartilage model, forming a **bone collar**. Two other events occur at the same time that the bone collar is forming. First, the cartilage model increases in size as a result of interstitial and appositional cartilage growth. Second, the chondrocytes in the center of the cartilage model absorb some of the cartilage matrix and **hypertrophy** (hī-per'trō-fē), or enlarge. The chondrocytes also release matrix vesicles, which initiate the formation of hydroxyapatite crystals in the cartilage matrix. At this point, the cartilage is called **calcified cartilage**. The chondrocytes in this calcified area eventually die, leaving enlarged lacunae with thin walls of calcified matrix.
3. Blood vessels grow into the enlarged lacunae of the calcified cartilage (figure 6.13, *step 3*). Osteoblasts and osteoclasts migrate into the calcified cartilage area from the periosteum by way of the connective tissue surrounding the outside of the blood vessels. The osteoblasts produce bone on the surface of the calcified cartilage, forming bone trabeculae, which transforms the calcified cartilage of the diaphysis into spongy bone. This area of bone formation is called the **primary ossification center**.

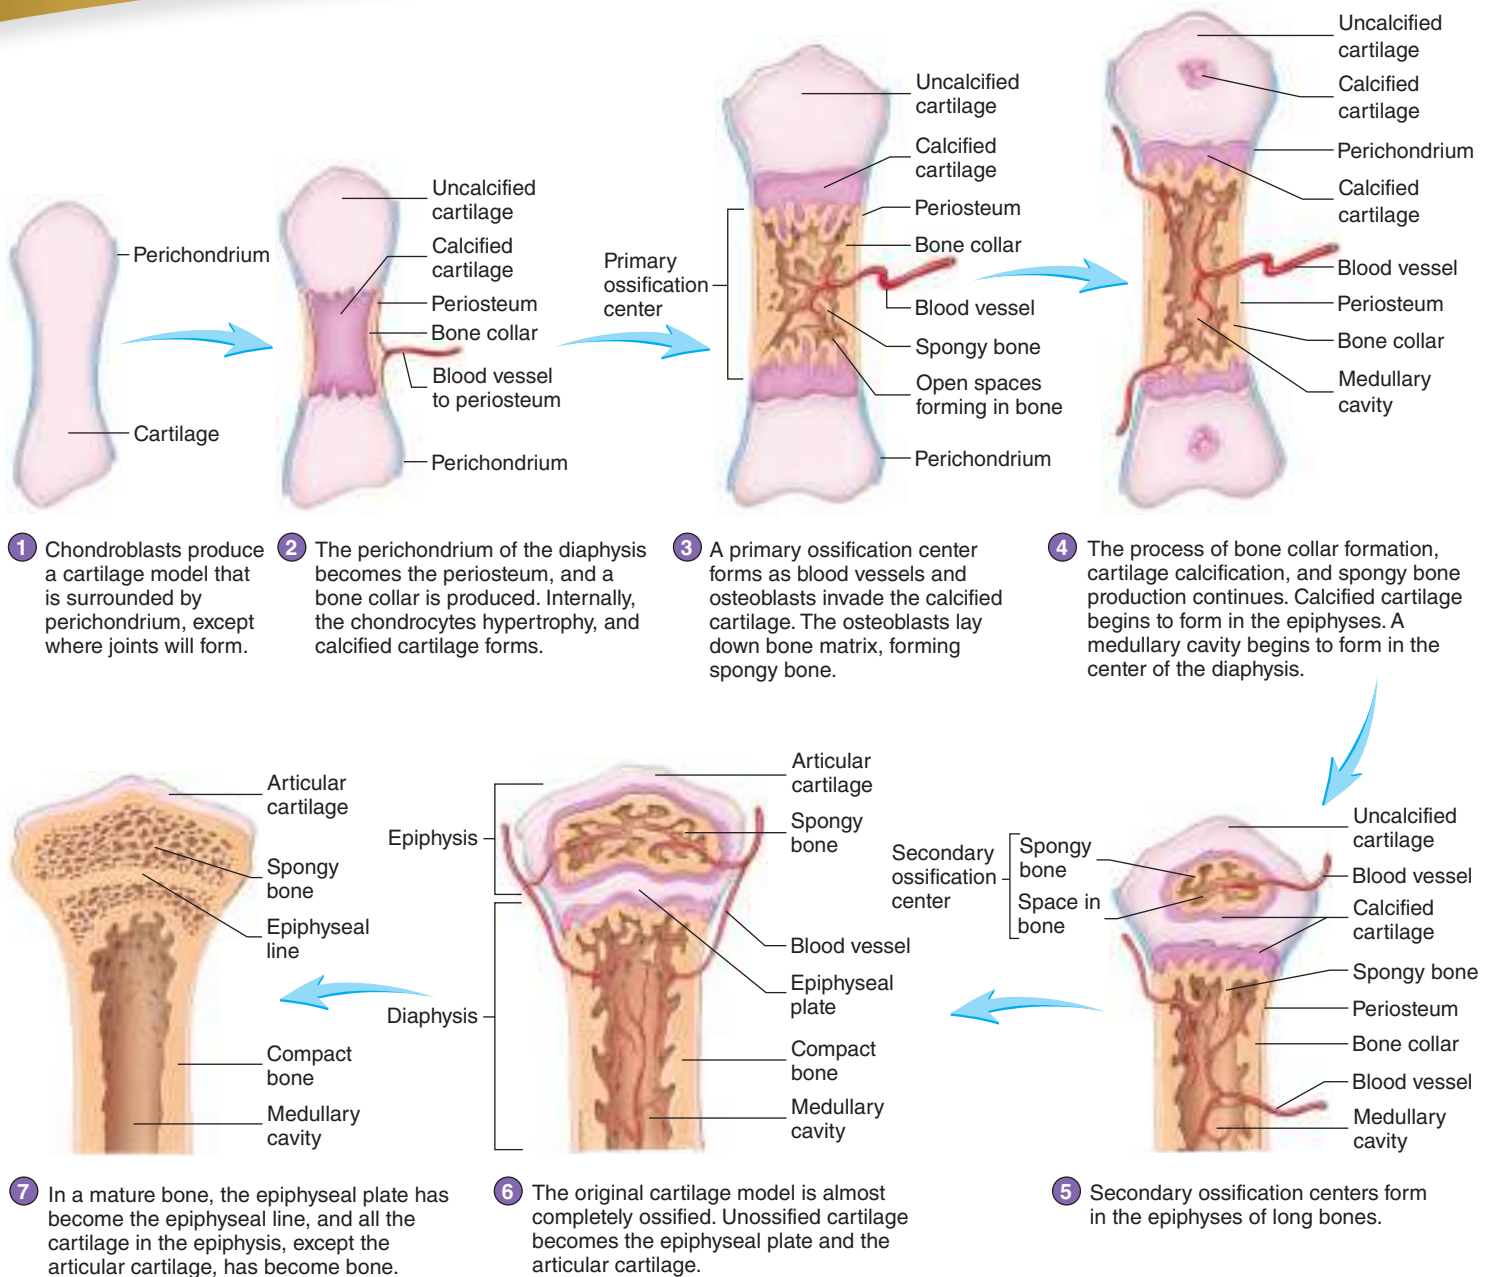

FIGURE 6.12 Bone Formation in a Fetus

Eighteen-week-old fetus showing intramembranous and endochondral ossification. Intramembranous ossification occurs at ossification centers in the flat bones of the skull. Endochondral ossification has formed bones in the diaphyses of long bones. The ends of the long bones are still cartilage at this stage of development.

FUNDAMENTAL Figure

PROCESS FIGURE 6.13 Endochondral Ossification

Endochondral ossification begins with the formation of a cartilage model. See successive steps as indicated by the blue arrows. **APR**

- As bone development proceeds, the cartilage model continues to grow, more perichondrium becomes periosteum, and the bone collar thickens and extends farther along the diaphysis. Additional cartilage within both the diaphysis and the epiphysis is calcified (figure 6.13, step 4). Remodeling converts woven bone to lamellar bone and contributes to the final shape of the bone. Osteoclasts remove bone from the center of the diaphysis to form the medullary cavity, and cells within the medullary cavity specialize to form red bone marrow.
- In long bones, the diaphysis is the primary ossification center, and additional sites of ossification, called **secondary ossification centers**, are created in the epiphyses by osteoblasts

that migrate into the epiphysis (figure 6.13, step 5). The events occurring at the secondary ossification centers are the same as those at the primary ossification centers, except that the spaces in the epiphyses do not enlarge to form a medullary cavity as in the diaphysis. Primary ossification centers appear during early fetal development, whereas secondary ossification centers appear in the proximal epiphysis of the femur, humerus, and tibia about 1 month before birth. A baby is considered full-term if one of these three ossification centers can be seen on radiographs at the time of birth. At about 18–20 years of age, the last secondary ossification center appears in the medial epiphysis of the clavicle.

6. Replacement of cartilage by bone continues in the cartilage model until all the cartilage, except that in the epiphyseal plate and on articular surfaces, has been replaced by bone (figure 6.13, *step 6*). The epiphyseal plate, which exists during the time a person's bones are actively growing, and the articular cartilage, which is a permanent structure, are derived from the original embryonic cartilage model. After a person's bones have stopped growing, the epiphyseal plate regresses into a "scar," called the epiphyseal line (see "Growth in Bone Length" in section 6.6).
7. In mature bone, spongy and compact bone are fully developed, and the epiphyseal plate has become the epiphyseal line. The only cartilage present is the articular cartilage at the ends of the bone (figure 6.13, *step 7*). All the original perichondrium that surrounded the cartilage model has become periosteum.

ASSESS YOUR PROGRESS

19. Describe the formation of spongy and compact bone during intramembranous ossification. What are centers of ossification? What are fontanels?
20. For the process of endochondral ossification, describe the formation of the following structures: cartilage model, bone collar, calcified cartilage, primary ossification center, medullary cavity, secondary ossification center, epiphyseal plate, epiphyseal line, and articular cartilage.
21. When do primary and secondary ossification centers appear during endochondral ossification?
22. What bones, or parts of bones, are formed from each type of ossification?

Predict 4

During endochondral ossification, calcification of cartilage results in the death of chondrocytes. However, ossification of the bone matrix does not result in the death of osteocytes. Explain.

6.6 Bone Growth

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Demonstrate an understanding of bone growth in length and width, as well as at the articular cartilage.
- B. Describe the factors that affect bone growth.

Unlike cartilage, bones cannot grow by interstitial growth. Bones increase in size only by appositional growth, the formation of new bone on the surface of older bone or cartilage. For example, trabeculae grow in size when osteoblasts deposit new bone matrix onto the surface of the trabeculae (see figure 6.11).

Predict 5

Explain why bones cannot undergo interstitial growth as cartilage does.

Growth in Bone Length

Long bones and bony projections increase in length because of growth at the epiphyseal plate. In a long bone, the epiphyseal plate separates the epiphysis from the diaphysis (figure 6.14a). Long projections of bones, such as the processes of vertebrae (see chapter 7), also have epiphyseal plates.

Long bones grow by creating new cartilage in the epiphyseal plate. New cartilage forms through interstitial cartilage growth followed by appositional bone growth on the surface of the existing cartilage. The epiphyseal plate is organized into four zones (figure 6.14b). The **zone of resting cartilage** is nearest the epiphysis and contains slowly dividing chondrocytes. The chondrocytes in the **zone of proliferation** produce new cartilage through interstitial cartilage growth. The chondrocytes divide and form columns resembling stacks of plates or coins. In the **zone of hypertrophy**, the chondrocytes produced in the zone of proliferation mature and enlarge. Thus, a maturation gradient exists in each column: The cells nearer the epiphysis are younger and actively proliferating, whereas the cells progressively nearer the diaphysis are older and undergoing hypertrophy. The **zone of calcification** is very thin and contains hypertrophied chondrocytes and calcified cartilage matrix. The hypertrophied chondrocytes die, and blood vessels from the diaphysis grow into the area. The connective tissue surrounding the blood vessels contains osteoblasts from the endosteum. The osteoblasts line up on the surface of the calcified cartilage and, through appositional bone growth, deposit new bone matrix, which is later remodeled. Cartilage calcification and ossification in the epiphyseal plate occur by the same basic process as calcification and ossification of the cartilage model during endochondral bone formation.

As new cartilage cells form in the zone of proliferation, and as these cells enlarge in the zone of hypertrophy, the overall length of the diaphysis increases (figure 6.14c). However, the thickness of the epiphyseal plate does not increase because the rate of cartilage growth on the epiphyseal side of the plate is equal to the rate of cartilage replacement by bone on the diaphyseal side of the plate.

As the bones achieve normal adult size, they stop growing in length because the epiphyseal plate has ossified and become the epiphyseal line. This event, called closure of the epiphyseal plate, occurs between approximately 12 and 25 years of age, depending on the bone and the individual.

Predict 6

An x-ray revealed that Jill had suffered a fracture of her left femur (figure 6.15) while playing soccer in junior high school. The bone was set, without surgery, and she had to have a cast on her leg for longer than the 6 weeks normally required for a fracture. A year after the accident, her left femur is shorter than her right femur. Explain how this occurred.

Growth at Articular Cartilage

Epiphyses increase in size because of growth at the articular cartilage. In addition, growth at the articular cartilage increases the size of bones that do not have an epiphysis, such as short bones. The process of growth in articular cartilage is similar to that occurring in the epiphyseal plate, except that the chondrocyte columns are not as obvious. The chondrocytes near the surface of the articular cartilage

FUNDAMENTAL Figure

PROCESS FIGURE 6.14 Epiphyseal Plate

(a) Radiograph and drawing of the knee, showing the epiphyseal plate of the tibia (shinbone). Because cartilage does not appear readily on x-ray film, the epiphyseal plate appears as a black area between the white diaphysis and the epiphyses. (b) Zones of the epiphyseal plate, including newly ossified bone. (c) New cartilage forms on the epiphyseal side of the plate at the same rate that new bone forms on the diaphyseal side of the plate. Consequently, the epiphyseal plate remains the same thickness but the diaphysis increases in length.

are similar to those in the zone of resting cartilage of the epiphyseal plate. In the deepest part of the articular cartilage, nearer bone tissue, the cartilage is calcified and ossified to form new bone.

When the epiphyses reach their full size, the growth of cartilage and its replacement by bone cease. The articular cartilage, however, persists throughout life and does not become ossified as the epiphyseal plate does.

Predict 7

Explain why it is advantageous for the articular cartilage never to become ossified.

Growth in Bone Width

Long bones increase in width (diameter) and other bones increase in size or thickness because of appositional bone growth beneath the periosteum. When a bone rapidly grows in

width, as occurs in young bones or during puberty, osteoblasts from the periosteum lay down bone to form a series of ridges with grooves between them (figure 6.16, *step 1*). The periosteum covers the bone ridges and extends down into the bottom of the grooves, and one or more blood vessels of the periosteum lie within each groove. As the osteoblasts continue to produce bone, the ridges increase in size, extend toward each other, and meet to change the groove into a tunnel (figure 6.16, *step 2*). The name of the periosteum in the tunnel changes to *endosteum* because the membrane now lines an internal bone surface. Osteoblasts from the endosteum lay down bone to form a concentric lamella (figure 6.16, *step 3*). The production of additional lamellae fills in the tunnel, encloses the blood vessel, and produces an osteon (figure 6.16, *step 4*).

When a bone grows in width slowly, the surface of the bone becomes smooth as osteoblasts from the periosteum lay down even layers of bone to form circumferential lamellae.

FIGURE 6.15 Fracture of the Epiphyseal Plate

Radiograph of an adolescent's knee. The femur (thighbone) is separated from the tibia (leg bone) by a joint cavity. The epiphyseal plate of the femur is fractured, thereby separating the diaphysis from the epiphysis.

The circumferential lamellae break down during remodeling to form osteons (see section 6.7).

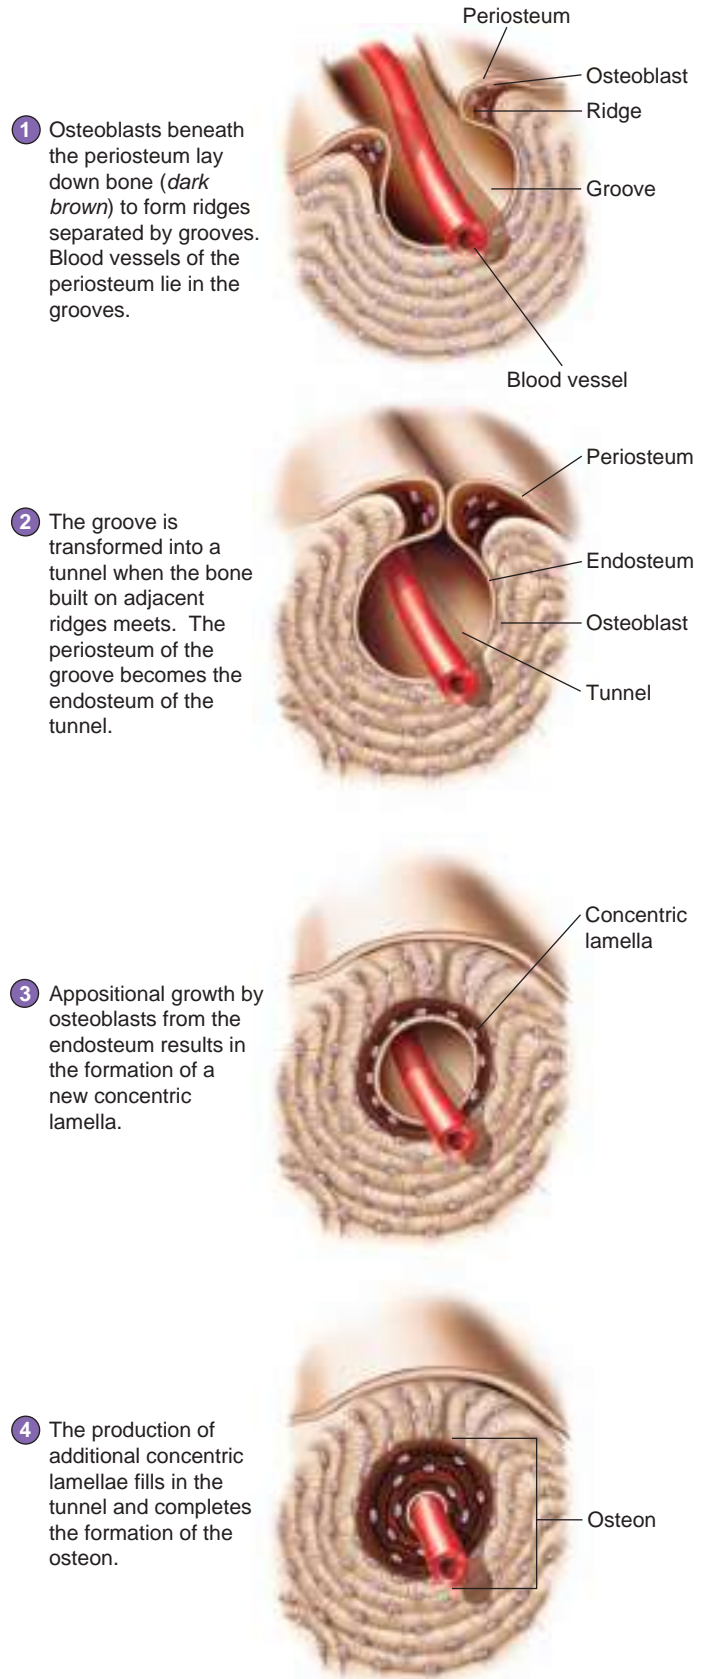

Factors Affecting Bone Growth

The bones of an individual's skeleton usually reach a certain length, thickness, and shape through the processes described in the previous sections. The potential shape and size of a bone and an individual's final adult height are determined genetically, but factors such as nutrition and hormones can greatly modify the expression of those genetic factors.

Nutrition

Because bone growth requires chondroblast and osteoblast proliferation, any metabolic disorder that affects the rate of cell proliferation or the production of collagen and other matrix components affects bone growth, as does the availability of calcium or other minerals needed in the mineralization process.

The long bones of a child sometimes exhibit lines of arrested growth, which are transverse regions of greater bone density crossing an otherwise normal bone (figure 6.17). These lines are caused by greater calcification below the epiphyseal plate of a bone, where it has grown at a slower rate during an illness or severe nutritional deprivation. They demonstrate that illness or malnutrition during the time of bone growth can cause a person to be shorter than he or she would have been otherwise.

PROCESS FIGURE 6.16 Bone Growth in Width

Bones can increase in width by the formation of new osteons beneath the periosteum. **APR**

FIGURE 6.17 Arrested Growth Lines

In this radiograph, the horizontal dark lines are lines of arrested growth.

Certain vitamins are important to bone growth in very specific ways. **Vitamin D** is necessary for the normal absorption of calcium from the intestines (see chapters 5 and 24). The body can either synthesize or ingest vitamin D. Its rate of synthesis increases when the skin is exposed to sunlight. Insufficient vitamin D in children causes **rickets**, a disease resulting from reduced mineralization of the bone matrix. Children with rickets may have bowed bones and inflamed joints. During the winter in northern climates, children who are not exposed to sufficient sunlight can take supplementary vitamin D to prevent rickets. The body's inability to absorb lipids in which vitamin D is soluble can also result in vitamin D deficiency. This condition sometimes occurs in adults who have digestive disorders. Low vitamin D levels can be one cause of "adult rickets," or **osteomalacia** (os'tē-ō-mă-lă'shē-ă), a softening of the bones due to calcium depletion.

Vitamin C is necessary for collagen synthesis by osteoblasts. Normally, as old collagen breaks down, new collagen is synthesized to replace it. Vitamin C deficiency results in bones and cartilage with fewer collagen fibers because collagen synthesis is impaired. In children, vitamin C deficiency can retard growth. In both children and adults, vitamin C deficiency can result in **scurvy**, which is marked by ulceration and hemorrhage in almost any area of the body because normal collagen synthesis is not occurring in connective tissues. Wound healing, which requires collagen synthesis, is hindered in patients with vitamin C deficiency. In extreme cases, the teeth fall out because the ligaments that hold them in place break down.

Hormones

Hormones are very important in bone growth. **Growth hormone** from the anterior pituitary increases general tissue growth

FIGURE 6.18 Effect of Growth Hormone on Stature

The taller man (giant) has excessive growth hormone secretion, whereas the shorter man (dwarf) has insufficient growth hormone secretion.

(see chapters 17 and 18), including overall bone growth, by stimulating interstitial cartilage growth and appositional bone growth. Disruptions in normal growth hormone can cause dramatic changes in an individual's height. Excessive growth hormone secretion results in pituitary gigantism, whereas insufficient growth hormone secretion results in pituitary dwarfism (figure 6.18). **Thyroid hormone** is also required for normal growth of all tissues, including cartilage; therefore, a decrease in this hormone can result in a smaller individual (table 6.3). **Reproductive hormones** also influence bone growth. Estrogen (a class of female reproductive hormones) and testosterone (a male reproductive hormone) initially stimulate bone growth, which accounts for the burst of growth at puberty when production of these hormones increases. However, both classes of reproductive hormones also stimulate ossification of epiphyseal plates, and thus the cessation of growth. Females usually stop growing earlier than males because estrogens cause quicker closure of the epiphyseal plate than testosterone does. Because their entire growth period is somewhat shorter, females usually do not reach the same height as males. Decreased levels of testosterone or estrogen can prolong the growth phase of the epiphyseal plates, even though the bones grow more slowly. Overall, growth is very complex and is influenced by many factors besides reproductive hormones, such as other hormones, genetics, and nutrition.

ASSESS YOUR PROGRESS

23. Name and describe the events occurring in the four zones of the epiphyseal plate. Explain how the epiphyseal plate remains the same thickness while the bone increases in length.
24. Explain the process of growth at the articular cartilage. What happens to the epiphyseal plate and the articular cartilage when bone growth ceases?
25. Describe how new osteons are produced as a bone increases in width.
26. Explain how illness or malnutrition can affect bone growth. How do vitamins D and C affect bone growth?
27. Bone growth is greatly affected by growth hormone and thyroid hormone. Explain these effects.
28. How do estrogen and testosterone affect bone growth? How do these effects account for the average height difference observed in men and women?

Predict 8

Nellie is a 12-year-old female who has an adrenal tumor that is producing a large amount of estrogen. If untreated, what effect will this condition have on her growth for approximately the next 6 months? How will her height have been affected by the time she is 18?

6.7 Bone Remodeling

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Explain the need for bone remodeling, particularly in long bones.
- B. Describe the role of a basic multicellular unit (BMU) in the remodeling process.
- C. Discuss how mechanical stress affects bone remodeling and bone strength.

Just as our homes must be remodeled when they become outdated, bone that becomes old is replaced with new bone in a process called **bone remodeling**. In this process, osteoclasts remove old bone and osteoblasts deposit new bone. Bone remodeling converts woven bone into lamellar bone and is involved in several important functions, including bone growth, changes in bone shape, adjustment of the bone to stress, bone repair, and calcium ion (Ca^{2+}) regulation in the body.

The structure of a long bone—a hollow cylinder with a medullary cavity in the center—has two mechanical advantages: (1) A hollow cylinder is lighter in weight than a solid rod, and (2) a hollow cylinder with the same height, weight, and composition as a solid rod, but with a greater diameter, can support much

more weight without bending. As a long bone increases in length and diameter, the size of the medullary cavity also increases (figure 6.19), keeping the bone from becoming very heavy. In addition, as the bone grows in diameter, the relative thickness of compact bone is maintained as osteoclasts remove bone on the inside and osteoblasts add bone to the outside.

Bone remodeling involves a **basic multicellular unit (BMU)**, a temporary assembly of osteoclasts and osteoblasts that travels through or across the surface of bone, removing old bone matrix and replacing it with new bone matrix. The average life span of a BMU is approximately 6 months, and BMU activity renews the entire skeleton every 10 years. In compact bone, the osteoclasts of a BMU break down bone matrix, forming a tunnel. Interstitial lamellae (see figure 6.7b) are remnants of osteons that were not completely removed when a BMU formed a tunnel. Blood vessels grow into the tunnel, and osteoblasts of the BMU move in and lay down a layer of bone on the tunnel wall, forming a concentric lamella. Additional concentric lamellae are produced, filling in the tunnel from the outside to the inside, until an osteon is formed, with the center of the tunnel becoming a central canal containing blood vessels. In spongy bone, the BMU removes bone matrix from the surface of a trabecula, forming a cavity, which the BMU then fills in with new bone matrix.

Mechanical Stress and Bone Strength

The amount of stress applied to a bone can modify the bone's strength through remodeling, the formation of additional bone, alteration in trabecular alignment to reinforce the scaffolding, or other changes. Mechanical stress applied to bone increases osteoblast activity in bone tissue, and the removal of mechanical stress decreases osteoblast activity. Under conditions of reduced stress,

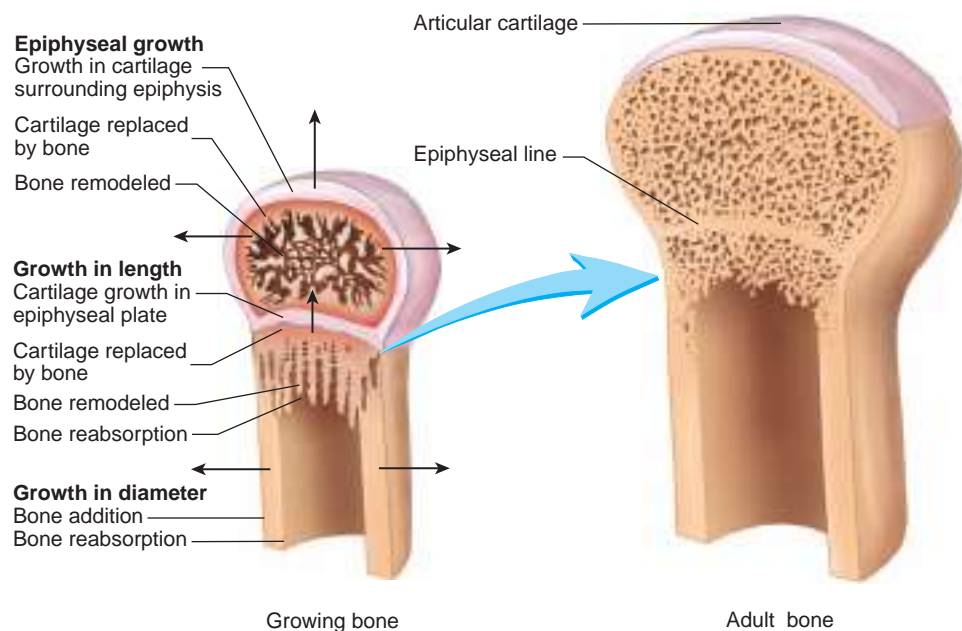

FIGURE 6.19 Remodeling of a Long Bone

The epiphysis enlarges and the diaphysis increases in length as new cartilage forms and is replaced by bone during remodeling. The diameter of the bone increases as a result of bone growth on the outside of the bone, and the size of the medullary cavity increases because of bone reabsorption.

as when a person is bedridden or paralyzed, osteoclast activity continues at a nearly normal rate but osteoblast activity decreases, resulting in less bone density. In addition, pressure in bone causes an electrical change that increases the activity of osteoblasts; therefore, applying weight (pressure) to a broken bone can speed the healing process. Weak pulses of electric current are sometimes applied to a broken bone to speed healing.

ASSESS YOUR PROGRESS

29. Why is it important for bone remodeling to occur?
30. What is a basic multicellular unit (BMU)? Explain how a BMU directs remodeling in compact bone and in spongy bone.
31. How does bone adjust to mechanical stress? Describe the roles of osteoblasts and osteoclasts in this process. What happens to bone that is not subject to mechanical stress?

6.8 Bone Repair

LEARNING OUTCOME

After reading this section, you should be able to

A. Outline and explain the steps in bone repair.

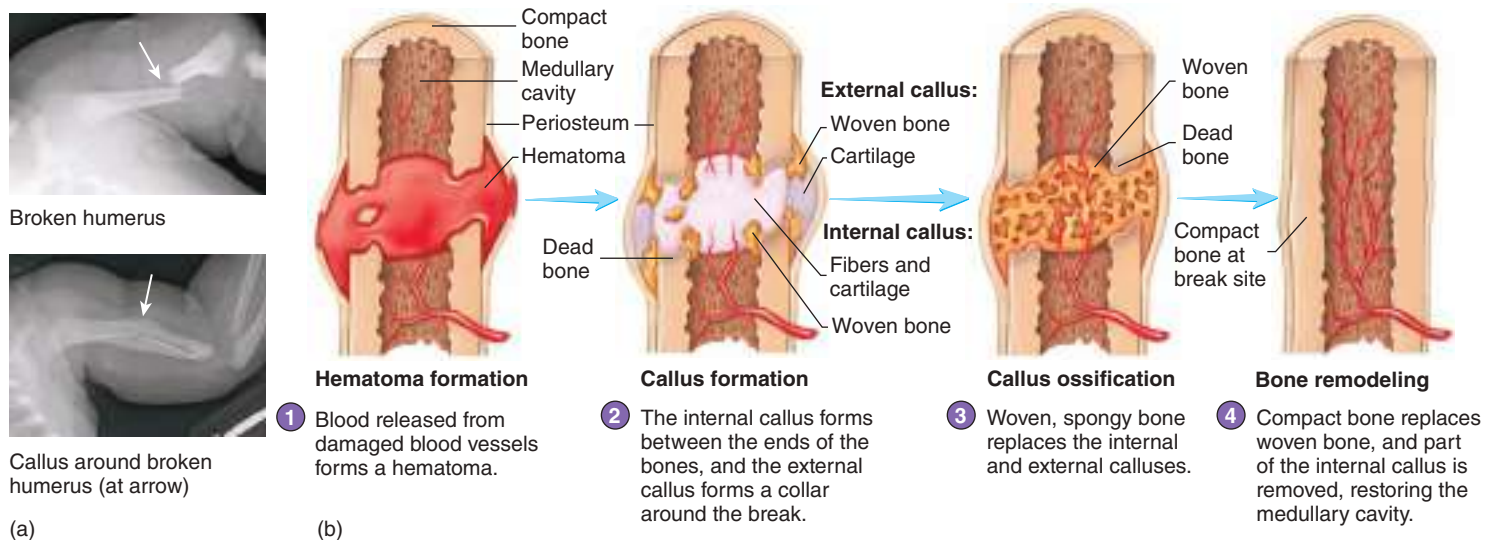

Bone is a living tissue that can undergo repair if it is damaged (figure 6.20a). This process has four major steps:

1. **Hematoma formation** (figure 6.20b, step 1). When a bone is fractured, the blood vessels in the bone and surrounding periosteum are damaged and a hematoma forms. A **hematoma** (hē-mă-tō'mă) is a localized mass of blood released from blood vessels but confined within an organ or a space. Usually, the blood in a hematoma forms a clot, which consists of fibrous proteins that stop the bleeding. Disruption of blood vessels in the central canals results in inadequate blood delivery to osteocytes, and

bone tissue adjacent to the fracture site dies. Tissues around the bone often become inflamed and swollen following the injury.

2. **Callus formation** (figure 6.20b, step 2). A **callus** (kal'ūs) is a mass of tissue that forms at a fracture site and connects the broken ends of the bone. An **internal callus** forms *between* the ends of the broken bone, as well as in the marrow cavity if the fracture occurs in the diaphysis of a long bone. Several days after the fracture, blood vessels grow into the clot. As the clot dissolves, macrophages clean up cell debris, osteoclasts break down dead bone tissue, and fibroblasts produce collagen and other extracellular materials to form granulation tissue (see chapter 4). As the fibroblasts continue to produce collagen fibers, a denser fibrous network, which helps hold the bone together, is produced. Chondroblasts derived from osteochondral progenitor cells of the periosteum and endosteum begin to produce cartilage in the fibrous network. As these events are occurring, osteochondral progenitor cells in the endosteum become osteoblasts and produce new bone, which contributes to the internal callus. If formation of the internal callus is prevented by infection, bone movements, or the nature of the injury, the two ends of the bone do not rejoin—a condition called nonunion of the bone. This condition can be treated surgically by implanting an appropriate substrate, such as living bone from another site in the body or dead bone from a cadaver. Other substrates have also been used. For example, a specific marine coral calcium phosphate is converted into a predominantly hydroxyapatite biomatrix that is very much like spongy bone.

The **external callus** forms a collar *around* the opposing ends of the bone fragments. Osteochondral progenitor cells from the periosteum become osteoblasts, which produce bone, and chondroblasts, which produce cartilage. Cartilage production is more rapid than bone production, and the cartilage from each side of the break eventually grows together. The external callus is a bone-cartilage collar that stabilizes the ends of the

PROCESS FIGURE 6.20 Bone Repair

(a) On the top is a radiograph of the broken humerus of author A. Russo's granddaughter, Viviana Russo. On the bottom is the same humerus a few weeks later, with a callus now formed around the break. (b) The steps in bone repair.

Clinical IMPACT

Classification of Bone Fractures

Bone fractures are classified in several ways. The most commonly used classification involves the severity of the injury to the soft tissues surrounding the bone. An **open fracture** (formerly called a *compound fracture*) occurs when an open wound extends to the site of the fracture or when a fragment of bone protrudes through the skin. If the skin is not perforated, the fracture is called a **closed fracture** (formerly called a *simple fracture*). If the soft tissues around a closed fracture are damaged, it is called a **complicated fracture**.

Figure 6B illustrates several other types of bone fractures. An **incomplete fracture** does not extend completely across the bone, whereas in a **complete fracture** the bone is broken into at least two fragments. An incomplete fracture on the convex side of the curve of the bone is a **greenstick fracture**. **Hairline fractures** are incomplete fractures in which the two sections of bone do not separate; hairline fractures are common in the skull.

A **comminuted** (kom'i-noo-ted) **fracture** is a complete fracture in which the bone breaks into more than two pieces—usually two major fragments and a smaller fragment. In an **impacted fracture**, one fragment is driven into the spongy portion of the other fragment.

Fractures are also classified according to the direction of the fracture within the bone. **Linear**

fractures run parallel to the length of the bone, and **transverse fractures** are at right angles to the length of the bone. **Spiral fractures** take a helical course around the bone, and **oblique fractures** run obliquely in relation to the length of the bone. **Dentate fractures** have rough, toothed, broken ends, and **stellate fractures** have breakage lines radiating from a central point.

FIGURE 6B Types of Bone Fractures

broken bone. In modern medical practice, applying a cast or surgically implanting metal supports can help stabilize the bone.

3. **Callus ossification** (figure 6.20b, step 3). Like the cartilage models formed during fetal development, the cartilage in the external callus is replaced by woven spongy bone through endochondral ossification. The result is a stronger external

callus. Even as the internal callus is forming and replacing the hematoma, osteoblasts from the periosteum and endosteum enter the internal callus and begin to produce bone. Eventually, the fibers and cartilage of the internal callus are replaced by woven spongy bone, which further stabilizes the broken bone.

Diseases and Disorders

TABLE 6.3 Skeletal System

Condition	Description
Tumors	May be malignant or benign and cause a range of bone defects
Growth and Developmental Disorders	
Gigantism	Abnormally increased body size due to excessive growth at the epiphyseal plates
Dwarfism	Abnormally small body size due to improper growth at the epiphyseal plates
Osteogenesis imperfecta	Brittle bones that fracture easily due to insufficient or abnormal collagen
Rickets	Growth retardation due to nutritional deficiencies in minerals (Ca^{2+}) or vitamin D; results in bones that are soft, weak, and easily broken
Bacterial Infections	
Osteomyelitis	Bone inflammation often due to a bacterial infection that may lead to complete destruction of the bone (see <i>Microbes in Your Body</i> , “Disruption of Bone Homeostasis by Bacteria” in this chapter)
Tuberculosis	Typically, a lung bacterium that can also affect bone
Decalcification	
Osteomalacia	Softening of adult bones due to calcium depletion; often caused by vitamin D deficiency
Osteoporosis	Reduction in overall quantity of bone tissue; see <i>Systems Pathology</i> , “Osteoporosis”

PROCESS FIGURE 6.21 Calcium Homeostasis

4. *Bone remodeling* (figure 6.20b, step 4). Filling the gap between bone fragments with an internal callus of woven bone is not the end of the repair process because woven bone is not as structurally strong as the original lamellar bone. Repair is complete only when the woven bone of the internal callus and the dead bone adjacent to the fracture site have been replaced by compact bone. In this compact bone, osteons from both sides of the break extend across the fracture line to “peg” the bone fragments together. This remodeling process takes time—as much as a year or more. As the internal callus is remodeled and becomes stronger, the external callus is reduced in size by osteoclast activity. Eventually, repair may be so complete that no evidence of the break remains; however, the repaired zone usually remains slightly thicker than the adjacent bone. If the fracture has occurred in the diaphysis of a long bone, remodeling also restores the medullary cavity.

ASSESS YOUR PROGRESS

32. What are the four steps of bone repair?
33. How does breaking a bone result in hematoma formation?
34. Distinguish between the location and composition of the internal callus and those of the external callus.
35. Why is remodeling of the ossified callus necessary?

6.9 Calcium Homeostasis

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Explain the role of bone in calcium homeostasis.**
- B. Describe how parathyroid hormone and calcitonin influence bone health and calcium homeostasis.**

Bones play an important role in regulating blood Ca^{2+} levels, which must be maintained within narrow limits for functions such as muscle contraction and membrane potentials to occur normally (see chapters 9 and 11). Bone is the major storage site for calcium in the body, and movement of Ca^{2+} into and out of bone helps determine blood Ca^{2+} levels. Calcium ions move into bone as osteoblasts build new bone, and they move out of bone as osteoclasts break down bone (figure 6.21; see section 6.3). When osteoblast and osteoclast activities are balanced, the movements of Ca^{2+} into and out of a bone are equal.

When blood Ca^{2+} levels are too low, osteoclast activity increases. Osteoclasts release more Ca^{2+} from bone into the blood than osteoblasts remove from the blood to make new bone. Consequently,

MICROBES In Your Body

Disruption of Bone Homeostasis by Bacteria

Osteomyelitis is a bacterial infection in bone. Usually, the aggressive pathogen *Staphylococcus aureus* is the causative organism. This bacterium is more commonly found on our skin but can move into bone in three major ways: (1) The bacterium spreads to the bone through the bloodstream from another infected location in the body, such as an abscessed tooth; (2) it penetrates the bone through an open wound on the skin, which may occur in severe cases of diabetes; and (3) it is introduced into a joint or bone during surgery—for example, while putting a pin in a broken bone. Once bacteria are in the bone, their presence induces a severe inflammatory response, which is then followed by progressive bone loss. Unfortunately, osteomyelitis can be difficult to treat. This difficulty is due to the bacteria simultaneously initiating three responses in the bone, which together result in devastating bone loss. These responses are increased development of osteoclasts, stimulation of the secretion of inflammation-causing chemicals, and disruption of the chemical signaling between osteoblasts and osteoclasts.

In order to understand how these three responses are activated, we need a brief overview of interactions between pathogens and immune cells. For a more detailed description, see the chapter 22 *Microbes in Your Body*, “Do Our Gut Bacteria Drive Immune Development and Function?” Bacterial cell walls possess unique combinations of marker proteins (see chapter 3) that our immune cells recognize and respond to. Our immune cells use cell membrane receptors to bind the marker

proteins. As it turns out, both osteoblasts and osteoclasts have these receptors. This is not too surprising when you recall that both cell types are formed from the same precursor cells that form certain immune cells. Because of this, bacteria can induce bone cells to produce chemicals that damage the bone.

In addition, an understanding of the highly orchestrated regulation mechanism between osteoblasts and osteoclasts involving RANKL, OPG, and RANK also sheds light on the mechanism of bone loss during osteomyelitis. During infection, osteoblasts are co-opted to overactivate osteoclasts, the bone-destroying cells. Recall that osteoblasts produce RANKL and OPG, whereas osteoclasts produce RANK. RANKL is related to a group of immune-stimulating molecules, which cause inflammation. RANK is related to the inflammation receptors, which when bound by their ligand cause many cellular responses. These can include either stimulation of or resistance to induced cell death, called apoptosis. Finally, we know that a particular bacterial cell marker stimulates the secretion of inflammation factors, including RANKL.

So how do all these chemicals and cells fit together to cause bone loss during osteomyelitis? *Staphylococcus aureus* cell walls contain a certain cell marker that alters signaling dynamics in such a way that the production of osteoclasts increases but the production of osteoblasts decreases. Bacterial infection prevents normal functioning of the bone-forming osteoblasts.

The first aspect of this uncoupling is when the bacterial cell marker stimulates excess

RANKL secretion by osteoblasts. Additionally, another *Staphylococcus aureus* cell wall protein induces osteoblast apoptosis. Thus, the increased RANKL triggers osteoclast bone reabsorption without inhibition, while the osteoblast apoptosis decreases the amount of new bone formation. The second aspect is a result of osteoblast-specific secretion of pro-inflammatory chemicals that directly damage bone and stimulate osteoclast formation. The final result is that although the host’s immune response is designed to remove the infection, it results in massive damage of the host’s own tissues.

The most common treatment for osteomyelitis is a 4- to 8-week course of antibiotics. The doctor may prescribe intravenous dosing with the antibiotics; thus, patients are often fitted with a peripherally inserted central catheter (PICC) line. If the infection persists, it may be necessary to perform surgery in which the infected tissue is removed, in a process called debridement. In cases of severe tissue damage, a bone graft is necessary. Fortunately, the incidence of osteomyelitis is low, 2 in 10,000 people, and the majority of osteomyelitis cases are successfully resolved.

Predict 9

In addition to targeting the bacteria for death, what is one theoretical medical approach that could help reduce the amount of bone loss during osteomyelitis?

a net movement of Ca^{2+} occurs from bone into blood, and blood Ca^{2+} levels increase. Conversely, if blood Ca^{2+} levels are too high, osteoclast activity decreases. Osteoclasts release fewer Ca^{2+} from bone into the blood than osteoblasts remove from the blood to produce new bone. As a result, a net movement of Ca^{2+} occurs from the blood to bone, and blood Ca^{2+} levels decrease.

Calcium homeostasis is maintained by three hormones: parathyroid hormone, vitamin D from a precursor in the skin or from the diet, and calcitonin from C-cells in the thyroid gland. **Parathyroid hormone (PTH)** is the major regulator of blood Ca^{2+} levels. PTH, secreted from the parathyroid glands (see figure 18.11) when blood Ca^{2+} levels are too low, stimulates an increase in the number of osteoclasts, which break down bone and elevate blood Ca^{2+} levels (see figure 6.20). In addition, PTH stimulates

osteoblasts to release enzymes that break down the layer of unmineralized organic bone matrix covering bone, thereby making the mineralized bone matrix available to osteoclasts.

Osteoclast numbers are regulated by the interactions of osteoblasts and red bone marrow stem cells of the monocyte/macrophage lineage. Osteoblasts and stem cells have receptors for PTH. When PTH binds to these receptors, osteoblasts respond by producing **receptor activator of nuclear factor kappaB ligand (RANKL)**. RANKL is expressed on the surface of the osteoblasts and combines with **receptor activator of nuclear factor kappaB (RANK)** found on the cell surfaces of osteoclast precursor stem cells. In a cell-to-cell interaction, RANKL on osteoblasts binds to RANK on osteoclast precursor stem cells, stimulating them to become osteoclasts.

Osteoclast production is inhibited by **osteoprotegerin** (os'tē-ō-prō-teg'er-in; **OPG**), which is secreted by osteoblasts and other cells. OPG inhibits osteoclast production by binding to RANKL and preventing RANKL from binding to its receptor on osteoclast precursor stem cells. Increased PTH causes decreased secretion of OPG from osteoblasts and other cells. Thus, increased PTH promotes an increase in osteoclast numbers by increasing RANKL and decreasing OPG. The increased RANKL stimulates osteoclast precursor cells, and the decreased OPG results in less inhibition of osteoclast precursor cells. Conversely, decreased PTH results in fewer osteoclasts by decreasing RANKL and increasing OPG.

PTH also regulates blood Ca^{2+} levels by indirectly increasing Ca^{2+} uptake from the small intestine (see figure 6.21). Increased PTH promotes the activation of vitamin D in the kidneys, and vitamin D increases the absorption of Ca^{2+} from the small intestine. PTH also stimulates the reabsorption of Ca^{2+} from urine in the kidneys, which reduces the amount of Ca^{2+} lost (excreted) in the urine.

Calcitonin (kal-si-tō'nin), secreted from the thyroid gland when blood Ca^{2+} levels are too high (see figure 18.8), inhibits osteoclast activity (see figure 6.20) by binding to receptors on the osteoclasts. PTH and calcitonin are described more fully in chapters 18 and 27.

ASSESS YOUR PROGRESS

36. How is calcium moved into and out of bone? What happens in bone when blood calcium levels decrease? When blood calcium levels increase?
37. Name the hormone that is the major regulator of Ca^{2+} levels in the body. What stimulates the secretion of this hormone?
38. Describe how PTH controls the number of osteoclasts. What are the effects of PTH on the formation of vitamin D, Ca^{2+} uptake in the small intestine, and reabsorption of Ca^{2+} from the urine?
39. What stimulates calcitonin secretion? How does calcitonin affect osteoclast activity?

6.10 Effects of Aging on the Skeletal System

LEARNING OUTCOME

After reading this section, you should be able to

A. Describe the effects of aging on bones.

The most significant age-related changes in the skeletal system affect the quality and quantity of bone matrix. Recall that a mineral (hydroxyapatite) in the bone matrix gives bone compression (weight-bearing) strength, but collagen fibers make the bone flexible. The bone matrix in an older bone is more brittle than a younger bone because decreased collagen production results in relatively more mineral and fewer collagen fibers. With aging, the amount of matrix also decreases because the rate of matrix formation by osteoblasts becomes slower than the rate of matrix breakdown by osteoclasts.

Bone mass is at its highest around age 30, and men generally have denser bones than women because of the effects of testosterone and greater body weight. Race and ethnicity also affect bone mass. African-Americans and Latinos have higher bone masses than Caucasians and Asians. After age 35, both men and women experience bone loss at a rate of 0.3–0.5% a year. This loss can increase by 10 times in women after menopause, when they can lose bone mass at a rate of 3–5% a year for approximately 5–7 years (see Systems Pathology, “Osteoporosis”).

At first, spongy bone is lost as the trabeculae become thinner and weaker. The ability of the trabeculae to provide support also decreases as they become disconnected from each other. Eventually, some of the trabeculae completely disappear. Spongy bone loss is greatest in the trabeculae that are under the least stress. In other words, more sedentary individuals experience greater bone loss.

A slow loss of compact bone begins about age 40 and increases after age 45. However, the rate of compact bone loss is approximately half the rate of spongy bone loss. Bones become thinner, but their outer dimensions change little, because most compact bone is lost under the endosteum on the inner surfaces of bones. In addition, the remaining compact bone weakens as a result of incomplete bone remodeling. In a young bone, when osteons are removed, the resulting spaces are filled with new osteons. With aging, the new osteons fail to completely fill in the spaces produced when the older osteons are removed.

Case STUDY

Bone Density

Henry is a 65-year-old man who was admitted to the emergency room after a fall. A radiograph confirmed that he had fractured the proximal part of his arm bone (surgical neck of the humerus). The radiograph also revealed that his bone matrix was not as dense as it should be for a man his age. A test for blood Ca^{2+} was normal. On questioning, Henry confessed that he is a junk food addict who eats few vegetables and never consumes dairy products. In addition, Henry never exercises and seldom goes outdoors except at night.

Predict 10

Use your knowledge of bone physiology and figure 6.21 to answer the following questions.

- A. Why is Henry more likely to break a bone than are most men his age?
- B. How have Henry's eating habits contributed to his low bone density?
- C. Would Henry's PTH levels be lower than normal, normal, or higher than normal?
- D. What effect has Henry's nocturnal lifestyle had on his bone density?
- E. How has lack of exercise affected his bone density?

Background Information

Osteoporosis (os'tē-ō-pō-rō'sis), or porous bone, is a loss of bone matrix. The loss of bone mass makes bones so porous and weakened that they become deformed and prone to fracture (figures 6C and 6D). The occurrence of osteoporosis increases with age. In both men and women (although it is 2.5 times more common in women), bone mass starts to decrease at about age 40 and continually decreases thereafter. Women can eventually lose approximately one-half, and men one-quarter, of their spongy bone.

The most common causes of osteoporosis include decreased reproductive hormone production, inadequate dietary intake or too little absorption of calcium, and too little exercise or disuse from injury.

Women are more susceptible to reproductive hormone (estrogen) declines because they tend to enter menopause in their midlife years (40s to late 50s); men's testosterone levels do not decrease significantly until after age 65. The decrease in estrogen can lead to osteoporosis, mostly in spongy bone, especially in the vertebrae of the spine and the bones of the forearm. Collapse of the vertebrae can cause a decrease in height or, in more severe cases, kyphosis in the upper back (figure 6E). Estrogen levels also decline in women who have had their ovaries removed and due to cigarette smoking. However, men are also prone to bone loss if they have a sedentary lifestyle, have a poor diet, or have had a broken bone immobilized. Significant amounts of bone are lost after 8 weeks of immobilization.

Early diagnosis of osteoporosis can lead to more preventive treatments. Instruments that measure the absorption of photons (particles of light) by bone are used; of these, dual-energy x-ray absorptiometry (DEXA) is considered the best. Doctors recommend consuming at least 1000 mg

Osteoporotic bone

Normal bone

Figure 6C Photomicrograph of Osteoporotic Bone and Normal Bone

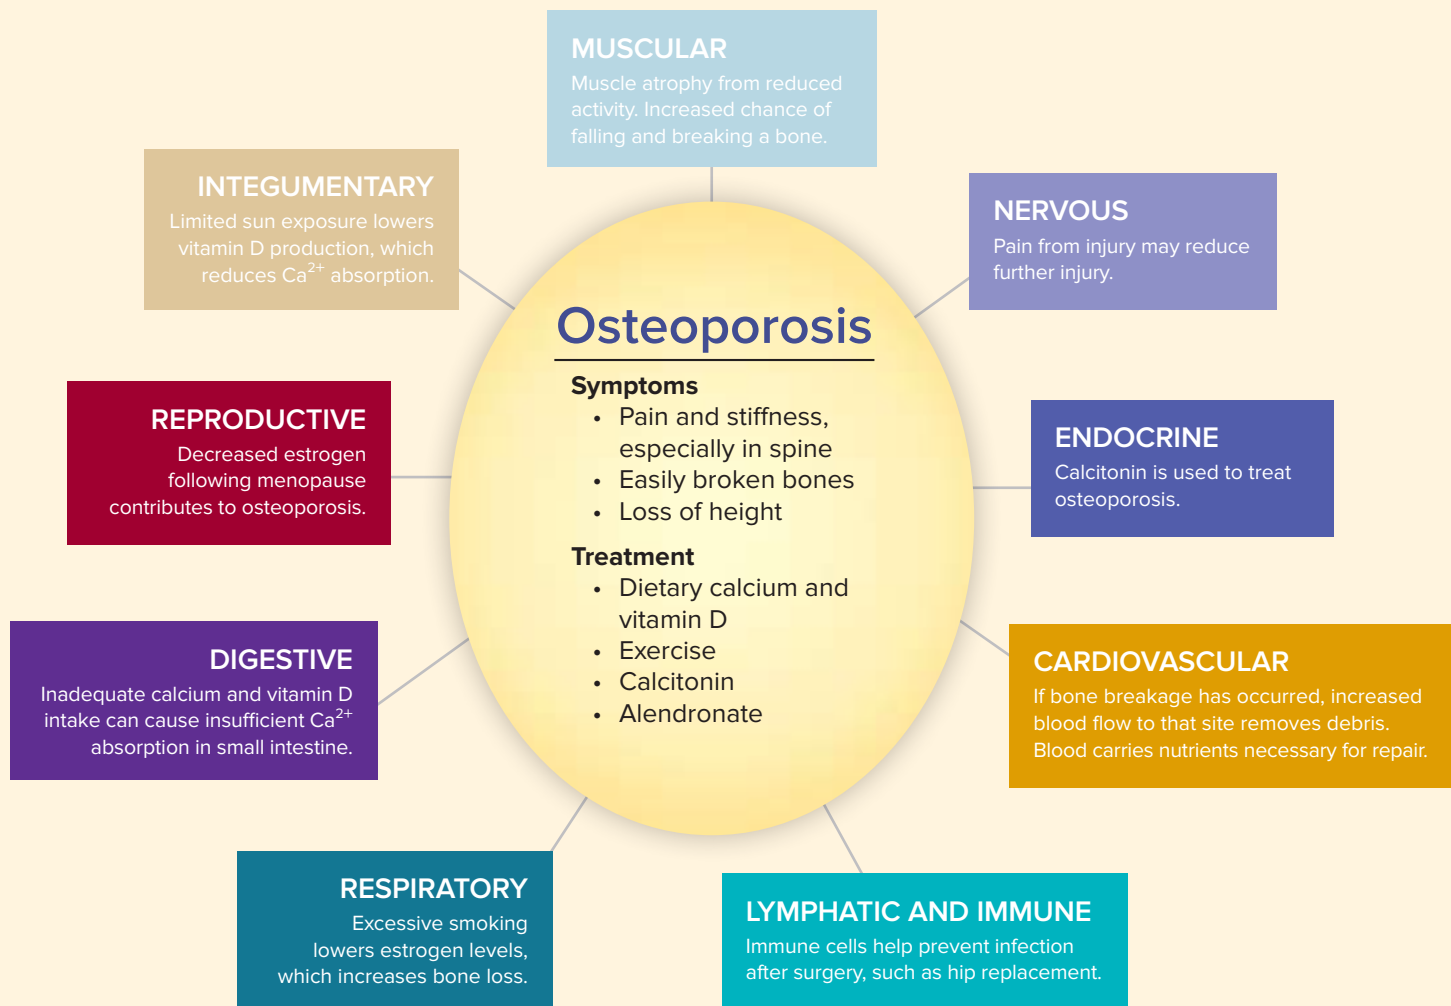

Figure 6D Radiograph

Figure 6E

of calcium per day (1200 mg/day for people over age 50). Calcium-rich foods include milk, yogurt, broccoli, cauliflower, salmon, tofu, and leafy green vegetables. However, most people consume only about one-third of their needed calcium, so physicians suggest taking a calcium supplement in combination with an 800-1000 IU vitamin D supplement to help absorb the calcium. Patients should also avoid high phosphorus foods such as red meat and soft drinks. In addition, doctors also suggest avoiding excess alcohol and caffeine because they decrease the amount of calcium that is absorbed. Regular weight-bearing exercises such as running, walking and weight lifting for 30-45 minutes three times a week can also help prevent bone loss or help regain mild bone loss. However, if bone loss has been excessive, there are medications that can prevent further loss from occurring. There are four classes of anti-osteoporosis medications: bisphosphonates, estrogen-like medications, antibodies that inactivate the bone-breakdown mechanism, and calcitonin-replacement medications. Bisphosphonates are osteoclast inhibitors and include alendronate (Fosamax) and risendronate (Actonel), which are taken once a week. Ibandronate (Boniva) is taken once a month. The newest medication, zoledronic acid (Reclast), is a once-per-year injec-

tion. The estrogen-like medicine is called raloxifene (Evista) and has not been associated with either breast or uterine cancer. The most common antibody medication is denosumab (Prolia) and is taken once every 6 months. Calcitonin-like medicines such as Calcimar and Miacalcin also inhibit osteoclasts.

A relatively new area of concern for patients with osteoporosis is for those who take proton pump inhibitors (PPIs) for acid reflux. Some studies have shown that long-term (after 5 years) use of PPIs is associated with increased risk of fractures, especially if other fracture risk factors are present. However, for the majority of people, the risk of PPI use causing fractures is low. Since PPIs reduce stomach acid production, it is thought they may contribute to reduced calcium absorption.

➤ Predict 11

What advice should Betty give her granddaughter, so that the granddaughter will be less likely to develop osteoporosis when she is Betty's age?

Significant bone loss increases the likelihood of bone fractures. For example, the loss of trabeculae greatly increases the risk for compression fractures of the vertebrae (backbones) because the weight-bearing body of a vertebra consists mostly of spongy bone. In addition, bone loss can lead to deformity, loss of height, pain, and stiffness. For example, compression fractures of the vertebrae can cause an exaggerated curvature of the spine, resulting in a bent-forward, stooped posture. Loss of bone from the jaws can lead to tooth loss.

The most effective preventive measure against the effects of aging on the skeletal system is the combination of increasing

physical activity and taking dietary calcium and vitamin D supplements. Intensive exercise, especially weight-bearing exercise, can even reverse the loss of bone matrix.

ASSESS YOUR PROGRESS

40. What effect does aging have on the quality and quantity of bone matrix?
41. How can a person be protected from the effects of aging on the skeletal system?

Answer

Learn to Predict From page 165

The question suggests that Amir is interested in eating a healthy diet, especially one that supports strong bones and joints. In this chapter, we learned that children whose diets lack adequate vitamin D develop rickets, a condition characterized by inflamed joints and bowed legs. Chapter 5 explained that vitamin D is necessary for normal Ca^{2+} absorption in the small intestine. Although we learned that the body can manufacture vitamin D in sun-exposed skin, this chapter informed us that vitamin D deficiency can also result from a lack of lipids in the diet. Growth of strong bones depends on adequate Ca^{2+} absorption. We also read in chapter 6 that vitamin C is important for normal bone growth. Vitamin C is necessary for the synthesis of collagen, a major

organic component of the bone matrix that is responsible for some of the major functional characteristics of bone. Collagen is also a common matrix protein in other connective tissues, such as ligaments and the dermis of the skin. Inadequate collagen synthesis due to vitamin C deficiency can result in short stature, poor wound healing, and loose permanent teeth. Thus, to help prevent any serious injuries, Amir should be sure to consume plenty of vitamin D- and vitamin C-rich foods in addition to healthy lipid-rich foods.

Answers to the rest of this chapter's Predict questions are in appendix G.

Summary

6.1 Functions of the Skeletal System (p. 166)

1. The skeletal system consists of bones, cartilage, tendons, and ligaments.
2. The skeletal system supports the body, protects the organs it surrounds, allows body movements, stores minerals and lipids, and is the site of blood cell production.

6.2 Cartilage (p. 166)

1. Chondroblasts produce cartilage and become chondrocytes. Chondrocytes are located in lacunae surrounded by matrix.
2. The matrix of cartilage contains collagen fibers (for strength) and proteoglycans (to trap water).
3. The perichondrium surrounds cartilage.
 - The outer layer contains fibroblasts.
 - The inner layer contains chondroblasts.
4. Cartilage grows by both appositional and interstitial growth.

6.3 Bone Histology (p. 167)

Bone Matrix

1. Collagen provides flexible strength.
2. Hydroxyapatite provides compressional strength.

Bone Cells

1. Osteoblasts produce bone matrix and become osteocytes.
 - Osteoblasts connect to one another through cell extensions and surround themselves with bone matrix to become osteocytes.
 - Osteocytes are located in lacunae and are connected to one another through canaliculi.
2. Osteoclasts break down bone (with assistance from osteoblasts).

- Osteoblasts originate from osteochondral progenitor cells, whereas osteoclasts originate from monocyte/macrophage lineage stem cells in red bone marrow.
- Ossification, the formation of bone, occurs through appositional growth.

Woven and Lamellar Bone

- Woven bone has collagen fibers oriented in many directions. It is remodeled to form lamellar bone.
- Lamellar bone is arranged in thin layers, called lamellae, which have collagen fibers oriented parallel to one another.

Spongy and Compact Bone

- Spongy bone has many spaces.
 - Lamellae combine to form trabeculae, beams of bone that interconnect to form a latticelike structure with spaces filled with bone marrow and blood vessels.
 - The trabeculae are oriented along lines of stress and provide structural strength.
- Compact bone is dense with few spaces.
 - Compact bone consists of organized lamellae: Circumferential lamellae form the outer surface of compact bones; concentric lamellae surround central canals, forming osteons; interstitial lamellae are remnants of lamellae left after bone remodeling.
 - Canals within compact bone provide a means for exchanging gases, nutrients, and waste products. From the periosteum or endosteum, perforating canals carry blood vessels to central canals, and canaliculi connect central canals to osteocytes.

6.4 Bone Anatomy (p. 171)

Bone Shapes

Individual bones can be classified as long, flat, short, or irregular.

Structure of a Long Bone

- The diaphysis is the shaft of a long bone, and the epiphyses are distinct from the diaphysis and house the epiphyseal plate.
- The epiphyseal plate is the site of lengthwise bone growth.
- The medullary cavity is a space within the diaphysis.
- Red marrow is the site of blood cell production, and yellow marrow consists of fat.
- The periosteum covers the outer surface of bone.
 - The outer layer contains blood vessels and nerves.
 - The inner layer contains osteoblasts, osteoclasts, and osteochondral progenitor cells.
 - Perforating fibers hold the periosteum, ligaments, and tendons in place.
- The endosteum lines cavities inside bone and contains osteoblasts, osteoclasts, and osteochondral progenitor cells.

Structure of Flat, Short, and Irregular Bones

Flat, short, and irregular bones have an outer covering of compact bone surrounding spongy bone.

6.5 Bone Development (p. 174)

Intramembranous Ossification

- Some skull bones, part of the mandible, and the diaphyses of the clavicles develop from membranes.
- Within the membrane at centers of ossification, osteoblasts produce bone along the membrane fibers to form spongy bone.

- Beneath the periosteum, osteoblasts lay down compact bone to form the outer surface of the bone.
- Fontanelles are areas of membrane that are not ossified at birth.

Endochondral Ossification

- Most bones develop from a cartilage model.
- The cartilage matrix is calcified, and chondrocytes die. Osteoblasts form bone on the calcified cartilage matrix, producing spongy bone.
- Osteoblasts build an outer surface of compact bone beneath the periosteum.
- Primary ossification centers form in the diaphysis during fetal development. Secondary ossification centers form in the epiphyses.
- Articular cartilage on the ends of bones and the epiphyseal plate does not ossify.

6.6 Bone Growth (p. 178)

- Bones increase in size only by appositional growth, the addition of new bone to the surface of older bone or cartilage.
- Trabeculae grow by appositional growth.

Growth in Bone Length

- Epiphyseal plate growth involves the interstitial growth of cartilage followed by appositional bone growth on the cartilage.
- Epiphyseal plate growth results in increased length of the diaphysis and bony processes. Bone growth in length ceases when the epiphyseal plate becomes ossified and forms the epiphyseal line.

Growth at Articular Cartilage

- Articular cartilage growth involves the interstitial growth of cartilage followed by appositional bone growth on the cartilage.
- Articular cartilage growth results in larger epiphyses and an increase in the size of bones that do not have epiphyseal plates.

Growth in Bone Width

- Appositional bone growth beneath the periosteum increases the diameter of long bones and the size of other bones.
- Osteoblasts from the periosteum form ridges with grooves between them. The ridges grow together, converting the grooves into tunnels filled with concentric lamellae to form osteons.
- Osteoblasts from the periosteum lay down circumferential lamellae, which can be remodeled.

Factors Affecting Bone Growth

- Genetic factors determine bone shape and size. The expression of genetic factors can be modified.
- Factors that alter the mineralization process or the production of organic matrix, such as deficiencies in vitamins D and C, can affect bone growth.
- Growth hormone, thyroid hormone, estrogen, and testosterone stimulate bone growth.
- Estrogen and testosterone cause increased bone growth and closure of the epiphyseal plate.

6.7 Bone Remodeling (p. 182)

- Remodeling converts woven bone to lamellar bone and allows bone to change shape, adjust to stress, repair itself, and regulate body calcium levels.
- Bone adjusts to stress by adding new bone and by realigning bone through remodeling.

6.8 Bone Repair (p. 183)

1. Fracture repair begins with the formation of a hematoma.
2. The hematoma is replaced by an internal callus consisting of fibers and cartilage.
3. The external callus is a bone-cartilage collar that stabilizes the ends of the broken bone.
4. The internal and external calluses are ossified to become woven bone.
5. The woven bone is replaced by compact bone.

6.9 Calcium Homeostasis (p. 185)

PTH increases blood Ca^{2+} by increasing bone breakdown, vitamin D activation, which increases Ca^{2+} absorption from the small intestine, and the reabsorption of Ca^{2+} from the urine. Calcitonin decreases blood Ca^{2+} by decreasing bone breakdown.

6.10 Effects of Aging on the Skeletal System (p. 187)

1. With aging, bone matrix is lost and the matrix becomes more brittle.
2. Spongy bone loss results from thinning and loss of trabeculae. Compact bone loss mainly occurs from the inner surface of bones and involves formation of fewer osteons.
3. Loss of bone increases the risk for fractures and causes deformity, loss of height, pain, stiffness, and loss of teeth.
4. Exercise and dietary supplements are effective at preventing bone loss.

REVIEW AND COMPREHENSION

1. Which of these is *not* a function of bone?
 - a. internal support and protection
 - b. attachment for the muscles
 - c. calcium and phosphate storage
 - d. blood cell production
 - e. vitamin D storage
2. Chondrocytes are mature cartilage cells within the _____, and they are derived from _____.
 - a. perichondrium, fibroblasts
 - b. perichondrium, chondroblasts
 - c. lacunae, fibroblasts
 - d. lacunae, chondroblasts
3. Which of these statements concerning cartilage is correct?
 - a. Cartilage often occurs in thin plates or sheets.
 - b. Chondrocytes receive nutrients and oxygen from blood vessels in the matrix.
 - c. Articular cartilage has a thick perichondrium layer.
 - d. The perichondrium contains both chondrocytes and osteocytes.
 - e. Appositional growth of cartilage occurs when chondrocytes within the tissue add more matrix from the inside.
4. Which of these substances makes up the major portion of bone?
 - a. collagen
 - b. hydroxyapatite
 - c. proteoglycan aggregates
 - d. osteocytes
 - e. osteoblasts
5. The flexible strength of bone occurs because of
 - a. osteoclasts.
 - b. ligaments.
 - c. hydroxyapatite.
 - d. collagen fibers.
 - e. periosteum.
6. The primary function of osteoclasts is to
 - a. prevent osteoblasts from forming.
 - b. become osteocytes.
 - c. break down bone.
 - d. secrete calcium salts and collagen fibers.
 - e. form the periosteum.
7. Central canals
 - a. connect perforating canals to canaliculi.
 - b. connect spongy bone to compact bone.
 - c. are where blood cells are produced.
 - d. are found only in spongy bone.
 - e. are lined with periosteum.
8. The lamellae found in osteons are _____ lamellae.
 - a. circumferential
 - b. concentric
 - c. interstitial
9. Spongy bone consists of interconnecting rods or plates of bone called
 - a. osteons.
 - b. canaliculi.
 - c. circumferential lamellae.
 - d. a haversian system.
 - e. trabeculae.
10. A fracture in the shaft of a bone is a break in the
 - a. epiphysis.
 - b. perichondrium.
 - c. diaphysis.
 - d. articular cartilage.
11. Yellow marrow is
 - a. found mostly in children's bones.
 - b. found in the epiphyseal plate.
 - c. important for blood cell production.
 - d. mostly adipose tissue.
12. The periosteum
 - a. is an epithelial tissue membrane.
 - b. covers the outer and internal surfaces of bone.
 - c. contains only osteoblasts.
 - d. becomes continuous with collagen fibers of tendons or ligaments.
 - e. has a single fibrous layer.
13. Given these events:
 - (1) Osteochondral progenitor cells become osteoblasts.
 - (2) Connective tissue membrane is formed.
 - (3) Osteoblasts produce woven bone.

Which sequence best describes intramembranous bone formation?

 - a. 1,2,3
 - b. 1,3,2
 - c. 2,1,3
 - d. 2,3,1
 - e. 3,2,1
14. Given these processes:
 - (1) Chondrocytes die.
 - (2) Cartilage matrix calcifies.
 - (3) Chondrocytes hypertrophy.
 - (4) Osteoblasts deposit bone.
 - (5) Blood vessels grow into lacunae.

Which sequence best represents the order in which these processes occur during endochondral bone formation?

 - a. 3,2,1,4,5
 - b. 3,2,1,5,4
 - c. 5,2,3,4,1
 - d. 3,2,5,1,4
 - e. 3,5,2,4,1

15. Intramembranous bone formation
- occurs at the epiphyseal plate.
 - is responsible for growth in diameter of a bone.
 - gives rise to the flat bones of the skull.
 - occurs within a hyaline cartilage model.
 - produces articular cartilage in the long bones.
16. The ossification regions formed during early fetal development
- are secondary ossification centers.
 - become articular cartilage.
 - become medullary cavities.
 - become the epiphyses.
 - are primary ossification centers.
17. Growth in the length of a long bone occurs
- at the primary ossification center.
 - beneath the periosteum.
 - at the center of the diaphysis.
 - at the epiphyseal plate.
 - at the epiphyseal line.
18. During growth in length of a long bone, cartilage forms and then ossifies. The location of the ossification is the zone of
- calcification.
 - hypertrophy.
 - proliferation.
 - resting cartilage.
19. Given these processes:
- An osteon is produced.
 - Osteoblasts from the periosteum form a series of ridges.
 - The periosteum becomes the endosteum.
 - Osteoblasts lay down bone to produce a concentric lamella.
 - Grooves are changed into tunnels.
- Which sequence best represents the order in which these processes occur during growth in the width of a long bone?
- 1,4,2,3,5
 - 2,5,3,4,1
 - 3,4,2,1,5
 - 4,2,1,5,3
 - 5,4,2,1,3
20. Chronic vitamin D deficiency results in which of these consequences?
- Bones become brittle.
 - The percentage of bone composed of hydroxyapatite increases.
 - Bones become soft and pliable.
 - Scurvy occurs.
 - Both a and b are correct.
21. Estrogen
- stimulates a burst of growth at puberty.
 - causes a later closure of the epiphyseal plate than testosterone does.
 - causes a longer growth period in females than testosterone causes in males.
 - tends to prolong the growth phase of the epiphyseal plates.
 - All of these are correct.
22. Bone remodeling can occur
- when woven bone is converted into lamellar bone.
 - as bones are subjected to varying patterns of stress.
 - as a long bone increases in diameter.
 - when new osteons form in compact bone.
 - All of these are correct.
23. Given these processes:
- cartilage ossification
 - external callus formation
 - hematoma formation
 - internal callus formation
 - remodeling of woven bone into compact bone
- Which sequence best represents the order in which the processes occur during repair of a fracture?
- 1,2,3,4,5
 - 2,4,3,1,5
 - 3,4,2,1,5
 - 4,1,5,2,3
 - 5,3,4,2,1
24. Which of these processes during bone repair requires the longest period of time?
- cartilage ossification
 - external callus formation
 - hematoma formation
 - internal callus formation
 - remodeling of woven bone into compact bone
25. If the secretion of parathyroid hormone (PTH) increases, osteoclast activity _____ and blood Ca^{2+} levels _____.
- decreases, decrease
 - decreases, increase
 - increases, decrease
 - increases, increase

Answers in appendix E

CRITICAL THINKING

- When a person develops Paget disease, for unknown reasons the collagen fibers in the bone matrix run randomly in all directions. In addition, the amount of spongy bone decreases. What symptoms would you expect to observe?
- Explain why running helps prevent osteoporosis in the elderly. Does the benefit include all bones or mainly those of the lower limbs and spine?
- Astronauts can experience a dramatic decrease in bone density while in a weightless environment. Explain how this happens, and suggest a way to slow the loss of bone tissue.
- In some cultures, eunuchs were responsible for guarding harems, which are the collective wives of one male. Eunuchs are males who were castrated as boys. Castration removes the testes, the major site of testosterone production in males. Because testosterone is responsible for the sex drive in males, the reason for castration is obvious. As a side effect of this procedure, the eunuchs grew to above normal heights. Can you explain why?
- When a long bone breaks, blood vessels at the fracture line are severed. The formation of blood clots stops the bleeding. Within a few days, bone tissue on both sides of the fracture site dies. However, the bone dies back only a certain distance from the fracture line. Explain.
- A patient has hyperparathyroidism because a tumor in the parathyroid gland is producing excessive amounts of PTH. How does this hormone affect bone? Would the administration of large doses of vitamin D help the situation? Explain.

Learn to Predict

Dave Plummer loves telling people around the pool that he has a pig valve in his heart. At the age of 70, Dave required replacement of a heart valve. The surgeon opened Dave's thoracic cavity by making a longitudinal midline incision from the superior to the inferior margin of his sternum through the skin and underlying soft tissue. Then he cut the sternum with a bone saw along the same line, so that the right and left halves of the sternum could be spread apart enough to expose the heart. After the defective valve had been replaced, the surgeon wired the two halves of the sternum back together. For several days after the surgery, Dave experienced significant discomfort in his back, and although he started walking within a few days, he could not resume his normal swimming routine until 2 months later.

After learning about bone repair and anatomy in chapter 6, and studying the structure of individual bones and their relationships to each other in chapter 7, name the specific parts of the skeletal system and the tissue layers of the bone that the surgeon cut. Also, explain Dave's back discomfort and why he could not resume swimming sooner.

Skeletal System

GROSS ANATOMY

If the body had no skeleton, it would look like a poorly stuffed rag doll. The skeletal system is the framework that helps maintain the body's shape and enables us to move normally. Muscles and bones work together to move our bodies. When the muscles contract, they pull on the bones, often with considerable force. Human bones are very strong and can resist tremendous bending and compression forces without breaking. Nonetheless, each year approximately 6.8 million Americans break a bone.

The skeletal system is composed of bones, cartilage, and ligaments. However, to study skeletal gross anatomy, anatomists use dried, prepared bones, so that they can view the major features of individual bones unobstructed by associated soft tissues. As you study the bones depicted in this chapter, keep in mind that living bones not only contain soft tissue, such as the periosteum (see chapter 6), but also have important relationships with many soft tissues, including muscles, tendons, ligaments, cartilage, nerves, and blood vessels.

Photo: Swimming is an effective form of exercise, but after some surgeries it may take a while before a patient can return to normal activities.

7.1 Skeletal Anatomy Overview

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Define the anatomical terms for bone features.
- B. List the two anatomical portions of the skeleton.

The average adult has 206 bones (table 7.1; figure 7.1). However, the actual number of bones varies between people and decreases with age as bones become fused.

Anatomists use several common terms to describe the features of bones (table 7.2). Most of these features involve the relationship between the bones and associated soft tissues. If a bone possesses a **tubercle** (too'ber-kl; lump) or a **process** (projection), most likely a ligament or tendon was attached to that tubercle or process

TABLE 7.1 Number of Named Bones Listed by Category

Bones	Number	Bones	Number
Axial Skeleton		Appendicular Skeleton	
<i>Skull (Cranium)</i>		<i>Pectoral Girdle</i>	
Braincase (neurocranium)		Scapula 2	
Paired (left and right)	Parietal 2	Clavicle 2	
	Temporal 2	<i>Upper Limb</i>	
Unpaired (single)	Frontal 1	Humerus 2	
	Sphenoid 1	Ulna 2	
	Occipital 1	Radius 2	
	Ethmoid 1	Carpal bones 16	
Face (viscerocranium)		Metacarpal bones 10	
Paired	Maxilla 2	Phalanges 28	
	Zygomatic 2	Total girdle and upper limb bones 64	
	Palatine 2	<i>Pelvic Girdle</i>	
	Lacrimal 2	Hipbone 2	
	Nasal 2	<i>Lower Limb</i>	
	Inferior nasal concha 2	Femur 2	
Unpaired	Mandible 1	Tibia 2	
	Vomer 1	Fibula 2	
	Total skull bones 22	Patella 2	
<i>Bones Associated with the Skull</i>		Tarsal bones 14	
Auditory ossicles		Metatarsal bones 10	
Malleus	2	Phalanges 28	
Incus	2	Total girdle and lower limb bones 62	
Stapes	2	Total appendicular skeleton bones 126	
Hyoid	1	Total axial skeleton bones 80	
	Total associated bones 7	Total appendicular skeleton bones 126	
<i>Vertebral Column</i>		Total bones 206	
Cervical vertebrae 7			
Thoracic vertebrae 12			
Lumbar vertebrae 5			
Sacrum 1

Total rib cage bones 25			
Total axial skeleton bones 80			

Axial Skeleton

Appendicular Skeleton

Axial Skeleton

FIGURE 7.1 Complete Skeleton

Bones of the axial skeleton are listed in the far left- and right-hand columns; bones of the appendicular skeleton are listed in the center. (The skeleton is not shown in the anatomical position.) **APR**

TABLE 7.2 Anatomical Terms for Bone Features

Term	Description
Body	Main part
Head	Enlarged, often rounded end
Neck	Constriction between head and body
Margin, border	Edge
Angle	Bend
Ramus	Branch off the body beyond the angle
Condyle	Smooth, rounded articular surface
Facet	Small, flattened articular surface
Ridges	
Line, linea	Low ridge
Crest, crista	Prominent ridge
Spine	Very high ridge
Projections	
Process	Prominent projection
Tubercle	Small, rounded bump
Tuberosity, tuber	Knob; larger than a tubercle
Trochanter	Tuberosity on the proximal femur
Epicondyle	Upon a condyle
Lingula	Flat, tongue-shaped process
Hamulus	Hook-shaped process
Cornu	Horn-shaped process
Openings	
Foramen	Hole
Canal, meatus	Tunnel
Fissure	Cleft
Sinus, labyrinth	Cavity
Depressions	
Fossa	General term for a depression
Notch	Depression in the margin of a bone
Fovea	Little pit
Groove, ulcus	Deep, narrow depression

during life. If a bone has a smooth, articular surface, that surface was part of a joint and was covered with articular cartilage. If the bone has a **foramen** (fō-rā'men; pl. foramina; fō-ram'i-nā; hole) in it, that foramen was the opening through which a nerve or blood vessel passed. Some skull bones contain mucous membrane-lined air spaces called **sinuses**.

The bones of the skeleton are divided into axial and appendicular portions (figure 7.1).

ASSESS YOUR PROGRESS

1. How are lumps, projections, and openings in bones related to soft tissues?
2. What do each of the following terms mean: tubercle, condyle, spine, foramen, fossa?
3. What are the two anatomical portions of the skeleton?

7.2 Axial Skeleton

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the general functions of the axial skeleton and list its parts.
- B. List the major sutures of the skull and the bones they connect.
- C. Name the bones of the skull and describe their features as seen from the superior, posterior, lateral, anterior, and inferior views.
- D. Name the bones that compose the orbit of the eye.
- E. List the bones and cartilage that form the nasal septum.
- F. Describe the locations and functions of the paranasal sinuses.
- G. List the bones of the braincase and face.
- H. Explain the unique structure of the hyoid bone.
- I. Describe the shape of the vertebral column, list its divisions, and state its functions.
- J. Discuss the common features of the vertebrae and contrast the structure of vertebrae from each region.
- K. List the bones and cartilage of the rib cage, including the three types of ribs.

The **axial skeleton** is composed of the skull, auditory ossicles, hyoid bone, vertebral column, and rib cage (thoracic cage). The axial skeleton forms the upright axis of the body. It protects the brain, the spinal cord, and the vital organs housed within the thorax.

Skull

The **skull**, or *cranium* (krā'nē-ŭm), protects the brain and houses our eyes, ears, nose, and mouth. When the skull is disassembled, the mandible is easily separated from the rest of the skull, which remains intact. Special effort is needed to separate the other bones. For this reason, it is convenient to think of the skull, except for the mandible, as a single unit. The top of the skull is called the **calvaria** (kal-vā'rē-ā), or *skullcap*. It is usually cut off to reveal the skull's interior. The exterior and interior of the skull have ridges, lines, processes, and plates. These structures are important for the attachment of muscles or for articulations between the bones of the skull. Selected features of the intact skull are listed in table 7.3 and are visible in figures 7.2–7.12. The fetal skull is considered in chapter 8.

Superior View of the Skull

The skull appears quite simple when viewed from above (figure 7.2). Only four bones are seen from this view: the frontal bone, two parietal bones, and a small part of the occipital bone. The paired **parietal bones** are joined at the midline by the **sagittal suture**, and the parietal bones are connected to the **frontal bone** by the **coronal suture**.

TABLE 7.3

Processes and Other Features of the Skull

Feature	Bone on Which Feature Is Found	Description
External Features		
Alveolar process	Mandible, maxilla	Ridges on the mandible and maxilla containing the teeth (shown in figure 7.6)
Angle	Mandible	Posterior, inferior corner of the mandible (shown in figure 7.4)
Coronoid process	Mandible	Attachment point for the temporalis muscle (shown in figure 7.4)
Mental protuberance	Mandible	Chin (resembles a bent knee; shown in figures 7.4 and 7.6)
Horizontal plate	Palatine	Posterior third of the hard palate (shown in figure 7.9)
Mandibular condyle	Mandible	Region where the mandible articulates with the skull (shown in figure 7.4)
Mandibular fossa	Temporal	Depression where the mandible articulates with the skull (shown in figure 7.12)
Mastoid process	Temporal	Enlargement posterior to the ear; attachment site for several muscles that move the head (shown in figures 7.3, 7.4, and 7.12)
Nuchal lines	Occipital	Attachment points for several posterior neck muscles (shown in figures 7.3 and 7.12)
Occipital condyle	Occipital	Point of articulation between the skull and the vertebral column (shown in figures 7.3 and 7.12)
Palatine process	Maxilla	Anterior two-thirds of the hard palate (shown in figures 7.9 and 7.12)
Pterygoid hamulus	Sphenoid	Hooked process on the inferior end of the medial pterygoid plate, around which the tendon of one palatine muscle passes; an important dental landmark (shown in table 7.7d)
Pterygoid plates (medial and lateral)	Sphenoid	Bony plates on the inferior aspect of the sphenoid bone; the lateral pterygoid plate is the site of attachment for two muscles of mastication (chewing; shown in figures 7.9 and 7.12)
Ramus	Mandible	Portion of the mandible superior to the angle (shown in figure 7.4)
Styloid process	Temporal	Attachment site for three muscles (to the tongue, pharynx, and hyoid bone) and some ligaments (shown in figure 7.4)
Temporal lines	Parietal	Attachment site for the temporalis muscle, which closes the jaw (shown in figure 7.4)
Internal Features		
Crista galli	Ethmoid	Process in the anterior part of the braincase to which one of the connective tissue coverings of the brain (dura mater) connects (shown in figures 7.9 and 7.11)
Petrous portion	Temporal	Thick, interior part of temporal bone containing the middle and inner ears and the auditory ossicles (shown in figure 7.11)
Sella turcica	Sphenoid	Bony structure, resembling a saddle, in which the pituitary gland is located (shown in figure 7.11)

**FIGURE 7.2 Superior View of the Skull**

(The names of the bones are in bold.)

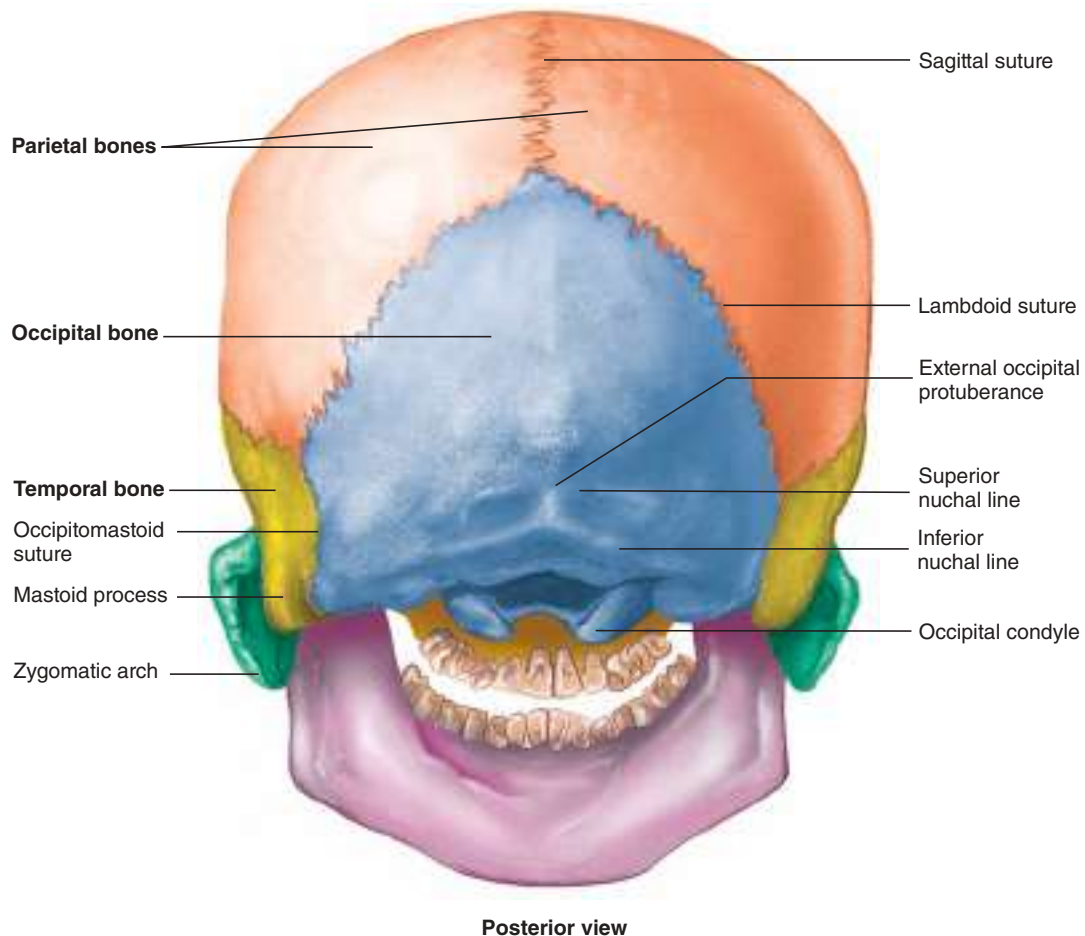

FIGURE 7.3 Posterior View of the Skull

(The names of the bones are in bold.)

Posterior View of the Skull

The parietal and occipital bones are the major structures visible in the posterior view (figure 7.3). The parietal bones are joined to the **occipital bone** by the **lambdoid** (lam'doyd) **suture**. Occasionally, extra small bones called **sutural** (soo'choor-äl) **bones** (*wormian bones*) form along the lambdoid suture.

An **external occipital protuberance** is present on the posterior surface of the occipital bone (figure 7.3). It can be felt through the scalp at the base of the head and varies considerably in size from person to person. The external occipital protuberance is the site of attachment of the **ligamentum nuchae** (noo'kē; nape of neck), an elastic ligament that extends down the neck and helps keep the head erect by pulling on the occipital region of the skull. **Nuchal lines**, a set of small ridges that extend laterally from the external occipital protuberance, are the points of attachment for several neck muscles.

Lateral View of the Skull

The parietal bone and the squamous part of the temporal bone form a major portion of the side of the head (figure 7.4). The term *temporal* means related to time, and the temporal bone is so named because the hair of the temples is often the first to turn white, indicating the passage of time. The **squamous suture** joins

these bones. A prominent feature of the temporal bone is a large hole, the **external auditory canal** (*external acoustic meatus*), which transmits sound waves toward the eardrum, or tympanic membrane. The external ear, or auricle, surrounds the canal. Just posterior and inferior to the external auditory canal is a large inferior projection, the **mastoid** (mas'toyd) **process**. The process can be seen and felt as a prominent lump just posterior to the ear. The process is not solid bone but is filled with cavities called **mastoid air cells**, which are connected to the middle ear. Important neck muscles involved in rotating the head attach to the mastoid process. The superior and inferior **temporal lines**, which are attachment points of the temporalis muscle, one of the major muscles of mastication, arch across the lateral surface of the parietal bone.

The lateral surface of the **greater wing** of the **sphenoid** (sfē'noyd) **bone** is immediately anterior to the temporal bone (figure 7.4). Although appearing to be two bones, one on each side of the skull, the sphenoid bone is actually a single bone that extends completely across the skull. Anterior to the sphenoid bone is the **zygomatic** (zī'gō-mat'ik) **bone**, or cheekbone, which can be easily seen and felt on the face (figure 7.5).

The **zygomatic arch**, which consists of joined processes from the temporal and zygomatic bones, forms a bridge across the side

FIGURE 7.4 Right Lateral View of the Skull

(The names of the bones are in bold.) **APR**

of the skull (figure 7.4). Note that bone processes are named for the bones to which they point. The zygomatic arch is easily felt on the side of the face, and the muscles on each side of the arch can be felt as the mandible opens and closes (figure 7.5).

The jaws are composed of three bones: two maxillae (upper jaw) and one mandible (lower jaw). The **maxilla** (mak-sil'ă; upper jaw) is anterior and inferior to the zygomatic bone to which it is joined. The **mandible** (lower jaw) is inferior to the maxilla and attaches posteriorly to the temporal bone (see figure 7.4). The mandible consists of two main portions: the **body**, which extends both anteriorly and posteriorly, and the **ramus** (branch), which extends superiorly from the body toward the temporal bone. The superior end of the ramus has a mandibular **condyle**, which articulates with the mandibular fossa of the temporal bone, and the **coronoid** (kōr'ō-noyd) **process**, to which the powerful temporalis muscle, one of the chewing muscles, attaches. The alveolar processes of the maxillae contain the superior set of teeth, and the alveolar process of the mandible contains the inferior teeth.

Anterior View of the Skull

The major structures seen from the anterior view are the frontal bone (forehead), the zygomatic bones (cheekbones), the maxillae, and the mandible (figure 7.6). The teeth, which are very prominent

in this view, are discussed in chapter 24. Many bones of the face can be easily felt through the skin (figure 7.7).

From this view, the most prominent openings into the skull are the orbits and the nasal cavity. Each of the two **orbits** is a cone-shaped

FIGURE 7.5 Lateral View of Bony Landmarks on the Face

FIGURE 7.6 Anterior View of the Skull
 (The names of the bones are in bold.) **APR**

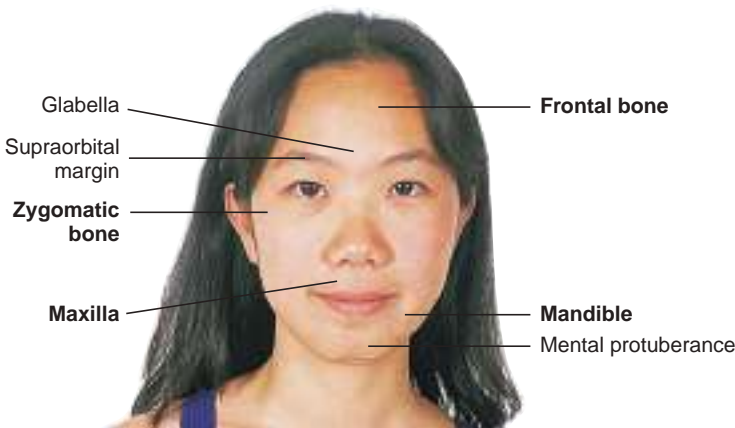

FIGURE 7.7 Anterior View of Bony Landmarks on the Face
 (The names of the bones are in bold.)

fossa with its apex directed posteriorly (figure 7.8; see figure 7.6). They are called orbits because the eyes rotate within the fossae. The bones that make up the orbits provide both protection for the eyes and attachment points for the muscles that move the eyes. The major portion of each eyeball is within the orbit, and the portion of the eye visible from the outside is relatively small. Each orbit contains blood vessels, nerves, and adipose tissue, as well as the eyeball and the muscles that move it. The bones forming the orbit are listed in table 7.4.

The orbit has several openings through which structures communicate between the orbit and other cavities. The nasolacrimal duct passes from the orbit into the nasal cavity through the **nasolacrimal canal**, carrying tears from the eyes to the nasal cavity. The optic nerve for vision passes from the eye through the **optic canal** at the posterior apex of the orbit and enters the cranial cavity. Superior and inferior fissures in the posterior region of the orbit provide openings through which nerves and blood vessels communicate with structures in the orbit or pass to the face.

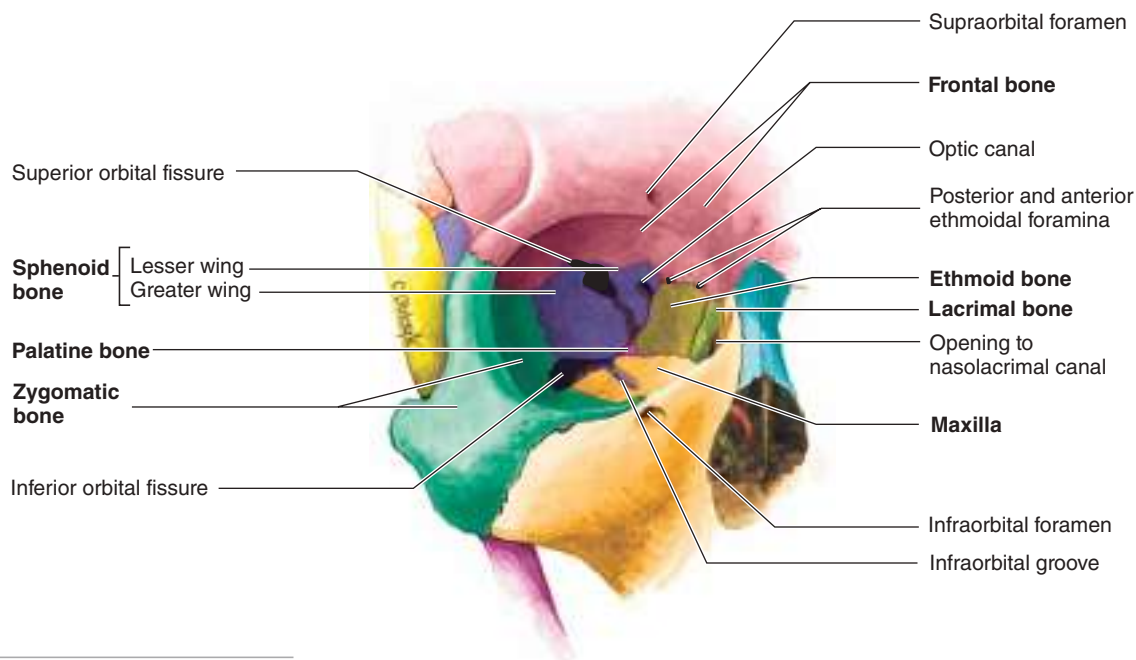

FIGURE 7.8 Bones of the Right Orbit

(The names of the bones are in bold.)

Anterior view

The **nasal cavity** (table 7.5 and figure 7.9; see figure 7.6) has a pear-shaped opening anteriorly and is divided into right and left halves by a **nasal septum** (sep'tūm; wall). The bony part of the nasal septum consists primarily of the vomer bone and the perpendicular plate of the ethmoid bone. Hyaline cartilage forms the anterior part of the nasal septum.

The external part of the nose, formed mostly of hyaline cartilage, is almost absent in the dried skeleton. The only remaining parts are the nasal bones and the frontal processes of the maxillary bones, which form the bridge of the nose.

➤ Predict 2

A direct blow to the nose may result in a “broken nose.” List at least three bones that may be broken.

The lateral wall of the nasal cavity has three bony shelves, called the **nasal conchae** (kon'kē), which are directed inferiorly (figure 7.9). The inferior nasal concha is a separate bone, and the middle and superior nasal conchae are projections from the ethmoid bone. The conchae increase the surface area in the nasal cavity, thereby facilitating moistening of, removal of particles from, and warming of the air inhaled through the nose.

Several of the bones associated with the nasal cavity have large spaces within them called the **paranasal sinuses**, which open into the nasal cavity (figure 7.10). The sinuses decrease the weight of the skull and act as resonating chambers during voice production. Compare a normal voice with the voice of a person who has a cold and whose sinuses are “stopped up.” The sinuses, which are

TABLE 7.4		Bones Forming the Orbit (see figures 7.6 and 7.8)
Bone	Part of Orbit	
Frontal	Roof	
Sphenoid	Roof and posterolateral wall	
Zygomatic	Lateral wall	
Maxilla	Floor	
Lacrimal	Medial wall	
Ethmoid	Medial wall	
Palatine	Medial wall

named for the bones in which they are located, include the frontal, maxillary, and sphenoidal sinuses. The sinuses within each ethmoid bone form a maze of interconnected ethmoidal air cells collectively called the ethmoidal labyrinth, or the ethmoidal sinuses.

Interior of the Cranial Cavity

The **cranial cavity** is the hollow part of the skull occupied by the brain. The cranial cavity can be exposed by cutting away the calvaria, the upper, domelike portion of the skull. Removing the calvaria reveals the floor of the cranial cavity (figure 7.11). That floor can be divided roughly into anterior, middle, and posterior cranial fossae, which are formed as the developing braincase conforms to the shape of the brain.

A prominent ridge, the **crista galli** (kris'tă găl'ē; rooster's comb), is located in the center of the anterior fossa just superior to the nasal cavity. The crista galli is a point of attachment for one of the **meninges** (mě-nin'jēz), the dura mater, a thick connective tissue membrane that supports and protects the brain (see chapter 13). On each side of the crista galli is an olfactory fossa. An olfactory bulb rests in each fossa and receives the olfactory nerves for the sense of smell. The **cribriform** (krib'ri-fōrm; sievelike) **plate** of the ethmoid bone forms the floor of each olfactory fossa. The olfactory nerves extend from the cranial cavity into the roof of the nasal cavity through sievelike perforations in the cribriform plate called **olfactory foramina** (see figure 7.9a and chapter 15).

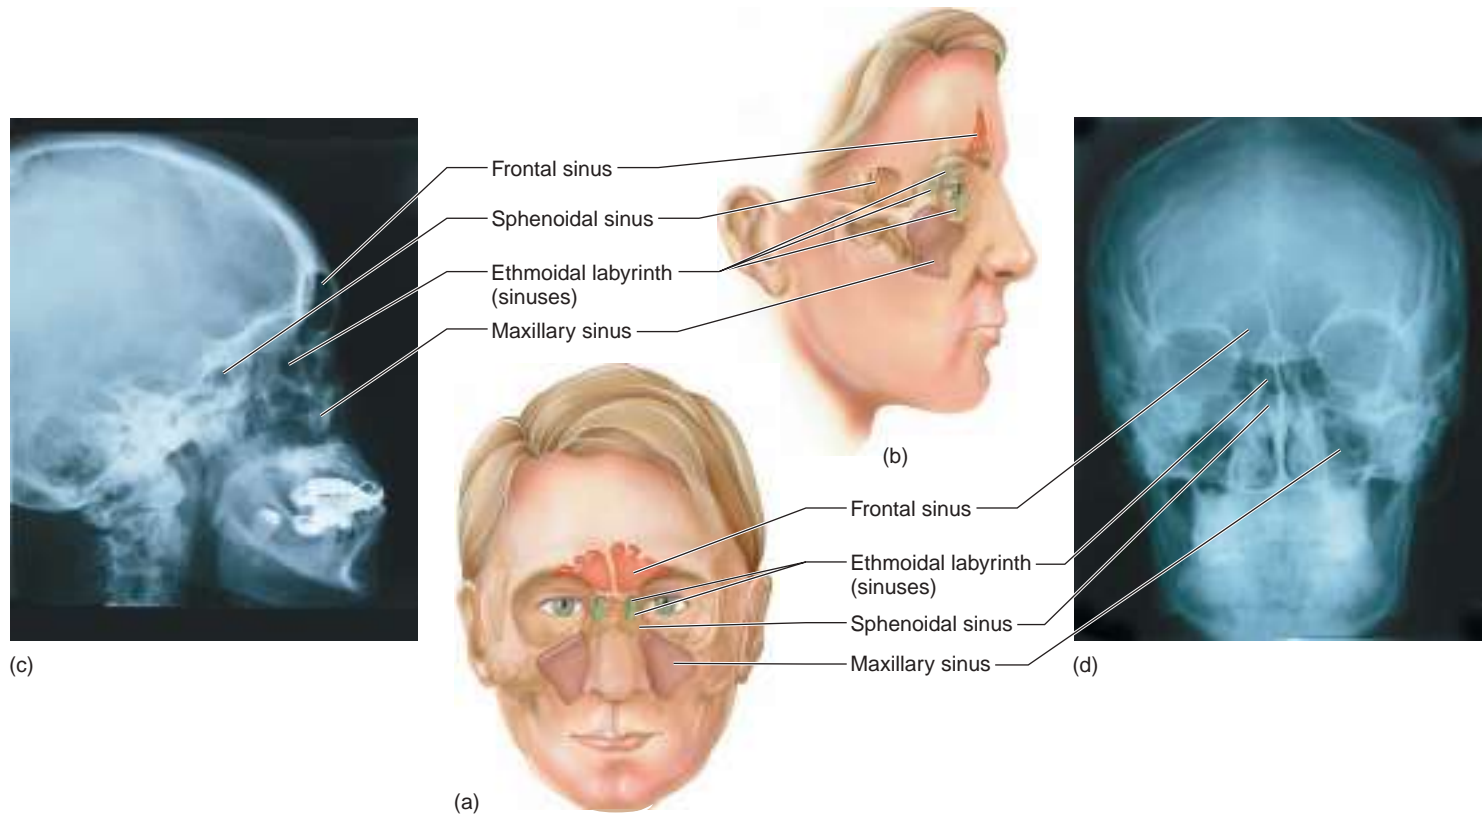

FIGURE 7.10 Paranasal Sinuses

(a) Anterior view. (b) Lateral view. (c) X-ray of the sinuses, lateral view. (d) X-ray of the sinuses, anterior view.

The body of the sphenoid bone forms a central prominence within the floor of the cranial cavity. This prominence is modified into a structure resembling a saddle, the **sella turcica** (sel'ă tūr'si-kă; Turkish saddle), which is occupied by the pituitary gland. An optic canal is located on each side just anterior to the sella turcica. The lesser wings of the sphenoid bone form a ridge to each side of the optic canals. This ridge separates the **anterior cranial fossa** from the **middle cranial fossa**.

The **petrous portion** of the temporal bone extends posterolaterally from each side of the sella turcica. This thick, bony ridge (*petrous*, rocky) is hollow and contains the middle and inner ears. The petrous portion separates the middle cranial fossa from the **posterior cranial fossa**.

Several important openings in the floor of the middle cranial fossa are the **superior orbital fissure**, the **foramen rotundum**, the **foramen ovale**, the **foramen spinosum**, and the internal opening of the carotid canal (table 7.6). The **foramen lacerum** (lă-ser'um), in the floor of the carotid canal, is an artifact of the dried skull. In life, it is filled with cartilage.

The prominent **foramen magnum** ("large hole"), is where the brainstem connects to the spinal cord. It is found in the posterior fossa. A **hypoglossal canal** is located on the anterolateral sides of the foramen magnum. **Jugular** (jŭg'ū-lar; throat) **foramina** lie on each side of the foramen magnum near the base of the petrous

portion. An **internal auditory canal** is located about midway up the face of each petrous portion (table 7.6).

Inferior View of the Skull

Viewed from below with the mandible removed, the base of the skull is complex, with a number of foramina and specialized surfaces (figure 7.12). The foramen magnum passes through the occipital bone just slightly posterior to the center of the skull base. **Occipital condyles**, smooth points of articulation between the skull and the vertebral column, lie on the lateral and anterior margins of the foramen magnum.

The major entry and exit points for blood vessels that supply the brain can be seen from this view. Blood reaches the brain through the internal carotid arteries, which pass through the **carotid** (ka-rot'id; put to sleep) **canals**, and the vertebral arteries, which pass through the foramen magnum. An internal carotid artery enters the inferior opening of each carotid canal (see figure 7.11) and passes through the carotid canal, which runs anteromedially through the temporal bone. A thin plate of bone separates the carotid canal from the middle ear, allowing a person to hear his or her own heartbeat—for example, when frightened or after running. Most blood leaves the brain through the internal jugular veins, which exit through the jugular foramina located lateral to the occipital condyles.

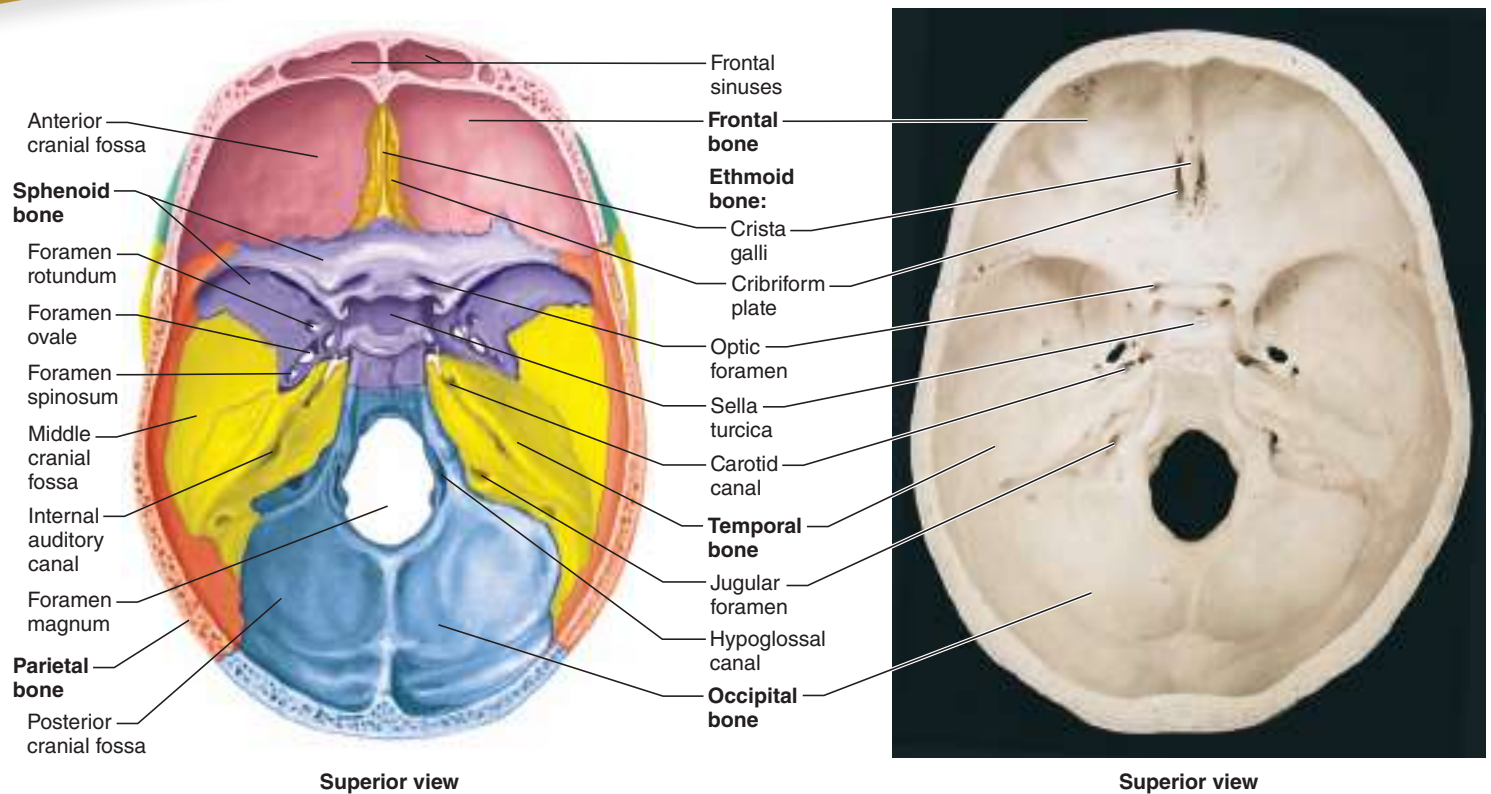

FIGURE 7.11 Floor of the Cranial Cavity

The roof of the skull has been removed, and the floor is seen from a superior view. (The names of the bones are in bold.) **APR**

Two long, pointed **styloid** (stī'loyd; stylus- or pen-shaped) **processes** project from the floor of the temporal bone (see figures 7.4 and 7.12). Three muscles involved in moving the tongue, hyoid bone, and pharynx attach to each process. The **mandibular fossa**, where the mandible articulates with the rest of the skull, is anterior to the mastoid process at the base of the zygomatic arch.

The posterior opening of the nasal cavity is bounded on each side by the vertical bony plates of the sphenoid bone: the **medial pterygoid** (ter'i-goyd; wing-shaped) **plate** and the **lateral pterygoid plate**. The medial and lateral pterygoid muscles, which help move the mandible, attach to the lateral plate (see chapter 10). The **vomer** forms most of the posterior portion of the nasal septum and can be seen between the medial pterygoid plates in the center of the nasal cavity.

The **hard palate**, or *bony palate*, forms the majority of the floor of the nasal cavity (and the roof of the mouth). Sutures join four bones to form the hard palate: The palatine processes of the two maxillary bones form the anterior two-thirds of the hard palate, and the horizontal plates of the two palatine bones form the posterior one-third of the hard palate. The tissues of the soft palate extend posteriorly from the hard palate. The hard and soft palates separate the nasal cavity from the mouth, enabling humans to chew and breathe at the same time.

Individual Bones of the Skull

The skull, or cranium, is composed of 22 separate bones (table 7.7; see table 7.1). In addition, the skull contains six inner ear bones,

Clinical IMPACT

Cleft Lip or Palate

During fetal development, the facial bones sometimes fail to fuse with one another. A **cleft lip** results if the maxillae do not form normally, and a **cleft palate** occurs when the palatine processes of the maxillae do not fuse with one another. A cleft palate produces an opening between the nasal and oral cavities, making it difficult to eat or drink or to speak distinctly. An artificial palate may be inserted into a newborn's mouth until the palate can be repaired. A cleft lip alone, or both cleft lip and palate, occurs approximately once in every 1000 births and is more common in males. A cleft palate alone occurs approximately once in every 2000 births and is more common in females. For more information on fetal development, see chapter 29.

TABLE 7.6 Skull Foramina, Fissures, and Canals (see figures 7:11 and 7:12)

Opening	Bone Containing the Opening	Structures Passing Through Openings
Carotid canal	Temporal	Carotid artery and carotid sympathetic nerve plexus
Ethmoidal foramina, anterior and posterior	Between frontal and ethmoid	Anterior and posterior ethmoidal nerves
External auditory canal	Temporal	Sound waves en route to the eardrum
Foramen lacerum	Between temporal, occipital, and sphenoid	The foramen is filled with cartilage during life; the carotid canal and pterygoid canal cross its superior part but do not actually pass through it
Foramen magnum	Occipital	Spinal cord, accessory nerves, and vertebral arteries
Foramen ovale	Sphenoid	Mandibular division of trigeminal nerve
Foramen rotundum	Sphenoid	Maxillary division of trigeminal nerve
Foramen spinosum	Sphenoid	Middle meningeal artery
Hypoglossal canal	Occipital	Hypoglossal nerve
Incisive foramen (canal)	Between maxillae	Incisive nerve
Inferior orbital fissure	Between sphenoid and maxilla	Infraorbital nerve and blood vessels and zygomatic nerve
Infraorbital foramen	Maxilla	Infraorbital nerve
Internal auditory canal	Temporal	Facial nerve and vestibulocochlear nerve
Jugular foramen	Between temporal and occipital	Internal jugular vein, glossopharyngeal nerve, vagus nerve, and accessory nerve
Mandibular foramen	Mandible	Inferior alveolar nerve to the mandibular teeth
Mental foramen	Mandible	Mental nerve
Nasolacrimal canal	Between lacrimal and maxilla	Nasolacrimal (tear) duct
Olfactory foramina	Ethmoid	Olfactory nerves
Optic canal	Sphenoid	Optic nerve and ophthalmic artery
Palatine foramina, anterior and posterior	Palatine	Palatine nerves
Pterygoid canal	Sphenoid	Sympathetic and parasympathetic nerves to the face
Sphenopalatine foramen	Between palatine and sphenoid	Nasopalatine nerve and sphenopalatine blood vessels
Stylomastoid foramen	Temporal	Facial nerve
Superior orbital fissures	Sphenoid	Oculomotor nerve, trochlear nerve, ophthalmic division of trigeminal nerve, abducens nerve, and ophthalmic veins
Supraorbital foramen or notch	Frontal	Supraorbital nerve and vessels
Zygomatofacial foramen	Zygomatic	Zygomatofacial nerve
Zygomatotemporal foramen	Zygomatic	Zygomatotemporal nerve

called **auditory ossicles**, which function in hearing (see chapter 15). Each temporal bone holds one set of auditory ossicles, which consists of the malleus, incus, and stapes. These bones cannot be observed unless the temporal bones are cut open.

The 22 bones of the skull are divided into two portions: the braincase and the facial bones. The **braincase**, or *neurocranium*, consists of 8 bones that immediately surround and protect the brain. They include the paired parietal and temporal bones and the unpaired frontal, occipital, sphenoid, and ethmoid bones.

The 14 **facial bones**, or *viscerocranium*, form the structure of the face in the anterior skull. They are the maxilla (2), zygomatic (2), palatine (2), lacrimal (2), nasal (2), inferior nasal concha (2),

mandible (1), and vomer (1) bones. The frontal and ethmoid bones, which are part of the braincase, also contribute to the face. The mandible is often listed as a facial bone, even though it is not part of the intact skull.

The facial bones protect the major sensory organs located in the face: the eyes, nose, and tongue. The bones of the face also provide attachment points for the muscles involved in **mastication** (mas-ti-kā'shūn; chewing), facial expression, and eye movement. The jaws (mandible and maxillae) possess **alveolar** (al-vē'ō-lār) **processes** with sockets for the attachment of the teeth. The bones of the face and their associated soft tissues determine the unique facial features of each individual.

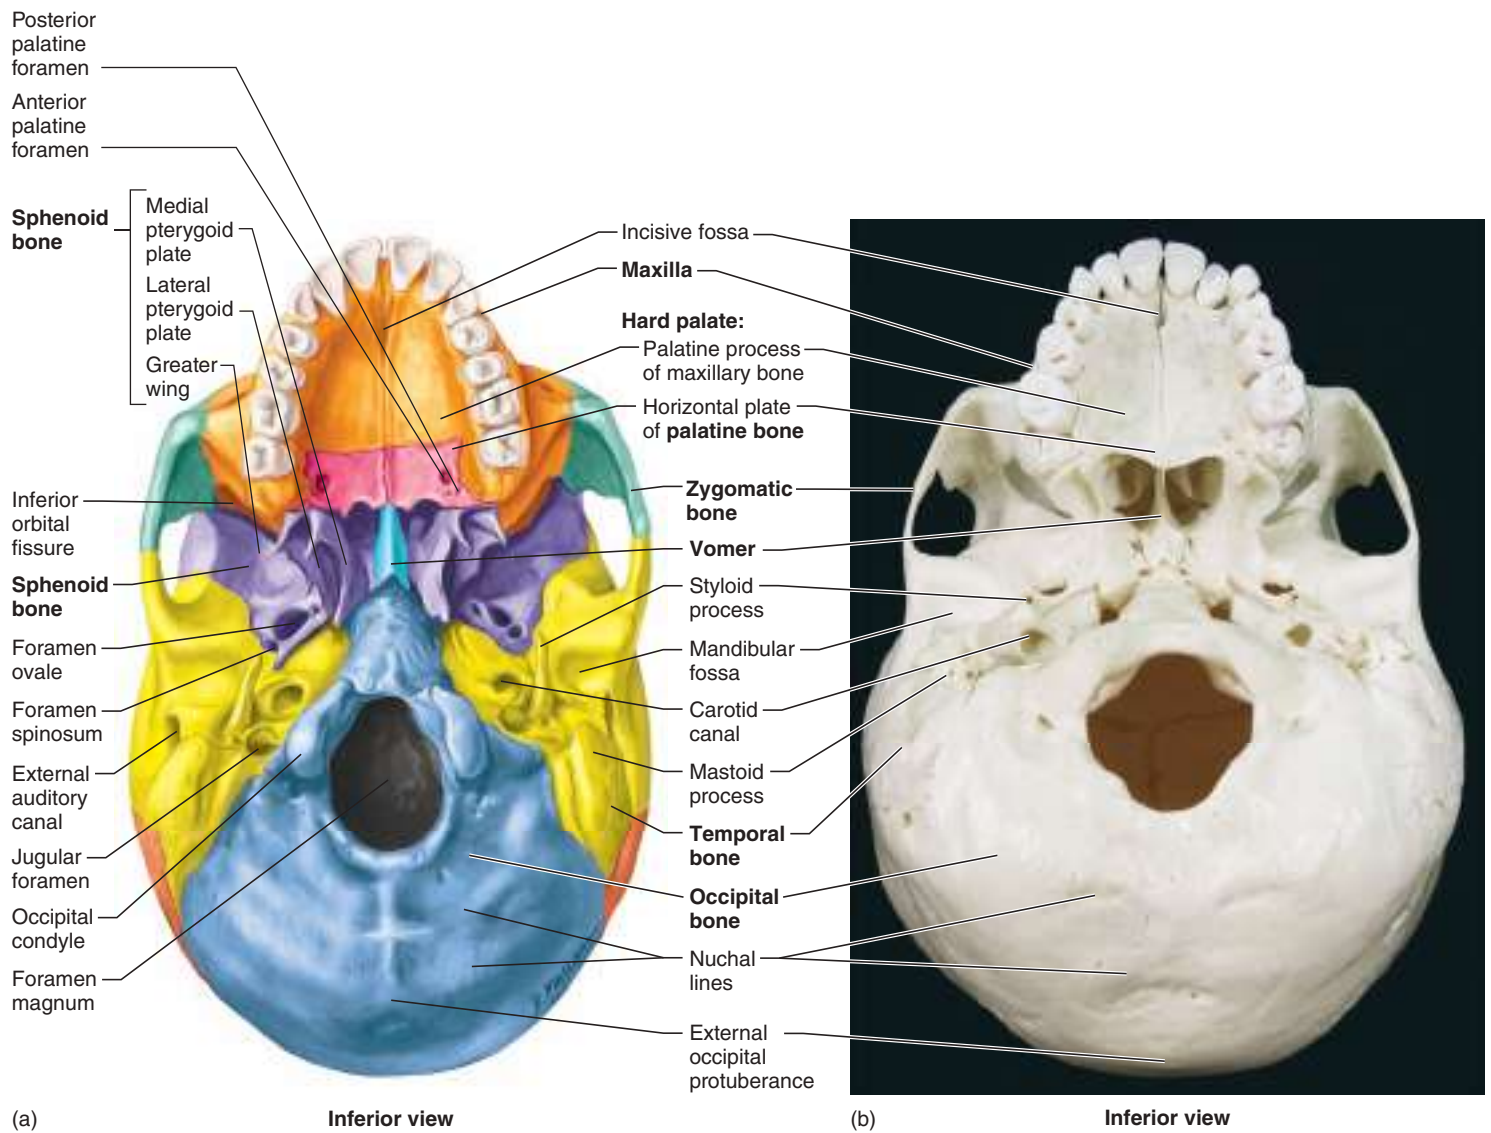

FIGURE 7.12 Inferior View of the Skull

The mandible has been removed. (The names of the bones are in bold.)

ASSESS YOUR PROGRESS

4. What are the parts and general functions of the axial skeleton?
5. Name the four major sutures of the skull and the bones they connect.
6. List the seven bones that form the orbit of the eye.
7. What is a sinus? What are the functions of sinuses? Give the locations of the paranasal sinuses.
8. Name the bones and cartilage that compose the nasal septum.
9. What bones form the hard palate, and what is the function of the hard palate?
10. What structure allows the brainstem to connect to the spinal cord?
11. Name the foramina that allow the passage of the following nerves and blood vessels: optic nerve, olfactory nerve, vestibulocochlear nerve, incisive nerve, facial nerve, carotid artery, and internal jugular vein.
12. What structure allows sound waves to reach the eardrum?
13. List the bones that make up the floor of the braincase.
14. State the bone features where the following muscles attach to the skull: neck muscles, throat muscles, muscles of mastication, muscles of facial expression, and muscles that move the eyeballs.
15. Name the bones of the braincase and face. What are the functions accomplished by each group?

Hyoid Bone

The **hyoid bone** (table 7.8), which is unpaired, is often listed as part of the facial bones because it has a common developmental origin with them. It is not, however, part of the adult skull (see table 7.1). The hyoid bone is the only bone in the body not directly attached to another bone. It has no direct bony attachment to the skull. Instead, muscles and ligaments attach it to the skull, so the hyoid “floats” in the superior aspect of the neck just below the mandible.

TABLE 7.7 Skull Bones

(a) Parietal Bone (Right)—Lateral View

**Landmark**

Parietal eminence

Superior and inferior temporal lines

Special Feature

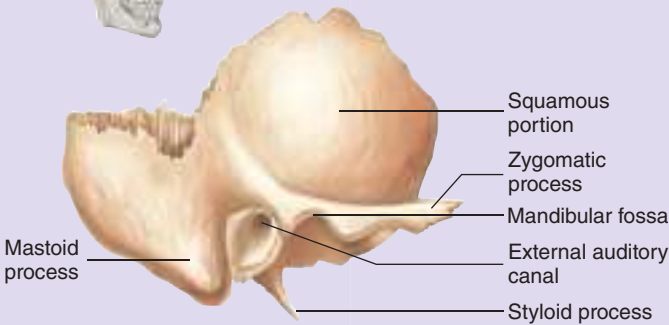

Forms lateral wall of skull

Description

The widest part of the head is from one parietal eminence to the other.

Attachment point for temporalis muscle

(b) Temporal Bone (Right)—Lateral and Medial Views

**Lateral view****Medial view****Landmark**

Carotid canal (shown in figures 7.11 and 7.12)

External auditory canal

Internal auditory canal (shown in figure 7.11)

Forms one side of jugular foramen (shown in figures 7.11 and 7.12)

Mandibular fossa

Mastoid process

Middle cranial fossa (shown in figure 7.11)

Petrous portion (shown in figure 7.11)

Squamous portion (shown in figure 7.11)

Styloid process

Stylomastoid foramen (shown in figure 7.12)

Zygomatic process

Special Features

Contains the middle and inner ear and the mastoid air cells

Place where the mandible articulates with the rest of the skull

Description

Canal through which the internal carotid artery enters the cranial cavity

External canal of the ear; carries sound to the ear

Opening through which the facial (cranial nerve VII) and vestibulocochlear (cranial nerve VIII) nerves enter the petrous portion of the temporal bone

Foramen through which the internal jugular vein exits the cranial cavity

Articulation point between the mandible and skull

Attachment point for muscles moving the head and for a hyoid muscle

Depression in the floor of the cranial cavity formed by the temporal lobes of the brain

Thick portion of the temporal bone

Flat, lateral portion of the temporal bone

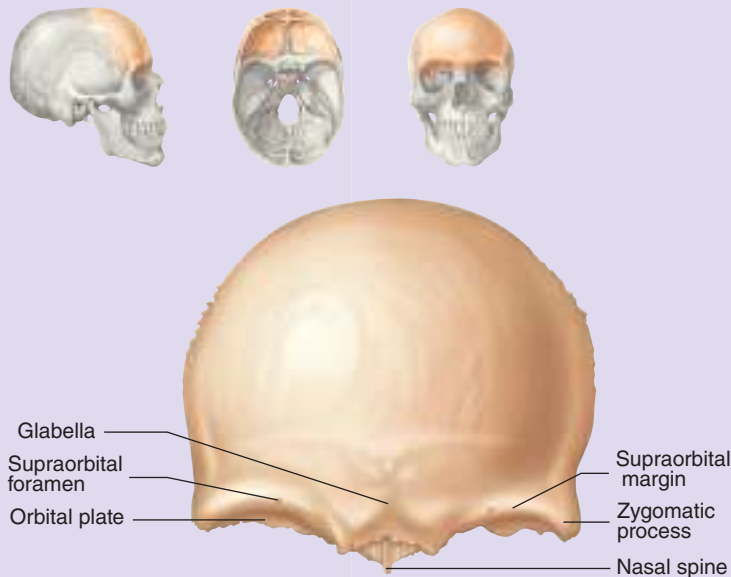

Attachment for muscles of the tongue, throat, and hyoid bone

Foramen through which the facial nerve (cranial nerve VII) exits the skull

Helps form the bony bridge extending from the cheek to just anterior to the ear; attachment for a muscle that moves the mandible

TABLE 7.7 Skull Bones—Continued

(c) Frontal Bone—Anterior View

Landmark

Glabella	Area between the supraorbital margins
Nasal spine	Superior part of the nasal bridge
Orbital plate	Roof of the orbit
Supraorbital foramen	Opening through which nerves and vessels exit the skull to the skin of the forehead
Supraorbital margin	Ridge forming the anterior superior border of the orbit
Zygomatic process	Connects to the zygomatic bone; helps form the lateral margin of the orbit

Special Features

- Forms the forehead and roof of the orbit
- Contains the frontal sinus

(d) Sphenoid Bone—Superior and Posterior Views

Landmark

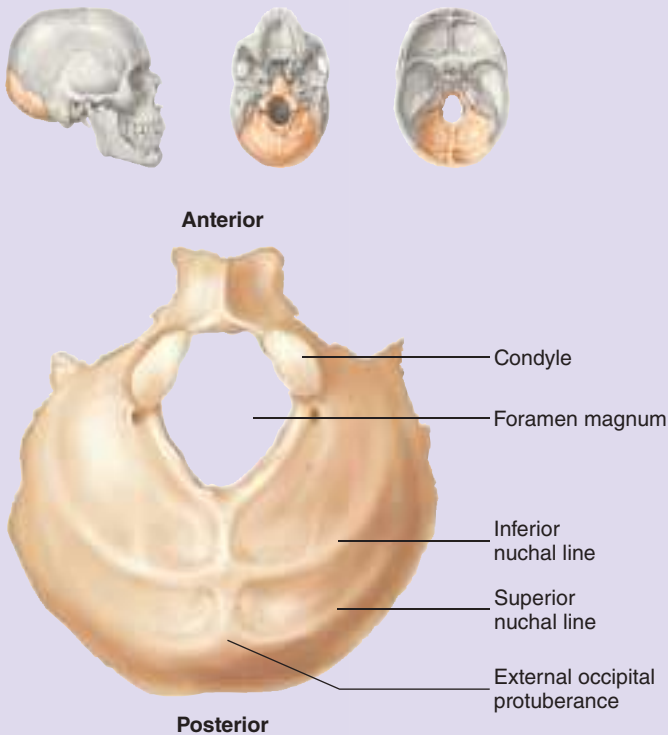

Body	Thickest part of the bone; articulates with the occipital bone
Foramen ovale	Opening through which a branch of the trigeminal nerve (cranial nerve V) exits the cranial cavity
Foramen rotundum	Opening through which a branch of the trigeminal nerve (cranial nerve V) exits the cranial cavity
Foramen spinosum	Opening through which a major artery to the meninges (membranes around the brain) enters the cranial cavity
Greater wing	Forms the floor of the middle cranial fossa; several foramina pass through this wing
Lateral pterygoid plate	Attachment point for muscles of mastication (chewing)
Lesser wing	Superior border of the superior orbital fissure
Medial pterygoid plate	Posterolateral walls of the nasal cavity
Optic canal	Opening through which the optic nerve (cranial nerve II) passes from the orbit to the cranial cavity
Pterygoid canal	Opening through which nerves and vessels exit the cranial cavity
Pterygoid hamulus	Process around which the tendon passes from a muscle to the soft palate
Sella turcica	Fossa containing the pituitary gland
Superior orbital fissure	Opening through which nerves and vessels enter the orbit from the cranial cavity

Special Feature

- Contains the sphenoidal sinus

TABLE 7.7 Skull Bones—Continued

(e) Occipital Bone—Inferior View

**Landmark**

Condyle

External occipital protuberance

Foramen magnum

Hypoglossal canal (shown in figure 7.11)

Inferior nuchal line

Posterior cranial fossa (shown in figure 7.11)

Superior nuchal line

Special Feature

Forms the base of the skull

Description

Articulation point between the skull and first vertebra

Attachment point for a strong ligament (nuchal ligament) in the back of the neck

Opening around the point where the brain and spinal cord connect

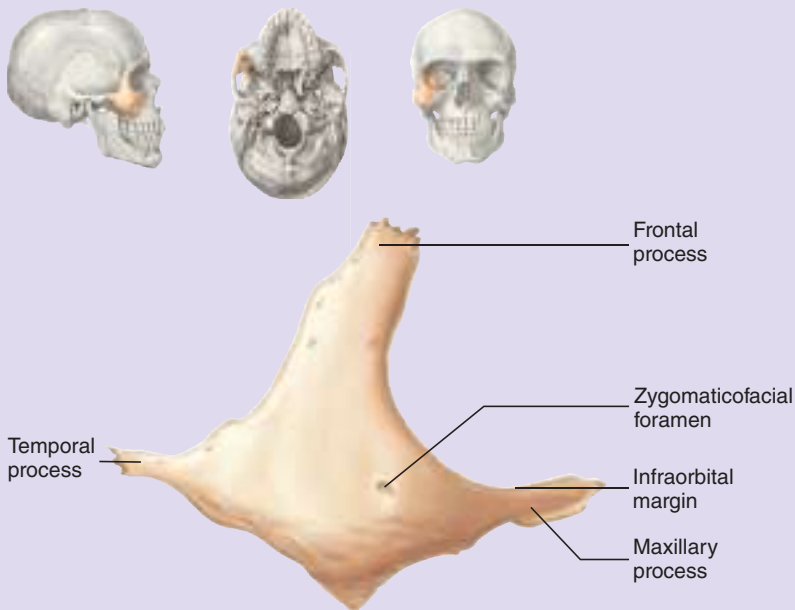

Opening through which the hypoglossal nerve (cranial nerve XII) passes

Attachment point for neck muscles

Depression in the posterior of the cranial cavity formed by the cerebellum

Attachment point for neck muscles

(f) Zygomatic Bone (Right)—Lateral View

**Landmark**

Frontal process

Infraorbital margin

Temporal process

Zygomaticofacial foramen

Special Features

Forms the prominence of the cheek

Forms the anterolateral wall of the orbit

Description

Connection to the frontal bone; helps form the lateral margin of the orbit

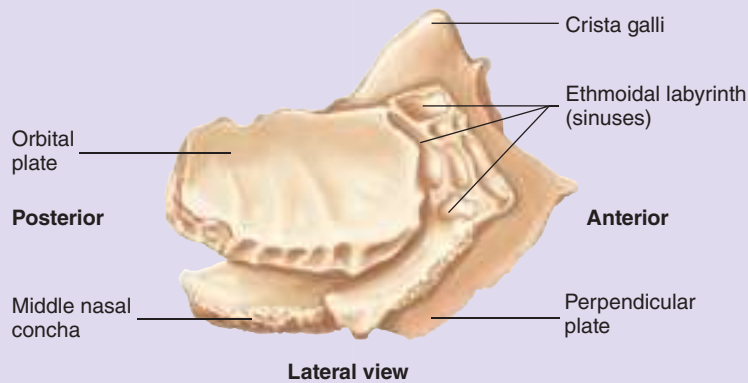

Ridge forming the inferior border of the orbit

Helps form the bony bridge from the cheek to just anterior to the ear

Opening through which a nerve and vessels exit the orbit to the face

TABLE 7.7 Skull Bones—Continued

(g) Ethmoid Bone—Superior, Lateral, and Anterior Views

Landmark

- Cribriform plate
- Crista galli
- Ethmoidal foramina (shown in figure 7.8)
- Middle nasal concha
- Orbital plate
- Perpendicular plate
- Superior nasal concha

Description

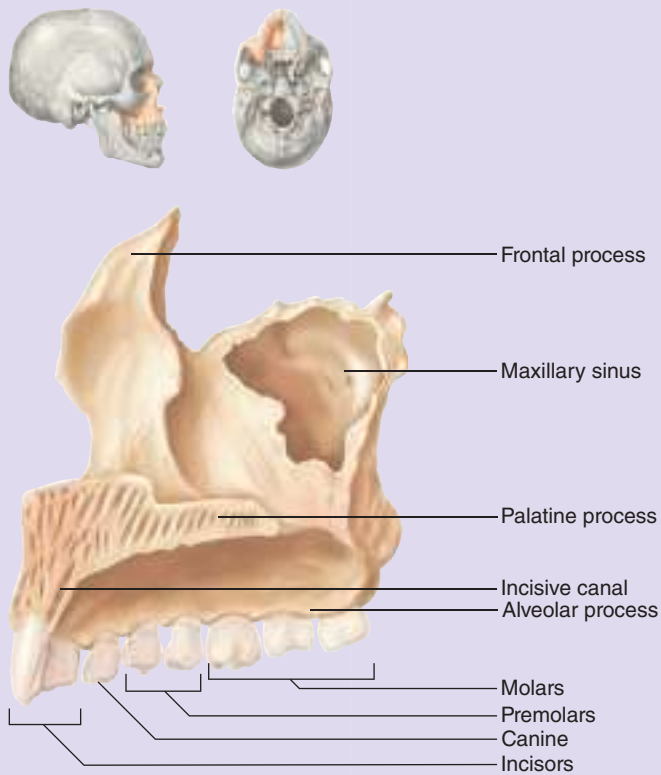

- Contains numerous olfactory foramina through which branches of the olfactory nerve (cranial nerve I) enter the cranial cavity from the nasal cavity
- Attachment for meninges (membranes around brain)
- Openings through which nerves and vessels pass from the orbit to the nasal cavity
- Ridge extending into the nasal cavity; increases surface area, helps warm and moisten air in the cavity
- Forms the medial wall of the orbit
- Forms the superior portion of the nasal septum
- Ridge extending into the nasal cavity; increases surface area, helps warm and moisten air in the cavity

Special Features

- Forms part of the nasal septum and part of the lateral walls and roof of the nasal cavity
- Contains the ethmoidal labyrinth, or ethmoidal sinuses; the labyrinth is divided into anterior, middle, and posterior ethmoidal cells

TABLE 7.7 Skull Bones—Continued

(h) Maxilla (Right)—Medial and Lateral Views

Medial view

Lateral view

Landmark

Alveolar process

Description

Ridge containing the teeth

Anterior nasal spine

Forms part of the nasal septum

Frontal process

Forms the sides of the nasal bridge

Incisive canal

Opening through which a nerve exits the nasal cavity to the roof of the oral cavity

Infraorbital foramen

Opening through which a nerve and vessels exit the orbit to the face

Orbital surface

Forms the floor of the orbit

Palatine process

Forms the anterior two-thirds of the hard palate

Maxillary tuberosity

Lump posterior to the last maxillary molar tooth

Zygomatic process

Connection to the zygomatic bone; helps form the interior margin of the orbit

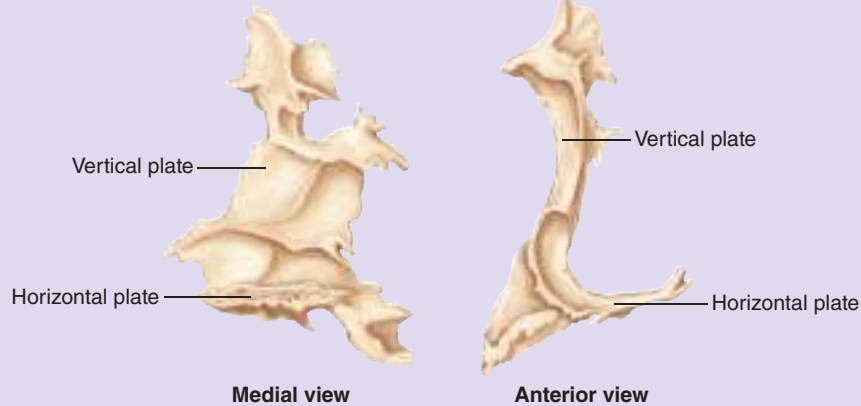

Special Features

Contains the maxillary sinus and maxillary teeth

Forms part of nasolacrimal canal

The hyoid bone provides an attachment point for some tongue muscles and for important neck muscles that elevate the larynx during speech or swallowing.

Vertebral Column

The **vertebral column** performs five major functions: (1) It supports the weight of the head and trunk, (2) it protects the spinal cord, (3) it allows spinal nerves to exit the spinal cord, (4) it provides a site for muscle attachment, and (5) it permits movement of the head and trunk.

The vertebral column usually consists of 26 bones, called **vertebrae**, which can be divided into five regions: 7 **cervical vertebrae** (ver'tě-brē), 12 **thoracic vertebrae**, 5 **lumbar vertebrae**, 1 **sacral bone**, and 1 **coccygeal** (kok-sij'ē-ăl) **bone** (figure 7.13). To remember how many vertebrae are in each region, think of mealtimes: 7, 12, and 5. The cervical vertebrae are designated “C,” thoracic “T,” and lumbar “L.” A number after the letter indicates the number of the vertebra, from superior to inferior, within each vertebral region. For example, “C1” refers to the first cervical vertebra. The developing embryo has about 33 or 34 vertebrae, but by adulthood the 5 sacral vertebrae have fused to form 1 bone, and the 4 or 5 coccygeal bones usually have fused to form 1 bone.

The adult vertebral column has four major curvatures (figure 7.13). Two of the curves appear during embryonic development and reflect the C-shaped curve of the embryo and fetus

within the uterus. When the infant raises its head in the first few months after birth, a secondary curve, which is convex anteriorly, develops in the neck. Later, when the infant learns to sit and then walk, the lumbar portion of the column also becomes convex anteriorly. Thus, in the adult vertebral column, the cervical region is convex anteriorly, the thoracic region is concave anteriorly, the lumbar region is convex anteriorly, and the sacral and coccygeal regions together are concave anteriorly. These spinal curvatures help accommodate our upright posture by aligning our body weight with our pelvis and lower limbs.

General Features of the Vertebrae

The general structure of an individual vertebra is outlined in table 7.9. Each vertebra consists of a body, vertebral arch, and various processes. Two of the vertebral column's major functions—to help support the body's weight and to protect the spinal cord—are achieved by two specific portions of the vertebrae. The weight-bearing portion of the vertebra is a solid, bony disk called the **body**. The protection of the spinal cord is achieved by the body and the **vertebral arch**, which projects posteriorly from the body.

The vertebral arch is divided into left and right halves, and each half has two parts: the **pedicle** (ped'i-kl; foot), which is attached to the body, and the **lamina** (lam'i-na; thin plate), which joins with the lamina from the opposite half of the arch. The vertebral arch and the posterior part of the body surround a

large opening called the **vertebral foramen**. The vertebral foramina of adjacent vertebrae combine to form the **vertebral canal**, which contains the spinal cord and cauda equina (see figure 12.1). The vertebral arches and bodies protect the spinal cord.

A **transverse process** extends laterally from each side of the arch between the lamina and the pedicle, and a single **spinous process** lies at the junction between the two laminae. The spinous

Abnormal Spinal Curvatures

In some people, the normal spinal curvature becomes distorted due to disease or a congenital defect. Figure 7A shows a healthy spine's curvature. The three most common spinal curvatures are lordosis, kyphosis, and scoliosis. **Lordosis** (lōr-dō'sis; hollow back) is an exaggeration of the convex curve of the lumbar region. **Kyphosis** (kī-fō'sis; hump back) is an exaggeration of the concave curve of the thoracic region. It is most common in postmenopausal women but can also occur in men and becomes more prevalent as people age. **Scoliosis** (skō'lē-ō'sis) is an abnormal lateral and rotational curvature of the vertebral column, which is often accompanied by secondary abnormal curvatures, such as kyphosis (figure 7B). Contrary to popular belief, scoliosis in school-age children is not associated with carrying overly heavy backpacks. Studies have shown that, although back pain is common in backpack-bearing school kids, structural changes in the vertebral column are not. Treatments for abnormal spinal curvature depend on the age and overall medical condition of the person. However, most treatments include repeated examinations to monitor the status of the curvature, a back brace, and surgery when the curving is not slowed by bracing.

FIGURE 7A Healthy Spine

FIGURE 7B Scoliosis Spine

FIGURE 7.13 Complete Vertebral Column Viewed from the Left Side **AP|R**

FIGURE 7.14 Surface View of the Back, Showing the Scapula and Vertebral Spinous Processes

processes can be seen and felt as a series of lumps down the midline of the back (figure 7.14). Much vertebral movement is accomplished by the contraction of the skeletal muscles attached to the transverse and spinous processes (see chapter 10).

The location where two vertebrae meet forms the **intervertebral foramina** (table 7.9*d*; see figure 7.13). Each intervertebral foramen is formed by **intervertebral notches** in the pedicles of adjacent vertebrae. These foramina are where spinal nerves exit the spinal cord.

Movement and additional support of the vertebral column are made possible by the vertebral processes. Each vertebra has two **superior** and two **inferior articular processes**, with the superior processes of one vertebra articulating with the inferior processes of the next superior vertebra (table 7.9*c,d*). Overlap of these processes increases the rigidity of the vertebral column. The region of overlap and articulation between the superior and inferior articular processes creates a smooth **articular facet** (fas'et; little face) on each articular process.

Intervertebral Disks

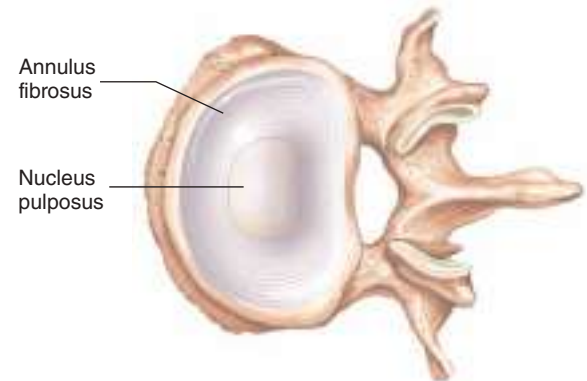

During life, **intervertebral disks** of fibrocartilage, which are located between the bodies of adjacent vertebrae (figure 7.15 and table 7.9; see figure 7.13), provide additional support and prevent the vertebral bodies from rubbing against each other. The intervertebral disks consist of an external **annulus fibrosus** (an'ū-lūs fī-brō'sūs; fibrous ring) and an internal, gelatinous **nucleus pulposus** (pūl-pō'sūs; pulp). The disk becomes more compressed with increasing age, so the distance between vertebrae—and therefore the overall height of the individual—decreases. The annulus fibrosus also becomes weaker with age and more susceptible to herniation.

Regional Differences in Vertebrae

The vertebrae in each region of the vertebral column have specific characteristics that tend to blend at the boundaries between regions (table 7.10). The **cervical vertebrae** (figure 7.16; see

(a) Lateral view

(b) Superior view

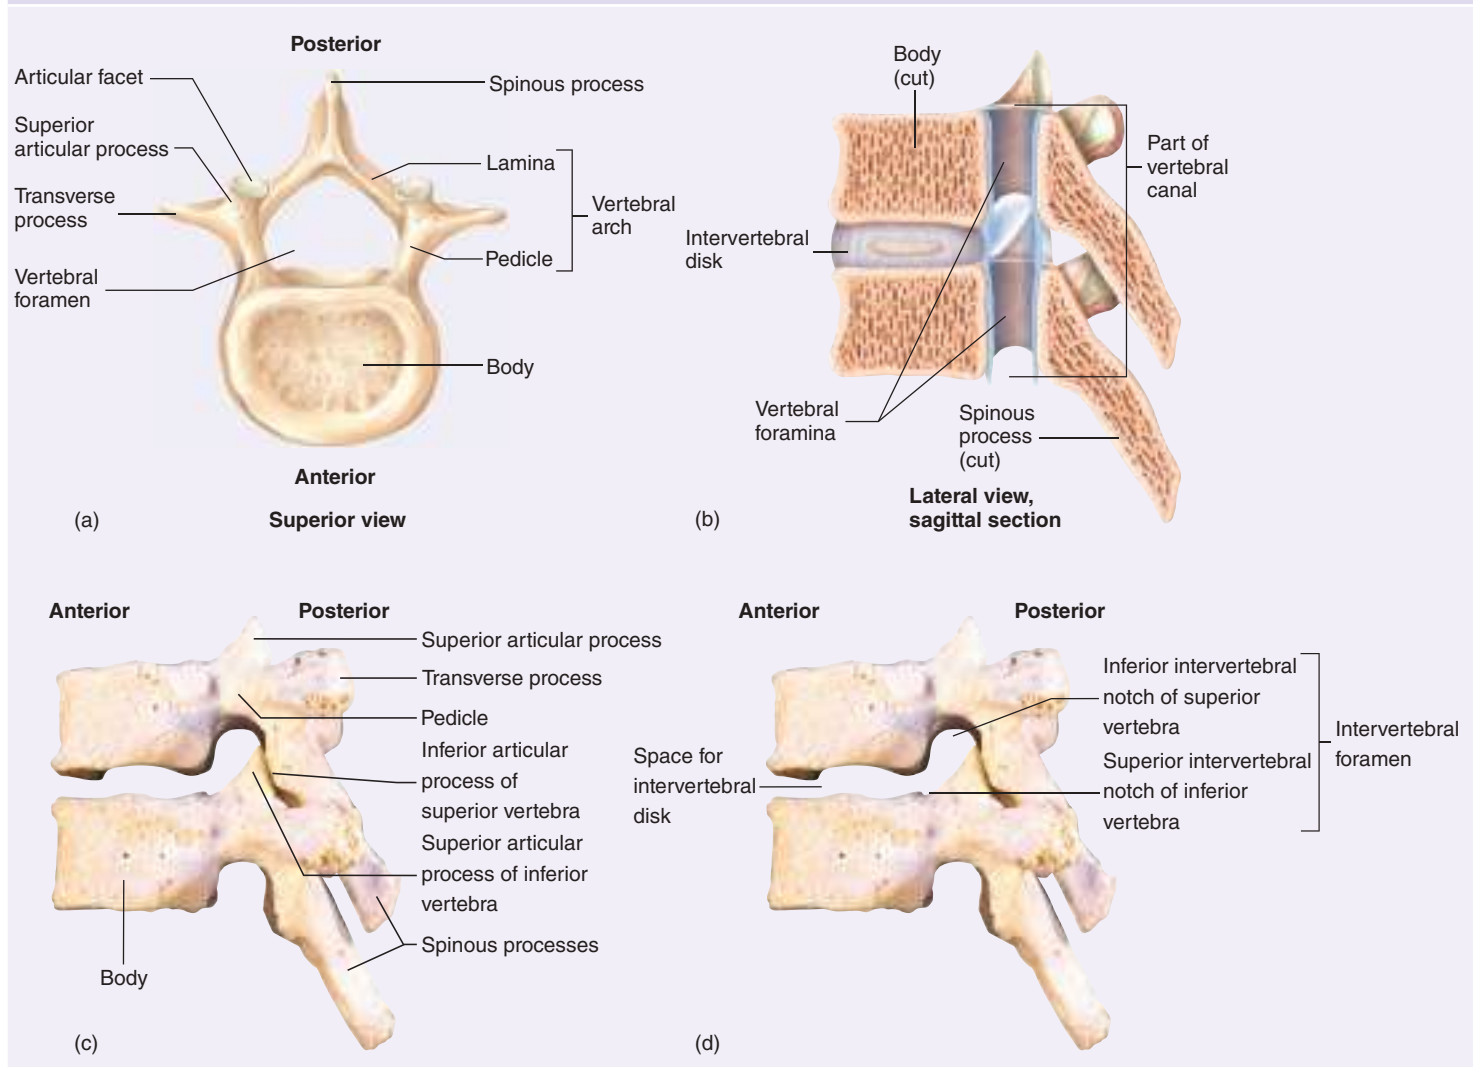

FIGURE 7.15 Intervertebral Disk **APR**

figure 7.13) have very small bodies; most have **bifid** (bī'fid; split) **spinous processes** and a **transverse foramen** in each transverse process through which the vertebral arteries extend toward the head. Only cervical vertebrae have transverse foramina. Because the cervical vertebrae are rather delicate and have small bodies, dislocations and fractures are more common in this area than in other regions of the column.

The first cervical vertebra is called the **atlas** (figure 7.16*a,b*) because it holds up the head, just as in classical mythology Atlas held up the world. The atlas has no body and no spinous process, but it has large superior facets, where it articulates with the occipital condyles on the base of the skull. The joint between the occipital condyles and the atlas allows the head to move in a “yes” motion and to tilt from side to side. The second cervical vertebra is called the **axis** (figure 7.16*c,d*) because a considerable amount of rotation occurs at the axis to produce a “no” motion of the head. The axis has a highly modified process on the superior side of its small body called the **dens**, or **odontoid** (ō-don'toyd; tooth-shaped) **process**. The dens fits into the enlarged vertebral foramen of the atlas, and the atlas rotates around this process. The spinous process of the seventh cervical vertebra, which is not bifid, is quite pronounced and

TABLE 7.9 General Structure of a Vertebra

Feature	Description
Body	Disk-shaped; usually the largest part with flat surfaces directed superiorly and inferiorly; forms the anterior wall of the vertebral foramen; intervertebral disks are located between the bodies
Vertebral foramen	Hole in each vertebra through which the spinal cord passes; adjacent vertebral foramina form the vertebral canal
Vertebral arch	Forms the lateral and posterior walls of the vertebral foramen; possesses several processes and articular surfaces
Pedicle	Foot of the arch with one on each side; forms the lateral walls of the vertebral foramen
Lamina	Posterior part of the arch; forms the posterior wall of the vertebral foramen
Transverse process	Process projecting laterally from the junction of the lamina and pedicle; a site of muscle attachment
Spinous process	Process projecting posteriorly at the point where the two laminae join; a site of muscle attachment; strengthens the vertebral column and allows for movement
Articular processes	Superior and inferior projections containing articular facets where vertebrae articulate with each other; strengthen the vertebral column and allow for movement
Intervertebral notches	Form intervertebral foramina between two adjacent vertebrae through which spinal nerves exit the vertebral canal

often can be seen and felt as a lump between the shoulders (see figure 7.14). The most prominent spinous process in this area is called the **vertebral prominens**. This is usually the spinous process of the seventh cervical vertebra, but it may be that of the sixth cervical

vertebra or even the first thoracic. The superior articular facets face superiorly, and the inferior articular facets face inferiorly.

Whiplash is a traumatic hyperextension of the cervical vertebrae. The head is a heavy object at the end of a flexible

Clinical IMPACT

Herniated Intervertebral Disk

A herniated disk (*ruptured disk*) results when the annulus fibrosus breaks or balloons, releasing all or part of the nucleus pulposus (figure 7C). The herniated part of the disk may push against and compress the spinal cord, cauda equina, or spinal nerves. The compression compromises the normal function of this nervous tissue and produces pain and numbness in the limb it supplies. The inferior lumbar and inferior cervical intervertebral disks are the most common disks to become herniated because the vertebral column has a lot of mobility in these areas. In addition, the lumbar region bears a significant amount of the body's weight.

Herniated disks can be repaired in one of several ways. One procedure is prolonged bed

rest, based on the tendency for the herniated part of the disk to recede and the annulus fibrosus to repair itself. However, many cases require surgery. A **laminectomy** is the removal of a vertebral lamina, or vertebral arch. A **hemilaminectomy** is the removal of a portion of a vertebral lamina. These procedures reduce the compression of the spinal nerve or spinal cord. **Fenestration** involves removal of the nucleus pulposus, leaving the annulus fibrosus intact. In extreme cases, the entire damaged disk is removed and a metal cage is inserted into the space previously occupied by the disk. Red bone marrow stem cells harvested from the hip are then injected into the space to allow for new bone growth. The bone marrow technique is one of the newest forms of vertebral

fusion surgery. Previously, a piece of hipbone from either the patient or a donor was inserted into the space vacated by the damaged disk. The vertebrae adjacent to the removed disk are usually further anchored together with a titanium plate held in place with titanium screws inserted into the vertebral bodies. Eventually, the adjacent vertebrae become fused by new bone growth across the gap. In figure 7D, a post-surgery MRI shows a cervical fusion after new bone has formed. The bright white structures are the screws and the plate that were added for stability. This is the type of surgery performed on author C. VanPutte.

column, and it may become hyperextended when the head “snaps back” as a result of sudden acceleration of the body. This commonly occurs in “rear-end” automobile accidents and athletic injuries, in which the body is quickly forced forward while the head remains stationary. A common injury resulting

from whiplash is fracture of the spinous processes of the cervical vertebrae or a herniated disk due to an anterior tear of the annulus fibrosus. These injuries can cause posterior pressure on the spinal cord or spinal nerves and strained or torn muscles, tendons, and ligaments.

FIGURE 7.17 Thoracic Vertebrae

The **thoracic vertebrae** (figure 7.17; see figure 7.13) possess long, thin spinous processes directed inferiorly, and they have relatively long transverse processes. The first 10 thoracic vertebrae have articular facets on their transverse processes, where they articulate with the tubercles of the ribs. Additional articular facets are on the superior and inferior margins of the body where the heads of the ribs articulate. The head of most ribs articulates with the inferior articular facet of one vertebra and with the superior articular facet for the rib head on the next vertebra down.

The **lumbar vertebrae** (figure 7.18; see figure 7.13) have large, thick bodies and heavy, rectangular transverse and spinous processes. The fifth lumbar vertebra or first coccygeal

vertebra may become fused into the sacrum. Conversely, the first sacral vertebra may fail to fuse with the rest of the sacrum, resulting in six lumbar vertebrae. The superior articular facets face medially, and the inferior articular facets face laterally. When the superior articular surface of one lumbar vertebra joins the inferior articulating surface of another lumbar vertebra, the resulting arrangement adds strength to the inferior portion of the vertebral column and limits rotation of the lumbar vertebrae. Because the lumbar vertebrae have massive bodies and carry a large amount of weight, fractures are less common, but ruptured intervertebral disks are more common in this area than in other regions of the column.

FIGURE 7.18 Lumbar Vertebrae

► Predict 3

Why are the lumbar vertebrae more massive than the cervical vertebrae? Describe some expected differences between the vertebrae of a person who engages in regular vigorous physical exercise and those of a person who never exercises.

The **sacral** (sā'krāl) **vertebrae** (figure 7.19; see figure 7.13) are highly modified compared with the others. These five vertebrae are fused into a single bone called the **sacrum** (sā'krūm).

The transverse processes of the sacral vertebrae fuse to form the lateral parts of the sacrum. The superior surfaces of the lateral parts are wing-shaped areas called the **alae** (ā'lē; wings). Much

FIGURE 7.19 Sacrum **APIFI**

of the lateral surfaces of the sacrum are ear-shaped **auricular surfaces**, which join the sacrum to the pelvic bones. The spinous processes of the first four sacral vertebrae partially fuse to form the **median sacral crest** along the dorsal surface of the sacrum. The spinous process of the fifth vertebra does not form, thereby leaving a **sacral hiatus** (hī-ā'tūs) at the inferior end of the sacrum, which is often the site of anesthetic injections. The intervertebral foramina are divided into anterior and posterior foramina, called the **sacral foramina**, which are lateral to the midline. Anterior and posterior branches of the spinal nerves pass through these foramina. **Transverse lines** are where the individual sacral

vertebrae fuse (see figure 7.19a). The anterior edge of the body of the first sacral vertebra bulges to form the **sacral promontory** (see figure 7.13), a landmark that separates the abdominal cavity from the pelvic cavity. The sacral promontory can be felt during a vaginal examination, and it is used as a reference point when measuring the pelvic inlet.

The **coccyx** (kok'siks; figure 7.19; see figure 7.13), or tailbone, is the most inferior portion of the vertebral column and usually consists of three to five semifused vertebrae that form a triangle, with the apex directed inferiorly. The coccygeal vertebrae are much smaller than the other vertebrae and have neither vertebral foramina nor well-developed processes. The coccyx is easily broken when a person falls by sitting down hard on a solid surface.

Rib Cage

The **rib cage**, or *thoracic cage*, protects the heart and lungs within the thorax and forms a semirigid chamber, which can increase and decrease in volume during respiration. It consists of the thoracic vertebrae, the ribs with their associated costal (rib) cartilages, and the sternum (figure 7.20a).

Ribs and Costal Cartilages

The 12 pairs of **ribs** are classified as either true ribs or false ribs. The superior 7 pairs are called **true ribs**, or *vertebrosternal* (ver'tē-brō-ster'nāl) ribs; they articulate with the thoracic vertebrae and attach directly through their **costal cartilages** to the sternum. The inferior 5 pairs, or **false ribs**, articulate with the thoracic vertebrae but do not attach directly to the sternum. The false ribs consist of two groups. The eighth, ninth, and tenth ribs, the **vertebrochondral** (ver'tē-brō-kon'drāl) ribs, are joined by a common cartilage to the costal cartilage of the seventh rib, which in turn is attached to the sternum. Two of the false ribs, the eleventh and twelfth ribs, are also called **floating ribs**, or *vertebral ribs*, because they do not attach to the sternum. The costal cartilages are flexible and permit the rib cage to expand during respiration. A **separated rib** is a dislocation between a rib and its costal cartilage that allows the rib to move, override adjacent ribs, and cause pain. Separation of the tenth rib is the most common.

Most ribs have two points of articulation with the thoracic vertebrae (figure 7.20b,c). First, the **head** articulates with the bodies of two adjacent vertebrae and the intervertebral disk between them. The head of each rib articulates with the inferior articular facet of the superior vertebra and the superior articular facet of the inferior vertebra. Second, the **tubercle** articulates with the transverse process of the inferior vertebra. The **neck** is between the head and tubercle, and the **body**, or shaft, is the main part of the rib. The **angle** of the rib is located just lateral to the tubercle and is the point of greatest curvature. The angle is the weakest part of the rib and can be fractured in a crushing injury, as may occur in an automobile accident. Sometimes the transverse processes of the seventh cervical vertebra form separate bones called **cervical ribs**. These ribs may be tiny pieces of bone or may be long enough to reach the sternum. In addition, the first lumbar vertebra may develop lumbar ribs.

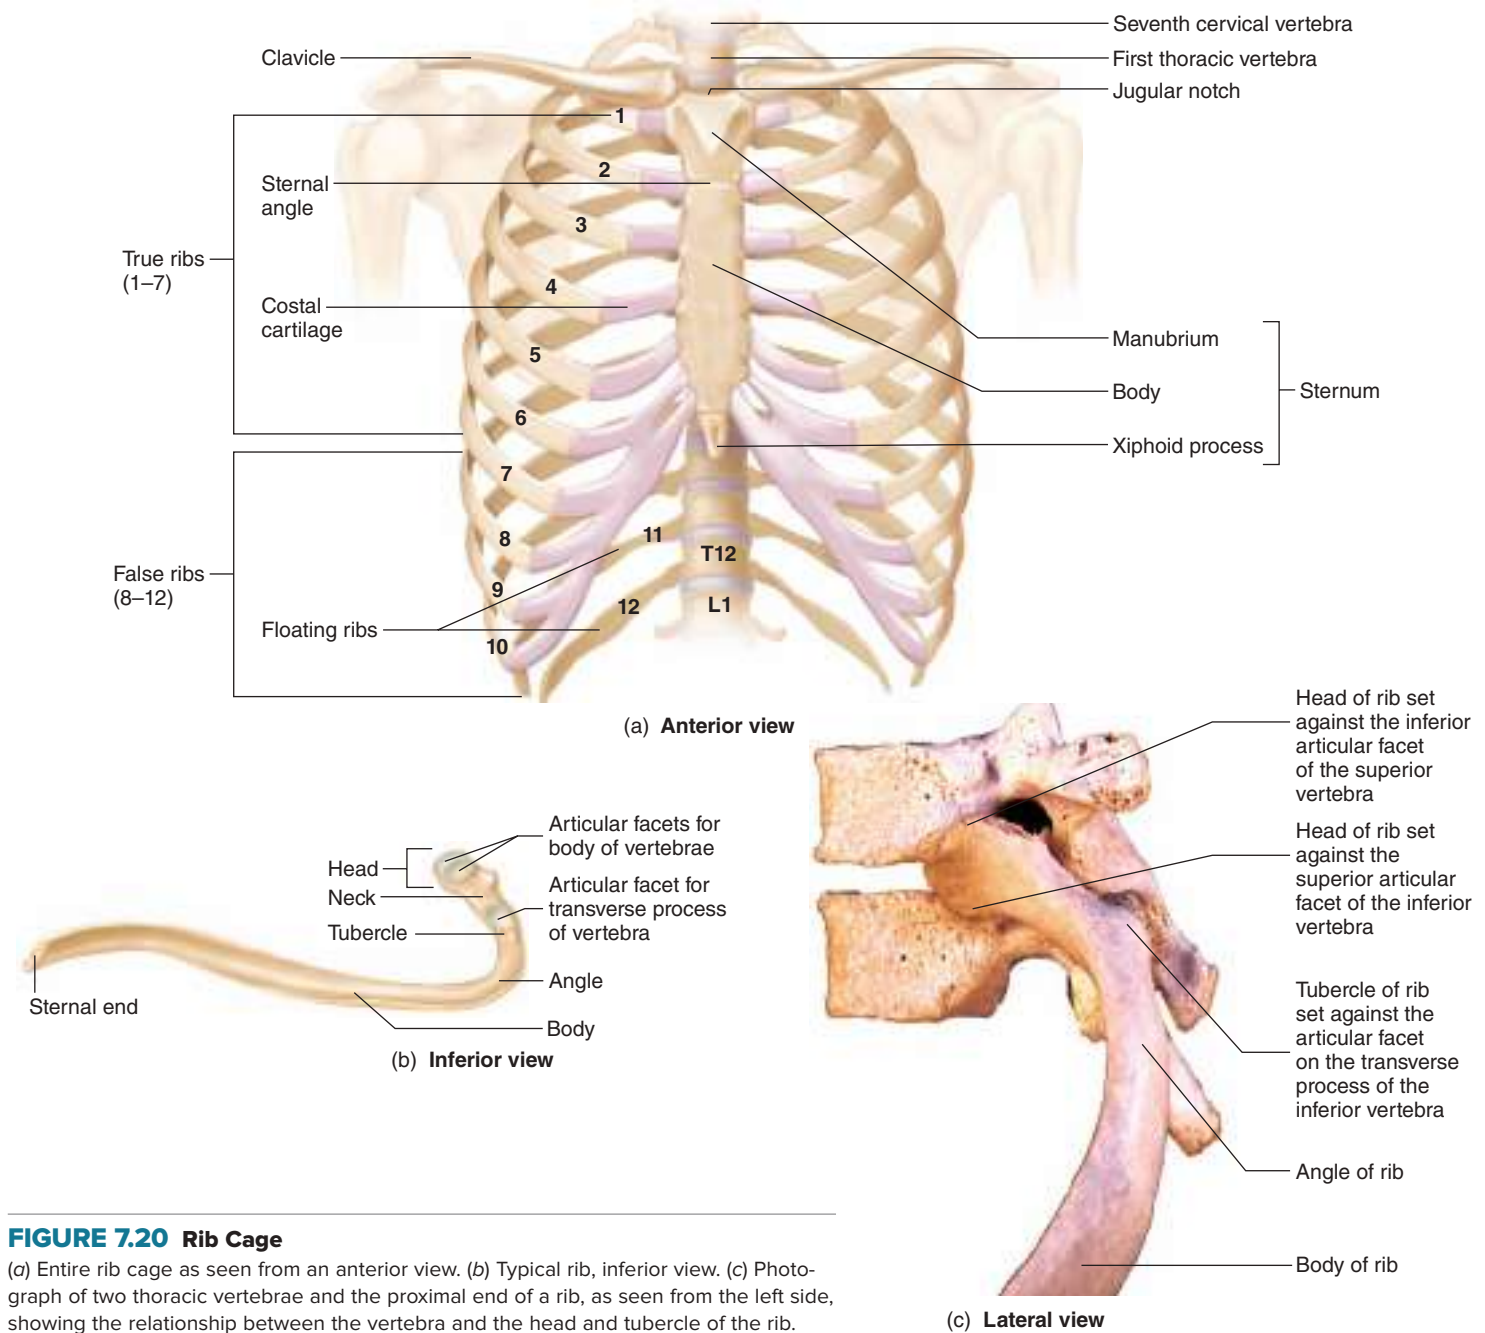

FIGURE 7.20 Rib Cage

(a) Entire rib cage as seen from an anterior view. (b) Typical rib, inferior view. (c) Photograph of two thoracic vertebrae and the proximal end of a rib, as seen from the left side, showing the relationship between the vertebra and the head and tubercle of the rib.

Sternum

The **sternum**, or breastbone, has been described as sword-shaped and has three parts (figure 7.20a): The **manubrium** (mă-noo'brē-ŭm; handle) is the “sword handle”; the **body**, or gladiolus (sword), is the “blade”; and the **xiphoid process** is the “sword tip.” The superior margin of the manubrium has a **jugular notch** (neck), or *suprasternal notch*, in the midline, which can be easily felt at the anterior base of the neck (figure 7.21). The first rib and the clavicle articulate with the manubrium. The point at which the manubrium joins the body of the sternum can be felt as a prominence on the anterior thorax called the **sternal angle** (see figure 7.20a). The cartilage of the second rib attaches

FIGURE 7.21 Surface Anatomy Showing Bones of the Upper Thorax

to the sternum at the sternal angle, the third through seventh ribs attach to the body of the sternum, and no ribs attach to the xiphoid process.

ASSESS YOUR PROGRESS

16. Where is the hyoid bone located? Why is it a unique bone? What are its functions?
17. What are the functions of the vertebral column?
18. Name the four major curvatures of the adult vertebral column, and explain what causes them. Describe scoliosis, kyphosis, and lordosis.
19. Describe the structures that are common to most vertebrae.
20. Where do spinal nerves exit the vertebral column?
21. Describe the structure and function of the intervertebral disks.
22. Explain how the superior and inferior articular processes help support and allow movement of the vertebral column.
23. Name and give the number of vertebrae in each of the five regions of the vertebral column. Describe the characteristics that distinguish the different regions of vertebrae.
24. What is the function of the rib cage? Distinguish among true, false, and floating ribs, and give the number of each type.
25. Describe the articulation of the ribs with thoracic vertebrae.
26. What are the parts of the sternum? Name the structures that attach to the sternum.

7.3 Appendicular Skeleton

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the girdles that make up the appendicular skeleton.
- B. Identify the bones that make up the pectoral girdle and relate their structure and arrangement to the function of the girdle.
- C. Name and describe the major bones of the upper limb.
- D. List the bones that make up the pelvic girdle and explain why the pelvic girdle is more stable than the pectoral girdle.
- E. Name the bones that make up the hipbone. Distinguish between the male and the female pelvis.
- F. Identify and describe the bones of the lower limb.

The appendicular skeleton (see figure 7.1) consists of the bones of the **upper limbs**, the **lower limbs**, and the **girdles**. The term *girdle*, which means a belt or a zone, refers to the two zones, pectoral and pelvic, where the limbs are attached to the body.

Pectoral Girdle and Upper Limb

Picture a baseball pitcher winding up to throw a fastball and you have a great demonstration of the mobility of your upper limb (figure 7.22). This mobility is possible because muscles

FIGURE 7.22 Bones of the Pectoral Girdle and Right Upper Limb

attach the upper limb and its girdle rather loosely to the rest of the body. Thus, the upper limb is capable of a wide range of movements, including throwing, lifting, grasping, pulling, and touching.

Pectoral Girdle

The **pectoral** (pek'tō-rāl) **girdle**, or *shoulder girdle*, consists of two pairs of bones that attach the upper limb to the body: Each pair is composed of a **scapula** (skap'ū-lă), or *shoulder blade* (figure 7.23), and a **clavicle** (klav'i-kl), or *collarbone* (see figures 7.20, 7.22, and 7.23). The scapula is a flat, triangular bone that can easily be seen and felt in a living person (see figure 7.14). The base of the triangle, the superior border, faces superiorly; the apex, the inferior angle, is directed inferiorly.

The large **acromion** (ă-krō'mē-on; shoulder tip) **process** of the scapula, which can be felt at the tip of the shoulder, has three functions: (1) to form a protective cover for the shoulder joint, (2) to form the attachment site for the clavicle, and (3) to provide attachment points for some of the shoulder muscles. The **scapular spine** extends from the acromion process across the posterior surface of the scapula and divides that surface into a small **supraspinous fossa** superior to the spine and a larger **infraspinous fossa**

FIGURE 7.23 Right Scapula and Clavicle

(a) Right scapula, anterior view. (b) Right scapula, posterior view. (c) Right clavicle, superior view. (d) Photograph of the right scapula and clavicle from a superior view, showing the relationship between the distal end of the clavicle and the acromion process of the scapula. **APR**

inferior to the spine. The deep, anterior surface of the scapula constitutes the **subscapular fossa**. The smaller **coracoid** (meaning “shaped like a crow’s beak”) **process** provides attachments for some shoulder and arm muscles. A **glenoid** (glē’noyd, glen’oyd) **cavity**, located in the superior lateral portion of the bone, articulates with the head of the humerus.

The clavicle (see figures 7.20, 7.22, and 7.23c) is a long bone with a slight sigmoid (S-shaped) curve. It is easily seen and felt in the living human (see figure 7.21). The lateral end of the clavicle articulates with the acromion process, and its medial end articulates with the manubrium of the sternum. These articulations form the only bony connections between the pectoral girdle and the axial skeleton. Because the clavicle holds the upper limb away from the body, it facilitates the limb’s mobility.

► Predict 4

Sarah fell off the trampoline in her backyard. She was crying and holding her right shoulder, so her mother took her to the emergency room. Dr. Smart diagnosed a broken collarbone (clavicle), based on the position of Sarah’s right upper limb. Explain.

Arm

The arm, the part of the upper limb from the shoulder to the elbow, contains only one bone, the **humerus** (figure 7.24). The humeral **head** articulates with the glenoid cavity of the scapula. The **anatomical neck**, immediately distal to the head, is almost nonexistent; thus, a surgical neck has been designated. The **surgical neck** is so named because it is a common fracture site

FIGURE 7.24 Right Humerus **APIR**

that often requires surgical repair. Removal of the humeral head due to disease or injury occurs down to the level of the surgical neck. The **greater tubercle** is on the lateral surface, and the **lesser tubercle** is on the anterior surface of the proximal end of the humerus, where both are sites of muscle attachment. The groove between the two tubercles contains one tendon of the biceps brachii muscle and is called the **intertubercular groove**, or *bicipital* (bī-sip'i-tāl) *groove*. The **deltoid tuberosity** is located on the lateral surface of the humerus a little more than a third of the way along its length and is the attachment site for the deltoid muscle.

The articular surfaces of the distal end of the humerus exhibit unusual features where the humerus articulates with the two forearm bones. The lateral portion of the articular surface is very rounded, articulates with the radius, and is called the **capitulum** (kā-pit'ū-lūm; head-shaped). The medial portion somewhat resembles a spool or pulley, articulates with the ulna, and is called the **trochlea** (trok'lē-ă; spool). Proximal to the capitulum and the trochlea are the **lateral** and **medial epicondyles**, which are points of attachment for the muscles of the forearm.

Forearm

The forearm has two bones. The **ulna** is on the medial side of the forearm, the side with the little finger. The **radius** is on the lateral, or thumb, side of the forearm (figure 7.25).

The proximal end of the ulna has a C-shaped articular surface, called the **trochlear notch**, or *semilunar notch*, that fits over the trochlea of the humerus. The trochlear notch is bounded by two processes. The larger, posterior process is the **olecranon** (ō-lek'ră-nōn; the point of the elbow) **process**. It can easily be felt and is commonly referred to as “the elbow” (figure 7.26). Posterior arm muscles attach to the olecranon process. The smaller, anterior process is the **coronoid** (kōr'ō-nōyd; crow's beak) **process**.

The distal end of the ulna has a small **head**, which articulates with both the radius and the wrist bones (see figures 7.25 and 7.26). The head can be seen on the posterior, medial (ulnar) side of the distal forearm. The posteromedial side of the head has a small **styloid** (stī'loyd; shaped like a stylus or writing instrument) **process**, to which ligaments of the wrist are attached.

The proximal end of the radius is the **head**. It is concave and articulates with the capitulum of the humerus. The lateral surfaces of the head constitute a smooth cylinder, where the radius rotates against

the **radial notch** of the ulna. As the forearm rotates (supination and pronation; see chapter 8), the proximal end of the ulna stays in place and the radius rotates. The **radial tuberosity** is the point at which a major anterior arm muscle, the biceps brachii, attaches.

The distal end of the radius, which articulates with the ulna and the carpal bones, is somewhat broadened, and a **styloid process** to which wrist ligaments are attached is located on the lateral side of the distal radius.

Wrist

The wrist is a relatively short region between the forearm and the hand; it is composed of eight **carpal** (kar'pāl) **bones** arranged into two rows of four each (figure 7.27). The proximal row of carpal bones, lateral to medial, includes the **scaphoid** (skaf'oyd), which is boat-shaped; the **lunate** (loo'nāt), which is moon-shaped; the three-cornered **triquetrum** (trī-kwē'trūm, trī-kwet'rūm); and the pea-shaped **pisiform** (pis'i-fōrm), which is located on the palmar surface of the triquetrum. The distal row of carpal bones, from medial to lateral, includes the **hamate** (ha'māt), which has a hooked process on its palmar side, called the hook of the hamate; the head-shaped **capitate** (kap'i-tāt); the **trapezoid** (trap'ē-zoyd), which is named for its resemblance to a four-sided geometric form with two parallel sides; and the **trapezium** (tra-pē'zē-ūm), which is named after a four-sided geometric form with no two sides parallel. A number of mnemonics have been developed to help students remember the carpal bones. The following one represents them in order from lateral to medial for the proximal row (top) and from medial to lateral (by the thumb) for the distal row: **So Long Top Part, Here Comes The Thumb**—that is, **Scaphoid, Lunate, Triquetrum, Pisiform, Hamate, Capitate, Trapezoid, and Trapezium**.

The eight carpal bones, taken together, are convex posteriorly and concave anteriorly. The anterior concavity of the carpal bones is accentuated by the tubercle of the trapezium at the base of the

FIGURE 7.25 Right Ulna and Radius

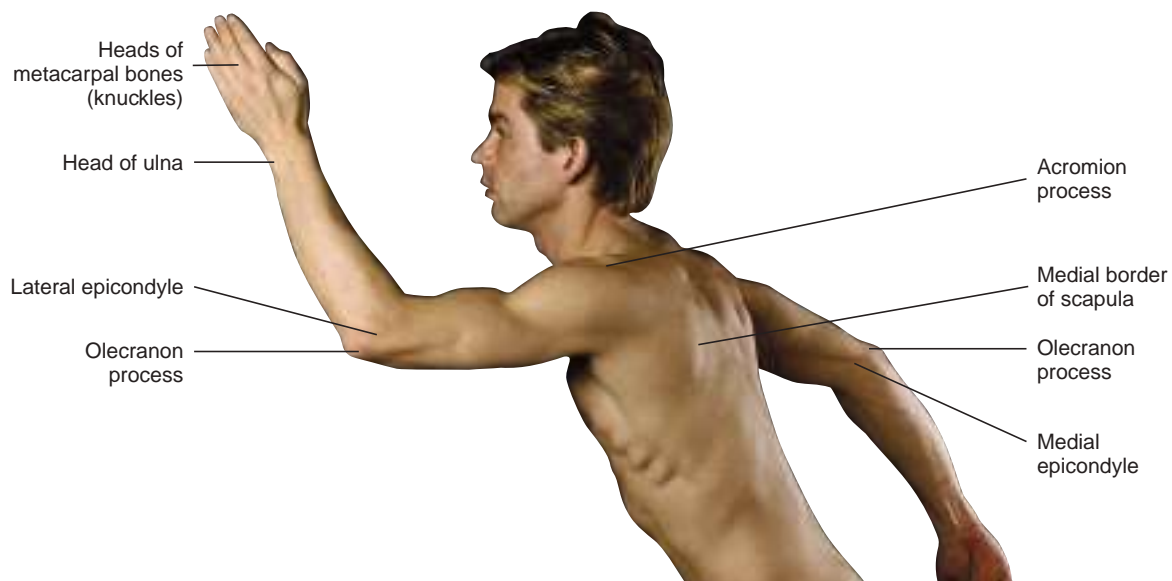

FIGURE 7.26 Surface Anatomy Showing Bones of the Pectoral Girdle and Upper Limb

FIGURE 7.27 Bones of the Right Wrist and Hand **AP|R**

thumb and the hook of the hamate at the base of the little finger. A ligament stretches across the wrist from the tubercle of the trapezium to the hook of the hamate to form a tunnel on the anterior surface of the wrist called the **carpal tunnel**. Tendons, nerves, and blood vessels pass through this tunnel to enter the hand (see Clinical Impact, “Carpal Tunnel Syndrome”).

Treatments for carpal tunnel syndrome vary, depending on the severity of the condition. Mild cases can be treated nonsurgically with either anti-inflammatory medications or stretching exercises. However, if symptoms have lasted for more than 6 months, surgery is recommended. Surgical techniques involve cutting the carpal ligament to enlarge the carpal tunnel and ease pressure on the nerve.

Hand

Five **metacarpal bones** are attached to the carpal bones and constitute the bony framework of the hand (figure 7.27). They are numbered one to five, starting with the most lateral metacarpal bone, at the base of the thumb. The metacarpal bones form a curve so that, in the resting position, the palm of the hand is concave. The distal ends of the metacarpal bones help form the knuckles of the hand (see figure 7.26). The spaces between the metacarpal bones are occupied by soft tissue.

The five **digits** of each hand include one thumb and four fingers. Each digit consists of small long bones called **phalanges** (fă-lan'jēz; sing. phalanx). The thumb has two phalanges, called proximal and distal. Each finger has three phalanges, designated proximal, middle, and distal. One or two **sesamoid** (ses'ă-moyd) **bones** (not shown in figure 7.27) often form near the junction between the proximal phalanx and the metacarpal bone of the thumb. Sesamoid bones are small bones located within some tendons that increase the mechanical advantage of tendons where they cross joints.

► Predict 5

Explain why the “fingers” appear much longer in a dried, articulated skeleton than in a hand with the soft tissue intact.

ASSESS YOUR PROGRESS

- Describe how the upper and lower limbs are attached to the axial skeleton.
- Name the bones that make up the pectoral girdle. Describe their functions.
- What are the functions of the acromion process and the coracoid process of the scapula?

Clinical IMPACT

Carpal Tunnel Syndrome

The bones and ligaments that form the walls of the carpal tunnel do not stretch. Edema (fluid buildup) or connective tissue deposition may occur within the carpal tunnel as a result of trauma or some other problem. The edema or connective tissue may apply pressure against the nerve and vessels passing through the tunnel, causing carpal tunnel syndrome, which is characterized by tingling, burning, and numbness in the hand (figure 7E). The vast majority of carpal tunnel syndrome cases have no known cause, but certain conditions predispose a person to develop it. For example, pregnancy, rheumatoid arthritis, too little thyroid hormone, and diabetes are all associated with an increased tendency to develop carpal tunnel syndrome.

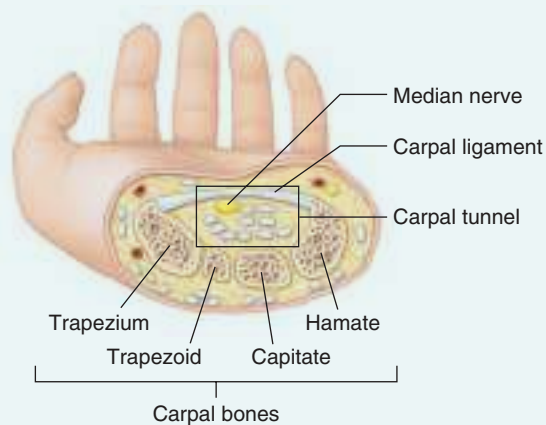

FIGURE 7E Carpal Tunnel

The carpal tunnel is bordered by carpals on the posterior side of the hand and the carpal ligament on the anterior side of the hand. Compression of the median nerve causes numbness of the hand.

30. Identify the bones of the upper limb, and describe their arrangement.
31. Name the important sites of muscle attachment on the humerus.
32. What is the function of the radial tuberosity? The styloid processes? Name the part of the ulna commonly referred to as the elbow.
33. List the eight carpal bones. What is the carpal tunnel?
34. What bones form the hand? How many phalanges are in each finger and in the thumb?

Pelvic Girdle and Lower Limb

The lower limbs support the body and are essential for normal standing, walking, and running. The general pattern of the lower

FIGURE 7.28 Bones of the Right Half of the Pelvic Girdle and the Right Lower Limb

limb (figure 7.28) is very similar to that of the upper limb, except that the pelvic girdle is attached much more firmly to the body than the pectoral girdle is and the bones in general are thicker, heavier, and longer than those of the upper limb. These structures reflect the function of the lower limb in supporting and moving the body.

Pelvic Girdle

The right and left **hipbones** (*ossa coxae* or *coxal bones*) join each other anteriorly and the **sacrum** posteriorly to form a ring of bone called the **pelvic girdle**. The **pelvis** (pel'vis; basin) includes the pelvic girdle and the coccyx (figure 7.29). Each hipbone consists of a large, concave, bony plate superiorly, a slightly narrower region in the center, and an expanded bony ring inferiorly, which surrounds a large **obturator** (ob'too-rā-tōr) **foramen**. A fossa called the **acetabulum** (as-ě-tab'ū-lūm) is located on the lateral surface of each hipbone and is the point where the lower limb articulates with the girdle (the hip socket). The articular surface of the acetabulum is crescent-shaped and occupies only the superior and lateral aspects of the fossa. The pelvic girdle serves as the place of attachment for the lower limbs, supports the weight of the body, and protects internal organs. Because the pelvic girdle is a complete bony

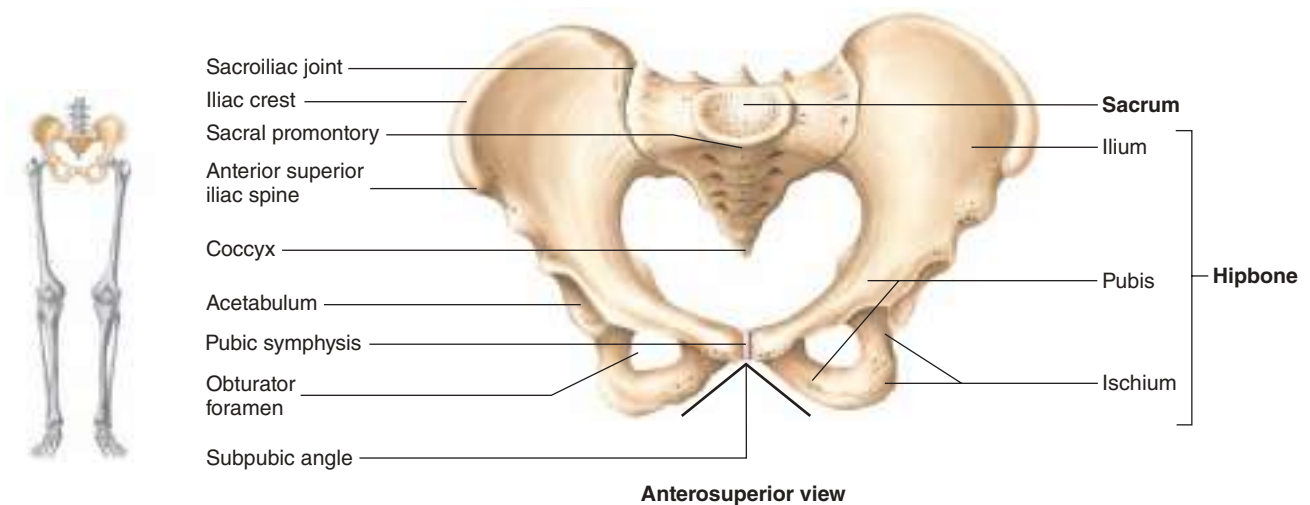

FIGURE 7.29 Pelvis

ring, it provides more stable support but less mobility than the incomplete ring of the pectoral girdle. In addition, the pelvis in a woman protects a developing fetus and forms a passageway through which the fetus passes during delivery.

Each hipbone is formed by the fusion of three bones during development: the **ilium** (il'ē-ŭm; groin), the **ischium** (is'kē-ŭm; hip), and the **pubis** (pū'bis; genital hair). All three bones join near the center of the acetabulum (figure 7.30*a*). The superior portion of the ilium is called the **iliac crest** (figure 7.30*b,c*). The crest ends anteriorly as the **anterior superior iliac spine** and posteriorly as the **posterior superior iliac spine**. The crest and anterior spine can be felt and even seen in thin individuals (figure 7.31). The anterior superior iliac spine is an important anatomical landmark used, for example, to find the correct location for giving gluteal injections into the hip (see Clinical Impact, “Gluteal Injections”). A dimple overlies the posterior superior iliac spine just superior to the buttocks. The **greater sciatic** (sī-at'ik) **notch** is on the posterior side of the ilium, just inferior to the posterior inferior iliac spine. The sciatic nerve passes through the greater sciatic notch. The **auricular surface** of the ilium joins the sacrum to form the **sacroiliac joint** (see figure 7.29). The medial side of the ilium consists of a large depression called the **iliac fossa**.

Each sacroiliac joint is formed by the junction of the auricular surface of a hipbone and one articular surface of the sacrum. The sacroiliac joints receive most of the weight of the upper body and are strongly supported by ligaments. However, excessive strain on the joints can allow slight joint movement and stretch connective tissue and associated nerve endings in the area, causing pain. Thus is derived the expression “My aching sacroiliac!” This problem sometimes develops in pregnant women because of the forward weight distribution of the fetus.

The ischium possesses a heavy **ischial** (is'kē-ăl) **tuberosity**, where posterior thigh muscles attach and on which a person sits (see figure 7.30*a*). The pubis has a **pubic crest** medially where

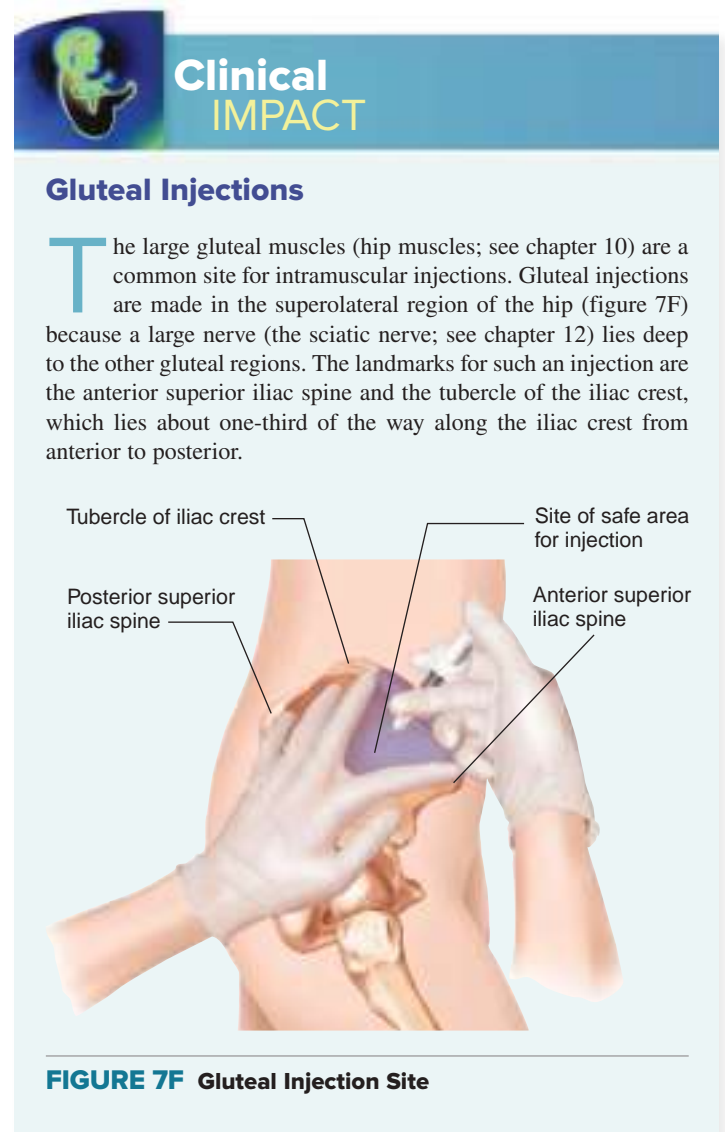

FIGURE 7F Gluteal Injection Site

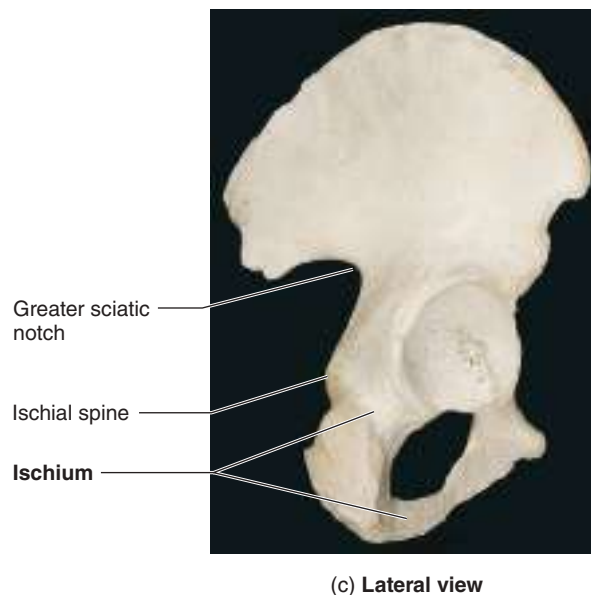

FIGURE 7.30 Hipbone

(a) Right hipbone, lateral view. Each hipbone is formed by fusion of the ilium, ischium, and pubis. The three bones can be seen joining near the center of the acetabulum, separated by lines of cartilage. (b) Right hipbone, medial view. (c) Right hipbone, lateral view. (The names of the three bones forming the hipbone are in bold.)

abdominal muscles attach and a **pubic tubercle** laterally where the inguinal ligament attaches (see figure 7.30b). The pubic crest can be felt anteriorly. Just inferior to the pubic crest is the point of junction, the **symphysis** (sim'fi-sis; a coming together) **pubis**, or **pubic symphysis**, between the two hipbones (see figure 7.29).

The pelvis is subdivided into a **true pelvis** and a **false pelvis** (figure 7.32). The opening to the true pelvis is the **pelvic inlet**, and the inferior opening of the true pelvis is the **pelvic outlet**. The false pelvis is formed by muscle overlying bone of the true pelvis.

Comparison of the Male Pelvis and the Female Pelvis

The male pelvis is usually more massive than the female pelvis as a result of the greater weight and size of the male body. The female pelvis is broader and has a larger, more rounded pelvic inlet and

outlet (figure 7.32a,b), consistent with the need to allow the fetus to pass through these openings in the female pelvis during childbirth. A wide, circular pelvic inlet and a pelvic outlet with widely spaced ischial spines can facilitate delivery of the newborn. A smaller pelvic outlet can cause problems during delivery; thus, the size of the pelvic inlet and outlet is routinely measured during prenatal pelvic examinations. If the pelvic outlet is too small for normal delivery, the physician may perform a **cesarean section**, which is the surgical removal of the fetus through the abdominal wall. Table 7.11 lists additional differences between the male pelvis and the female pelvis.

Thigh

The thigh, like the arm, contains a single bone, the **femur**. The femur has a prominent, rounded **head**, where it articulates

FIGURE 7.31 Surface Anatomy Showing an Anterolateral View of the Hipbone and Femur

TABLE 7.11

Differences Between the Male Pelvis and the Female Pelvis (see figure 7.32)

Area	Description
General	In females, somewhat lighter in weight and wider laterally but shorter superiorly to inferiorly and less funnel-shaped; less obvious muscle attachment points in females
Sacrum	Broader in females, with the inferior part directed more posteriorly; the sacral promontory does not project as far anteriorly in females
Pelvic inlet	Heart-shaped in males; oval in females
Pelvic outlet	Broader and more shallow in females
Subpubic angle	Less than 90 degrees in males; 90 degrees or more in females
Ilium	More shallow and flared laterally in females
Ischial spines	Farther apart in females
Ischial tuberosities	Turned laterally in females and medially in males

FUNDAMENTAL Figure

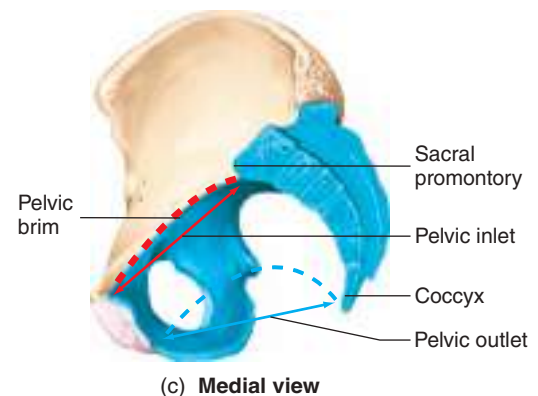

FIGURE 7.32 True and False Pelvises in Males and Females

(a) In a male, the pelvic inlet (red dashed line) and outlet (blue dashed line) are small and the subpubic angle is less than 90 degrees. The true pelvis is shown as blue. The false pelvis is shown as natural bone color. (b) In a female, the pelvic inlet (red dashed line) and outlet (blue dashed line) are larger and the subpubic angle is 90 degrees or greater. (c) Midsagittal section through the pelvis to show the pelvic inlet (red arrow and red dashed line) and the pelvic outlet (blue arrow and blue dashed line).

FIGURE 7.33 Right Femur

with the acetabulum, and a well-defined **neck**; both are located at an oblique angle to the shaft of the femur (figure 7.33). The proximal shaft exhibits two projections: a **greater trochanter** (trō-kan'ter; runner) lateral to the neck and a smaller, **lesser trochanter** inferior and posterior to the neck. Both trochanters are attachment sites for muscles that fasten the hip to the thigh. The greater trochanter and its attached muscles form a bulge that can be seen as the widest part of the hips (see figure 7.31). The distal end of the femur has **medial** and **lateral condyles**, smooth, rounded surfaces that articulate with the tibia. These condyles allow us to bend at the knees. Located proximally to the condyles are the **medial** and **lateral epicondyles**, important sites of ligament attachment. An **adductor tubercle**, to which muscles attach, is located just proximal to the medial epicondyle.

The **patella**, or kneecap, is a large sesamoid bone located within the tendon of the quadriceps femoris muscle group, which is the major muscle group of the anterior thigh (figure 7.34). The patella articulates with the patellar groove of the femur to create a smooth articular surface over the anterior distal end of the femur. The patella holds the tendon away from the distal end of the femur and thereby changes the angle of the tendon between the quadriceps femoris muscle and the tibia, where the tendon attaches. This change in angle increases the force that can be applied from the muscle to the tibia. As a result, less muscle contraction is required to move the tibia.

Leg

The leg is the part of the lower limb between the knee and the ankle. Like the forearm, it consists of two bones: the **tibia** (tib'ē-ă), or shinbone, and the **fibula** (fib'ū-lă; figure 7.35). The tibia, by

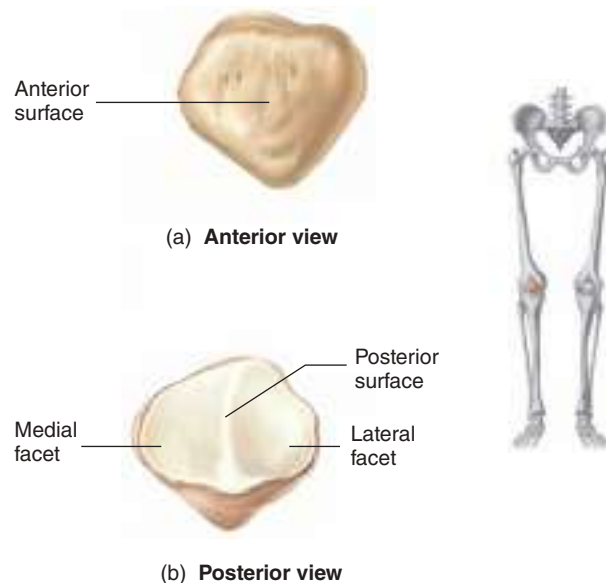

FIGURE 7.34 Right Patella

Clinical IMPACT

Patellar Defects

If the patella is severely fractured, the tendon from the quadriceps femoris muscle group may be torn, severely reducing muscle function. In extreme cases, it may be necessary to remove the patella to repair the tendon. Patella removal decreases the amount of power the quadriceps femoris muscle can generate at the tibia.

The patella normally tracks in the patellar groove on the antero-distal end of the femur. Abnormal tracking of the patella can become a problem in some teenagers, especially females. As a young woman's hips widen during puberty, the angles at the joints between the hips and the tibia may change considerably. As the knee becomes located more medially relative to the hip, the patella may be forced to track more laterally than normal. This lateral tracking may result in pain in the knees of physically active women.

far the larger of the two, supports most of the weight of the leg. A **tibial tuberosity**, which is the attachment point for the quadriceps femoris muscle group, can easily be seen and felt just inferior to the patella (figure 7.36). The **anterior crest** forms the shin. The proximal end of the tibia has flat **medial** and **lateral condyles**, which articulate with the condyles of the femur. Located between the condyles is the **intercondylar eminence**, a ridge between the two articular surfaces of the proximal tibia. The distal end of the tibia is enlarged to form the **medial malleolus** (ma-lē'ō-lūs; mallet-shaped), which helps form the medial side of the ankle joint.

The fibula does not articulate with the femur but has a small proximal head where it articulates with the tibia. The distal end of the fibula is also slightly enlarged as the **lateral malleolus** to create the lateral wall of the ankle joint. The lateral and medial

FIGURE 7.35 Right Tibia and Fibula

malleoli can be felt and seen as prominent lumps on both sides of the ankle (figure 7.36). The thinnest, weakest portion of the fibula is just proximal to the lateral malleolus.

Predict 6

Explain why modern ski boots are designed with high tops that extend partway up the leg.

FIGURE 7.36 Surface Anatomy Showing Bones of the Lower Limb

Foot

To continue our comparison of the lower limb with the upper limb, the proximal foot is relatively much larger than the wrist. It consists of seven **tarsal** (tar'sāl; sole of the foot) **bones** (figure 7.37). Three of these bones—the talus, the calcaneus, and the navicular—are proximal in the foot but do not form a row. The **talus** (tā'lūs), or ankle bone, articulates with the tibia and the fibula to form the ankle joint. It also articulates with the calcaneus and navicular bones. The **calcaneus** (kal-kā'nē-us; heel), the heel bone, is the largest and strongest bone in the foot. It is located inferior to the talus and supports that bone. The calcaneus

FIGURE 7.37 Bones of the Right Foot

The medial longitudinal arch is formed by the calcaneus, the talus, the navicular, the cuneiforms, and three medial metatarsal bones. The lateral longitudinal arch is formed by the calcaneus, the cuboid, and two lateral metatarsal bones. The transverse arch is formed by the cuboid and the cuneiforms. **APR**

protrudes posteriorly, is the important attachment point for the large calf muscles, and can be easily felt as the heel of the foot. The **navicular** (nă-vik'ū-lar), which is boat-shaped, lies between the talus posteriorly and the cuneiforms anteriorly. A mnemonic for the proximal three bones is **No Thanks Cow**—that is, **Navicular, Talus, and Calcaneus**.

Unlike the proximal tarsal bones, the distal four bones do form a row. The three medial, wedge-shaped bones are the **medial cuneiform**, the **intermediate cuneiform**, and the **lateral cuneiform**, collectively called the **cuneiforms** (kū'nē-i-fōrmz). The **cuboid** (kū'boyd), which is cube-shaped, is the most lateral of the distal row. A mnemonic for the distal

row is MILC—that is, the **M**edial, **I**ntermediate, and **L**ateral cuneiforms and the **C**uboid.

The **metatarsal bones** and **phalanges** of the foot are arranged in a manner very similar to that of the metacarpal bones and phalanges of the hand, with the great toe comparable to the thumb (figure 7.37). Small sesamoid bones often form in the tendons of muscles attached to the great toe. The ball of the foot is the junction between the metatarsal bones and the phalanges.

Predict 7

A decubitus ulcer is a chronic ulcer that appears in pressure areas of skin overlying a bony prominence in bedridden or otherwise immobilized patients. Where are decubitus ulcers likely to occur?

The foot as a unit is convex dorsally and concave ventrally to form three major **arches**: the medial longitudinal arch, the lateral longitudinal arch, and the transverse arch (figure 7.37b). This system of arches distributes the weight of the body between the heel and the ball of the foot during standing and walking. As the foot is placed on the ground, weight is transferred from the tibia and fibula to the talus. From there, the weight is distributed first to the heel (calcaneus) and then through the arch system along the lateral side of the foot to the ball of the foot (head of the metatarsal bones). This effect can be observed when a person with wet, bare feet walks across a dry surface; the heel, the lateral border of the foot, and the ball of the foot make an imprint, but the middle of the plantar surface and the medial border leave no impression because the arches on this side of

the foot are higher than those on the lateral side. The shape of the arches is maintained by the configuration of the bones, the ligaments connecting them, and the muscles acting on the foot. The ligaments of the arches and some arch disorders are described in chapter 8.

ASSESS YOUR PROGRESS

35. What bones form the pelvic girdle? Explain why the pelvic girdle is more stable than the pectoral girdle. How does this stability affect movement?
36. Describe the structure of the hipbone. What articulations does the hipbone make?
37. Name the important sites of muscle attachment on the pelvis.
38. Describe the differences between a male and a female pelvis.
39. Distinguish between the lower limb and the leg.
40. What is the function of the greater trochanter? The lesser trochanter?
41. Describe the function of the patella.
42. What is the function of the tibial tuberosity?
43. Name the seven tarsal bones. Which bones form the ankle joint? What bone forms the heel?
44. Describe the bones of the foot. How many phalanges are in each toe?
45. List the three arches of the foot, and describe their function.

Case STUDY

A “Broken Hip”

An 85-year-old woman who lived alone was found lying on her kitchen floor by her daughter, who had gone to check on her. The woman could not rise, even with help; when she tried, she experienced extreme pain in her right hip. Her daughter immediately dialed 911, and paramedics took the mother to the hospital.

The elderly woman’s hip was x-rayed in the emergency room, and physicians determined that she had a fracture of the right femoral neck. A femoral neck fracture is commonly, but incorrectly, called a broken hip. Two days later, she received a partial hip replacement in which the head and neck of the femur were replaced, but not the acetabulum.

In the case of falls involving femoral neck fracture, it is not always clear whether the fall caused the femoral neck to fracture or a fracture of the femoral neck caused the fall.

Femoral neck fractures are among the most common injuries resulting in morbidity

FIGURE 7G X-ray of a Broken Femoral Neck

(disease) and mortality (death) in older adults. Four percent of women over age 85 experience femoral neck fractures each year. Despite treatment with anticoagulants and antibiotics, about 5% of patients with femoral neck fractures develop deep vein thrombosis (blood clot), and about 5% develop wound infections; either condition can be life-threatening. Hospital mortality is 1–7% among patients with femoral neck fractures, and nearly 20% of patients die within 3 months of the fracture. Only about 25% of victims ever fully recover from the injury.

Predict 8

The incidence of fracture of the femoral neck increases dramatically with age, and 81% of patients are women. The average age at such injury is 82. Why is the femoral neck so commonly injured (*hint*: see figure 7.1), and why are elderly women most commonly affected?

Clinical IMPACT

Fractures of the Malleoli

Turning the plantar surface of the foot (the sole) outward so that it faces laterally is called eversion. Forceful eversion of the foot, as occurs when a person slips and twists the ankle or jumps and lands incorrectly on the foot, may cause the distal ends of the tibia and/or fibula to fracture (figure 7Ga). Such fractures are common in soccer, football, and basketball players. When the foot is forcefully everted, the medial malleolus moves inferiorly toward the ground or the floor and the talus slides laterally, forcing the medial and lateral malleoli to separate. The ligament holding the medial malleolus to the tarsal bones is stronger than the bones it connects, and often it does not tear as the bones separate because of the eversion. Instead, the medial malleolus breaks. Also, as the talus slides laterally, the force can shear off the lateral malleolus or, more commonly, cause the fibula to break superior to the lateral malleolus. This type of injury to the tibia and fibula is often called a Pott fracture.

Turning the plantar surface of the foot inward so that it faces medially is called inversion. Forceful inversion of the foot can fracture the fibula just proximal to the lateral malleolus (figure 7Gb). More often, because the

ligament holding the medial malleolus to the tarsal bones is weaker than the bones it connects, inversion of the foot causes a sprain in which ligaments are damaged.

FIGURE 7H Fracture of the Medial or Lateral Malleolus

Learn to Predict ◀ From page 194

In this question we are asked to address four different topics; two are identification of anatomy, and two relate to the function of the skeletal system. The description of the surgery provided useful information for addressing these topics.

The anatomy questions ask us to identify (1) the specific parts of the skeletal system and (2) the layers of bone tissue the surgeon cut. We are told exactly where the surgeon made the cut: a longitudinal midline incision through the sternum. We learned in this chapter that the sternum is composed of the manubrium, the body, and the xiphoid process. All three of these parts would have to be cut to allow the surgeon to spread the sternum halves apart to expose the heart. We learned in chapter 6 that a bone, such as the sternum, is surrounded by a periosteum and is composed of an outer layer of compact bone and internal spongy bone. Thus, the layers of bone tissue cut during the surgery were the periosteum, compact bone, and spongy bone.

Next we must explain why Dave experienced back discomfort following the surgery, and why he needed to wait 2 months before resuming his normal swimming routine. Chapter 6 explained

Answer

that movements between bones occur at joints, and this chapter outlined the relationships among the sternum, the ribs, and the vertebrae. We can assume that, when the two halves of the sternum were spread apart, stress was applied to other structures of the thoracic cavity. Therefore, we can attribute Dave's discomfort in his back to stress on the joints between the ribs and the vertebrae when the two halves of the sternum were separated.

The last question we need to address is why Dave needed to wait 2 months before resuming his normal swimming routine. Chapter 6 stated that the skeletal system plays a major role in body movement, specifically as attachment sites for skeletal muscles. Movement occurs when muscles contract and pull on the bone. Just like the repair of a bone fracture, healing of the sternum requires time. Contraction of the muscles involved in swimming would apply undue stress to the sternum; therefore, Dave had to delay swimming until the sternum had healed properly.

Answers to the rest of this chapter's Predict questions are in appendix G.

Summary

The gross anatomy of the skeletal system considers the features of bone, cartilage, and ligaments that can be seen without the use of a microscope. Dried, prepared bones display the major features of bone but obscure the relationship between bone and soft tissue.

7.1 Skeletal Anatomy Overview (p. 195)

Bones have processes, smooth surfaces, and holes that are associated with ligaments, muscles, joints, nerves, and blood vessels.

7.2 Axial Skeleton (p. 197)

The axial skeleton consists of the skull, auditory ossicles, hyoid bone, vertebral column, and rib cage.

Skull

- The skull, or cranium, can be thought of as a single unit.
- The parietal bones are joined at the midline by the sagittal suture; they are joined to the frontal bone by the coronal suture, to the occipital bone by the lambdoid suture, and to the temporal bone by the squamous suture.
- Nuchal lines are the points of attachment for neck muscles.
- Several skull features are visible from a lateral view.
 - The external auditory canal transmits sound waves toward the eardrum.
 - Important neck muscles attach to the mastoid process.
 - The temporal lines are attachment points of the temporalis muscle.
 - The zygomatic arch, from the temporal and zygomatic bones, forms a bridge across the side of the skull.
- Several skull features are visible from an anterior view.
 - The orbits contain the eyes.
 - The nasal cavity is divided by the nasal septum, and the hard palate separates the nasal cavity from the oral cavity.
 - Sinuses within bone are air-filled cavities. The paranasal sinuses, which connect to the nasal cavity, are the frontal, sphenoidal, and maxillary sinuses and the ethmoidal labyrinth.
 - The mandible articulates with the temporal bone.
- Several skull features are inside the cranial cavity.
 - The crista galli is a point of attachment for one of the meninges.
 - The olfactory nerves extend into the roof of the nasal cavity through the cribriform plate.
 - The sella turcica is occupied by the pituitary gland.
 - The spinal cord and brain are connected through the foramen magnum.
- Several features are on the inferior surface of the skull.
 - Occipital condyles are points of articulation between the skull and the vertebral column.
 - Blood reaches the brain through the internal carotid arteries, which pass through the carotid canals, and through the vertebral arteries, which pass through the foramen magnum.
 - Most blood leaves the brain through the internal jugular veins, which exit through the jugular foramina.
 - Styloid processes provide attachment points for three muscles involved in moving the tongue, hyoid bone, and pharynx.
 - The hard palate forms the floor of the nasal cavity.
- The skull is composed of 22 bones.
 - The auditory ossicles, which function in hearing, are located inside the temporal bones.
 - The braincase protects the brain.

- The facial bones protect the sensory organs of the head and are muscle attachment sites (mastication, facial expression, and eye muscles).
- The mandible and maxillae possess alveolar processes with sockets for the attachment of the teeth.

Hyoid Bone

The hyoid bone, which “floats” in the neck, is the attachment site for the throat and tongue muscles.

Vertebral Column

- The vertebral column provides flexible support and protects the spinal cord.
- The vertebral column has four major curvatures: cervical, thoracic, lumbar, and sacral/coccygeal. Abnormal curvatures include lordosis in the lumbar region, kyphosis in the thoracic region, and scoliosis, an abnormal lateral curvature.
- A typical vertebra consists of a body, a vertebral arch, and various processes.
 - Part of the body and the vertebral arch (pedicle and lamina) form the vertebral foramen, which contains and protects the spinal cord.
 - Spinal nerves exit through the intervertebral foramina.
 - The transverse and spinous processes are points of muscle and ligament attachment.
 - Vertebrae articulate with one another through the superior and inferior articular processes.
- Adjacent bodies are separated by intervertebral disks. Each disk has a fibrous outer covering (annulus fibrosus) surrounding a gelatinous interior (nucleus pulposus).
- Vertebrae can be distinguished by region.
 - All seven cervical vertebrae have transverse foramina, and most have bifid spinous processes.
 - The 12 thoracic vertebrae are characterized by long, downward-pointing spinous processes and demifacets.
 - The five lumbar vertebrae have thick, heavy bodies and processes.
 - The sacrum consists of five fused vertebrae and attaches to the hipbones to form the pelvis.
 - The coccyx consists of four fused vertebrae attached to the sacrum.

Rib Cage

- The rib cage (consisting of the ribs, their associated costal cartilages, and the sternum) protects the thoracic organs and changes volume during respiration.
- Twelve pairs of ribs attach to the thoracic vertebrae. They are divided into seven pairs of true ribs and five pairs of false ribs. Two pairs of false ribs are floating ribs.
- The sternum is composed of the manubrium, the body, and the xiphoid process.

7.3 Appendicular Skeleton (p. 225)

The appendicular skeleton consists of the upper and lower limbs and the girdles that attach the limbs to the body.

Pectoral Girdle and Upper Limb

- The upper limb is attached loosely and functions in grasping and manipulation.

2. The pectoral girdle consists of the scapulae and clavicles.
 - The scapula articulates with the humerus and the clavicle. It is an attachment site for shoulder, back, and arm muscles.
 - The clavicle holds the shoulder away from the body, permitting the arm to move freely.
 3. The arm bone is the humerus.
 - The humerus articulates with the scapula (head), the radius (capitulum), and the ulna (trochlea).
 - Sites of muscle attachment are the greater and lesser tubercles, the deltoid tuberosity, and the epicondyles.
 4. The forearm contains the ulna and the radius.
 - The ulna and the radius articulate with each other and with the humerus and the wrist bones.
 - The wrist ligaments attach to the styloid processes of the radius and the ulna.
 5. Eight carpal bones, or wrist bones, are arranged in two rows.
 6. The hand consists of five metacarpal bones.
 7. The phalanges are digital bones. Each finger has three phalanges, and the thumb has two phalanges.
2. The pelvic girdle consists of the right and left hipbones and the sacrum. Each hipbone is formed by the fusion of the ilium, the ischium, and the pubis.
 - The hipbones articulate with each other (symphysis pubis) and with the sacrum (sacroiliac joint) and the femur (acetabulum).
 - Important sites of muscle attachment are the iliac crest, the iliac spines, and the ischial tuberosity.
 - The female pelvis has a larger pelvic inlet and outlet than the male pelvis.
 3. The thighbone is the femur.
 - The femur articulates with the hipbone (head), the tibia (medial and lateral condyles), and the patella (patellar groove).
 - Sites of muscle attachment are the greater and lesser trochanters and the adductor tubercle.
 - Sites of ligament attachment are the lateral and medial epicondyles.
 4. The leg consists of the tibia and the fibula.
 - The tibia articulates with the femur, the fibula, and the talus. The fibula articulates with the tibia and the talus.
 - Tendons from the thigh muscles attach to the tibial tuberosity.
 5. Seven tarsal bones form the proximal portion of the foot.
 6. The foot consists of five metatarsal bones.
 7. The toes have three phalanges each, except for the big toe, which has two.
 8. The bony arches transfer weight from the heels to the toes and allow the foot to conform to many different positions.

Pelvic Girdle and Lower Limb

1. The lower limb is attached solidly to the hipbone and functions in support and movement.

REVIEW AND COMPREHENSION

1. Which of these is part of the appendicular skeleton?
 - a. cranium
 - b. ribs
 - c. clavicle
 - d. sternum
 - e. vertebra
2. A knoblike lump on a bone is called a
 - a. spine.
 - b. facet.
 - c. tuberosity.
 - d. sulcus.
 - e. ramus.
3. The perpendicular plate of the ethmoid and the _____ form the nasal septum.
 - a. palatine process of the maxilla
 - b. horizontal plate of the palatine
 - c. vomer
 - d. nasal bone
 - e. lacrimal bone
4. Which of these bones does *not* contain a paranasal sinus?
 - a. ethmoid
 - b. sphenoid
 - c. frontal
 - d. temporal
 - e. maxilla
5. The mandible articulates with the skull at the
 - a. styloid process.
 - b. occipital condyle.
 - c. mandibular fossa.
 - d. zygomatic arch.
 - e. medial pterygoid.
6. The nerves for the sense of smell pass through the
 - a. cribriform plate.
 - b. nasolacrimal canal.
 - c. internal auditory canal.
 - d. optic canal.
 - e. orbital fissure.
7. The major blood supply to the brain enters through the
 - a. foramen magnum.
 - b. carotid canals.
 - c. jugular foramina.
 - d. Both a and b are correct.
 - e. All of these are correct.
8. The site of the sella turcica is the
 - a. sphenoid bone.
 - b. maxillae.
 - c. frontal bone.
 - d. ethmoid bone.
 - e. temporal bone.
9. Which of these bones is *not* in contact with the sphenoid bone?
 - a. maxilla
 - b. inferior nasal concha
 - c. ethmoid
 - d. parietal
 - e. vomer
10. A herniated disk occurs when
 - a. the annulus fibrosus ruptures.
 - b. the intervertebral disk slips out of place.
 - c. the spinal cord ruptures.
 - d. too much fluid builds up in the nucleus pulposus.
 - e. All of these are correct.
11. The weight-bearing portion of a vertebra is the
 - a. vertebral arch.
 - b. articular process.
 - c. body.
 - d. transverse process.
 - e. spinous process.
12. Transverse foramina are found only in
 - a. cervical vertebrae.
 - b. thoracic vertebrae.
 - c. lumbar vertebrae.
 - d. the sacrum.
 - e. the coccyx.
13. Which of these statements concerning ribs is correct?
 - a. The true ribs attach directly to the sternum with costal cartilage.
 - b. There are five pairs of floating ribs.
 - c. The head of the rib attaches to the transverse process of the vertebra.
 - d. Vertebrochondral ribs are classified as true ribs.
 - e. Floating ribs do not attach to vertebrae.
14. The point where the scapula and clavicle connect is the
 - a. coracoid process.
 - b. styloid process.
 - c. glenoid cavity.
 - d. acromion process.
 - e. capitulum.

15. The distal medial process of the humerus to which the ulna joins is the
 - a. epicondyle.
 - b. deltoid tuberosity.
 - c. malleolus.
 - d. capitulum.
 - e. trochlea.
16. Which of these is *not* a point of muscle attachment on the pectoral girdle or upper limb?
 - a. epicondyles
 - b. mastoid process
 - c. radial tuberosity
 - d. spine of scapula
 - e. greater tubercle
17. The bone(s) of the foot on which the tibia rests is (are) the
 - a. talus.
 - b. calcaneus.
 - c. metatarsal bones.
 - d. navicular.
 - e. phalanges.
18. The projection on the hipbone of the pelvic girdle that is used as a landmark for finding an injection site is the
 - a. ischial tuberosity.
 - b. iliac crest.
 - c. anterior superior iliac spine.
 - d. posterior inferior iliac spine.
 - e. ischial spine.
19. When comparing the pectoral girdle with the pelvic girdle, which of these statements is correct?
 - a. The pectoral girdle has greater mass than the pelvic girdle.
 - b. The pelvic girdle is more firmly attached to the body than the pectoral girdle.
 - c. The pectoral girdle has the limbs more securely attached than the pelvic girdle.
 - d. The pelvic girdle allows greater mobility than the pectoral girdle.
20. When comparing a male pelvis with a female pelvis, which of these statements is correct?
 - a. The pelvic inlet in males is larger and more circular.
 - b. The subpubic angle in females is less than 90 degrees.
 - c. The ischial spines in males are closer together.
 - d. The sacrum in males is broader and less curved.
21. A site of muscle attachment on the proximal end of the femur is the
 - a. greater trochanter.
 - b. epicondyle.
 - c. greater tubercle.
 - d. intercondylar eminence.
 - e. condyle.

Answers in appendix E

CRITICAL THINKING

1. A patient has an infection in the nasal cavity. Name seven adjacent structures to which the infection could spread.
2. A patient is unconscious. X-rays reveal that the superior articular facet of the atlas has been fractured. Would this condition result from falling on the top of the head or being hit in the jaw with an uppercut? Explain.
3. If the vertebral column is forcefully rotated, what part of a vertebra is most likely to be damaged? In what area of the vertebral column is such damage most likely?
4. What might be the consequences of breaking both the ulna and the radius if the two bones fuse to each other during repair of the fracture?
5. A paraplegic person develops decubitus ulcers (pressure sores) on the buttocks from sitting in a wheelchair for extended periods. Name the bony protuberance responsible.
6. Why do women tend to suffer more knee pain and injuries than men?
7. On the basis of the bone structure of the lower limb, explain why it is easier to turn the foot medially (sole of the foot facing toward the midline of the body) than laterally. Why is it easier to bend the wrist medially than laterally?
8. Justin Time leaped from his second-floor hotel room to avoid burning to death in a fire. If he landed on his heels, what bone was likely fractured? Unfortunately for Justin, a 240-pound firefighter ran by and stepped heavily on the proximal part of Justin's foot (not the toes). Which bones could have been broken?

Learn to Predict

Andy was excited as he started his last ski run down the mountain. Then his ski caught the edge of a mogul, and he heard and felt a pop in his left knee. When he tried to stand up, the pain immediately convinced him to wait for the ski patrol. In the emergency clinic, x-rays showed that bones were not broken. However, based on a clinical mobility examination called the anterior drawer test, it was apparent that ligaments of Andy's left knee were damaged. In the test, his leg was moved in an anterior direction relative to the thigh, while his knee was flexed at a 90-degree angle. Andy's results showed a greater mobility than normally expected. A subsequent magnetic resonance image confirmed that ligaments were torn. Fortunately, after reconstructive surgery and physical therapy to maintain range of motion and rebuild strength, Andy was soon able to play sports and ski again. In chapters 6 and 7 you learned about bone anatomy, growth, and repair. **After focusing on the structure and function of joints in chapter 8, describe the likely injury to Andy's knee and how this ligament damage would affect mobility of the tibia relative to the femur.**

Joints and Movement

Watch a skier attack moguls on a mountain, or a player dribble a ball past defenders, and you are watching joints in action. Muscles pull on bones to make them move, but movement would not be possible without the joints between the bones. A joint is a place where two or more bones come together. Although we usually think of joints as movable, that is not always the case. Many joints allow only limited movement, and others allow no apparent movement at all. The structure of a given joint is directly correlated with its degree of movement.

Movable joints are places in the body where the bones move in close contact with each other. When working with machines, we know that the parts that make contact require the most maintenance. But in our bodies we tend to pay little attention to the movable joints until disease or damage makes movement very difficult.

Photo: Magnetic resonance image (MRI) of the left knee of one of the authors (A. Russo) after a ski accident. A sagittal view of the joint is shown, with the kneecap on the left.

8.1 Classes of Joints

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the two systems for classifying joints.
- Explain the structure of a fibrous joint, list the three types, and give an example of each type.
- Contrast the two types of cartilaginous joints and give examples of each type.
- Illustrate the structure of a synovial joint and explain the roles of the components of a synovial joint.
- Classify synovial joints based on the shape of the bones in the joint and give an example of each type.
- Distinguish among uniaxial, biaxial, and multiaxial synovial joints.

Joints, or *articulations*, are commonly named according to the bones or portions of bones that join together; for example, the temporomandibular joint is between the temporal bone and the mandible. Some joints are given the Greek or Latin equivalent of the common name, such as cubital (kū'bi-tāl; cubit, elbow or forearm) joint for the elbow joint.

Joints are classified structurally as fibrous, cartilaginous, or synovial, according to the major connective tissue type that binds the bones together and whether a fluid-filled joint capsule is present. Joints can also be classified in functional categories according to their degree of motion as *synarthroses* (nonmovable joints), *amphiarthroses* (slightly movable joints), or *diarthroses* (freely movable joints). In general, fibrous and cartilaginous joints have little or no movement, while synovial joints have considerable movement. Because this functional classification is somewhat limited, our discussions are based on the more precise structural classification scheme.

Fibrous Joints

Fibrous joints are the articulating surfaces of two bones united by fibrous connective tissue. They have no joint cavity and exhibit little or no movement. Joints in this group are further subdivided on the basis of structure as sutures, syndesmoses, or gomphoses (table 8.1).

Sutures

Sutures (soo'choorz) are seams found only between the bones of the skull (figure 8.1). Some sutures may become completely immovable in older adults. Few sutures are smooth, and the opposing bones often interdigitate (have interlocking, fingerlike processes). This interdigitation adds considerable stability to sutures. The tissue between the bones is dense regular collagenous connective tissue, and the periosteum on the inner and outer surfaces of the adjacent bones continues over the joint. The two layers of periosteum plus the dense fibrous connective tissue in between form a **sutural ligament**.

In a newborn, some of the sutures have a membranous area called a **fontanel** (fon'tā-nel'; little fountain, so named because the membrane can be seen to move with the pulse; soft spot).

TABLE 8.1 Fibrous and Cartilaginous Joints

Class and Example of Joint	Bones or Structures Joined	Movement
Fibrous Joints		
<i>Sutures</i>		
Coronal	Frontal and parietal	None
Lambdoid	Occipital and parietal	None
Sagittal	The two parietal bones	None
Squamous	Parietal and temporal	Slight
<i>Syndesmoses</i>		
Radioulnar	Radius and ulna	Slight
Stylohyoid	Styloid process and hyoid bone	Slight
Stylomandibular	Styloid process and mandible	Slight
Tibiofibular	Tibia and fibula	Slight
<i>Gomphoses</i>		
Dentoalveolar	Tooth and alveolar process	Slight
Cartilaginous Joints		
<i>Synchondroses</i>		
Epiphyseal plate	Diaphysis and epiphysis of a long bone	None
Sternocostal	Anterior cartilaginous part of first rib; between rib and sternum	Slight
Sphenoccipital	Sphenoid and occipital	None
<i>Symphyses</i>		
Intervertebral	Bodies of adjacent vertebrae	Slight
Manubriosternal	Manubrium and body of sternum	None
Symphysis pubis	The two hipbones	None except during childbirth
Xiphisternal	Xiphoid process and body of sternum	None

The fontanels make the skull flexible during the birth process and allow for growth of the head after birth (figure 8.2).

The margins of bones within sutures are sites of continuous intramembranous bone growth, and many sutures eventually become ossified. For example, ossification of the suture between the two frontal bones occurs shortly after birth, so that they usually form a single frontal bone in the adult skull. In most normal adults, the coronal, sagittal, and lambdoid sutures are not fused. However, in some very old adults, even these sutures ossify. When a suture becomes fully ossified, it becomes a **synostosis** (sin-os-tō'sis). A synostosis results when two bones grow together across a joint to form a single bone.

Predict 2

Predict the result of a sutural synostosis that occurs prematurely in a child's skull before the brain has reached its full size.

FIGURE 8.1 Sutures, Superior View of the Skull

Syndesmoses

A **syndesmosis** (sin'dez-mō'sis) is a slightly movable type of fibrous joint. The bones are farther apart than in a suture and are joined by ligaments. Some movement may occur at syndesmoses because the ligaments are flexible; this occurs in the radioulnar syndesmosis, for example, which binds the radius and ulna together (figure 8.3).

Gomphoses

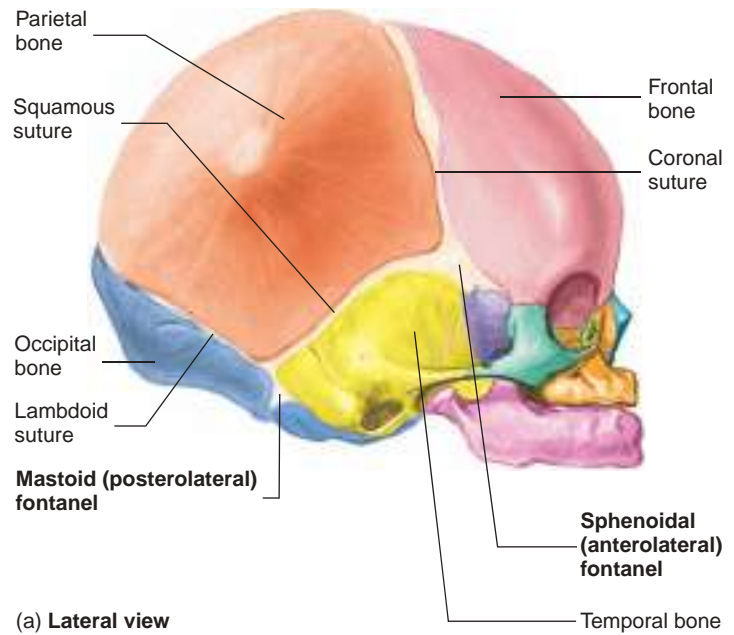

Gomphoses (gom-fō'sēz) are specialized joints consisting of pegs that fit into sockets and are held in place by fine bundles of regular collagenous connective tissue. The only gomphoses in the human body are the joints between the teeth and the sockets (alveoli) of the mandible and maxillae (figure 8.4). The connective tissue bundles between the teeth and their sockets are called **periodontal** (per'ē-ō-don'tāl) **ligaments**; they allow a slight amount of “give”

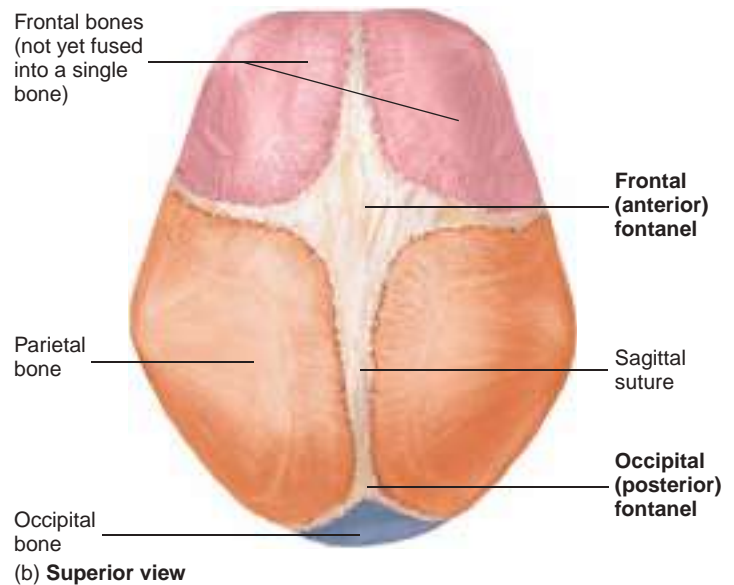

Clinical IMPACT

Gingivitis

The gingiva, or gums, are the soft tissues covering the alveolar process. Neglect of the teeth can result in **gingivitis**, an inflammation of the gingiva that is often caused by bacterial infection. Left untreated, gingivitis can spread to the tooth socket, resulting in periodontal disease, the leading cause of tooth loss in the United States. In periodontal disease, plaque and bacteria accumulate, resulting in inflammation that gradually destroys the periodontal ligaments and the bone. Teeth may become so loose that they come out of their sockets. Proper brushing, flossing, and professional cleaning to remove plaque can usually prevent gingivitis and periodontal disease.

(a) Lateral view

(b) Superior view

FIGURE 8.2 Fetal Skull Showing Fontanels and Sutures

to the teeth during mastication. This small amount of movement also allows teeth to be gradually realigned by braces.

Cartilaginous Joints

Cartilaginous joints unite two bones by cartilage. The connections can be by either hyaline cartilage or fibrocartilage (table 8.1). Joints containing hyaline cartilage are called **symphyses**; joints containing fibrocartilage are called **symphyses**.

Symphyses

A **symphysis** (sin'kon-drō'sis) consists of two bones joined by hyaline cartilage where little or no movement occurs (figure 8.5a).

FIGURE 8.3 Right Radioulnar Syndesmosis

FIGURE 8.4 Gomphosis Between a Tooth and Alveolar Bone of the Mandible

Most synchondroses are temporary. The epiphyseal plates of growing bones are synchondroses (figure 8.5*b*). In the case of epiphyseal plates, the synchondrosis is converted to a synostosis as bone replaces the existing cartilage (see “Bone Growth” in chapter 6). Other synchondroses are converted to synovial joints, whereas others persist throughout life. An example of a synchondrosis joint in an adult is the sternocostal synchondrosis between the first rib and the sternum by way of the first costal cartilage (figure 8.5*c*). All the costal cartilages begin as synchondroses but, because movement occurs between them and the sternum, all but the first usually develop

synovial joints at those junctions. As a result, even though the **costochondral joints** (between the ribs and the costal cartilages) are retained, most costal cartilages no longer qualify as synchondroses.

Symphyses

A **symphysis** (sim’fi-sis) consists of fibrocartilage uniting two bones. Examples of symphyses include the junction between the manubrium and the body of the sternum (figure 8.5*c*), the symphysis pubis (figure 8.6), and the intervertebral disks (see figures 7.13 and 7.15). Some of these joints are slightly movable because of the somewhat flexible nature of fibrocartilage. This is especially important for the intervertebral disks because the disk also acts as a shock absorber between the vertebrae.

ASSESS YOUR PROGRESS

1. What two standards are used to classify joints? List and describe the classification system used in this text.
2. What are the characteristics of a fibrous joint? Name the three types, and give an example of each.
3. What is a synostosis? Where are periodontal ligaments found?
4. Name the two types of cartilaginous joints, tell the type of cartilage present, and give an example of each.

Synovial Joints

Synovial (si-nō’vē-ăl) **joints** contain synovial fluid and allow considerable movement between articulating bones (figure 8.7). These joints are anatomically more complex than fibrous and

Joint Changes During Pregnancy

During pregnancy, certain hormones, such as estrogen, progesterone, and relaxin, act on the connective tissue of joints, particularly the symphysis pubis, making them more stretchable and allowing the joints to loosen. This change allows the pelvic opening to enlarge at the time of delivery. After delivery, the connective tissue of the symphysis pubis returns to its original condition. However, the enlarged pelvic opening may not return completely to its original size, and the woman may have slightly wider hips after the birth of the child.

The same hormones may act on the connective tissue of other joints in the body, such as the arches of the feet, causing them to relax, which may result in fallen arches. They may also act on some of a baby’s joints, such as the hip, causing them to become more mobile than normal. Increased mobility of the hip can result in congenital (appearing at birth) partial or complete dislocation of the hip. Congenital hip dislocation occurs approximately once in every 1000 births. Fortunately, if detected early the condition can be corrected using a specialized harness or traction to realign the joint.

FIGURE 8.5 Synchondroses

FIGURE 8.6 Symphysis Pubis

cartilaginous joints. Most joints that unite the bones of the appendicular skeleton are synovial joints, reflecting the far greater mobility of the appendicular skeleton compared with the axial skeleton.

The articular surfaces of bones within synovial joints are covered with a thin layer of hyaline cartilage called **articular cartilage**. The articular cartilage provides a smooth surface where the bones meet. In some synovial joints, a flat pad of fibrocartilage, called an **articular disk**, or **meniscus** (mĕ-nis'kus; pl. menisci, crescent-shaped), lies between the articular cartilages of bones. The circumference of the disk is attached to the fibrous capsule. A meniscus is a type of articular disk that only partially spans the synovial cavity such that there is an opening in the center. Joints with menisci include the knee and wrist, while the disks in the temporomandibular, sternoclavicular, and acromioclavicular joints span the entire cavity. Articular disks help adjust the connection

FUNDAMENTAL Figure

FIGURE 8.7 General Structure of a Synovial Joint **AP®**

between articulating bones, which improves joint stability and reduces wear on the articular cartilage.

The articular surfaces of the bones that meet at a synovial joint are enclosed within a **joint cavity** filled with synovial fluid (figure 8.7). The joint cavity is surrounded by a **joint capsule** that helps hold the bones together while still allowing for movement. The joint capsule consists of two layers: an outer fibrous capsule and an inner synovial membrane.

The **fibrous capsule** is the outer layer of the joint capsule (figure 8.7). It consists of dense irregular connective tissue and is continuous with the fibrous layer of the periosteum that covers the bones united at the joint. Portions of the fibrous capsule may thicken, and the collagen fibers may become regularly arranged to form ligaments. In addition, ligaments and tendons may be present outside the fibrous capsule, thereby contributing to the strength and stability of the joint while limiting movement in some directions.

The **synovial membrane** is the inner layer of the joint capsule (figure 8.7). It lines the joint cavity, except over the articular cartilage and articular disks. This thin, delicate membrane consists of a collection of modified connective tissue cells either intermixed with part of the fibrous capsule or separated from it by a layer of areolar tissue or adipose tissue. In some

joints, such as the elbow and knee, there are prominent areas of adipose tissue, called **fat pads**, that lie between the fibrous capsule and the synovial membrane. Fat pads help protect the articular cartilage by acting as a cushion around the joint. The membrane produces **synovial fluid**, a viscous lubricating film that covers the surfaces of a joint. Synovial fluid is a complex mixture of polysaccharides, proteins, lipids, and cells derived from serum (blood fluid) filtrate and secretions from the synovial cells. The major polysaccharide, hyaluronic acid, provides much of the slippery consistency and lubricating qualities of synovial fluid.

Predict 3

What would happen if a synovial membrane covered the articular cartilage?

In certain synovial joints, such as the shoulder and knee, the synovial membrane extends as a pocket, or sac, called a **bursa** (ber'sä; pocket; figure 8.7). A bursa can extend for a distance away from the rest of the joint cavity. Bursae contain synovial fluid and provide a cushion between structures that would otherwise rub against each other, such as tendons rubbing on bones or other tendons. Some bursae, such as the subcutaneous olecranon bursae, are not associated with joints but provide a cushion between the skin and underlying bony prominences, where friction could damage the tissues. Other bursae extend along tendons for some distance, forming **tendon sheaths**. **Bursitis** (ber-sī'tis), inflammation of a bursa, may cause considerable pain around the joint and restrict movement.

Articular cartilage receives nourishment from blood vessels that form a vascular circle at the peripheral margin of the cartilage but do not actually penetrate the cartilage or enter the joint cavity. Additional nourishment to the articular cartilage comes from the underlying spongy bone and from the synovial fluid covering the articular cartilage. Sensory nerves enter the fibrous capsule and, to a lesser extent, the synovial membrane. They not only supply the brain with information about pain in the joint but also furnish constant information about the joint's position and degree of movement (see chapter 14). Nerves do not enter the cartilage or joint cavity.

Types of Synovial Joints

Synovial joints are classified according to the shape of the adjoining articular surfaces. The six types of synovial joints are plane, saddle, hinge, pivot, ball-and-socket, and ellipsoid (figure 8.8). Movements at synovial joints are described as **uniaxial**, occurring around one axis; **biaxial**, occurring around two axes situated at right angles to each other; or **multiaxial**, occurring around several axes.

A **plane joint**, or *gliding joint*, consists of two flat bone surfaces of about equal size between which a slight gliding motion can occur (figure 8.8). These joints are considered uniaxial because some rotation is also possible but is limited by ligaments and adjacent bone. Examples are the articular processes between vertebrae.

Clinical IMPACT

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is the second most common type of arthritis. It affects about 3% of all women and about 1% of all men in the United States. RA is a general connective tissue disorder that affects the skin, vessels, lungs, and other organs, but it is most pronounced in the joints. RA is severely disabling and most commonly destroys small joints, such as those in the hands and feet (figure 8A).

The initial cause of RA is unknown but may involve a transient infection or an autoimmune disease (an immune reaction to one's own tissues; see chapter 22) that develops against collagen. A genetic predisposition may also exist. Whatever the cause, the ultimate course appears to be immunological. People with classic RA have a protein, **rheumatoid factor**, in their blood. In RA,

the synovial fluid and associated connective tissue cells proliferate, forming a *pannus* (clothlike layer), which causes the joint capsule to become thickened and destroys the articular cartilage. In advanced stages, opposing joint surfaces can become fused. **Juvenile rheumatoid arthritis** is similar to the adult type in many ways, but no rheumatoid factor is found in the serum.

(a)

(b)

FIGURE 8A Rheumatoid Arthritis

(a) Photograph of hands with rheumatoid arthritis. (b) Radiographs of the same hands shown in (a).

A **saddle joint** consists of two saddle-shaped articulating surfaces oriented at right angles to each other so that their complementary surfaces articulate (figure 8.8). Saddle joints are biaxial joints. The carpometacarpal joint of the thumb is an example.

A **hinge joint** is a uniaxial joint in which a convex cylinder in one bone is applied to a corresponding concavity in the other bone (figure 8.8). Examples include the elbow and knee joints.

A **pivot joint** is a uniaxial joint that restricts movement to rotation around a single axis (figure 8.8). A pivot joint consists of a relatively cylindrical bony process that rotates within a ring composed partly of bone and partly of ligament. The articulation between the head of the radius and the proximal end of the ulna is an example. The articulation between the dens, a process on the axis (see chapter 7), and the atlas is another example.

A **ball-and-socket joint** consists of a ball (head) at the end of one bone and a socket in an adjacent bone into which a portion of the ball fits (figure 8.8). This type of joint is multiaxial, allowing a wide range of movement in almost any direction. Examples are the shoulder and hip joints.

An **ellipsoid joint** (condyloid joint) is a modified ball-and-socket joint (figure 8.8). The articular surfaces are ellipsoid in shape, rather than spherical as in regular ball-and-socket joints. Ellipsoid joints are biaxial, because the shape of the joint limits its range of movement almost to a hinge motion in two axes and restricts rotation. The atlantooccipital joint of the neck is an example.

ASSESS YOUR PROGRESS

- Describe the structure of a synovial joint. How do the different parts of the joint contribute to joint movement?
- What are articular disks, and where are they found?
- What are bursae and tendon sheaths? What is the function of each?
- On what basis are synovial joints classified? List and describe the six types of synovial joints, and give an example of each.
- What directional movements are permitted at each type of synovial joint?

Plane

Intervertebral

Saddle

Carpometacarpal

Hinge

Class and Example of Joint	Structures Joined	Movement
Plane Acromioclavicular	Acromion process of scapula and clavicle	Slight
Carpometacarpal	Carpals and metacarpals 2-5	Slight
Costovertebral	Ribs and vertebrae	Slight
Intercarpal	Between carpal bones	Slight
Intermetatarsal	Between metatarsal bones	Slight
Intertarsal	Between tarsal bones	Slight
Intervertebral	Between articular processes of adjacent vertebrae	Slight
Sacroiliac	Between sacrum and hipbone (complex joint with several planes and synchondroses)	Slight
Tarsometatarsal	Tarsal bones and metatarsal bones	Slight
Saddle Carpometacarpal pollicis	Carpal and metacarpal of thumb	Two axes
Intercarpal	Between carpal bones	Slight
Sternoclavicular	Manubrium of sternum and clavicle	Slight
Hinge Cubital (elbow)	Humerus, ulna, and radius	One axis
Knee	Femur and tibia	One axis
Interphalangeal	Between phalanges	One axis
Talocrural (ankle)	Talus, tibia, and fibula	Multiple axes; one predominates
Pivot Atlantoaxial	Atlas and axis	Rotation
Proximal radioulnar	Radius and ulna	Rotation
Distal radioulnar	Radius and ulna	Rotation
Ball-and-Socket Hip	Hipbone and femur	Multiple axes
Glenohumeral (shoulder)	Scapula and humerus	Multiple axes
Ellipsoid Atlantooccipital	Atlas and occipital bone	Two axes
Metacarpophalangeal (knuckles)	Metacarpal bones and phalanges	Two axes
Metatarsophalangeal (ball of foot)	Metatarsal bones and phalanges	Two axes
Radiocarpal (wrist)	Radius and carpal bones	Multiple axes
Temporomandibular	Mandible and temporal bone	Multiple axes; one predominates

FIGURE 8.8 Types of Synovial Joints

8.2 Types of Movement

LEARNING OUTCOMES

After reading this section, you should be able to

- Categorize movements as gliding, angular, circular, special, or a combination of types.
- Demonstrate the difference between the following pairs of movements: flexion and extension; plantar flexion and dorsiflexion; abduction and adduction; supination and pronation; elevation and depression; protraction and retraction; opposition and reposition; inversion and eversion.
- Distinguish between rotation and circumduction. What is excursion?

A joint's structure dictates the movements that occur at that joint. Some joints are limited to only one type of movement; others can move in several directions. With few exceptions, movement is best described in relation to the anatomical position. Because most movements are also possible in the opposite direction, they are often illustrated in pairs. There are three general types of movement: gliding, angular, and circular. In addition, there are special movements that are unique to a small number of joints, as well as combination movements that are the composite of specific movements.

Gliding Movements

Gliding movements are the simplest of all the types of movement. These movements occur in plane joints between two flat or nearly flat surfaces that slide or glide over each other. These joints often allow only slight movement, as occurs between carpal bones.

Angular Movements

In angular movements, one part of a linear structure, such as the trunk or a limb, bends relative to another part of the structure, thereby changing the angle between the two parts. Angular movements also involve the movement of a solid rod, such as a limb, that is attached at one end to the body so that the angle at which it meets the body changes. The most common angular movements are flexion and extension and abduction and adduction.

Flexion and Extension

Flexion and extension are common opposing movements (figure 8.9). **Flexion** is a bending movement that *decreases* the angle of the joint to bring the articulating bones closer together. **Extension** is a straightening movement that *increases* the angle of the joint to extend the articulating bones. These bending and extending movements can easily be seen at the elbow and knee joints (figure 8.9*a,b*). **Hyperextension** is usually defined as extension of a joint beyond 180 degrees (figure 8.9*c,d*). Hyperextension can be

FIGURE 8.9 Flexion and Extension

Flexion, extension, and hyperextension of (a) the elbow, (b) the knee, (c) the neck, and (d) the wrist.

FIGURE 8.10 Dorsiflexion and Plantar Flexion of the Foot

a normal movement, such as looking up at the stars, but it can also result in injury. For example, when a person attempts to break a fall by putting out a hand, the force of the fall can result in hyperextension of the wrist, resulting in a sprained joint or broken bone.

There are special cases of flexion when describing the movement of the foot. Movement of the foot toward the plantar surface, as when standing on the toes, is commonly called **plantar flexion**; movement of the foot toward the shin, as when walking on the heels, is called **dorsiflexion** (figure 8.10).

Abduction and Adduction

Abduction (to take away) is movement away from the midline; **adduction** (to bring together) is movement toward the midline. Moving the upper limbs away from the body, as is done in the outward step of jumping jacks, is abduction, and bringing the upper limbs back toward the body is adduction (figure 8.11a). In the hand, abduction spreads the fingers apart, away from the midline of the hand, and adduction brings them back together (figure 8.11b). Abduction of the thumb moves it anteriorly, away from the palm. Abduction of the wrist, which is sometimes called radial deviation, moves the hand away from the midline of the body, and adduction of the wrist, sometimes called ulnar deviation, moves the hand toward the midline. Abduction of the head, which involves tilting the head to one side, is commonly called **lateral flexion** of the vertebral column, rather than abduction.

Circular Movements

Circular movements involve rotation around an axis or movements in an arc.

Rotation

Rotation is the turning of a structure around its long axis, as in rotating the head to shake the head “no” or rotating the arm or the entire body (figure 8.12). Medial rotation of the humerus with the forearm flexed brings the hand toward the body. Lateral rotation of the humerus moves the hand away from the body.

FIGURE 8.11 Abduction and Adduction

Abduction and adduction of (a) the upper limb and (b) the fingers.

Pronation and Supination

Pronation (prō-nā'shūn) and **supination** (soo'pi-nā'shūn) refer to the unique rotation of the forearm (figure 8.13). The word *prone* means lying facedown; the word *supine* means lying faceup. Pronation is rotation of the forearm so that the palm faces posteriorly in relation to the anatomical position. The palm of the hand faces inferiorly if the elbow is flexed to 90 degrees. Supination is rotation of the forearm so that the palm faces anteriorly in relation to the anatomical position. The palm of the hand faces superiorly if the elbow is flexed to 90 degrees. In pronation, the radius and ulna cross; in supination, they are parallel. The head of the radius rotates against the radial notch of the ulna during supination and pronation.

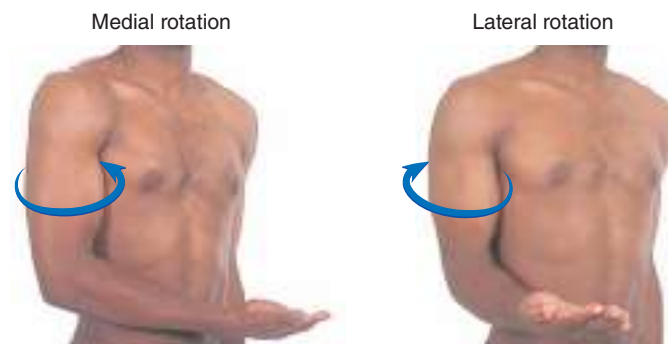

FIGURE 8.12 Medial and Lateral Rotation of the Arm

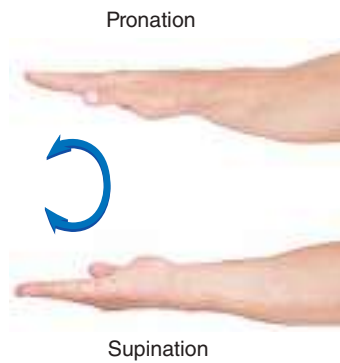

FIGURE 8.13 Pronation and Supination of the Forearm

Circumduction

Circumduction is a combination of flexion, extension, abduction, and adduction (figure 8.14). It occurs at freely movable joints, such as the shoulder. In circumduction, the arm moves in an arc so that it traces a cone, with the shoulder joint at the apex of the cone, as occurs when pitching a baseball.

Special Movements

Special movements are those movements that are unique to only one or two joints and do not fit neatly into any of the other categories.

FIGURE 8.14 Circumduction

FIGURE 8.15 Elevation and Depression of the Scapula

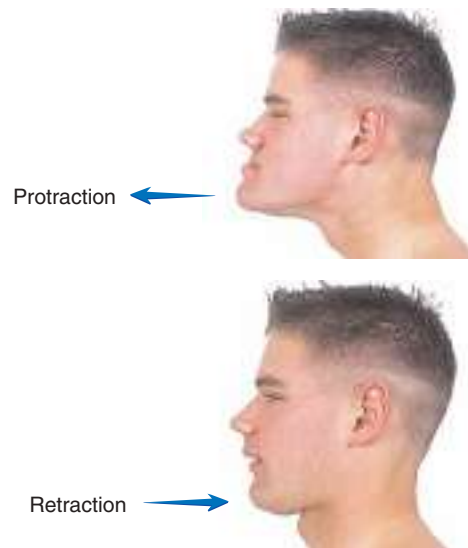

FIGURE 8.16 Protraction and Retraction of the Mandible

Elevation and Depression

Elevation moves a structure superiorly; **depression** moves it inferiorly (figure 8.15). Shrugging the shoulders is an example of scapular elevation. Depression of the mandible opens the mouth, and elevation closes it.

Protraction and Retraction

Protraction is a gliding motion that moves a structure in an anterior direction (figure 8.16). Jutting out the jaw and hunching the shoulders are examples of protraction. **Retraction** is a gliding motion that moves a structure in a posterior direction (figure 8.16). Pulling the jaw back and pinching or pulling the scapulae back toward the vertebral column illustrate retraction.

Excursion

Lateral excursion is moving the mandible to either the right or the left of the midline (figure 8.17), as occurs when grinding the teeth or chewing. **Medial excursion** returns the mandible to the midline position.

FIGURE 8.17 Excursion of the Mandible

Opposition and Reposition

Opposition is a movement unique to the thumb (figure 8.18). It occurs when the thumb and the tip of a finger on the same hand are brought toward each other across the palm. **Reposition** returns the thumb to the neutral, anatomical position.

Inversion and Eversion

Inversion turns the ankle so that the plantar surface of the foot faces medially, toward the opposite foot, with the weight on the outside edge of the foot (rolling out). **Eversion** turns the ankle so that the plantar surface faces laterally, with the weight on the inside edge of the foot (rolling in; figure 8.19). Sometimes inversion of the foot is called supination and eversion is called pronation. Although commonly used as clinical terms, *supination* and *pronation* of the feet are more complex than just inversion and eversion,

FIGURE 8.18 Opposition and Reposition of the Thumb and Little Finger

FIGURE 8.19 Inversion and Eversion of the Right Foot

and they involve movements at multiple joints of the ankle and foot. Some supination and pronation are normal, but excessive pronation is a common cause of injury among runners.

Combination Movements

Most movements that we perform in the course of normal activities are combinations of the movements named previously. These combined movements are described by naming the individual movements involved. For example, when a person steps forward and to the side at a 45-degree angle, the movement at the hip is a combination of flexion and abduction.

Predict 4

What combination of movements at the shoulder and elbow joints allows a person to move the right upper limb from the anatomical position to touch the right side of the head with the fingertips?

ASSESS YOUR PROGRESS

- Describe flexion and extension. How are they different for the upper and lower limbs? What is hyperextension?
- Contrast abduction and adduction. Describe these movements for the head, upper limbs, wrist, fingers, waist, lower limbs, and toes. For what part of the body is the term lateral flexion used?
- Distinguish among rotation, circumduction, pronation, and supination. Give an example of each.
- Explain the following jaw movements: protrusion, retraction, lateral excursion, medial excursion, elevation, and depression.
- Describe opposition and reposition.
- What terms are used for turning the side of the foot medially or laterally?

8.3 Range of Motion

LEARNING OUTCOMES

After reading this section, you should be able to

- Explain the difference between active and passive range of motion.
- Describe the consequences of movement beyond the normal range.
- List the factors that affect normal range of motion.

Range of motion describes the amount of mobility that can be demonstrated in a given joint. **Active range of motion** is the amount of movement that can be accomplished by contracting the muscles that normally act across a joint. **Passive range of motion** is the amount of movement that can be accomplished when the structures that meet at the joint are moved by an outside force, as when a therapist holds on to a patient's forearm and moves it toward the arm, flexing the elbow joint. The active and passive ranges of motion for normal joints are usually about equal.

Movement of joints beyond the normal range of motion can cause dislocations and sprains. A **dislocation**, or *luxation*, of a joint occurs when the articulating surfaces of the bones are moved out of proper alignment. A *subluxation* is a partial dislocation. Dislocations are often accompanied by painful damage to the supporting ligaments and articular cartilage. A **sprain** occurs when ligaments are damaged. The degree of damage can range from stretched to completely torn ligaments. Sprains often result in inflammation, swelling, and pain. Dislocations and sprains are common sports injuries.

The range of motion for a given joint is influenced by a number of factors:

1. Shape of the articular surfaces of the bones forming the joint
2. Amount and shape of cartilage covering those articular surfaces
3. Strength and location of ligaments and tendons surrounding the joint
4. Strength and location of the muscles associated with the joint
5. Amount of fluid in and around the joint
6. Amount of pain in and around the joint
7. Amount of use or disuse the joint has received over time

Abnormalities in the range of motion can occur when any of those components change. For example, damage to a ligament associated with a given joint may increase that joint's range of motion. A torn piece of cartilage within a joint can limit its range of motion. If the nerve supply to a muscle is damaged so that the muscle is weakened, the active range of motion for the joint acted on by that muscle may decrease, but the joint's passive range of motion should remain unchanged. Fluid buildup and/or pain in or around a joint (as occurs when the soft tissues around the joint develop edema following an injury) can severely limit both the active and passive ranges of motion for that joint. With disuse, both the active and passive ranges of motion for a given joint decrease.

ASSESS YOUR PROGRESS

16. What is range of motion? Contrast active and passive range of motion.
17. Discuss some examples of the changes that may occur with movement beyond the normal range.

8.4 Description of Selected Joints

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the structure and movements of the TMJ.**
- B. Compare and contrast the ball-and-socket joints of the shoulder and hip.**
- C. Compare and contrast the hinge joints of the elbow, knee, and ankle.**
- D. Describe the ligaments that support the complex ellipsoid joint of the knee.**
- E. Explain the structure and functions of the arches of the foot.**
- F. Discuss the common disorders that affect these major joints.**

It is impossible in a limited space to describe all the joints of the body; therefore, we have chosen to describe only selected joints, based on their representative structure, important function, or clinical significance.

Temporomandibular Joint

The mandible articulates with the temporal bone to form the **temporomandibular joint (TMJ)**. The mandibular condyle fits into the mandibular fossa of the temporal bone. A fibrocartilage articular disk is located between the mandible and the temporal bone, dividing the joint into superior and inferior joint cavities (figure 8.20). The joint is surrounded by a fibrous capsule, to which the articular disk is attached at its margin, and is strengthened by lateral and accessory ligaments.

The temporomandibular joint is a combination plane and ellipsoid joint, with the ellipsoid portion predominating. Opening of the jaw first involves the inferior cavity of the TMJ below the articular disk. The mandibular condyle rotates anteriorly on the disk in the familiar hingelike movement of the jaw. The second portion of jaw opening occurs in the superior cavity of the TMJ. The articular disk and condyle together glide anteriorly. This is similar to the motion that occurs in protraction of the mandible. In addition, mediolateral movements of the mandibular condyle allow lateral excursion, or side-to-side, motions of the jaw. Together, these movements allow chewing and grinding in mastication.

Clinical IMPACT

TMJ Disorders

TMJ disorders are the most common cause of chronic orofacial pain. The primary symptom is pain in the jaw muscles and/or joint. Other symptoms include radiating pain in the face, head, and neck; reduced range of motion or locking of the jaw; and painful clicking or grating when moving the jaw. Ear pain is another symptom, which often leads patients to their physicians, who then refer them to a dentist. It is estimated that 5–12% of the population experience TMJ pain. It is at least twice as prevalent among women.

TMJ disorders often have no obvious cause or trigger. They are not easily treated, and chronic TMJ pain is often associated with other types of poorly understood chronic pain, such as fibromyalgia. Many TMJ cases can improve with treatment, although for some patients the pain is persistent or continues to recur. A physical therapist or other specialist can sometimes help relax and restore function to involved muscles, as well as identify habits that may be contributing to the condition, such as forward head posture or holding a phone between the ear and jaw. Reducing stress and anxiety and avoiding hard food or chewing gum can help. Certain analgesic and anti-inflammatory medications and oral splints at night may also be helpful.

FIGURE 8.20 Right Temporomandibular Joint, Lateral View

TABLE 8.2

Ligaments of the Shoulder Joint
(see figure 8.21)

Ligament	Description
Glenohumeral (superior, middle, and inferior)	Three slightly thickened longitudinal sets of fibers on the anterior side of the capsule; extend from the humerus to the margin of the glenoid cavity
Transverse humeral	Lateral, transverse, fibrous thickening of the joint capsule; crosses between the greater and lesser tubercles and holds down the tendon from the long head of the biceps brachii muscle
Coracohumeral	Crosses from the root of the coracoid process to the humeral neck
Coracoacromial	Crosses above the joint between the coracoid process and the acromion process; an accessory, protective ligament

Shoulder Joint

The **shoulder joint**, or *glenohumeral joint*, is a ball-and-socket joint (figure 8.21) that has less stability but more mobility than the other ball-and-socket joint, the hip. Flexion, extension,

abduction, adduction, rotation, and circumduction can all occur at the shoulder joint. The rounded head of the humerus articulates with the shallow glenoid cavity of the scapula. The rim of the glenoid cavity is built up slightly by the **glenoid labrum**, a fibrocartilage ring to which the joint capsule is attached. A **subscapular bursa** (not shown in figure 8.21) opens into the joint cavity. A **subacromial bursa** is located near the joint cavity but separated from the cavity by the joint capsule (figure 8.21).

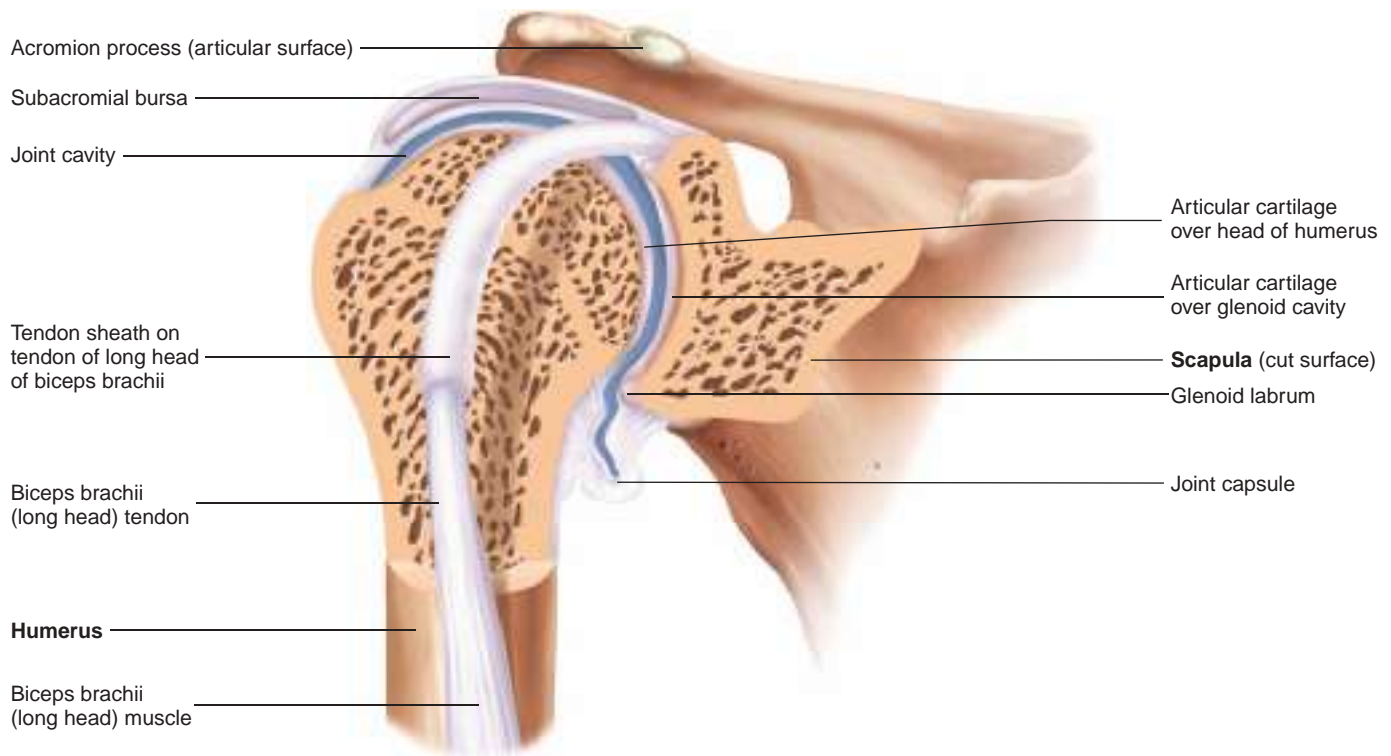

The stability of the shoulder joint is maintained primarily by four sets of ligaments and four muscles. The ligaments are listed in table 8.2. The four muscles are referred to collectively as the **rotator cuff**, which holds the humeral head tightly within the glenoid cavity (see chapter 10). The head of the humerus is also supported against the glenoid cavity by the tendon from the biceps brachii muscle in the anterior part of the arm. This tendon is unusual in that it passes through the articular capsule of the shoulder joint before crossing the head of the humerus and attaching to the scapula at the supraglenoid tubercle (see figure 7.23a).

The most common traumatic shoulder disorders are dislocation of bones and tears in muscles or tendons. The shoulder is the most commonly dislocated joint in the body. Major ligaments cross the superior part of the shoulder joint, and no major

FUNDAMENTAL Figure

ligaments or muscles are associated with the inferior side. As a result, the humerus is most likely to become dislocated inferiorly into the axilla. Because the axilla contains very important nerves and arteries, severe and permanent damage may occur when the humeral head dislocates inferiorly. The axillary nerve is the most commonly damaged (see chapter 12). Chronic shoulder disorders include tendinitis (inflammation of tendons), bursitis (inflammation of bursae), and arthritis (inflammation of joints). Bursitis of the subacromial bursa can become very painful when the large shoulder muscle, called the deltoid muscle, compresses the bursa during shoulder movement.

Predict 5

Separation of the shoulder consists of stretching or tearing the ligaments of the acromioclavicular joint, a condition called acromioclavicular, or AC, separation. Using figure 8.21 (anterior view) and your knowledge of the articulated skeleton, explain the nature of a shoulder separation and predict the problems that may follow a separation.

Elbow Joint

The **elbow joint** or *cubital joint*, is a compound hinge joint (figure 8.22). It consists of the **humeroulnar joint**, between the humerus and ulna, and the **humeroradial joint**, between the humerus and radius. The **proximal radioulnar joint**, between the proximal radius and ulna, is also closely related. Movement at

the elbow joint is limited to flexion and extension because of the shape of the trochlear notch and its association with the trochlea of the humerus (figure 8.22a). However, the rounded radial head rotates in the radial notch of the ulna and against the capitulum of the humerus (figure 8.22b), allowing pronation and supination of the hand.

The elbow joint is surrounded by a joint capsule. The humeroulnar joint is reinforced by the **ulnar collateral ligament** (figure 8.22c). The humeroradial and proximal radioulnar joints are reinforced by the **radial collateral ligament** and the **radial annular ligament** (figure 8.22d). A subcutaneous **olecranon bursa** covers the proximal and posterior surfaces of the olecranon process.

Elbow problems are commonly caused by excessive use or stress placed on the joint. Overuse of a joint can cause tendinitis, an inflammation or injury to the tendons that attach muscle to bone. A classic example is *tennis elbow*, although it can be caused by many repetitive activities in addition to tennis and other sports. **Olecranon bursitis** is inflammation of the olecranon bursa. It can be caused by excessive pressure of the elbow against a hard surface and is sometimes referred to as *student's elbow*. This condition typically develops over a period of months, but it can also result from a hard blow to the elbow. A common condition called *nursemaid's elbow* can be caused when the radial head becomes subluxated (partially separated) from the annular ligament of the radius. This can happen if a young child (usually under age 5) is lifted by one hand or swung by the arms.

FIGURE 8.23 Right Hip Joint (Coxal Joint) **AP|R**

Hip Joint

The femoral head articulates with the relatively deep, concave acetabulum of the hipbone to form the **hip joint**, or *coxal joint* (figure 8.23). The head of the femur is more nearly a complete ball than the articulating surface of any other bone of the body. The acetabulum is deepened and strengthened by the **acetabular labrum**, a lip of fibrocartilage, which is incomplete inferiorly. The acetabulum is further deepened and strengthened by a **transverse acetabular ligament**, which crosses the acetabular notch on the inferior edge of the acetabulum. The hip is capable of a wide range of movement, including flexion, extension, abduction,

adduction, rotation, and circumduction. Dislocation of the hip may occur when the femur is driven posteriorly while the hip is flexed, as when a person sitting in an automobile is involved in an accident. The head of the femur usually dislocates posterior to the acetabulum, tearing the acetabular labrum, the fibrous capsule, and the ligaments. Fracture of the femur and the hipbone often accompanies hip dislocation.

An extremely strong joint capsule, reinforced by several ligaments, extends from the rim of the acetabulum to the neck of the femur (table 8.3). The **iliofemoral ligament** is especially strong. When standing, most people tend to thrust the hips

TABLE 8.3 Ligaments of the Hip Joint (see figure 8.23)

Ligament	Description
Transverse acetabular	Bridges gap in the inferior margin of the fibrocartilaginous acetabular labrum
Iliofemoral	Strong, thick band between the anterior inferior iliac spine and the intertrochanteric line of the femur
Pubofemoral	Extends from the pubic portion of the acetabular rim to the inferior portion of the femoral neck
Ischiofemoral	Bridges the ischial acetabular rim and the superior portion of the femoral neck; less well defined
Ligament of the head of the femur	Weak, flat band from the margin of the acetabular notch and the transverse ligament to a fovea in the center of the femoral head

anteriorly. This position is relaxing because the iliofemoral ligament supports much of the body's weight. The **ligament of the head of the femur** (round ligament of the femur) is located inside the hip joint between the femoral head and the acetabulum. This ligament does not contribute much toward strengthening the hip joint; however, it does carry a small nutrient artery to the head of the femur in about 80% of the population. The deepened acetabular labrum, ligaments of the hip, and surrounding muscles make the hip joint much more stable but less mobile than the shoulder joint.

Knee Joint

The **knee joint** is traditionally classified as a modified hinge joint located between the femur and the tibia (figure 8.24). Actually, it is a complex ellipsoid joint that allows flexion, extension, and a small amount of rotation of the leg. The distal end of the femur has two large, ellipsoid surfaces with a deep fossa between them. The femur articulates with the proximal end of the tibia, which is flattened and smooth laterally, with a crest called the intercondylar eminence in the center (see figure 7.35). The margins of the tibia are built up by menisci—thick, articular disks of fibrocartilage (figure 8.24*b,d*), which deepen the articular surface. The fibula articulates only with the lateral side of the tibia, not with the femur.

The knee joint is stabilized by a combination of ligaments and tendons. The major ligaments that provide knee joint stability are the cruciate and collateral ligaments. Two **cruciate** (kroo'shē-āt; crossed) **ligaments** extend between the intercondylar eminence of the tibia and the fossa of the femur (figure 8.24*b,d,e*). The **anterior cruciate ligament** prevents anterior displacement of the tibia relative to the femur, and the **posterior cruciate ligament** prevents posterior displacement of the tibia. The **medial** (tibial) and **lateral** (fibular) **collateral ligaments** stabilize the medial and lateral sides, respectively, of the knee. Joint strength is also provided by popliteal ligaments and tendons of the thigh muscles that extend around the knee (table 8.4).

A number of bursae surround the knee (figure 8.24*f*). The largest is the **suprapatellar bursa**, a superior extension of the joint capsule that allows the anterior thigh muscles to move over the distal end of the femur. Other knee bursae include the subcutaneous prepatellar bursa and the deep infrapatellar bursa, as well as the popliteal bursa, the gastrocnemius bursa, and the subcutaneous infrapatellar bursa (not shown in figure 8.24).

Ankle Joint and Arches of the Foot

The **ankle joint**, or *talocrural* (tā'lō-kroo'rāl) joint, is a highly modified hinge joint formed by the distal tibia and fibula (figure 8.25). The medial and lateral malleoli of the tibia and fibula, which form the medial and lateral margins of the ankle, are rather extensive, whereas the anterior and posterior margins are almost nonexistent. As a result, a hinge joint is created. A fibrous capsule surrounds the joint, with the medial and lateral parts thickened to form ligaments. Other ligaments also help stabilize the joint (table 8.5). Dorsiflexion, plantar flexion, and limited inversion and eversion can occur at this joint.

The arches (see figure 7.37) have ligaments that serve two major functions: to hold the bones in their proper relationship as segments of the arch and to provide ties across the arch somewhat like a bowstring. As weight is transferred through the arch system, some of the ligaments are stretched, giving the foot more flexibility and allowing it to adjust to uneven surfaces. When weight is removed from the foot, the ligaments recoil and restore the arches to their unstressed shape.

The arches of the foot normally form early in fetal life. Failure to form results in congenital **flat feet**, or fallen arches, in which the arches, primarily the medial longitudinal arch, are depressed or collapsed (see figure 7.37). This condition is sometimes, but not always, painful. Flat feet may also occur when the muscles and ligaments supporting the arch fatigue and allow the arch, usually the medial longitudinal arch, to collapse. During prolonged standing, the plantar calcaneonavicular ligament may stretch, flattening the medial longitudinal arch. The transverse arch may also become flattened. The strained ligaments can become painful. The plantar fascia is composed of the deep connective tissue superficial to the ligaments in the central plantar surface of the foot and the thinner fascia on the medial and lateral sides of the plantar surface (see figure 8.25). **Plantar fasciitis**, an inflammation of the plantar fascia, can be a problem for distance runners.

Predict 6

Ford Dent hurt his knee in an auto accident when his knee was rammed into the dashboard. The doctor tested the knee for ligament damage by having Ford sit on the edge of a table with his knee flexed at a 90-degree angle. The doctor attempted to pull the tibia in an anterior direction (anterior drawer test) and then tried to push the tibia in a posterior direction (posterior drawer test). Results of the anterior drawer test were normal, but unusual movement did occur during the posterior drawer test. Explain the purpose of each test, and describe which ligament was damaged.

TABLE 8.4 Ligaments of the Knee Joint (see figure 8.24)	
Ligament	Description
Patellar	Thick, heavy, fibrous band between the patella and the tibial tuberosity; actually part of the quadriceps femoris tendon
Patellar retinaculum	Thin band from the margins of the patella to the sides of the tibial condyles
Oblique popliteal	Thickening of the posterior capsule; extension of the semimembranous tendon
Arcuate popliteal	Extends from the posterior fibular head to the posterior fibrous capsule
Medial (tibial) collateral	Thickening of the lateral capsule from the medial epicondyle of the femur to the medial surface of the tibia; also called the medial collateral ligament
Lateral (fibular) collateral	Round ligament extending from the lateral femoral epicondyle to the head of the fibula; also called the lateral collateral ligament
Anterior cruciate	Extends obliquely, superiorly, and posteriorly from the anterior intercondylar eminence of the tibia to the medial side of the lateral femoral condyle
Posterior cruciate	Extends superiorly and anteriorly from the posterior intercondylar eminence to the lateral side of the medial condyle
Coronary (medial and lateral)	Attaches the menisci to the tibial condyles (not illustrated)
Transverse	Connects the anterior portions of the medial and lateral menisci
Menisfemoral (anterior and posterior)	Joins the posterior part of the lateral menisci to the medial condyle of the femur, passing anterior and posterior to the posterior cruciate ligament

Clinical IMPACT

Knee Injuries and Disorders

Injuries to the medial side of the knee are much more common than injuries to the lateral side for several reasons. First, the **lateral (fibular) collateral ligament** strengthens the joint laterally and is stronger than the **medial (tibial) collateral ligament**. Second, severe blows to the medial side of the knee are far less common than blows to the lateral side of the knee. Finally, the **medial meniscus** is fairly tightly attached to the medial collateral ligament and is damaged 20 times more often in knee injuries than the lateral meniscus, which is thinner and not attached to the lateral collateral ligament.

A **tornd meniscus** may cause a “clicking” sound during extension of the leg; if the damage is more severe, the torn piece of cartilage may move between the articulating surfaces of the tibia and femur, causing the knee to “lock” in a partially flexed position.

If the knee is driven anteriorly or hyperextended, the **anterior cruciate ligament** may be torn, which makes the knee joint very unstable. If the knee is flexed and the tibia is driven posteriorly, the **posterior cruciate ligament** may be torn. Surgical replacement of a cruciate ligament with a transplanted or an artificial ligament repairs the damage.

A common football injury results from a block or tackle to the lateral side of the knee, which can cause the knee to bend inward, tearing the medial collateral ligament and opening the medial side of the joint. The medial meniscus is often torn as well. In severe medial knee injuries, the anterior cruciate ligament is also damaged (figure 8B). Tearing of the medial collateral ligament, medial meniscus, and anterior cruciate ligament is often referred to as “the unhappy triad of injuries.”

Bursitis in the **subcutaneous prepatellar bursa** (see figure 8.24f), commonly called

housemaid’s knee, may result from prolonged work while on the hands and knees. Another form of bursitis, *clergyman’s knee*, results from excessive kneeling and affects the **subcutaneous infrapatellar bursa**. This type of bursitis is common among carpet layers and roofers.

Other common knee problems are **chondromalacia** (kon’drō-mā-lā’shē-ă), or softening of the cartilage, which results from

abnormal movement of the patella within the patellar groove, and **fat pad syndrome**, which occurs when fluid accumulates in the fat pad posterior to the patella. Acute swelling in the knee appearing immediately after an injury is usually a sign of a **hemarthrosis** (hē’mar-thrō’sis, hem’ar-thrō’sis), blood accumulation within the joint cavity. A slower accumulation of fluid, “water on the knee,” may be caused by bursitis.

FIGURE 8B Injury to the Right Knee

ASSESS YOUR PROGRESS

- For each of the following joints, name the bones of the joint, the specific parts of the bones that form the joint, the type of joint, and the possible movement(s) at the joint: temporomandibular, shoulder, elbow, hip, knee, and ankle.
- Describe dislocations of the shoulder and hip. What conditions are most likely to cause each type?
- Explain the differences in stability and movement between the shoulder and the hip joints.
- List the common knee injuries, and tell which part of the knee is most often damaged in each type.
- Describe a sprain, and identify which portions of the ankle joint are most commonly damaged when it is sprained.

FIGURE 8.25 Ligaments of the Right Ankle Joint **AP|R**

TABLE 8.5		Ligaments of the Ankle and Arch (see figure 8.25)
Ligament	Description	
Medial	Thickening of the medial fibrous capsule that attaches the medial malleolus to the calcaneus, navicular, and talus; also called the deltoid ligament	
Calcaneofibular	Extends from the lateral malleolus to the lateral surface of the calcaneus; separate from the capsule	
Anterior talofibular	Extends from the lateral malleolus to the neck of the talus; fused with the joint capsule	
Long plantar	Extends from the calcaneus to the cuboid and bases of metatarsal bones 2–5	
Plantar calcaneocuboid	Extends from the calcaneus to the cuboid	
Plantar calcaneonavicular (short plantar)	Extends from the calcaneus to the navicular	

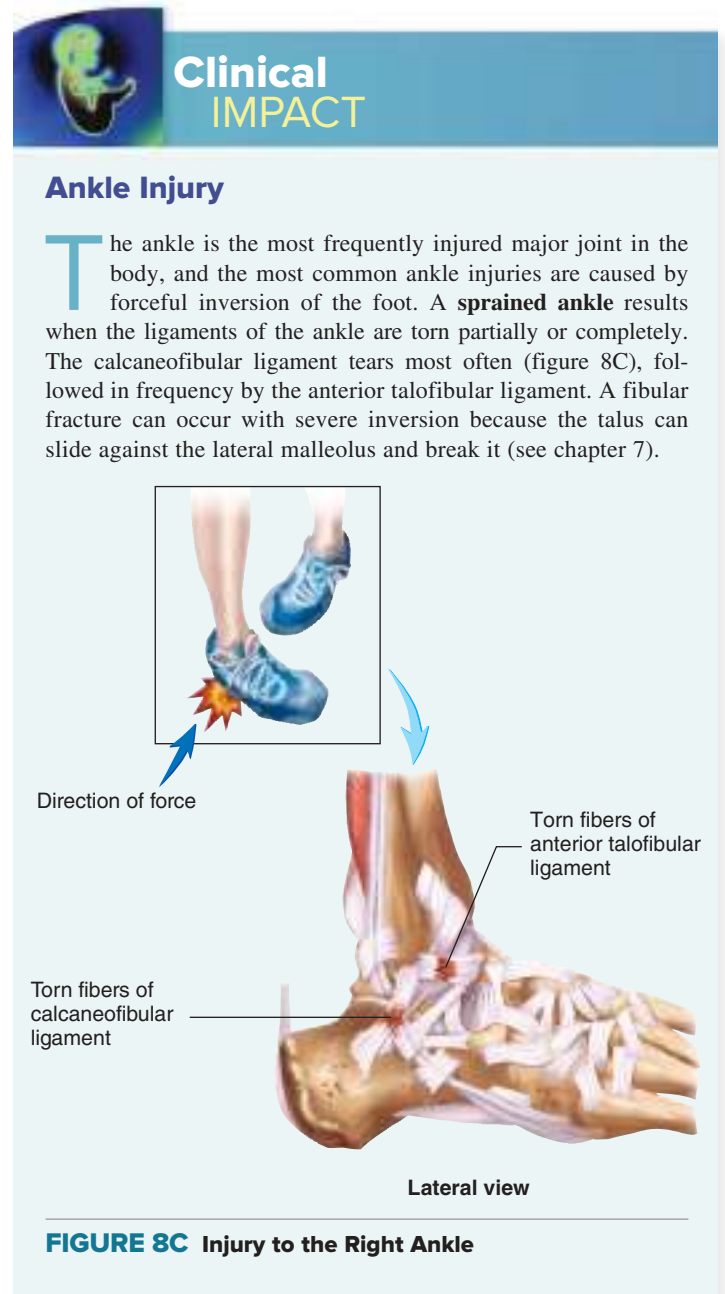

FIGURE 8C Injury to the Right Ankle

8.5 Effects of Aging on the Joints

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the effects of aging on the joints.
- Explain the most effective preventive measures against the effects of aging on the joints.

A number of changes occur within the joints as a person ages. Those that occur in synovial joints have the greatest impact and often present major problems for elderly people. In general, as a person ages, the tissues of the body become less flexible and less elastic, in part due to changes in protein structure caused by

Clinical IMPACT

Joint Replacement

As a result of recent advances in biomedical technology, many joints of the body can now be replaced by artificial ones. Joint replacement, called **arthroplasty**, was first developed in the late 1950s. One of its major purposes is to eliminate unbearable pain in patients in the age range of 55–60 who have joint disorders. Osteoarthritis is the leading disease requiring joint replacement and accounts for two-thirds of the patients. Rheumatoid arthritis accounts for more than half of the remaining cases.

The major design objectives for joint prostheses (artificial replacements) include developing stable articulations, low friction, solid fixation to the bone, and normal range

of motion. Biomedical engineers are designing synthetic replacement materials to accomplish these objectives. Prosthetic joints are usually composed of metal, such as stainless steel, titanium alloys, or cobalt-chrome alloys, in combination with modern plastics, such as high-density polyethylene, silastic, or elastomer.

The bone of the articular area is removed on one side (a procedure called **hemireplacement**) or on both sides (**total replacement**) of the joint, and the artificial articular areas are glued to the bone with a synthetic adhesive, such as methylmethacrylate. The smooth metal surface rubbing against the smooth plastic surface provides low-friction contact, with a range of movement that depends on the design.

The success of joint replacement depends on the joint being replaced, the age and condition of the patient, the state of the technology, and the definition of success. Success is usually defined as minimizing pain while maintaining movement. Most reports are based on examinations of patients 2–10 years after joint replacement. The technology is improving constantly, so current reports do not adequately reflect the effect of the most recent improvements. Still, reports indicate a success rate of 80–90% in hip replacements and 60% or more in ankle and elbow replacements. The major reason for the failure of prosthetic joints is loosening of the artificial joint from the bone to which it is attached. New prostheses with porous surfaces help overcome this problem.

age-related modifications that cross-link proteins together. These changes are most prevalent in long-lived proteins, such as collagen, which is abundant in fibrous connective tissue. Hence, the flexibility and strength of tendons and ligaments decrease with age. Tissue repair slows as cell proliferation rates decline and the rate of new blood vessel development decreases. These general changes can significantly affect synovial joints.

In addition, with use, the cartilage covering articular surfaces can wear down. When a person is young, the production of new,

resilient matrix compensates for the wear. However, as a person ages, the rate of replacement declines and the matrix becomes more rigid, thus increasing its rate of wear. The production rate of lubricating synovial fluid also declines with age, further contributing to the wear of the articular cartilage. Furthermore, the ligaments and tendons surrounding a joint shorten and become less flexible with age, resulting in decreased range of motion. With age, muscles, which strengthen the joints, also tend to weaken. Finally, many older people are less physically active, which

Diseases and Disorders

TABLE 8.6

Joints

Condition	Description
Arthritis	Inflammation of a joint, leading to pain and stiffness of the joint; over 100 causes, including infectious agents, metabolic disorders, trauma, and immune disorders
Degenerative joint disease (osteoarthritis)	Most common type of arthritis; affects 85% of Americans over age 70; characterized by gradual degeneration of a joint with advancing age; can be delayed with exercise
Rheumatoid arthritis	General connective tissue autoimmune disorder that predominantly affects joints
Gout	Group of metabolic disorders that lead to increased production and accumulation of uric acid crystals in tissues, including joint capsules; can lead to arthritis
Lyme disease	Caused by a bacterial infection that affects multiple organs, including the joints; can lead to chronic arthritis
Bursitis	Inflammation of a bursa, often due to forceful contact or prolonged contact, such as <i>student's elbow</i> from leaning on a desk
Bunion	Most bunions are deformations of the first metatarsal (the great toe); bursitis may accompany this deformity; irritated by tight shoes
Tendinitis	Inflammation of tendon sheaths, often from overuse, such as tennis elbow
Dislocation	Movement of bones out of their correct alignment at a joint; a partial dislocation is a <i>subluxation</i>
Sprain	Stretching or tearing of ligaments supporting a joint

causes the joints to become less flexible and decreases their range of motion.

The most effective preventive measure against the effects of aging on the joints is to strengthen the bones and muscles and maintain flexibility. This can be accomplished through a combination of regular physical activity, stretching, and a healthy diet.

ASSESS YOUR PROGRESS

23. List the age-related factors that contribute to cartilage wear in synovial joints.
24. Describe the age-related factors that cause loss of flexibility and loss of range of motion in synovial joints.
25. Discuss preventive measures to reduce age-related changes to joints.

Answer

Learn to Predict ◀ From page 242

To answer this question, we first need to review the functions of the major knee ligaments that stabilize the knee joint: the cruciate and collateral ligaments. The anterior cruciate ligament (ACL) prevents extreme anterior movement of the tibia relative to the femur, which can occur from twisting the leg, such as when playing sports. The posterior cruciate ligament (PCL) prevents extreme posterior movement of the tibia relative to the femur, which can occur from a hard blow, such as in a car crash. The medial collateral ligament (MCL) prevents excessive abduction of the knee and can be damaged from a lateral blow to the knee, such as from a tackle in football. The lateral collateral ligament (LCL) prevents excessive adduction of the knee and can be damaged from a blow to the inside of the knee, such as from a tackle in soccer, but is less common than MCL injuries. Among these, the function of the ACL most closely fits the description of Andy's injury. The ACL and MCL are the most commonly injured ligaments in ski accidents. The ACL stabilizes the

knee joint by stretching diagonally from the femur at the back of the joint to the tibia in the front, which normally prevents forward or anterior movement of the tibia from underneath the femur. It also resists medial rotation of the tibia. Thus, loss of the ACL increases mobility of the tibia in the anterior direction. This increased mobility can be detected using the anterior drawer test. In this test, the patient lies on his or her back with the hips flexed at a 45-degree angle, knees bent at a 90-degree angle, and feet flat on the examining table. A torn ACL yields increased mobility when the physician pulls the tibia forward (anterior direction) relative to the femur. Other physical tests can detect damage to the PCL, MCL, and LCL. In this case, the diagnosis of a torn ACL was confirmed by an MRI that revealed a complete tear of the ligament.

Answers to the rest of this chapter's Predict questions are in appendix G.

8.1 Classes of Joints (p. 243)

1. A joint, or an articulation, is a place where two bones come together.
2. Joints are named according to the bones or parts of bones involved.
3. Joints are classified structurally according to the type of connective tissue that binds them together and whether fluid is present between the bones.

Fibrous Joints

1. Fibrous joints, in which bones are connected by fibrous tissue with no joint cavity, are capable of little or no movement.
2. Sutures involve interdigitating bones held together by dense fibrous connective tissue. They occur between most skull bones.
3. Syndesmoses are joints consisting of fibrous ligaments.
4. Gomphoses are joints in which pegs fit into sockets and are held in place by periodontal ligaments (teeth in the jaws).
5. Some sutures and other joints can become ossified (synostoses).

Cartilaginous Joints

1. Synchondroses are immovable joints in which bones are joined by hyaline cartilage. Epiphyseal plates are examples.
2. Symphyses are slightly movable joints made of fibrocartilage.

Summary

Synovial Joints

1. Synovial joints are capable of considerable movement. They consist of the following:
 - Articular cartilage on the ends of bones that provides a smooth surface for articulation. Articular disks can provide additional support.
 - A joint cavity is surrounded by a joint capsule of fibrous connective tissue, which holds the bones together while permitting flexibility. A synovial membrane produces synovial fluid, which lubricates the joint.
2. Bursae are extensions of synovial joints that protect skin, tendons, or bone from structures that could rub against them.
3. Synovial joints are classified according to the shape of the adjoining articular surfaces: plane (two flat surfaces), saddle (two saddle-shaped surfaces), hinge (concave and convex surfaces), pivot (cylindrical projection inside a ring), ball-and-socket (rounded surface into a socket), and ellipsoid (ellipsoid concave and convex surfaces).

8.2 Types of Movement (p. 250)

1. Gliding movements occur when two flat surfaces glide over one another.
2. Angular movements include flexion and extension, plantar flexion and dorsiflexion, and abduction and adduction.
3. Circular movements include rotation, pronation and supination, and circumduction.
4. Special movements include elevation and depression, protraction and retraction, excursion, opposition and reposition, and inversion and eversion.
5. Combination movements involve two or more of the previously mentioned movements.

8.3 Range of Motion (p. 253)

Range of motion is the amount of movement, active or passive, that can occur at a joint.

8.4 Description of Selected Joints (p. 254)

1. The temporomandibular joint is a complex hinge and gliding joint between the temporal and mandibular bones. It is capable of elevation and depression, protraction and retraction, and lateral and medial excursion.
2. The shoulder joint is a ball-and-socket joint between the head of the humerus and the glenoid cavity of the scapula that permits a wide range of motion. It is strengthened by ligaments and the muscles of the rotator cuff. The tendon of the biceps brachii passes through the

joint capsule. The shoulder joint is capable of flexion and extension, abduction and adduction, rotation, and circumduction.

3. The elbow joint is a compound hinge joint between the humerus, the ulna, and the radius. Movement at this joint is limited to flexion and extension.
4. The hip joint is a ball-and-socket joint between the head of the femur and the acetabulum of the hipbone. It is greatly strengthened by ligaments and is capable of a wide range of motion, including flexion, extension, abduction, adduction, rotation, and circumduction.
5. The knee joint is a complex ellipsoid joint between the femur and the tibia that is supported by many ligaments. The joint allows flexion and extension and slight rotation of the leg.
6. The ankle joint is a special hinge joint of the tibia, the fibula, and the talus that allows dorsiflexion and plantar flexion and inversion and eversion.
7. Ligaments hold the bones of the foot arches and transfer weight in the foot.

8.5 Effects of Aging on the Joints (p. 263)

1. With age, the connective tissue of the joints becomes less flexible and less elastic. The resulting joint rigidity increases the rate of wear in the articulating surfaces. The changes in connective tissue also reduce the range of motion.
2. The effects of aging on the joints can be slowed by exercising regularly and consuming a healthy diet.

REVIEW AND COMPREHENSION

1. Which of these joints is *not* matched with the correct joint type?
 - a. parietal bone to occipital bone—suture
 - b. between the hipbones—symphysis
 - c. humerus and scapula—synovial
 - d. shafts of the radius and ulna—synchrondrosis
 - e. teeth in alveolar process—gomphosis
2. Which type of joint is the most movable?

a. sutures	c. symphyses	e. gomphoses
b. syndesmoses	d. synovial	
3. The intervertebral disks are examples of

a. sutures.	c. symphyses.	e. gomphoses.
b. syndesmoses.	d. synovial joints.	
4. Joints containing hyaline cartilage are called _____, and joints containing fibrocartilage are called _____.
 - a. sutures, synchrondroses
 - b. syndesmoses, symphyses
 - c. symphyses, syndesmoses
 - d. synchrondroses, symphyses
 - e. gomphoses, synchrondroses
5. The inability to produce the fluid that keeps most joints moist would likely be caused by a disorder of the

a. cruciate ligaments.	c. supination	e. extension
b. synovial membrane.	d. flexion	
c. articular cartilage.		
d. bursae.		
e. tendon sheath.		
6. Assume that a sharp object penetrated a synovial joint. Given these structures:
 - (1) tendon or muscle
 - (2) ligament
 - (3) articular cartilage
 - (4) fibrous capsule (of joint capsule)
 - (5) skin
 - (6) synovial membrane (of joint capsule)
 Choose the order in which they would most likely be penetrated.

a. 5,1,2,6,4,3	d. 5,1,2,4,3,6
b. 5,2,1,4,3,6	e. 5,1,2,4,6,3
c. 5,1,2,6,3,4	
7. Which of these joints is correctly matched with the type of joint?
 - a. atlas to occipital condyle—pivot
 - b. tarsal bones to metatarsal bones—saddle
 - c. femur to hipbone—ellipsoid
 - d. tibia to talus—hinge
 - e. scapula to humerus—plane
8. When you grasp a doorknob, what movement of your forearm is necessary to unlatch the door—that is, to turn the knob in a clockwise direction? (Assume using the right hand.)

a. pronation	c. supination	e. extension
b. rotation	d. flexion	
9. After the door is unlatched, what movement of the elbow is necessary to open it? (Assume the door opens in and you are on the inside.)

a. pronation	c. supination	e. extension
b. rotation	d. flexion	

10. After the door is unlatched, what movement of the shoulder is necessary to open it? (Assume the door opens in and you are on the inside.)
 - a. pronation
 - b. rotation
 - c. supination
 - d. flexion
 - e. extension
11. When grasping a doorknob, the thumb and finger undergo
 - a. opposition.
 - b. reposition.
 - c. lateral excursion.
 - d. medial excursion.
 - e. dorsiflexion.
12. A runner notices that the lateral side of her right shoe is wearing much more than the lateral side of her left shoe. This could mean that her right foot undergoes more _____ than her left foot.
 - a. eversion
 - b. inversion
 - c. plantar flexion
 - d. dorsiflexion
 - e. lateral excursion
13. For a ballet dancer to stand on her toes, her feet must
 - a. evert.
 - b. invert.
 - c. plantar flex.
 - d. dorsiflex.
 - e. abduct.
14. A meniscus is found in the
 - a. shoulder joint.
 - b. elbow joint.
 - c. hip joint.
 - d. knee joint.
 - e. ankle joint.
15. A lip (labrum) of fibrocartilage deepens the joint cavity of the
 - a. temporomandibular joint.
 - b. shoulder joint.
 - c. elbow joint.
 - d. knee joint.
 - e. ankle joint.
16. Which of these joints has a tendon inside the joint cavity?
 - a. temporomandibular joint
 - b. shoulder joint
 - c. elbow joint
 - d. knee joint
 - e. ankle joint
17. Which of these structures help stabilize the shoulder joint?
 - a. rotator cuff muscles
 - b. cruciate ligaments
 - c. medial and lateral collateral ligaments
 - d. articular disks
 - e. All of these are correct.
18. Bursitis of the subacromial bursa could result from
 - a. flexing the wrist.
 - b. kneeling.
 - c. overusing the shoulder joint.
 - d. running a long distance.
 - e. extending the elbow.
19. Which of these events does *not* occur with the aging of joints?
 - a. decrease in production of new cartilage matrix
 - b. decline in synovial fluid production
 - c. stretching of ligaments and tendons and increase in range of motion
 - d. weakening of muscles
 - e. increase in protein cross-linking in tissues

Answers in appendix E

CRITICAL THINKING

1. How would body function be affected if the sternal synchondroses and the sternocostal synchondrosis of the first rib were to become synostoses?
2. Using an articulated skeleton, describe the type of joint and the movement(s) possible for each of the following joints:
 - a. joint between the zygomatic bone and the maxilla
 - b. ligamentous connection between the coccyx and the sacrum
 - c. elbow joint
3. For each of the following muscles, describe the motion(s) produced when the muscle contracts. It may be helpful to use an articulated skeleton.
 - a. The biceps brachii muscle attaches to the coracoid process of the scapula (one head) and to the radial tuberosity of the radius. Name two movements that the muscle accomplishes in the forearm.
 - b. The rectus femoris muscle attaches to the anterior inferior iliac spine and the tibial tuberosity. How does contraction move the thigh? The leg?
 - c. The supraspinatus muscle is located in and attached to the supraspinatus fossa of the scapula. Its tendon runs over the head of the humerus to the greater tubercle. When it contracts, what movement occurs at the glenohumeral (shoulder) joint?
 - d. The gastrocnemius muscle attaches to the medial and lateral condyles of the femur and to the calcaneus. What movement of the leg results when this muscle contracts? Of the foot?
4. At first, Donnie's wife accused her once active 25-year-old husband of trying to get out of housework by constantly complaining about pain and stiffness in his lower back. But over the next 5 months, the pain and stiffness increased and seemed to be spreading up his vertebral column. The family doctor referred Donnie to a rheumatologist, who diagnosed ankylosing spondylitis (AS). AS, a chronic inflammation of joints at points where ligaments, tendons, and joint capsule insert into bone, causes fibrosis (the development of scar tissue), ossification, and fusion of joints. Combine your knowledge about bone growth, repair, and anatomy from chapters 6 and 7 and joint structure and function from this chapter to identify the category of joints primarily affected by AS, and explain how chronic inflammation of Donnie's joints led to their fusion.

Answers in appendix F

9

Learn to Predict

Winning a 1-month membership to a health club changed Bob's life. He gave up junk food and now works out daily. In one of his aerobic exercises, he slowly flexes his elbow and supinates his right hand while lifting a 35-pound weight; then he lowers the weight back to its starting position. He repeats this process several times. **After reading chapter 9 and building on your previous knowledge about bone anatomy and joints in chapters 7 and 8, explain how Bob's muscles are able to lift and lower the weight slowly.**

Photo: Skeletal muscle cells lie parallel to each other, forming powerful units such as the one shown in this scanning electron micrograph. Tiny levers rhythmically pull one protein strand past another, shortening (contracting) the cell.

Muscular System

HISTOLOGY AND PHYSIOLOGY

In order to turn the pages of this chapter, move your eyes across the page, and continue breathing, electrical impulses must travel to millions of tiny motors throughout your body. These “motors” are really your muscle cells, which, on receiving a nerve impulse, convert chemical ATP energy into the mechanical energy of moving cell parts. The body has three types of muscle tissue, each with a different purpose. The muscles you voluntarily control are called skeletal muscles, and they work with the skeletal system to produce coordinated movements of your limbs. The digestive, cardiovascular, urinary, and reproductive systems all use smooth muscle to propel materials through the body. The heart contains specialized cardiac muscle tissue to pump blood. No matter where muscle tissues are in the body, they all share the same feature: contraction.

9.1 Functions of the Muscular System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Summarize the major characteristics of skeletal, smooth, and cardiac muscle.**
- B. Summarize the functions of the muscular system.**

Most of the body's movements, from the beating of the heart to the running of a marathon, result from muscle contractions. As described in chapter 4, there are three types of muscle tissue: skeletal, smooth, and cardiac. Because skeletal muscle is the most abundant and most studied type, this chapter examines the physiology of skeletal muscle in greatest detail. Chapter 10 focuses on the anatomy of the skeletal muscle system.

Types of Muscle Tissue

Table 9.1 compares the major characteristics of skeletal, smooth, and cardiac muscle. Skeletal muscle, with its associated connective tissue, constitutes about 40% of the body's weight and is responsible for locomotion, facial expressions, posture, respiratory functions, and many other body movements. The nervous system voluntarily, or consciously, controls the functions of the skeletal muscles.

Smooth muscle is the most widely distributed type of muscle in the body. It is found in the walls of hollow organs, such as the stomach and uterus, and tubes, such as blood vessels and the ducts of certain glands. This muscle type is also found in the iris of the eye for pupil dilation. Smooth muscle performs a variety of functions, including propelling urine through the urinary tract, mixing food in the stomach and the small intestine, dilating and constricting the pupil of the eye, and regulating the flow of blood through blood vessels.

Cardiac muscle is found only in the heart, and its contractions provide the major force for moving blood through the circulatory system. Unlike skeletal muscle, cardiac muscle and many smooth muscles can contract spontaneously and rhythmically. This property is autorhythmicity; nervous or hormonal stimulation is not always required for them to contract. Furthermore, unlike skeletal muscle, smooth muscle and cardiac muscle are not consciously controlled by the nervous system. Rather, they are controlled involuntarily, or unconsciously, by the autonomic nervous and endocrine systems (see chapters 16 and 18).

The following list summarizes the major functions of all three types of muscle:

1. *Movement of the body.* Most skeletal muscles are attached to bones and are responsible for the majority of body movements, including walking, running, chewing, and manipulating objects with the hands.
2. *Maintenance of posture.* Skeletal muscles constantly maintain tone, which keeps us sitting or standing erect.

TABLE 9.1 Comparison of Muscle Types

	Skeletal Muscle	Smooth Muscle	Cardiac Muscle
Location	Attached to bones	Walls of hollow organs, blood vessels, eyes, glands, and skin	Heart
Appearance			
Cell Shape	Very long and cylindrical (1 mm–4 cm, or as much as 30 cm, in length, 10 μm–100 μm in diameter)	Spindle-shaped (15–200 μm in length, 5–8 μm in diameter)	Cylindrical and branched (100–500 μm in length, 12–20 μm in diameter)
Nucleus	Multiple nuclei: peripherally located	Single, centrally located	Single, centrally located
Special Cell-to-Cell Attachments	None	Gap junctions join some visceral smooth muscle cells together	Intercalated disks join cells to one another
Striations	Yes	No	Yes
Control	Voluntary and involuntary (reflexes)	Involuntary	Involuntary
Capable of Spontaneous Contraction	No	Yes (some smooth muscle)	Yes
Function	Body movement	Moving food through the digestive tract, emptying the urinary bladder, regulating blood vessel diameter, changing pupil size, contracting many gland ducts, moving hair, and having many other functions	Pumping blood; contractions provide the major force for propelling blood through blood vessels

3. *Respiration.* Skeletal muscles of the thorax carry out breathing movements.
4. *Production of body heat.* When skeletal muscles contract, heat is given off as a by-product. This released heat is critical for maintaining body temperature.
5. *Communication.* Skeletal muscles are involved in all aspects of communication, including speaking, writing, typing, gesturing, and smiling or frowning.
6. *Constriction of organs and vessels.* The contraction of smooth muscle within the walls of internal organs and vessels causes those structures to constrict. This constriction can help propel and mix food and water in the digestive tract; remove materials from organs, such as the urinary bladder or sweat glands; and regulate blood flow through vessels.
7. *Contraction of the heart.* The contraction of cardiac muscle causes the heart to beat, propelling blood to all parts of the body.

ASSESS YOUR PROGRESS

1. List and describe the functions performed by skeletal muscle tissue.
2. State the functions of smooth and cardiac muscle tissues.
3. Using table 9.1, distinguish among skeletal, smooth, and cardiac muscle tissues as to their locations, appearance, cell shape, and cell-to-cell attachments.

9.2 General Properties of Muscle Tissue

LEARNING OUTCOME

After reading this section, you should be able to

- A. Explain the four functional properties of muscle tissue.

Muscle tissue is highly specialized. It has four major functional properties: contractility, excitability, extensibility, and elasticity.

1. **Contractility** is the ability of muscle to shorten forcefully, or contract. For example, lifting this textbook requires certain muscles to contract. When muscle contracts, it either causes the structures to which it is attached (such as a bone) to move or increases pressure inside a blood vessel or a hollow organ, such as the intestine. On the other hand, it lengthens passively. Forces that oppose contraction cause muscles to lengthen. Examples of this type of force include gravity pulling on a limb and the pressure of fluid in a hollow organ, such as urine in the bladder. Thus, muscle shortening is forceful and muscle lengthening is passive.
2. **Excitability** is the capacity of muscle to respond to an electrical stimulus. Normally, the stimulus is from nerves that we consciously control. For instance, if you decide to wave to a friend, the conscious decision to lift your arm is sent via nerves. Smooth muscle and cardiac muscle also respond to stimulation by nerves and hormones but can sometimes contract spontaneously.
3. **Extensibility** means a muscle can be stretched beyond its normal resting length and still be able to contract. If you

stretch to reach a dropped pencil, your muscles are longer than they are normally, but you can still retrieve the pencil.

4. **Elasticity** is the ability of muscle to spring back to its original resting length after it has been stretched. Taking a deep breath demonstrates elasticity because exhalation is simply the recoil of your respiratory muscles back to the resting position, similar to releasing a stretched rubberband.

ASSESS YOUR PROGRESS

4. Identify the four specialized functional properties of muscle tissue, and give an example of each.
5. Outline the differences in control and function for skeletal, smooth, and cardiac muscle.

9.3 Skeletal Muscle Anatomy

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the connective tissue components of skeletal muscle.
- B. Explain the blood supply and innervation of skeletal muscle.
- C. Discuss the origin of muscle fibers and explain how muscle hypertrophy occurs.
- D. Describe the components of a muscle fiber.
- E. Relate the types of myofilaments and describe their structures.
- F. Produce diagrams that illustrate the arrangement of myofilaments in a sarcomere.
- G. Describe how the sliding filament model explains the contraction of muscle fibers.
- H. Explain what happens to the length of the A band, I band, and H zone during contraction.

Whole Skeletal Muscle Anatomy

Each skeletal muscle is a complete organ consisting of cells, called **skeletal muscle fibers**, associated with smaller amounts of connective tissue, blood vessels, and nerves. The connective tissue fibers that surround a muscle and its internal components extend beyond the center of the muscle to become tendons, which connect muscles to bones or to the dermis of the skin (figure 9.1).

Connective Tissue Coverings

A muscle is composed of numerous visible bundles called muscle **fascicles** ((fas'i-klz) sing. fã-sik'u-lus). Each fasciculus is surrounded by a connective tissue layer called the **perimyseum** (per'i-miz'ē-üm, per'i-mis'ē-üm). The entire muscle is surrounded by a layer of dense irregular collagenous connective tissue called the **epimysium** (ep-ĩ-mis'ē-üm). **Fascia** (fash'ē-ã) is a general term for sheets of dense irregular collagenous connective tissue within the body. **Muscular fascia** is located superficial to the epimysium and separates individual muscles or groups of muscles.

FIGURE 9.1 Whole Skeletal Muscle Structure: Connective Tissue, Innervation, and Blood Supply

A muscle is composed of muscle fascicles, each surrounded by perimysium. The fascicles are composed of bundles of individual muscle fibers (muscle cells), each surrounded by endomysium. This figure shows the relationship among muscle fibers, fascicles, and associated connective tissue layers: the epimysium, perimysium, and endomysium. Arteries, veins, and nerves course together through the connective tissue of muscles. They branch frequently as they approach individual muscle fibers. At the level of the perimysium, axons of neurons branch, and each branch extends to a muscle fiber. **APR**

Nerves and Blood Vessels

Skeletal muscles have a rich supply of blood vessels and nerves (figure 9.1). The specialized nerve cells responsible for stimulating skeletal muscle contraction are called **motor neurons**. Motor neurons originate in the brain and spinal cord and extend to skeletal muscle fibers through nerves. At the fascicles, the axons of motor neurons branch repeatedly, each branch projecting toward the center of one muscle fiber. Every skeletal muscle fiber in the body is in contact with a branch of a motor neuron. The contact points between the axons and the muscle fibers, called synapses or neuromuscular junctions, are described later in this section. Each motor neuron innervates more than one muscle fiber. However, more than one motor neuron innervates most whole muscles.

An artery and either one or two veins extend together with a nerve through the connective tissue layers of skeletal muscles. Numerous branches of the arteries supply the extensive capillary beds surrounding the muscle fibers, and blood is carried away from the capillary beds by branches of the veins.

Skeletal Muscle Fiber Anatomy

The cells found in skeletal muscle are highly specialized with a unique structure. As previously noted, each cell is called a muscle fiber. Skeletal muscle fibers are long, cylindrical cells, each with several nuclei located near the plasma membrane. A single fiber can extend the entire length of a muscle. In most muscles, the fibers range from approximately 1 millimeter (mm) to about 4 centimeters (cm) in length and from 10 micrometers (μm) to

FIGURE 9.2 Skeletal Muscle Fibers

Skeletal muscle fibers in longitudinal section. 

100 μm in diameter. For comparison, a skin cell is approximately 30 μm in diameter and a red blood cell is about 8 μm in diameter. Keep in mind that the naked eye can only see objects around 500 μm in size. Large muscles contain many large-diameter fibers, whereas small, delicate muscles contain many small-diameter fibers. However, most muscles contain a mixture of small- and large-diameter fibers. As seen in a longitudinal section, alternating light and dark bands give the muscle fiber a **striated** (strī'at-ed; banded), or striped, appearance (figure 9.2).

Muscle Fiber Development

Muscle fibers develop from less mature, multinucleated cells called **myoblasts** (mī'ō-blāsts). The multiple nuclei found in skeletal muscle fibers result from the fusion of myoblast precursor cells, not from the division of nuclei within myoblasts. Myoblasts differentiate into functional muscle fibers as contractile proteins accumulate within their cytoplasm. Shortly after the myoblasts form, nerves begin to innervate the developing muscle fibers.

The number of skeletal muscle fibers remains relatively constant after birth. Enlargement, or **hypertrophy**, of muscles in children and adults results from an increase in the *size* of each muscle fiber, not from a substantial increase in the *number* of muscle fibers. Similarly, hypertrophy of muscles in response to exercise is due mainly to an increase in muscle fiber size, rather than an increase in number.

Histology of Muscle Fibers

Muscle contraction is much easier to understand when we consider the structure of a muscle fiber (figure 9.3). The plasma membrane of a muscle fiber is called the **sarcolemma** (sar'kō-lem'ă; sarco, flesh + lemma, husk). Two delicate connective tissue layers are located just outside the sarcolemma. The deeper and thinner of the two is the **external lamina**. It consists mostly of reticular (collagen) fibers and is so thin that to see it, a powerful electron microscope is needed. The second layer also consists mostly of reticular fibers, but it is a much thicker layer, called the **endomysium** (en'dō-miz'ē-ŭm; en'dō-mis'ē-ŭm; mys, muscle).

Along the surface of the sarcolemma are many tubelike invaginations of the sarcolemma, called **transverse tubules**, or **T tubules**. They occur at regular intervals along the muscle fiber and extend inward, connecting the extracellular environment with the interior of the muscle fiber (figure 9.3b). The T tubules lie adjacent to the highly organized smooth endoplasmic reticulum, called the **sarcoplasmic reticulum** (sar-kō-plaz'mik re-tik'ū-lŭm), in skeletal muscle fibers. Other organelles, such as the numerous mitochondria and energy-storing glycogen granules, are packed into the cell and constitute the cytoplasm, which in muscles is called the **sarcoplasm** (sar'kō-plazm).

The sarcoplasm also contains numerous bundles of protein filaments called **myofibrils** (mī'ō-ft'brilz). Each myofibril is a threadlike structure, approximately 1–3 μm in diameter, that extends the length of the muscle fiber. When considering the diameter of the muscle fibers, a helpful comparison is a human hair, which is 17 μm in diameter. A myofibril contains two kinds of long, thin protein filaments, called **myofilaments** (mī'ō-fil'ă-ments; figure 9.3c). **Actin** (ak'tin) **myofilaments**, or thin myofilaments, are approximately 8 nanometers (nm) in diameter and 1000 nm in length, whereas **myosin** (mī'ō-sin) **myofilaments**, or thick myofilaments, are approximately 12 nm in diameter and 1800 nm in length. In comparison, the common cold virus is 30 nm in diameter. The actin and myosin myofilaments are arranged into highly ordered units called **sarcomeres** (sar'kō-mērz), which join end to end to form the myofibrils (figure 9.4a).

ASSESS YOUR PROGRESS

6. Name the connective tissue layers that surround muscle fibers, muscle fascicles, and whole muscles. Distinguish between a sarcolemma and muscular fascia.
7. What are motor neurons? How do the axons of motor neurons and blood vessels extend to muscle fibers?
8. What is the origin of muscle fibers? How do you explain the enlargement of muscle fibers?
9. What are T tubules and the sarcoplasmic reticulum?
10. Describe myofibrils and myofilaments.

Sarcomeres

The sarcomere is the basic structural and functional unit of skeletal muscle because it is the smallest portion of skeletal muscle capable of contracting. Structures called Z disks separate one sarcomere from the next. A Z disk is a filamentous network

FIGURE 9.3 Parts of a Muscle

(a) Part of a muscle attached by a tendon to a bone. (b) Enlargement of one muscle fiber. The muscle fiber contains several myofibrils. (c) A myofibril extended out the end of the muscle fiber. The banding patterns of the sarcomeres are shown in the myofibril. (d) A single sarcomere of a myofibril is composed of actin myofilaments and myosin myofilaments. The Z disk anchors the actin myofilaments, and the myosin myofilaments are held in place by titin molecules and the M line.

of protein that forms a stationary anchor for the attachment of actin myofilaments. Each sarcomere extends from one Z disk to the next Z disk (figures 9.4 and 9.5). The arrangement of the actin and myosin myofilaments gives the myofibril a banded, or striated, appearance when viewed longitudinally. Each sarcomere consists of two light-staining bands separated by a dark-staining band (see figure 9.4a). The light-staining bands are called isotropic (*i-sō-trop'ik*; uniform) bands, or I bands. Each I band includes a Z disk and extends to the ends of the myosin myofilaments. When seen in longitudinal and cross sections, the I band on either side of a Z disk consists only of actin myofilaments.

The dark-staining band in the center of each sarcomere is called an anisotropic (*an-i-sō-trop'ik*; not uniform) band, or A band. Each A band extends the length of the myosin myofilament within a sarcomere. The actin and myosin myofilaments overlap for some distance at both ends of the A band. In a cross

section of the A band where actin and myosin myofilaments overlap, each myosin myofilament is visibly surrounded by six actin myofilaments. In the center of each A band is a smaller band, called the H zone, where the actin and myosin myofilaments do not overlap and only myosin myofilaments are present. A dark line, called the M line, is in the middle of the H zone and consists of delicate filaments that attach to the center of the myosin myofilaments. The M line helps hold the myosin myofilaments in place, similar to the way the Z disk holds actin myofilaments in place (figure 9.5b,c). The numerous myofibrils are oriented within each muscle fiber so that A bands and I bands of parallel myofibrils are aligned and thus produce the striated pattern seen through a microscope. In addition to actin and myosin, there are other, less visible proteins within sarcomeres. These proteins help hold actin and myosin in place, and one of them accounts for a muscle's ability to stretch (extensibility) and to recoil (elasticity). Titin (*ti'tin*; see figure 9.3) is one of the

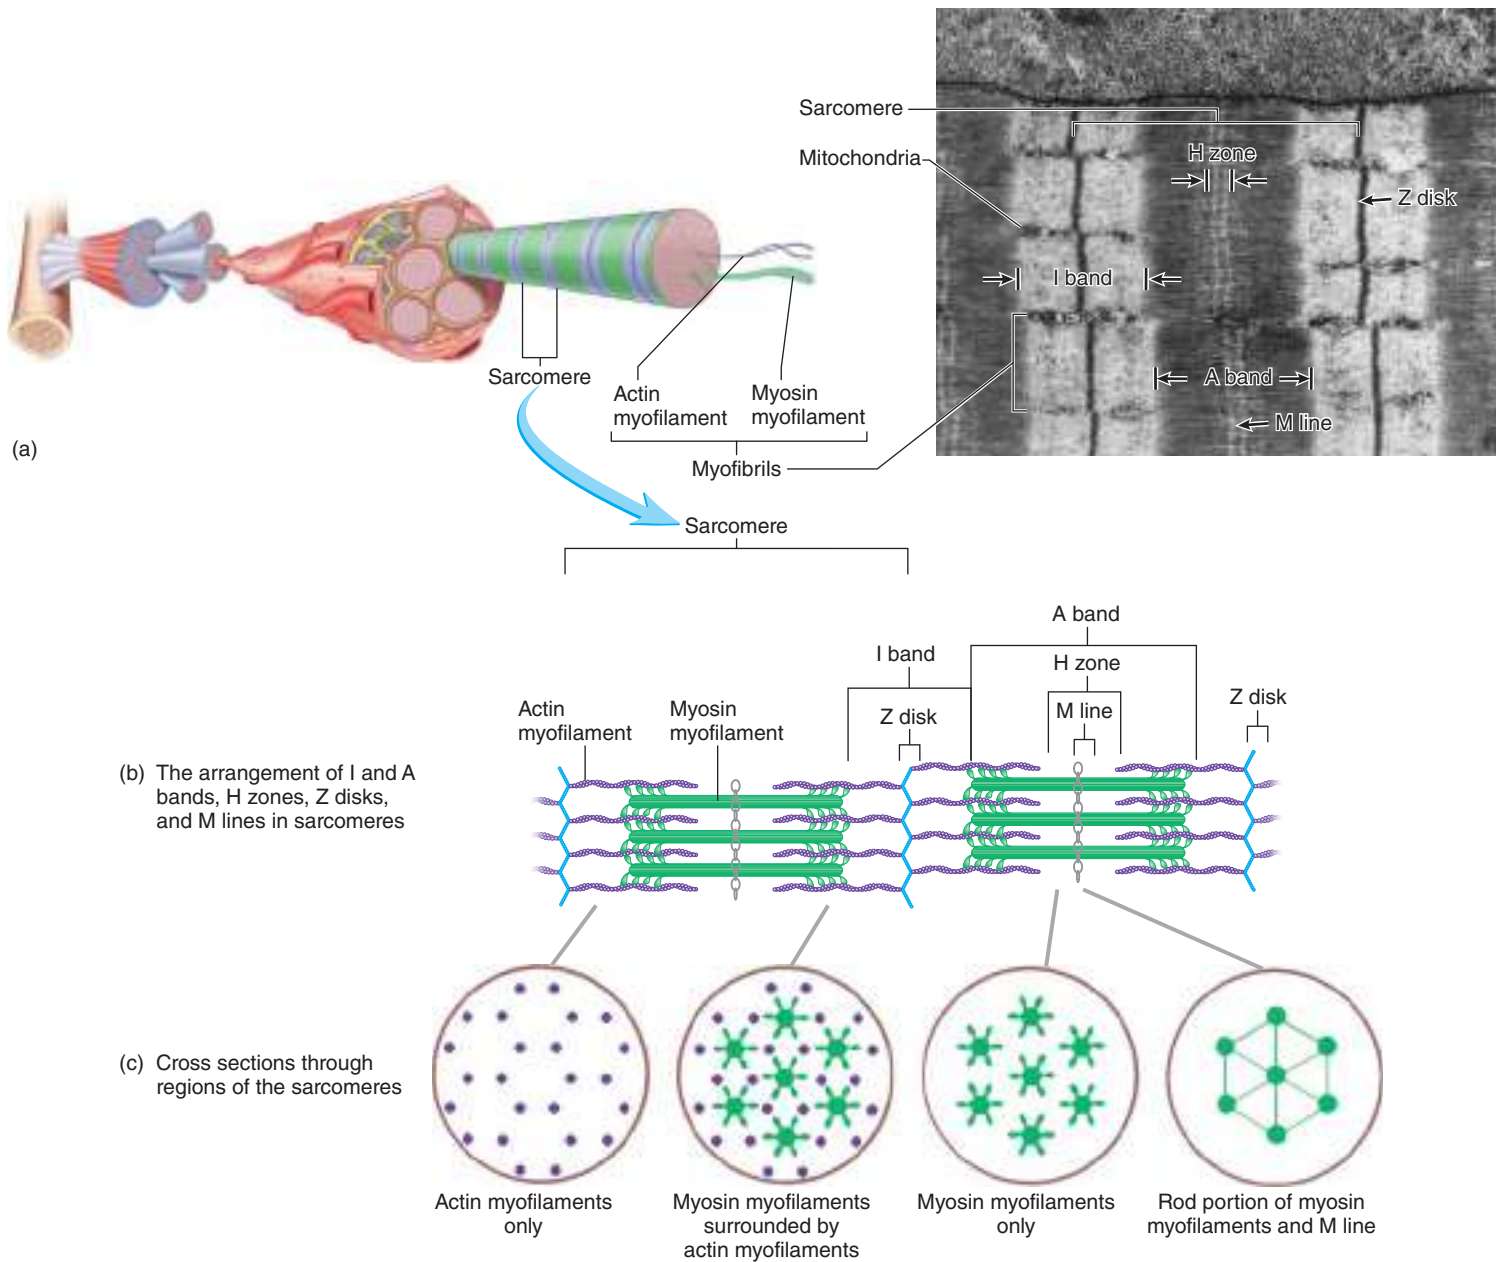

FIGURE 9.4 Organization of Sarcomeres

(a) Electron micrograph of a skeletal muscle. Several sarcomeres are shown in the myofibrils of a muscle fiber. (b) Diagram of two adjacent sarcomeres, depicting structures responsible for the banding pattern. The I band is between the ends of myosin myofilaments on each side of a Z disk. The A band is formed by the myosin myofilaments within a sarcomere. The H zone is between the ends of the actin myofilaments within a sarcomere. Myosin myofilaments are attached to the M line. (c) Cross sections through regions of the sarcomeres show the arrangement of proteins in three dimensions.

largest known proteins, consisting of a single chain of nearly 27,000 amino acids. It attaches to Z disks and extends along myosin myofilaments to the M line. The myosin myofilaments are attached to the titin molecules, which help hold them in position. Part of the titin molecule in the I band functions as a spring, allowing the sarcomere to stretch and recoil.

Actin and Myosin Myofilament Structure

Each actin myofilament is composed of two strands of **fibrous actin (F actin)**, a series of **tropomyosin** (trō-pō-mī'ō-sin)

molecules, and a series of **troponin** (trō'pō-nin) **molecules** (figure 9.5b,c). The two strands of F actin are coiled to form a double helix, which extends the length of the actin myofilament. Each F actin strand is a polymer of approximately 200 small, globular units called **globular actin (G actin)** monomers. Each G actin monomer has an active site, to which myosin molecules can bind during muscle contraction. Tropomyosin is an elongated protein that winds along the groove of the F actin double helix. Each tropomyosin molecule is sufficiently long to cover seven G actin active sites. Troponin is composed of three subunits: one that

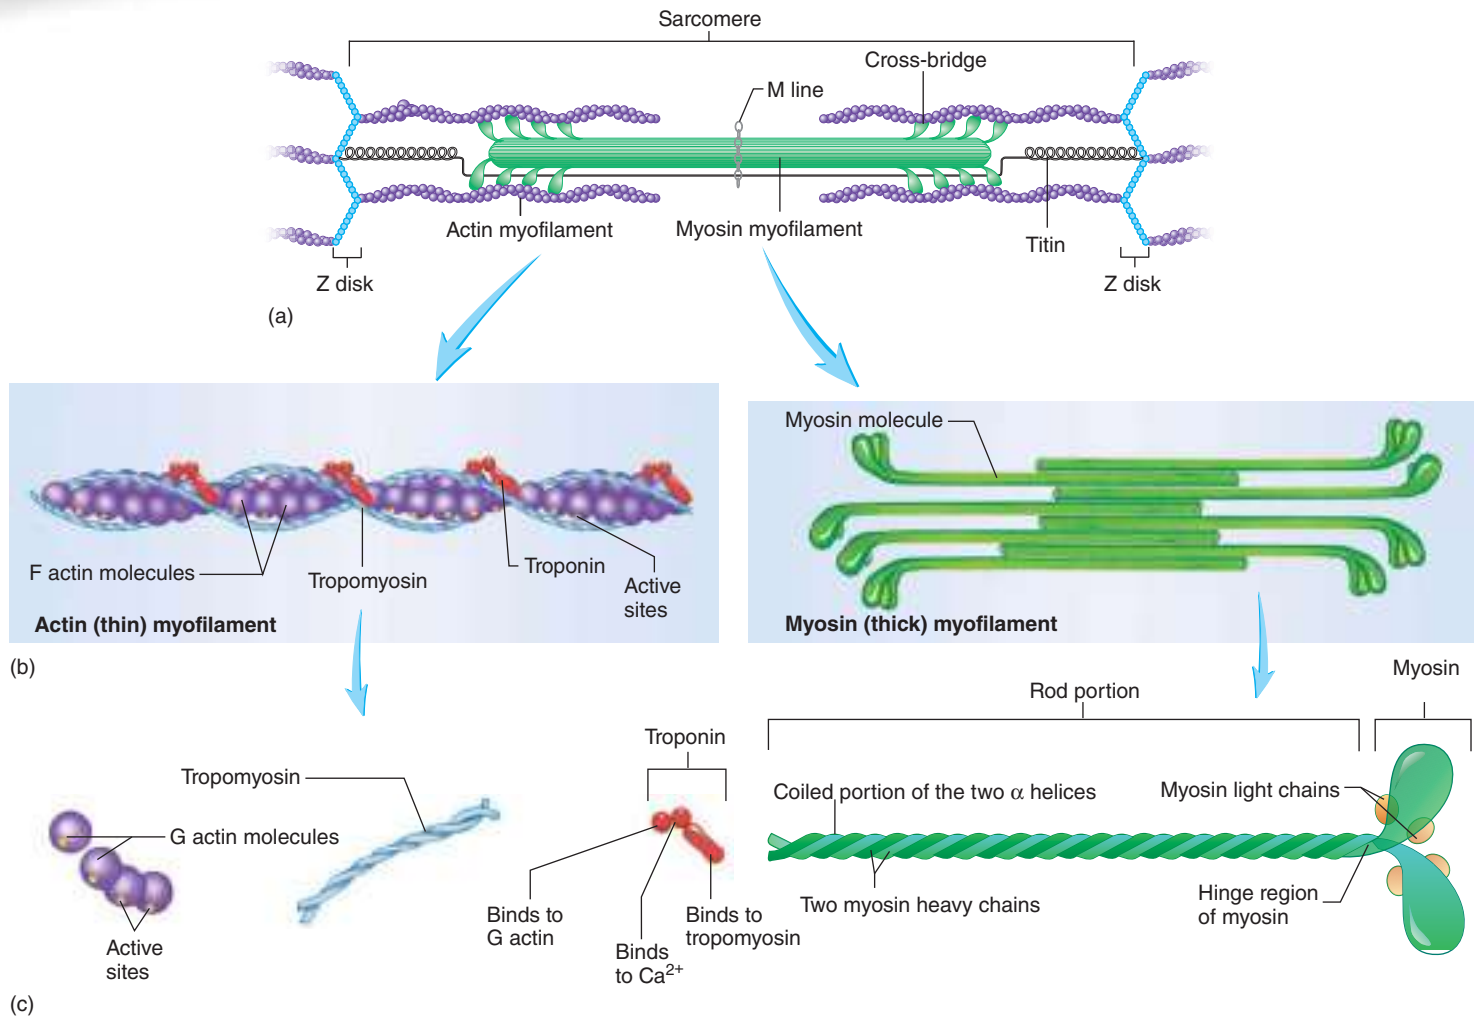

FIGURE 9.5 Structure of Actin and Myosin

(a) The sarcomere consists of actin (thin) myofilaments, attached to the Z disks, and myosin (thick) myofilaments, suspended between the actin myofilaments. (b) Actin myofilaments are composed of F actin (chains of purple spheres), tropomyosin (blue strands), and troponin (red spheres and rod). Myosin myofilaments are made up of many golf-club-shaped myosin molecules, with all the heads pointing in one direction at one end and the opposite direction at the other end. (c) G actin molecules (purple spheres), with their active sites (yellow), tropomyosin, and troponin, make up actin myofilaments. Myosin molecules (green) are golf-club-shaped structures composed of two molecules of heavy myosin wound together to form the rod portion and double globular heads. Four small, light myosin molecules are located on the heads of each of the myosin molecules. **APR**

binds to actin, a second that binds to tropomyosin, and a third that has a binding site for Ca^{2+} . The troponin molecules are spaced between the ends of the tropomyosin molecules in the groove between the F actin strands. The complex of tropomyosin and troponin regulates the interaction between active sites on G actin and myosin.

Myosin myofilaments are composed of many elongated **myosin molecules** shaped like golf clubs (figure 9.5*b,c*). Each myosin molecule consists of two **myosin heavy chains** wound together to form a **rod portion** lying parallel to the myosin myofilament and two **myosin heads** that extend laterally (figure 9.5*b*; see figure 9.3*d*). Four light myosin chains are attached to the heads of each myosin molecule. Each myosin myofilament consists of about 300 myosin molecules arranged so that about 150 of them have their heads projecting toward each end. The centers of the

myosin myofilaments consist of only the rod portions of the myosin molecules. The myosin heads have three important properties: (1) The heads can bind to active sites on the actin molecules to form **cross-bridges**; (2) the heads are attached to the rod portion by a hinge region that can bend and straighten during contraction; and (3) the heads are ATPase enzymes, which break down adenosine triphosphate (ATP), releasing energy. Part of the energy is used to bend the hinge region of the myosin molecule during contraction.

Neuromuscular Junction Structure

Recall that each muscle fiber is in contact with a branch of a motor neuron axon from the brain or spinal cord (see figure 9.1). The motor neurons carry electrical signals called **action potentials**, which stimulate muscle fiber action potentials followed by muscle

contraction. The point of contact of motor neuron axon branches with the muscle fiber is called the **neuromuscular junction**, or **synapse** (figure 9.6).

The neuromuscular junction consists of a group of enlarged axon terminals that rests in an invagination of the sarcolemma. Therefore, a neuromuscular junction consists of the axon terminals and the area of the muscle fiber sarcolemma they innervate. Each axon terminal is the presynaptic (prē'si-nap'tik) terminal. The space between the presynaptic terminal and the muscle fiber is the synaptic (si-nap'tik) cleft, and the muscle plasma membrane in the area of the junction is the postsynaptic (pōst-si-nap'tik) membrane, or motor end-plate (figure 9.6). Each presynaptic terminal contains numerous mitochondria and many small, spherical sacs approximately 45 μm in diameter, called synaptic vesicles. The vesicles contain **acetylcholine** (as-e-til-kō'lēn; **ACh**), an organic molecule composed of acetic acid and choline. Acetylcholine is a neurotransmitter (noor' ð-transmit'er), a substance released from a presynaptic membrane that diffuses across the synaptic cleft and alters the activity of the postsynaptic cell. Neurotransmitters can stimulate (or inhibit) the production of an

action potential in the postsynaptic membrane (the sarcolemma) by binding to ligand-gated ion channels.

Sliding Filament Model

The primary function of skeletal muscle cells is to generate force by contracting, or shortening. The parallel arrangement of myofilaments in a sarcomere allows them to interact, which causes muscle contraction. This interaction is described by the sliding filament model (figure 9.7).

When a muscle contracts, the actin and myosin myofilaments in the sarcomere slide past one another but remain the same length as when the muscle is at rest. When the myofilaments slide past each other and the sarcomeres shorten, the myofibrils also shorten because the myofibrils consist of sarcomeres joined end to end. The myofibrils extend the length of the muscle fibers, and when they shorten the muscle fibers shorten. Groups of muscle fibers make up a muscle fasciculus, and several muscle fascicles make up a whole muscle. Therefore, when sarcomeres shorten, myofibrils, muscle fibers, muscle fascicles, and muscles shorten to produce muscle contraction.

FIGURE 9.6 Neuromuscular Junction

(a) Several branches of an axon form the neuromuscular junction with a single muscle fiber. (b) The presynaptic terminal containing synaptic vesicles is separated from the postsynaptic membrane (sarcolemma) by the synaptic cleft. This region of the postsynaptic membrane is specialized and is shown in blue.

(c) Photomicrograph of neuromuscular junctions. **APR**

**(a) Relaxed sarcomere**

In a relaxed muscle, the actin and myosin myofilaments overlap slightly, and the H zone is visible. The sarcomere length is at its normal resting length. As a muscle contraction is initiated, actin myofilaments slide past the myosin myofilaments, the Z disks are brought closer together, and the sarcomere begins to shorten.

**(b) Fully contracted sarcomere**

In a contracted muscle, the A bands, which are equal to the length of the myosin myofilaments, do not narrow because the length of the myosin myofilaments does not change, nor does the length of the actin myofilaments. In addition, the ends of the actin myofilaments are pulled to and overlap in the center of the sarcomere, shortening it and the H zone disappears.

FIGURE 9.7 Sarcomere Shortening 

During muscle relaxation, the sarcomeres lengthen. For this to happen, an external force must be applied to a muscle by other muscles or by gravity. For example, muscle contraction causes a joint, such as the elbow or knee, to flex. Extension of the joint

and lengthening of the muscle result from the contraction of muscles that produce the opposite movement (see chapter 10). However, knowing the mechanism by which muscles shorten is a small step toward understanding muscle contraction. What stimulates the sarcomeres to shorten in the first place? In order to fully understand muscle contraction, we must first consider the electrical properties of skeletal muscle fibers.

ASSESS YOUR PROGRESS

11. How do G actin, F actin, tropomyosin, and troponin combine to form an actin myofilament? Name the ion or molecule to which each of the three subunits of troponin binds.
12. Describe the structure of myosin molecules and how they combine to form a myosin myofilament.
13. List the three important properties of a myosin head. What is a cross-bridge?
14. What is a sarcomere? Illustrate how Z disks, actin myofilaments, myosin filaments, the M line, and titin form a sarcomere. Describe how this arrangement produces the A band, the I band, and the H zone. Label these areas on your illustration.
15. How does the shortening of sarcomeres explain muscle contraction?
16. What must occur for a muscle to relax?
17. Referring to figure 9.7, explain why the I band and H zone shorten during muscle contraction, while the length of the A band remains unchanged.

9.4 Skeletal Muscle Fiber Physiology

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the resting membrane potential and how it is generated and maintained.**
- B. Explain the role of ion channels in the production of an action potential.**
- C. Discuss the production of an action potential, including depolarization and repolarization.**
- D. State the all-or-none principle as it pertains to action potentials.**
- E. Describe the structure of a neuromuscular junction and explain how an action potential is transmitted across the junction.**
- F. Explain the events of excitation-contraction coupling.**
- G. Summarize the events of cross-bridge movement and relate them to muscle contraction.**
- H. State the conditions needed for muscle relaxation.**

Excitability of Muscle Fibers

Muscle fibers, like other cells of the body, are electrically excitable. A description of the electrical properties of skeletal muscle fibers is presented next, and later sections illustrate the role of these properties in contraction. Action potentials travel from the brain or spinal cord along the axons to muscle fibers and cause them to contract.

Electrically excitable cells, like other cells, are polarized. That is, the inside of most plasma membranes is negatively charged compared with the outside. Thus, a voltage difference, or electrical charge difference, exists across each plasma membrane. This charge difference across the plasma membrane of an unstimulated cell is called the resting membrane potential (figure 9.8; see figure 11.14).

Ion Channels

In order to understand the electrical properties of skeletal muscle fibers, a review of the permeability characteristics of cell membranes and the role membrane transport proteins play in their permeability will be helpful. The phospholipid bilayer interior is a hydrophobic environment, which inhibits the movement of charged particles, particularly ions, across the membrane; however, the basis of the electrical properties of skeletal muscle cells is the movement of ions across the membrane. Recall from chapter 3 that ions can move across the membrane through ion channels. There are two major types of ion channels: nongated, or leak, and gated. These two channel types contribute to the electrical properties of both a resting cell and a stimulated cell. In resting cells, the nongated ion channels allow for the slow leak of ions down their concentration gradient. Like all membrane transport proteins, leak channels are specific for a particular ion. The gated ion channels are most important in stimulated cells. It is their presence that governs the production of action potentials. There are two major gated ion channels:

1. **Ligand-gated ion channels.** **Ligand-gated ion channels** open when a ligand (lī'gand), a chemical signal such as a neurotransmitter, binds to a receptor that is part of the ion channel (see figure 3.8). For example, the axons of neurons supplying skeletal muscle fibers release a **neurotransmitter**, which binds to ligand-gated Na^+ channels in the membranes of the muscle fibers. As a result, the Na^+ channels open, allowing Na^+ to enter the cell.
2. **Voltage-gated ion channels.** These channels are gated membrane channels that open and close in response to a particular membrane potential. When a neuron or muscle fiber is stimulated, the charge difference changes, and a particular charge causes certain voltage-gated ion channels to open or close. The voltage-gated channels that play major roles in an action potential are voltage-gated Na^+ , K^+ , and Ca^{2+} channels. For example, opening voltage-gated Na^+ channels allows Na^+ to cross the plasma membrane, whereas opening voltage-gated K^+ channels allows K^+ to cross and opening Ca^{2+} channels allows Ca^{2+} to cross.

The Resting Membrane Potential

Action potentials cannot be produced without a resting membrane potential. The resting membrane potential is the result of three factors: (1) The concentration of K^+ inside the plasma membrane

is higher than that outside the plasma membrane, (2) the concentration of Na^+ outside the plasma membrane is higher than that inside the plasma membrane, and (3) the plasma membrane is more permeable to K^+ than to Na^+ . Because the concentration gradient for an ion determines whether that ion enters or leaves the cell after its ion channel opens, when voltage-gated Na^+ channels open, Na^+ moves through the channels into the cell. In a similar fashion, when gated K^+ channels open, K^+ moves out of the cell. Since excitable cells have many K^+ leak ion channels, at rest, K^+ moves out of the cell faster than Na^+ moves into the cell. In addition, negatively charged molecules, such as proteins, are “trapped” inside the cell because the plasma membrane is impermeable to them. For these reasons, the inside of the plasma membrane is more negatively charged than the outside.

Some K^+ is able to diffuse down the concentration gradient from inside to just outside the plasma membrane. Because K^+ is positively charged, its movement from inside the cell to outside causes the inside of the plasma membrane to become even more negatively charged compared with the outside.

Potassium ions diffuse down their concentration gradient only until the charge difference across the plasma membrane is great enough to prevent any additional diffusion of K^+ out of the cell. The resting membrane potential is an equilibrium in which the tendency for K^+ to diffuse out of the cell is opposed by the negative charges inside the cell, which tend to attract the positively charged K^+ into the cell. It is the active transport of Na^+ and K^+ by the sodium-potassium pump that maintains the uneven distribution of Na^+ and K^+ across the plasma membrane (see chapter 3). In a resting cell, the sodium-potassium pump transports K^+ from outside the cell to the inside and transports Na^+ from inside the cell to the outside. The details of the resting membrane potential are described more fully in chapter 11.

The resting membrane potential can be measured in units called **millivolts** (mV; $\text{mV} = 1/1000$ volt). The potential differences across the plasma membranes of neurons and muscle fibers are between -70 and -90 mV. In comparison, a “AA” battery is about 1.5 V. The potential difference is reported as a negative number because the inner surface of the plasma membrane is negative compared with the outside.

Predict 2

If ligand-gated K^+ channels were to open in an unstimulated muscle fiber, how would this affect the resting membrane potential?

ASSESS YOUR PROGRESS

18. What type of ion channel contributes to the resting membrane potential? Describe the permeability characteristics of the plasma membrane.
19. What are the two types of gated ion channels in the plasma membrane? Explain what causes each type to open and close.
20. What is the resting membrane potential? What three factors create the resting membrane potential?
21. How does the sodium-potassium pump help maintain the polarized nature of the resting membrane?

(a) Measuring the resting membrane potential

1 In a resting cell, there is a higher concentration of K^+ (purple circles) inside the cell membrane and a higher concentration of Na^+ (pink circles) outside the cell membrane. Because the membrane is not permeable to negatively charged proteins (green) they are isolated to inside of the cell membrane.

2 There are more K^+ leak channels than Na^+ leak channels. In the resting cell, only the leak channels are opened; the gated channels (not shown) are closed. Because of the ion concentration differences across the membrane, K^+ diffuses out of the cell down its concentration gradient and Na^+ diffuses into the cell down its concentration gradient. The tendency for K^+ to diffuse out of the cell is opposed by the tendency of the positively charged K^+ to be attracted back into the cell by the negatively charged proteins.

3 The sodium-potassium pump helps maintain the differential levels of Na^+ and K^+ by pumping three Na^+ out of the cell in exchange for two K^+ into the cell. The pump is driven by ATP hydrolysis. The resting membrane potential is established when the movement of K^+ out of the cell is equal to the movement of K^+ into the cell.

(b) Generation of the resting membrane potential

PROCESS FIGURE 9.8 Measuring the Resting Membrane Potential

A device called an oscilloscope is able to measure the resting membrane potential in skeletal muscle. The recording electrode is inside the membrane, and the reference electrode is outside. Here, a potential difference of about -85 mV is recorded, with the inside of the membrane negative with respect to the outside of the membrane. **APR**

Action Potentials

An action potential is a reversal of the resting membrane potential such that the inside of the plasma membrane becomes positively charged compared with the outside. The permeability

characteristics of the plasma membrane change because ion channels open when a cell is stimulated. The diffusion of ions through these channels changes the charge across the plasma membrane and produces an action potential.

An action potential lasts from approximately 1 millisecond to a few milliseconds, and it has two phases, depolarization and repolarization. Figure 9.9 depicts the changes that occur in the membrane potential during an action potential. Stimulation of a cell can cause its plasma membrane to become depolarized. Specifically, the inside of the plasma membrane becomes more positive, as indicated by movement of the curve upward toward zero in figure 9.9*a*. If the depolarization changes the membrane potential to a value called **threshold**, an action potential is triggered. The **depolarization phase** of the action potential is a brief period during which further depolarization occurs and the inside of the cell becomes positively charged (figure 9.9*b*). The charge difference across the plasma membrane is said to be reversed when the membrane potential becomes a positive value. The **repolarization phase** is the return of the membrane potential to its resting value.

The opening and closing of voltage-gated ion channels change the permeability of the plasma membrane to ions, resulting in depolarization and repolarization. Before a neuron or a muscle fiber is stimulated, these voltage-gated ion channels are closed (figure 9.10, *step 1*). When the cell is stimulated, gated Na^+ channels open, and Na^+ diffuses into the cell. The positively charged Na^+ makes the inside of the plasma membrane more positive. If this depolarization reaches threshold, many voltage-gated Na^+ channels are stimulated and open rapidly, causing Na^+ to diffuse into the cell until the inside of the membrane becomes positive for a brief time (figure 9.10, *step 2*). As the inside of the cell becomes positive, this voltage change causes additional permeability changes in the plasma membrane, which stop depolarization and start repolarization. Repolarization results from the closing of voltage-gated Na^+ channels and the opening of voltage-gated K^+ channels (figure 9.10, *step 3*). Thus, Na^+ stops moving into the cell, and more K^+ moves out of the cell. These changes cause the inside of the plasma membrane to become more negative and the outside to become more positive. The action potential ends, and the resting membrane potential is reestablished when the voltage-gated K^+ channels close.

Action potentials occur according to the **all-or-none principle**, which means that all action potentials are identical. If a stimulus is strong enough to produce a depolarization that reaches threshold, or even if it exceeds threshold by a substantial amount, all of the permeability changes responsible for an action potential proceed without stopping. Consequently, all of the action potentials in a given cell are alike (the “all” part). If a stimulus is so weak that the depolarization does not reach threshold, few of the permeability changes occur. The membrane potential returns to its resting level after a brief period without producing an action potential (the “none” part). An action potential can be compared to the starter in a car. Once the ignition switch is pressed (reaches threshold), the car starts (an action potential is produced) and each time, the engine runs the same as the previous time the car started (the “all” part). If the ignition switch is pressed but not fully (does not reach threshold), the car does not start (the “none” part).

An action potential occurs in a very small area of the plasma membrane and does not affect the entire plasma membrane at one time. Action potentials can travel, or **propagate**, across the plasma membrane because an action potential produced at one location in the plasma membrane can stimulate the production

(a) Depolarization is a change of the charge difference across the plasma membrane, making the charge inside the cell more positive and the charge outside the plasma membrane less positive. Once threshold is reached, an action potential is produced.

(b) During the depolarization phase of the action potential, the membrane potential changes from approximately -85 mV to approximately $+20$ mV. During the repolarization phase, the inside of the plasma membrane changes from approximately $+20$ mV back to -85 mV.

FIGURE 9.9 Depolarization and the Action Potential in Skeletal Muscle

of an action potential in an adjacent location (figure 9.11). Note that an action potential does not actually move along the plasma membrane. Rather, an action potential at one location stimulates the production of another action potential in an adjacent location, which in turn stimulates the production of another, and so on. It is much like a long row of toppling dominoes in which each domino knocks down the next. Each domino falls, but no single domino actually travels the length of the row.

- 1 Resting membrane potential.** Na^+ channels (pink) and some, but not all, K^+ channels (purple) are closed. K^+ diffuses down its concentration gradient through the open K^+ channels, making the inside of the cell membrane negatively charged compared to the outside.

- 2 Depolarization.** Na^+ channels are open. Na^+ diffuses down its concentration gradient through the open Na^+ channels, making the inside of the cell membrane positively charged compared to the outside.

- 3 Repolarization.** Na^+ channels are closed, and Na^+ movement into the cell stops. More K^+ channels open. K^+ movement out of the cell increases, making the inside of the cell membrane negatively charged compared to the outside, once again.

PROCESS FIGURE 9.10 Gated Ion Channels and the Action Potential

Step 1 illustrates the status of gated Na^+ and K^+ channels in a resting cell. Steps 2 and 3 show how the channels open and close to produce an action potential. At the far right, the charge difference across the plasma membrane at each stage is illustrated. **APR**

If all action potentials are identical, how does the brain distinguish between a strong stimulus, such as a loud noise, and a weaker stimulus, such as a quiet noise? A stronger stimulus causes more action potentials to be sent. This is called the **action potential frequency**.

The action potential frequency is the number of action potentials produced per unit of time. As the strength of the stimulus applied to a neuron or a muscle fiber increases (once threshold is reached), the action potential frequency increases. All the action potentials are identical. The action potential frequency can affect

1 An action potential in a local area of the plasma membrane is indicated by the orange band. Note the reversal of charge across the membrane.

2 The action potential is a stimulus that causes another action potential to be produced in the adjacent plasma membrane.

3 The action potential propagates along the plasma membrane (orange arrow).

PROCESS FIGURE 9.11 Action Potential Propagation in a Muscle Fiber

the strength of a muscle contraction (see “Stimulus Frequency and Whole Muscle Contraction,” in section 9.5).

In summary, the resting membrane potential results from a charge difference across the plasma membrane. An action potential, which is a reversal of that charge difference, stimulates cells to respond by contracting. The nervous system controls muscle contractions by sending action potentials along axons to muscle fibers, which then stimulate action potentials in the muscle fibers. An increased frequency of action potentials sent to the muscle fibers can result in stronger muscle contraction. Next, we consider the specific communication between a motor neuron and the skeletal muscle fiber.

ASSESS YOUR PROGRESS

22. List the two types of voltage-gated channels that play important roles in the production of action potentials.
23. What value must depolarization reach in an electrical cell to trigger an action potential?
24. Describe the changes that occur during the depolarization and repolarization phases of an action potential.
25. Describe the propagation of an action potential.
26. How does the frequency of action potentials affect muscle contractions?

The Function of the Neuromuscular Junction

Recall that each muscle fiber is innervated by a motor neuron at the neuromuscular junction. This point of contact results in an action potential along the sarcolemma. The primary stimulus for this action potential is the release of acetylcholine from the motor neuron.

When an action potential reaches the presynaptic terminal of a motor neuron, it causes voltage-gated calcium ion (Ca^{2+}) channels in the plasma membrane of the axon to open; as a result, Ca^{2+} diffuses into the axon terminal (figure 9.12). Once inside the cell, the Ca^{2+} causes the contents of a few synaptic vesicles to be secreted by exocytosis from the presynaptic terminal into the synaptic cleft. The acetylcholine molecules released from the synaptic vesicles then diffuse across the cleft and bind to receptor molecules within the postsynaptic membrane of the skeletal muscle fiber. This causes ligand-gated Na^+ channels to open, increasing the permeability of the membrane to Na^+ . Sodium ions then diffuse into the cell, causing depolarization. In skeletal muscle, each action potential in the motor neuron causes a depolarization that exceeds threshold, which causes changes in voltage-gated ion channels that produce an action potential in the muscle fiber.

Predict 3

Predict the consequence if presynaptic action potentials in an axon release insufficient acetylcholine to depolarize a skeletal muscle fiber to threshold.

Acetylcholine released into the synaptic cleft is rapidly broken down to acetic acid and choline by the enzyme **acetylcholinesterase** (as'e-til-kō-lin-es'ter-ās; figure 9.12). Acetylcholinesterase keeps acetylcholine from accumulating within the synaptic cleft, where it would act as a constant stimulus at the postsynaptic terminal, producing many action potentials and continuous contraction in the muscle fiber. The release of acetylcholine and its rapid degradation in the synaptic cleft ensure that one presynaptic action potential yields only one postsynaptic action potential. Choline molecules are actively reabsorbed by the presynaptic terminal and then combined with the acetic acid produced within the cell to form acetylcholine. Recycling choline molecules requires less energy and is more rapid than completely synthesizing new acetylcholine molecules each time they are released from the presynaptic terminal. Acetic acid is an intermediate in the process of glucose metabolism (see chapter 25), which can be taken up and used by a variety of cells near the neuromuscular junction.

ASSESS YOUR PROGRESS

27. Describe the structure of a neuromuscular junction, or synapse.
28. Outline the process of transferring the action potential in the presynaptic terminal to the postsynaptic membrane, or motor end-plate.
29. What ion is needed to release neurotransmitters from the synaptic vesicle? What neurotransmitter is released to skeletal muscle fibers?
30. What is the importance of acetylcholinesterase in the synaptic cleft? What would occur if acetylcholinesterase were not present?

Excitation-Contraction Coupling

Action potentials produced in the sarcolemma of a skeletal muscle fiber can lead to contraction of the fiber. The mechanism by which

FUNDAMENTAL Figure

- 1 An action potential (orange arrow) arrives at the presynaptic terminal and causes voltage-gated Ca^{2+} channels in the presynaptic membrane to open.
- 2 Calcium ions enter the presynaptic terminal and initiate the release of the neurotransmitter acetylcholine (ACh) from synaptic vesicles.
- 3 ACh is released into the synaptic cleft by exocytosis.
- 4 ACh diffuses across the synaptic cleft and binds to ligand-gated Na^+ channels on the postsynaptic membrane.
- 5 Ligand-gated Na^+ channels open and Na^+ enters the postsynaptic cell, causing the postsynaptic membrane to depolarize. If depolarization passes threshold, an action potential is generated along the postsynaptic membrane.
- 6 ACh unbinds from the ligand-gated Na^+ channels, which then close.
- 7 The enzyme acetylcholinesterase, which is attached to the postsynaptic membrane, removes acetylcholine from the synaptic cleft by breaking it down into acetic acid and choline.
- 8 Choline is symported with Na^+ into the presynaptic terminal, where it can be recycled to make ACh. Acetic acid diffuses away from the synaptic cleft.
- 9 ACh is re-formed within the presynaptic terminal using acetic acid generated from metabolism and from choline recycled from the synaptic cleft. ACh is then taken up by synaptic vesicles.

PROCESS FIGURE 9.12 Function of the Neuromuscular Junction

an action potential causes contraction of a muscle fiber is called **excitation-contraction coupling**. Excitation-contraction coupling occurs because of the anatomical association between the T tubules and the sarcoplasmic reticulum. Recall that Ca^{2+} is stored in the sarcoplasmic reticulum and that Ca^{2+} binds to the troponin component of actin myofilaments. T tubules project into the muscle fiber and wrap around sarcomeres in the region where actin and myosin myofilaments overlap (figure 9.13; see figure 9.3). The lumen of each T tubule is filled with extracellular fluid and is continuous with the exterior of the muscle fiber. Near the T tubules, the sarcoplasmic reticulum is enlarged to form

terminal cisternae (sis-ter'nē). A T tubule and the two adjacent terminal cisternae together are called a **triad** (tri'ad; figure 9.13). The sarcoplasmic reticulum actively transports Ca^{2+} into its lumen; thus, the concentration of Ca^{2+} is approximately 2000 times higher within the sarcoplasmic reticulum than in the sarcoplasm of a resting muscle fiber.

Excitation-contraction coupling begins at the neuromuscular junction with the production of an action potential in the sarcolemma. The action potential is propagated along the entire sarcolemma of the muscle fiber and into the T tubules. The T tubules carry action potentials into the interior of the muscle fiber, where

FIGURE 9.13 T Tubules and Sarcoplasmic Reticulum

A T tubule and the sarcoplasmic reticulum on each side of the T tubule form a triad.

they cause voltage-gated Ca^{2+} channels in the terminal cisternae of the sarcoplasmic reticulum to open. When the Ca^{2+} channels open, Ca^{2+} rapidly diffuses into the sarcoplasm surrounding the myofibrils (figure 9.14).

Calcium ions bind to the Ca^{2+} binding sites on the troponin molecules of the actin myofilaments. The combination of Ca^{2+} with troponin causes the troponin-tropomyosin complex to move deeper into the groove between the two F actin strands, which exposes active sites on the actin myofilaments. The heads of the myosin molecules then bind to the exposed active sites to form cross-bridges (figure 9.14). Movement of the cross-bridges results in contraction.

Cross-Bridge Movement

A cycle of events resulting in contraction proceeds very rapidly (figure 9.15). The heads of myosin molecules move at their hinged region, resulting in cross-bridge movement. This movement forces the actin myofilament, to which the heads of the myosin molecules are attached, to slide over the surface of the myosin myofilament. After cross-bridge movement, each myosin head releases from the actin and returns to its original position. It can then form another

cross-bridge at a different site on the actin myofilament, followed by movement, release of the cross-bridge, and return to its original position. During a single contraction, each myosin molecule undergoes the cycle of cross-bridge formation, movement, release, and return to its original position many times. This process is called **cross-bridge cycling**.

The energy from one ATP molecule is required for each cycle of cross-bridge formation, movement, and release. Before a myosin head binds to the active site on an actin myofilament, the head of the myosin molecule is in its resting position, and ADP and phosphate are bound to the head of the myosin molecule (figure 9.15). Once Ca^{2+} binds to troponin and the tropomyosin moves, the active sites on actin myofilaments are exposed. The head of a myosin molecule can then bind to an exposed active site, and the phosphate is released from the head of the myosin molecule. Energy stored in the head of the myosin molecule causes the head of the myosin molecule to move. Movement of the head causes the actin myofilament to slide past the myosin myofilament, and ADP is released from the myosin head. ATP must then bind to the head of the myosin before the cross-bridge can release. As the ATP molecule binds to the head of the myosin molecule, the myosin head breaks

- 1 An action potential that was produced at the neuromuscular junction is propagated along the sarcolemma of the skeletal muscle. The depolarization also spreads along the membrane of the T tubules.
- 2 The depolarization of the T tubule causes voltage-gated Ca^{2+} channels in the sarcoplasmic reticulum to open, resulting in an increase in the permeability of the sarcoplasmic reticulum to Ca^{2+} , especially in the terminal cisternae. Calcium ions then diffuse from the sarcoplasmic reticulum into the sarcoplasm.
- 3 Calcium ions released from the sarcoplasmic reticulum bind to troponin molecules. The troponin molecules bound to G actin molecules are released, causing tropomyosin to move, and to expose the active sites on G actin.
- 4 Once active sites on G actin molecules are exposed, the heads of the myosin myofilaments bind to them to form cross-bridges.

PROCESS FIGURE 9.14 Action Potentials and Muscle Contraction **AP|R**

Clinical IMPACT

The Effect of Blocking Acetylcholine Receptors and Acetylcholinesterase

Any factor that affects the production, release, and degradation of acetylcholine or its ability to bind to its receptor molecule also affects the transmission of action potentials across the neuromuscular junction. For example, some insecticides contain organophosphates that bind to and inhibit the function of acetylcholinesterase. As a result, acetylcholine is not degraded but accumulates in the synaptic cleft, where it acts as a constant stimulus to the muscle fiber. Insects exposed to such insecticides die, partly because their muscles contract and cannot relax—a condition called **spastic paralysis** (spas'tik pã-ral'i-sis), which is followed by muscle fatigue.

Humans respond similarly to these insecticides. The skeletal muscles responsible for

respiration cannot undergo their normal cycle of contraction and relaxation. Instead, they remain in a state of spastic paralysis until they become fatigued, causing the patients to die of respiratory failure. Other organic poisons, such as curare, the substance originally used by South American Indians in poison arrows, bind to the acetylcholine receptors, preventing acetylcholine from binding to them. Curare does not allow the activation of the receptors, and therefore the muscle is incapable of contracting in response to nervous stimulation—a condition called **flaccid** (flak'sid, flas'id) **paralysis**. Curare is not a poison to which people are commonly exposed, but it has been used to investigate the role of acetylcholine in the neuromuscular

synapse and is sometimes administered in small doses to relax muscles during certain kinds of surgery.

Myasthenia gravis (mī-as-thē'nē-ã grãv'is) results from the production of antibodies that bind to acetylcholine receptors, eventually destroying the receptor and thus reducing the number of receptors. As a consequence, muscles exhibit a degree of flaccid paralysis or are extremely weak (see table 11.5). A class of drugs that includes neostigmine partially blocks the action of acetylcholinesterase and is sometimes used to treat myasthenia gravis. The drugs increase the level of acetylcholine in the synaptic cleft, so that it can bind more effectively to the remaining acetylcholine receptors.

PROCESS FIGURE 9.15 Breakdown of ATP and Cross-Bridge Movement During Muscle Contraction **APR**

- 1 An action potential travels along an axon membrane to a neuromuscular junction.
- 2 Ca^{2+} channels open and Ca^{2+} enters the presynaptic terminal.
- 3 Acetylcholine is released from presynaptic vesicles.
- 4 Acetylcholine stimulates Na^+ channels on the postsynaptic membrane to open.
- 5 Na^+ diffuses into the muscle fiber, initiating an action potential that travels along the sarcolemma and T tubule membranes.
- 6 Action potentials in the T tubules cause the sarcoplasmic reticulum to release Ca^{2+} .
- 7 On the actin, Ca^{2+} binds to troponin, which moves tropomyosin and exposes myosin head attachment sites.
- 8 ATP molecules on myosin heads are broken down to ADP and P, which releases energy needed to move the myosin heads.
- 9 The heads of the myosin myofilaments bend, causing the actin to slide past the myosin. As long as Ca^{2+} is present, the cycle repeats.

PROCESS FIGURE 9.16 Summary of Skeletal Muscle Contraction

ATP apart into ADP and phosphate, and the myosin head releases from the active site on actin. The ADP and phosphate remain attached to the head of the myosin molecule, and the head of the myosin returns to its resting position. Energy released from the breakdown of ATP is stored in the head of the myosin molecule.

Movement of the myosin molecule while the cross-bridge is attached is called the **power stroke**, whereas return of the myosin head to its original position after cross-bridge release is called the **recovery stroke**. Many cycles of power and recovery strokes occur during each muscle contraction. While muscle is relaxed, energy stored in the heads of the myosin molecules is held in reserve until the next contraction. When Ca^{2+} is released from the sarcoplasmic reticulum in response to an action potential, the cycle of cross-bridge formation, movement, and release, which results in contraction, begins (see figures 9.14 and 9.15). Figure 9.16 summarizes the overall sequence of events that occurs as a stimulus causes a skeletal muscle to contract.

Muscle Relaxation

Muscle relaxation occurs when acetylcholine is no longer released at the neuromuscular junction. The cessation of action potentials

along the sarcolemma stops Ca^{2+} release from the sarcoplasmic reticulum and Ca^{2+} is actively transported back into the sarcoplasmic reticulum. As the Ca^{2+} concentration decreases in the sarcoplasm, the Ca^{2+} diffuses away from the troponin molecules. The troponin-tropomyosin complex then reestablishes its position, which blocks the active sites on the actin molecules. As a consequence, cross-bridges cannot re-form once they have been released, and the muscle relaxes.

Thus, energy is needed not only to make muscle fibers contract but also to make muscle fibers relax. Three major ATP-dependent events are required for muscle relaxation:

1. After an action potential has occurred in the muscle fiber, the sodium-potassium pump must actively transport Na^+ and K^+ to return to and maintain resting membrane potential.
2. ATP is required to detach the myosin heads from the actin and return them to their resting position.
3. ATP is needed for the active transport of Ca^{2+} into the sarcoplasmic reticulum.

Because the reuptake of Ca^{2+} into the sarcoplasmic reticulum is much slower than the diffusion of Ca^{2+} out of the sarcoplasmic reticulum, a muscle fiber takes at least twice as long to relax as it does to contract.

ASSESS YOUR PROGRESS

31. Identify the steps that show how an action potential produced in the postsynaptic membrane of the neuromuscular junction eventually results in contraction of the muscle fiber.
32. What ion is necessary for movement of the troponin-tropomyosin complex?
33. Describe the power stroke and the recovery stroke. How is ATP used?
34. What events occur during the relaxation of the muscle fiber? What is the role of ATP?

9.5 Whole Skeletal Muscle Physiology

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe a muscle twitch and the events that occur in each phase of a twitch.
- B. Describe a motor unit and how motor unit number affects muscle control.
- C. Explain how whole muscles respond in a graded fashion and how the force of contraction can be increased.
- D. Summarize what occurs in treppe.
- E. Relate recruitment to multiple-motor-unit summation.
- F. Describe incomplete tetanus and complete tetanus.
- G. Explain the connection between the initial length of a muscle and the amount of tension produced.
- H. Distinguish between isometric and isotonic contractions.
- I. Relate how muscle tone is maintained.

The Muscle Twitch

A single, brief contraction and relaxation cycle in a muscle fiber is called a **muscle twitch**. A twitch does not last long enough or generate enough tension to perform any work. Even though the normal function of muscles is more complex, a muscle twitch can serve as an example of how muscles function in living organisms.

Figure 9.17 shows a hypothetical contraction of a single muscle fiber in response to a single action potential. The gap between the time of stimulus application to the motor neuron and the beginning of contraction is the **lag phase** (*latent phase*); the time during which contraction occurs is the **contraction phase**; and the time during which relaxation occurs is the **relaxation phase**.

An action potential is an electrochemical event, but contraction is a mechanical event. An action potential is measured in millivolts and is completed in less than 2 milliseconds. Muscle contraction

FIGURE 9.17 Phases of a Muscle Twitch in a Single Muscle Fiber

After the stimulus is applied, a short lag phase occurs, followed by a contraction phase and a relaxation phase.

is measured as a force, also called tension. It is reported as the number of grams lifted, or the distance the muscle shortens, and requires up to 1 second to occur.

ASSESS YOUR PROGRESS

35. List the phases of a muscle twitch, and describe the events that occur in each phase.

Motor Units

A **motor unit** consists of a single motor neuron and all the muscle fibers it innervates (figure 9.18). An action potential in the motor neuron generates an action potential in each of the muscle fibers of its motor unit. However, not all motor units are identical. Motor units vary in terms of the number of muscle fibers they contain, and they vary in terms of their sensitivity to stimuli for contraction; some motor units respond readily to weak stimuli, whereas others respond only to strong stimuli. That is why human skeletal muscles are capable of fluid movements.

Motor Unit Number

Motor units in different muscles do not always contain the same number of muscle fibers. Muscles performing delicate and precise movements have many motor units, each containing a small number of muscle fibers. On the other hand, muscles performing more powerful but less precise contractions have fewer motor units, each containing many muscle fibers. For example, in very delicate muscles, such as those that move the eye, the number of muscle fibers per motor unit can be less than 10, whereas in the heavy muscles of the thigh the number can be several hundred. Thus, having many, small motor units allows for a great deal of control over a particular muscle. Conversely, having few, large motor units only allows for coarse control over a particular muscle.

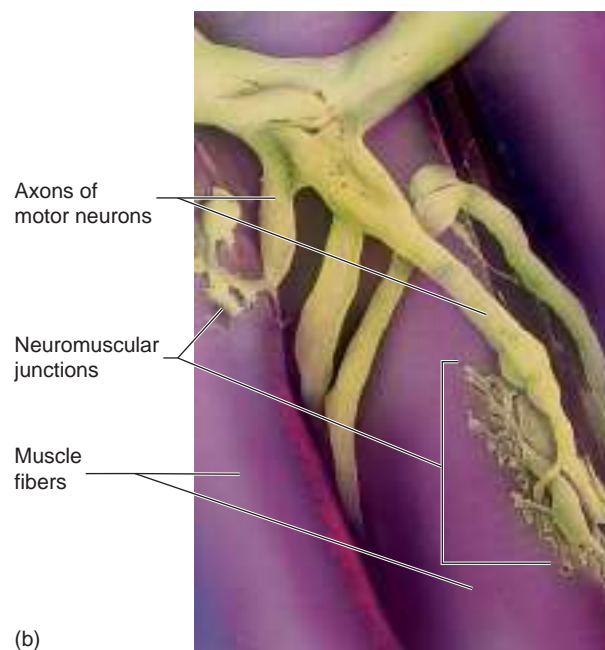

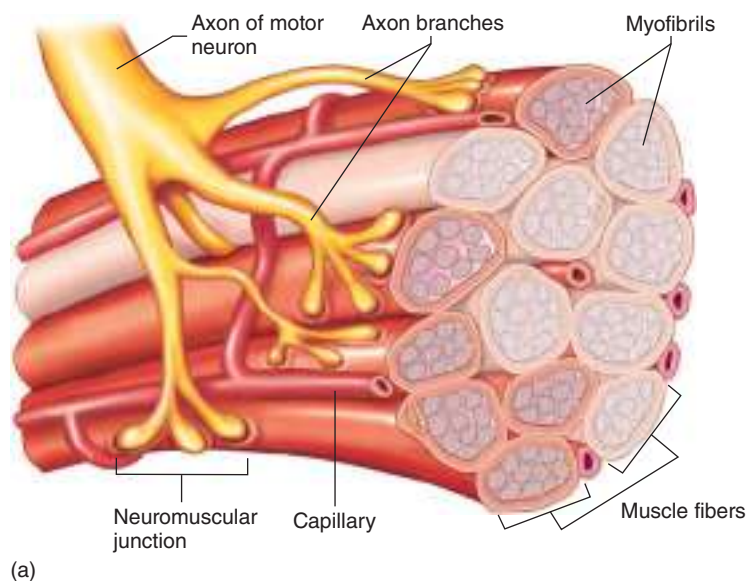

FIGURE 9.18 Motor Unit

(a) A motor unit consists of a single motor neuron and all the muscle fibers its branches innervate. The muscle fibers shown in dark pink are part of one motor unit, and the muscle fibers shown in light pink are part of a different motor unit. In this figure the motor neuron is innervating the dark pink muscle fibers. (b) Photomicrograph of motor units.

Predict 4

The disease poliomyelitis (pō'īlē-ō-mī'ē-lī'tis) destroys motor neurons, causing loss of muscle function and even flaccid paralysis. Some patients recover because axon branches form from the remaining motor neurons. These branches innervate the paralyzed muscle fibers to produce motor units with many more muscle fibers than usual. How does this reinnervation of muscle fibers affect the degree of muscle control in a person who has recovered from poliomyelitis?

Stimulus Strength and Motor Unit Response

The strength of muscle contractions varies from weak to strong. In other words, whole muscles respond to stimuli in a **graded** fashion. For example, the force muscles generate to lift a feather is much less than the force required to lift a 25-pound weight. The force of a contraction is increased in two ways: (1) **Summation** involves increasing the force of contraction of the muscle fibers within the muscle, and (2) **recruitment** involves increasing the number of muscle fibers contracting.

When a muscle fiber demonstrates summation, it is usually because conditions within the muscle fiber have changed. A muscle fiber, when stimulated in rapid succession, contracts with greater force with each subsequent stimulus, a phenomenon called **treppe** (trep'ē; staircase process; figure 9.19). Treppe occurs in a muscle fiber that has rested for a prolonged period. If the muscle fiber is maximally stimulated at a *low frequency*, which allows complete relaxation between the stimuli, the successive contractions are stronger and stronger.

A possible explanation for treppe is an increase in Ca^{2+} levels around the myofibrils. The Ca^{2+} released in response to the first stimulus is not completely removed by the sarcoplasmic reticulum before a second stimulus causes the release of additional Ca^{2+} , even though the muscle relaxes completely between the muscle twitches. As a consequence, during the first few contractions of the muscle, the Ca^{2+} concentration in the sarcoplasm increases slightly, making contraction more efficient because of the

FIGURE 9.19 Treppe

When a rested muscle is stimulated repeatedly with maximal stimuli at a low frequency, which allows complete relaxation between stimuli, the second contraction produces a slightly greater tension than the first, and the third contraction produces greater tension than the second. After a few contractions, the levels of tension produced by all the contractions are equal.

FIGURE 9.20 Multiple-Motor-Unit Summation in a Muscle

Multiple-motor-unit summation occurs as stimuli of increasing strength are applied to a nerve that innervates a muscle. The amount of tension (height of peaks) is influenced by the number of motor units responding.

increased number of ions available to bind to troponin and allowing for more cross-bridges to form. For athletes, *treppe* achieved during warm-up exercises can contribute to improved muscle efficiency. Factors such as increased blood flow to the muscle and increased muscle temperature are probably involved, and because higher temperature causes the enzymes to function more rapidly. Thus, muscle fibers do not display a rigid all-or-none response. Intracellular conditions can increase the fiber's response to repeated stimuli.

When a whole muscle undergoes recruitment, more and more motor units contract as the stimulus *strength* increases. The relationship between increased stimulus strength and an increased number of contracting motor units is called **multiple-motor-unit summation** because the force of contraction increases as more and more motor units are stimulated. Multiple-motor-unit summation resulting in graded responses can be demonstrated by applying brief electrical stimuli of increasing strength to the nerve supplying a muscle (figure 9.20). Various results are possible, depending on the strength of the stimulus:

- A **subthreshold stimulus** is not strong enough to cause an action potential in any of the axons in a nerve and does not cause a contraction.
- As the stimulus strength increases, it eventually becomes a **threshold stimulus**, which is strong enough to produce an action potential in a single motor unit axon, causing all the muscle fibers of the motor unit to contract.
- Progressively stronger stimuli, called **submaximal stimuli**, produce action potentials in axons of additional motor units.

- A **maximal stimulus** produces action potentials in the axons of all the motor units of that muscle. Consequently, even greater stimulus strengths (called *supramaximal stimuli*) have no additional effect.

Stimulus Frequency and Whole Muscle Contraction

An action potential in a single muscle fiber causes it to contract, but the action potential is completed long before the contraction phase is completed. In addition, the contractile mechanism in a muscle fiber exhibits no unresponsive period. That is, relaxation of a muscle fiber is not required before a second action potential can stimulate a second contraction. As the *frequency* of action potentials in a skeletal muscle fiber increases, the frequency of contraction also increases until a period of sustained contraction, or **tetanus** (tet'ă-nŭs), is achieved. In **incomplete tetanus**, muscle fibers partially relax between the contractions; in **complete tetanus**, muscle fibers produce action potentials so rapidly that no relaxation occurs between them. As the frequency of contractions increases, the increased tension produced is called **multiple-wave summation** (figure 9.21).

Tetanus of a muscle caused by stimuli of increasing frequency can be explained at the chemical level. As with *treppe*, a muscle fiber that has been stimulated at a *high frequency* accumulates more Ca^{2+} in the sarcoplasm, and thus the number of cross-bridges formed increases. Therefore, in comparing *treppe* and tetanus, we see that the mechanism is very similar—increased sarcoplasmic Ca^{2+} —but the delivery of stimulus to the muscle is different. For *treppe* the

FIGURE 9.21 Multiple-Wave Summation

Stimuli 1–4 increase in frequency. For each stimulus, the arrow indicates the start of stimulation. Stimulus frequency 1: A single action potential arriving at a muscle fiber causes twitches that completely relax before the next action potential arrives. Stimulus frequencies 2–3: As the action potential frequency increases, muscle fibers only partially relax before the next action potential arrives and the fiber contracts again; this results in incomplete tetanus. Stimulus frequency 4: Action potential frequency can increase to the point where the muscle fiber does not relax at all before the next action potential arrives, causing the muscle fiber to contract continuously; this results in complete tetanus.

stimulus is maximal but delivered at a low frequency, whereas for tetanus the stimulus is at threshold but delivered at a high frequency.

A significant factor in multiple-wave summation is the fact that the sarcoplasm and the connective tissue components of muscle have some elasticity. During each separate muscle twitch, some of the tension produced by the contracting muscle fibers is used to stretch those elastic elements, and the remaining tension is applied to the load to be lifted. In a single muscle twitch, relaxation begins before the elastic components are totally stretched. The maximum

tension produced during a single muscle twitch is therefore not applied to the load to be lifted. However, in a muscle stimulated at a high frequency, the elastic elements stretch during the very early part of the prolonged contraction. After that, all the tension produced by the muscle is applied to the load to be lifted, and the observed tension produced by the muscle increases.

Muscle Length Versus Tension

Active tension is the force applied to an object to be lifted when a muscle contracts. The initial length of a muscle has a strong influence on the amount of active tension it produces. As the length of a muscle increases, its active tension also increases, to a point. If the muscle stretches farther than its optimum length, the active tension it produces begins to decline. The muscle length plotted against the tension produced by the muscle in response to maximal stimuli is the **active tension curve** (figure 9.22).

If a muscle stretches so that the actin and myosin myofilaments within the sarcomeres do not overlap—or overlap to a very small extent—the muscle produces very little active tension when it is stimulated. Also, if the muscle does not stretch at all, the myosin myofilaments touch each of the Z disks in each sarcomere, and very little contraction of the sarcomeres can occur. If the muscle stretches to its optimum length, optimal overlap of the actin and myosin myofilaments takes place. When the muscle is stimulated, cross-bridge formation results in maximal contraction.

Before lifting heavy objects, weight lifters and others usually assume positions in which their muscles are stretched close to their optimum length. For example, the position a weight lifter assumes before power lifting stretches the upper limb and lower limb muscles to a near-optimum length for muscle contraction, and the stance a lineman assumes in a football game stretches most muscle groups in the lower limbs so that they are near their optimum length for suddenly moving the body forward.

Case STUDY

Organophosphate Poisoning

John has a number of prize apple trees in his backyard. To prevent them from becoming infested with insects, he sprayed them with an organophosphate insecticide. Being in a rush to spray the trees before leaving town on vacation, he failed to pay attention to the safety precautions on the packaging and sprayed the trees without using any skin or respiratory protection. Soon he experienced severe stomach cramps, double vision, difficulty breathing, and spastic contractions of his skeletal muscles. John's wife took him to the emergency room, where he was diagnosed with organophosphate poisoning and given medication. Soon many of John's symptoms subsided.

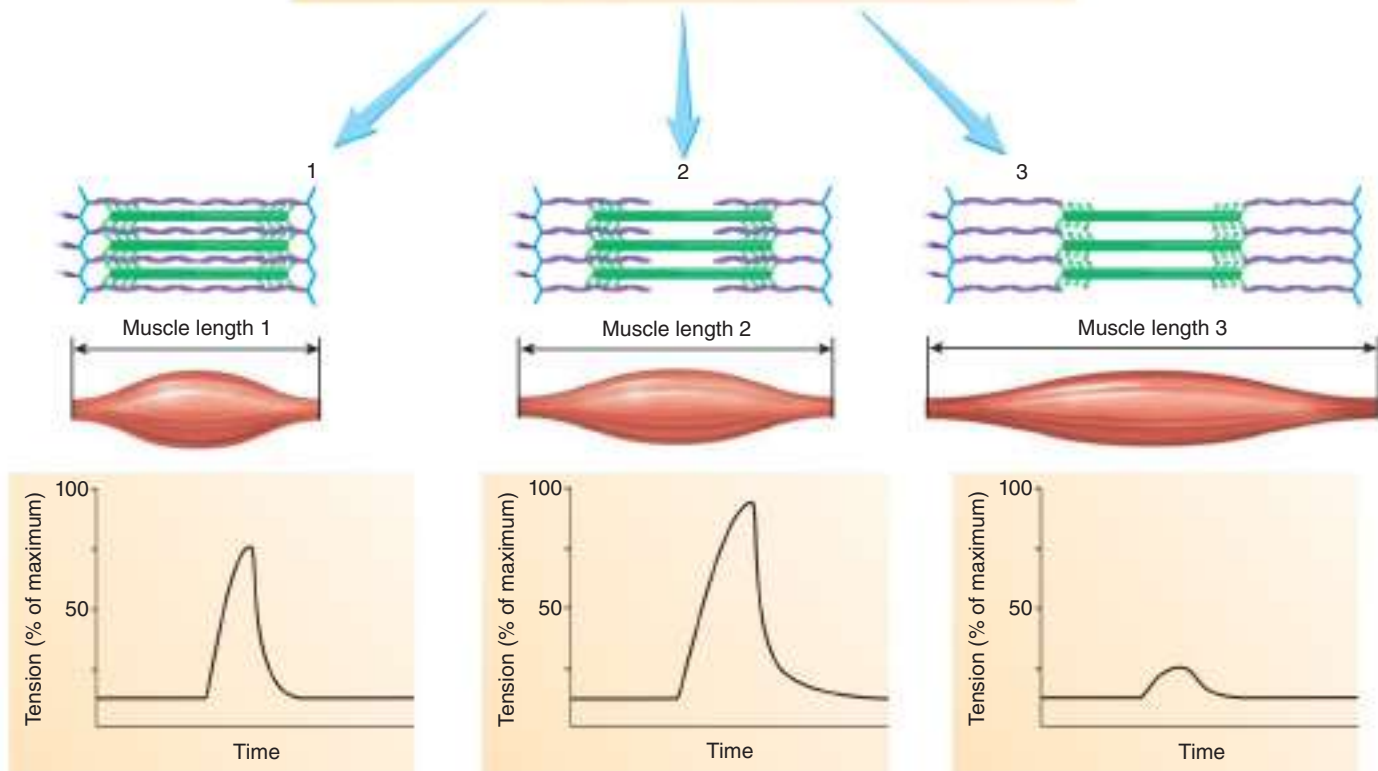

Organophosphate insecticides exert their effects by binding to the enzyme acetylcholinesterase within synaptic clefts, rendering it ineffective. Thus, the organophosphate poison and acetylcholine “compete” for the acetylcholinesterase and, as the organophosphate poison increases in concentration, the enzyme is less effective in degrading acetylcholine. Organophosphate poisons affect synapses in which acetylcholine is the neurotransmitter, including skeletal muscle synapses and smooth muscle synapses, such as those in the walls of the stomach, intestines, and air passageways.

Predict 5

Organophosphate insecticides exert their effects by binding to the enzyme acetylcholinesterase within synaptic clefts, rendering it ineffective. Use figures 9.12 and 9.21 to help answer the following questions.

- Explain the spastic contractions that occurred in John's skeletal muscles.
- Propose as many mechanisms as you can by which a drug could counteract the effects of organophosphate poisoning.

At the normal resting length of a muscle, the sarcomeres are also at an optimal length. The muscle produces maximum tension in response to a maximal stimulus at this length.

At muscle/sarcomere length 1, the muscle is not stretched, and the tension produced when the muscle contracts is small because there is too much overlap between actin and myosin myofilaments. The myosin myofilaments run into the Z disks, and the actin myofilaments interfere with each other at the center of the sarcomere, reducing the number of cross-bridges that can form.

At muscle/sarcomere length 2, the muscle is optimally stretched, and the tension produced when the muscle contracts is maximal because there is optimal overlap of actin and myosin myofilaments, so the number of cross-bridges that can form is maximal.

At muscle/sarcomere length 3, the muscle is stretched severely, and the tension produced when the muscle contracts is small because there is little overlap between actin and myosin myofilaments, and few cross-bridges can form.

FIGURE 9.22 Muscle Length and Tension

The length of a muscle before it is stimulated influences the muscle's force of contraction. As the muscle changes length, the sarcomeres also change length.

Passive tension is the tension applied to the load when a muscle stretches but is not stimulated. It is similar to the tension that would be produced if the muscle were replaced with an elastic band. Passive tension exists because the muscle and its connective tissue have some elasticity. The sum of active and passive tension is called **total tension**.

Types of Muscle Contractions

Muscle contractions are classified based on the type of contraction that predominates. In **isometric** (ī-sō-met'rik) **contractions**, the length of the muscle does not change but the amount of tension increases during contraction. Isometric contractions are responsible for the constant length of the postural muscles of the body, such

as the muscles that hold the spine erect while a person is sitting or standing. In **isotonic** (ī-sō-ton'ik) **contractions**, the amount of tension produced by the muscle is constant during contraction but the length of the muscle changes. Movements of the upper limbs or fingers, as in waving or using a computer keyboard, are predominantly isotonic contractions. Although some mechanical differences exist, both types of contraction result from the same contractile process within muscle fibers. Also, most muscle contractions are not strictly isometric or isotonic. For example, both the length and the tension of muscles change when a person walks or opens a heavy door.

Concentric (kon-sen'trik) **contractions** are isotonic contractions in which tension in the muscle is great enough to overcome the opposing resistance, and the muscle shortens. Concentric contractions result in an increasing tension as the muscle shortens. Many of the movements performed by muscles require concentric contractions—for example, lifting a loaded backpack from the floor to a table top. **Eccentric** (ek-sen'trik) **contractions** are isotonic contractions in which tension is maintained in a muscle, but the opposing resistance is great enough to cause the muscle to increase in length. For example, eccentric contractions occur when a person slowly lowers a heavy weight. Eccentric contractions produce substantial force—in fact, eccentric contractions during exercise often produce greater tension than concentric contractions do. Eccentric contractions are of clinical interest because repetitive eccentric contractions, as occur in the lower limbs of people who run downhill for long distances, tend to injure muscle fibers and muscle connective tissue.

Muscle tone is the constant tension produced by muscles for long periods of time. Muscle tone is responsible for keeping the back

and lower limbs straight, the head upright, and the abdomen flat. Muscle tone depends on a small percentage of all the motor units contracting out of phase with one another at any point in time. The frequency of nerve impulses causes incomplete tetanus for short periods, but the contracting motor units are stimulated in such a way that the tension produced by the whole muscle remains constant.

➤ Predict 6

Mary Myosin overheard an argument between two students who could not decide if a weight lifter who lifts a weight above the head and then holds it there before lowering it is using isometric, concentric, or eccentric muscle contractions. Mary is an expert on muscle contractions, so she settles the debate. What is her explanation?

Movements of the body are usually smooth and occur at widely differing rates—some very slowly and others quite rapidly. Very few body movements resemble the rapid contractions of individual muscle twitches. Rather, smooth, slow contractions result from an increasing number of motor units contracting out of phase as the muscles shorten, as well as from a decreasing number of motor units contracting out of phase as muscles lengthen. Each motor unit exhibits either incomplete or complete tetanus but, because the contractions are out of phase and because the number of motor units activated varies at each point in time, a smooth contraction results. Consequently, muscles are capable of contracting either slowly or rapidly, depending on the number of motor units stimulated and the rate at which that number increases or decreases. A summary of physiological muscle responses is presented in table 9.2.

TABLE 9.2 Types of Physiological Muscle Responses

Physiological Response	Characteristics
Multiple-motor-unit summation	Each motor unit responds in an all-or-none fashion. A whole muscle is capable of producing an increasing amount of tension as the number of motor units stimulated increases.
Multiple-wave summation	Summation results when many action potentials are produced in a muscle fiber. <ul style="list-style-type: none"> ■ Contraction occurs in response to the first action potential, but there is not enough time for relaxation to occur between action potentials. ■ Because each action potential causes the release of Ca^{2+} from the sarcoplasmic reticulum, the ion levels remain elevated in the sarcoplasm to produce a tetanic contraction. ■ The tension produced as a result of multiple-wave summation is greater than the tension produced by a single muscle twitch. The increased tension results from the greater concentration of Ca^{2+} in the sarcoplasm and the stretch of the elastic components of the muscle early in contraction.
Treppe	Tension produced increases for the first few contractions in response to a maximal stimulus at a <i>low frequency</i> in a muscle that has been at rest for some time. Increased tension may result from the accumulation of small amounts of Ca^{2+} in the sarcoplasm for the first few contractions or from an increasing rate of enzyme activity.
Tetanus of muscles	Tetanus of muscles results from multiple-wave summation; frequency of stimulus is higher than for treppe. <ul style="list-style-type: none"> ■ Incomplete tetanus occurs when the action potential frequency is low enough to allow partial relaxation of the muscle fibers. ■ Complete tetanus occurs when the action potential frequency is high enough that no relaxation of the muscle fibers occurs.
Isometric contractions	A muscle produces increasing tension as it remains at a constant length; this is characteristic of postural muscles that maintain a constant tension without changing their length.
Isotonic contractions	A muscle produces a constant tension and shortens during contraction; this is characteristic of finger and hand movements. <ul style="list-style-type: none"> ■ In concentric contractions, a muscle produces tension as it shortens; this is characteristic of biceps brachii curl exercises. ■ In eccentric contractions, a muscle produces tension as it resists lengthening; this is characteristic of slowly descending a flight of stairs.

ASSESS YOUR PROGRESS

36. What is a motor unit? Explain why the size of motor units can be different in different muscles.
37. What does it mean to say that a whole muscle responds to stimuli in a graded fashion? What are the two ways to increase the force of contraction?
38. What is treppe? Explain the physiological reason for it.
39. What is multiple-motor-unit summation? Explain the five possible results of multiple-motor-unit summation.
40. How does the lack of an unresponsive period in skeletal muscle fiber contraction explain multiple-wave summation? What is the relationship to incomplete tetanus and complete tetanus?
41. Distinguish between active tension and passive tension of a muscle.
42. Explain how the initial length of the muscle affects actin and myosin overlap, and therefore the amount of contraction that occurs.
43. Describe isometric, isotonic, concentric, and eccentric contractions, and give an example of each.
44. What is muscle tone, and how is it maintained?

9.6 Muscle Fiber Types

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Distinguish between fast-twitch and slow-twitch muscle fibers.
- B. Explain the functions for which each type is best adapted.
- C. Describe how training can increase the size and efficiency of both types of muscle fibers.
- D. Explain how muscle metabolism causes normal body temperature.
- E. Describe how muscles respond to changes from normal body temperature.

There are two major types of skeletal muscle fibers: slow-twitch and fast-twitch. Not all skeletal muscles have identical functional capabilities. They differ in several respects, including the composition of their muscle fibers, which may contain slightly different forms of myosin. The myosin of slow-twitch muscle fibers causes the fibers to contract more slowly and to be more resistant to fatigue, whereas the myosin of fast-twitch muscle fibers causes the fibers to contract quickly and to fatigue quickly (table 9.3). The proportion of muscle fiber types differs within individual muscles.

Slow-Twitch Muscle Fibers

Slow-twitch muscle fibers (type I) contract more slowly, have a better-developed blood supply, have more mitochondria, and are more fatigue-resistant than fast-twitch muscle fibers. Slow-twitch muscle fibers respond relatively slowly to nervous

stimulation. The enzymes on the myosin heads responsible for the breakdown of ATP are called **myosin ATPase**. Slow-twitch fibers break down ATP slowly because their myosin heads have a slow form of myosin ATPase. The relatively slow breakdown of ATP means that cross-bridge movement occurs slowly, which causes the muscle to contract slowly. Aerobic respiration is the primary source for ATP synthesis in slow-twitch muscles, and their capacity to perform aerobic respiration is enhanced by a plentiful blood supply and the presence of numerous mitochondria. They are called oxidative muscle fibers because of their enhanced capacity to carry out aerobic respiration. Slow-twitch fibers also contain large amounts of **myoglobin** (mī-ō-glō'bin), a dark pigment similar to hemoglobin in red blood cells, which binds oxygen and acts as an oxygen reservoir in the muscle fiber when the blood does not supply an adequate amount. Myoglobin thus enhances the capacity of the muscle fibers to perform aerobic respiration.

Fast-Twitch Muscle Fibers

Fast-twitch muscle fibers (type II) respond rapidly to nervous stimulation, and their myosin heads have a fast form of myosin ATPase, which allows them to break down ATP more rapidly than slow-twitch muscle fibers. This allows their cross-bridges to release and form more rapidly than those in slow-twitch muscle fibers. Muscles containing a high percentage of fast-twitch fibers have a less-well-developed blood supply than muscles containing a high percentage of slow-twitch fibers. In addition, fast-twitch muscle fibers have very little myoglobin and fewer and smaller mitochondria. Fast-twitch muscle fibers have large deposits of glycogen and are well adapted to perform anaerobic respiration. However, the anaerobic respiration of fast-twitch muscle fibers is not adapted for supplying a large amount of ATP for a prolonged period. The muscle fibers tend to contract rapidly for a shorter time and to fatigue relatively quickly. Fast-twitch muscle fibers come in two forms: type IIa, or fast-twitch oxidative glycolytic (FOG) fibers, and type IIb, or fast-twitch glycolytic (FG) fibers (table 9.3). Type IIa fibers rely on both anaerobic and aerobic ATP production, whereas type IIb fibers rely almost exclusively on anaerobic glycolysis for ATP production.

Distribution of Fast-Twitch and Slow-Twitch Muscle Fibers

The muscles of many animals are composed primarily of either fast-twitch or slow-twitch muscle fibers. A chicken or pheasant breast, which is composed mainly of fast-twitch fibers, appears whitish because of its relatively poor blood supply and lack of myoglobin. The muscles are adapted to contract rapidly for a short time, but they fatigue quickly. By contrast, the meat of a chicken leg or a duck breast is composed of slow-twitch fibers and appears reddish or darker because of the relatively well-developed blood supply and large amount of myoglobin. These muscles are adapted to contract slowly for a longer time and to fatigue slowly. The distribution of slow-twitch and fast-twitch muscle fibers is consistent with the behavior of these animals. For example, pheasants

TABLE 9.3 Characteristics of Skeletal Muscle Fiber Types

Characteristic	Slow-Twitch Oxidative (SO) (Type I)	Fast-Twitch Oxidative Glycolytic (FOG) (Type IIa)	Fast-Twitch Glycolytic (FG) (Type IIb)
Myoglobin Content	High	High	Low
Mitochondria	Many	Many	Few
Capillaries	Many	Many	Few
Metabolism	High aerobic capacity, low anaerobic capacity	Intermediate aerobic capacity, high anaerobic capacity	Low aerobic capacity, highest anaerobic capacity
Fatigue Resistance	High	Intermediate	Low
Myosin ATPase Activity	Slow	Fast	Fast
Glycogen Concentration	Low	High	High
Location Where Fibers Are Most Abundant	Generally in postural muscles and more in lower limbs than upper limbs	Generally in lower limbs	Generally in upper limbs
Functions	Maintenance of posture and performance of endurance activities	Endurance activities in endurance-trained muscles	Rapid, intense movements of short duration

can fly relatively fast for short distances, whereas ducks fly more slowly for long distances.

Human muscles exhibit no clear separation of slow-twitch and fast-twitch muscle fibers. Most muscles have both types of fibers, although the number of each varies for each muscle. The large postural muscles contain more slow-twitch fibers, whereas the muscles of the upper limbs contain more fast-twitch fibers.

The distribution of slow-twitch and fast-twitch muscle fibers in a given muscle is fairly constant for each individual and apparently is established during early development. Sprinters have a greater percentage of fast-twitch muscle fibers, whereas long-distance runners have a higher percentage of slow-twitch muscle fibers in their lower limb muscles. Athletes who perform a variety of anaerobic and aerobic exercises tend to have a more balanced mixture of fast-twitch and slow-twitch muscle fibers.

Effects of Exercise

Neither fast-twitch nor slow-twitch muscle fibers can be easily converted to muscle fibers of the other type without specialized training. Training can increase the size and capacity of both types of muscle fibers so that they perform more efficiently. Intense exercise that requires anaerobic respiration, such as weight lifting, increases muscular strength and mass and causes fast-twitch muscle fibers to enlarge more than slow-twitch muscle fibers. Conversely, aerobic exercise increases the vascularity of muscle and causes slow-twitch muscle fibers to enlarge more. Aerobic exercise training can convert some fast-twitch muscle fibers that fatigue readily (type IIb) to fast-twitch muscle fibers that resist fatigue (type IIa). In addition to changes in myosin, increases occur in both the number of mitochondria in the muscle fibers and their blood supply. Weight training followed by periods of rest can convert some muscle fibers from type IIa to type IIb. However, a type I muscle fiber cannot be converted to a type II fiber, and vice versa. Through specific training, a person

with more fast-twitch muscle fibers can run long distances, and a person with more slow-twitch muscle fibers can increase the speed at which he or she runs.

Predict 7

Susan recently began racing her bicycle. Her training consists entirely of long rides at a steady pace. When she entered her first race, she was excited that she was able to keep pace with the rest of the riders. However, during the final sprint to the finish line, the other riders left her in their dust, and she finished in last place. Why was she unable to keep pace during the finishing sprint? As her coach, what advice would you give Susan about training for her next race?

In response to exercise, a muscle increases in size, or hypertrophies (hī-per'trō-fēz), and increases in strength and endurance. Conversely, a muscle that is not used decreases in size, or atrophies (at'rō-fēz). For example, muscular atrophy occurs in an arm or a leg that is placed in a cast for several weeks. Because muscle fiber numbers do not change appreciably during most of a person's life, atrophy and hypertrophy result from changes in the size of individual muscle fibers. As a fiber increases in size, the number of myofibrils and sarcomeres increases. The number of nuclei in each muscle fiber increases in response to exercise, but the nuclei of muscle fibers cannot divide. New nuclei are added to muscle fibers because small satellite cells near skeletal muscle fibers increase in number in response to exercise and then fuse with the skeletal muscle fibers. Other elements, such as blood vessels, connective tissue, and mitochondria, also increase in number. Atrophy due to lack of exercise results from a decrease in all these elements without a decrease in muscle fiber number. However, severe atrophy, as occurs in elderly people who cannot readily move their limbs, does involve an irreversible decrease in the number of muscle fibers and can lead to paralysis.

Clinical IMPACT

Anabolic Steroids and Growth Hormone

Some people take synthetic hormones called anabolic steroids (an-ă-bol'ik stēr'oydz, ster'oydz) to increase the size and strength of their muscles. Anabolic steroids are related to testosterone, a reproductive hormone secreted by the testes, except that the steroids have been altered so that their reproductive effects are minimized but their effect on skeletal muscles is maintained. Testosterone and anabolic steroids cause skeletal muscle tissue to hypertrophy. People who take large doses of anabolic steroid exhibit increases in body weight and total skeletal muscle mass, and many athletes believe that anabolic steroids improve performance that depends on strength. Unfortunately, harmful side effects are associated with taking anabolic steroids, including periods of irritability, testicular atrophy and sterility, cardiovascular diseases (such as heart attack or stroke), and abnormal liver function. Most athletic organizations prohibit the use of anabolic steroids; some analyze urine samples either randomly or periodically and have possible penalties in place for athletes whose urine shows evidence of anabolic steroid metabolites.

Some individuals use growth hormone inappropriately to increase muscle size. Growth hormone increases protein synthesis in muscle tissue, although it does not produce the same kinds of side effects as those attributed to anabolic steroids. Nevertheless, large doses of growth hormone can cause harmful side effects if taken over a long period (see chapter 18).

The increased strength of trained muscle is greater than would be expected if that strength were based only on the change in muscle size. In a trained person, part of the increase in strength results from the nervous system's ability to recruit a large number of motor units simultaneously to perform movements with better neuromuscular coordination. In addition, trained muscles are usually less restricted by excess adipose tissue. Metabolic enzymes increase in hypertrophied muscle fibers, resulting in a greater capacity to take in nutrients and produce ATP. Improved endurance in trained muscles is in part due to improved metabolism, increased circulation to the exercising muscles, increased numbers of capillaries, more efficient respiration, and a greater capacity of the heart to pump blood.

ASSESS YOUR PROGRESS

45. Contrast the structural and physiological differences between slow-twitch and fast-twitch muscle fibers.
46. Explain the functions for which each type of muscle fiber is best adapted and how slow-twitch and fast-twitch fibers are distributed.
47. How does anaerobic versus aerobic exercise affect muscles?
48. What factors contribute to increases in muscle size, strength, and endurance?

Heat Production

The rate of metabolism in skeletal muscle differs before, during, and after exercise. As chemical reactions occur within cells, some energy is released in the form of heat. Normal body temperature results primarily from this heat. Because the rate of chemical reactions increases in muscle fibers during contraction, the rate of heat production also increases, causing a rise in body temperature. After exercise, increased metabolism resulting from recovery oxygen consumption helps keep the body temperature elevated, but sweating and vasodilation of blood vessels in the skin speed heat loss and keep body temperature within its normal range (see chapter 25).

When body temperature declines below a certain level, the nervous system responds by inducing shivering, rapid skeletal muscle contractions that produce shaking rather than coordinated movements. During shivering, the muscle movement increases heat production up to 18 times that of resting levels, and the heat produced can exceed the amount produced during moderate exercise. Thus, shivering helps raise body temperature to its normal range.

ASSESS YOUR PROGRESS

49. How do muscles contribute to body temperature before, during, and after exercise?
50. What is accomplished by shivering?

9.7 Energy Sources for Muscle Contraction

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the three sources of energy to produce ATP for muscles.
- B. Distinguish between oxygen deficit and recovery oxygen consumption.
- C. Compare the mechanisms involved in the major types of muscle fatigue.
- D. Contrast physiological contracture and rigor mortis.

Muscle fibers are very energy-demanding cells, whether at rest or during any form of exercise. This energy comes from either aerobic (with O₂) or anaerobic (without O₂) ATP production (see chapter 25).

Generally, ATP is derived from four processes in skeletal muscle:

1. Aerobic production of ATP during most exercise and normal conditions
2. Anaerobic production of ATP during intensive short-term work
3. Conversion of a molecule called **creatine phosphate** to ATP
4. Conversion of two ADP to one ATP and one AMP (adenosine monophosphate) during heavy exercise

Aerobic (ār-ō'bik) **respiration**, which occurs mostly in mitochondria, requires O₂ and breaks down glucose to produce ATP, CO₂, and H₂O. Aerobic respiration can also process lipids or

amino acids to make ATP. **Anaerobic** (an-ār-ō'biĕk) **respiration**, which does not require O₂, breaks down glucose to produce ATP and lactate.

Aerobic and Anaerobic Respiration

In general, slow-twitch fibers work aerobically, whereas fast-twitch fibers are more suited for working anaerobically. Low-intensity, long-duration exercise is supported through mainly aerobic pathways. Higher-intensity, shorter-duration exercise, such as sprinting or carrying something very heavy, is supported through partially anaerobic pathways. There are very few, if any, activities that are supported through exclusively anaerobic pathways, and those that are can be sustained for only a few seconds. Because exercise is not usually exclusively aerobic or anaerobic, both muscle fiber types contribute to most types of muscle function.

Historically, ATP production in skeletal muscle was thought to be clearly delineated into purely aerobic activities versus purely anaerobic activities and that the product of anaerobic respiration was principally lactic acid. Lactic acid was considered to be a harmful waste product that must be removed from the body. However, it is now widely recognized that anaerobic respiration ultimately gives rise to lactic acid's alternate chemical form, lactate. Moreover, it is now known that lactate is a critical metabolic intermediate that is formed and used continuously even under fully aerobic conditions. Lactate is produced by skeletal muscle cells at all times, but particularly during exercise, and is subsequently broken down (70–75%) or used to make new glucose (30–35%). Thus, the aerobic and anaerobic mechanisms of ATP production are linked through lactate.

Aerobic respiration is much more efficient than anaerobic respiration but takes several minutes. With aerobic respiration pathways, the breakdown of a single glucose molecule produces approximately 18 times more ATP than that produced through anaerobic respiration pathways. Aerobic respiration produces up to 36 ATP molecules for each glucose molecule compared to only 2 ATP molecules per glucose molecule from anaerobic respiration. Additionally, aerobic respiration is more flexible than anaerobic respiration because of the ability to break down lipids and amino acids to form ATP, as noted earlier.

In aerobic respiration, pyruvic acid is metabolized by chemical reactions within mitochondria. Two closely coupled sequences of reactions in mitochondria, called the citric acid cycle and the electron-transport chain, produce many ATP molecules. Carbon dioxide molecules are produced and, in the last step, oxygen atoms combine with hydrogen atoms to form water. Thus, carbon dioxide, water, and ATP are major end products of aerobic respiration. The following equation represents the aerobic respiration of one molecule of glucose:

Although aerobic respiration produces many more ATP molecules than anaerobic respiration does, the rate at which the ATP molecules are produced is slower. Resting muscles or muscles involved in long-term exercise, such as long-distance running or other endurance activities, depend primarily on aerobic respiration for ATP synthesis.

Anaerobic respiration produces far less ATP than aerobic respiration, but anaerobic respiration can produce ATP in a matter of a few seconds compared to aerobic respiration, which takes a few minutes. However, ATP production rate by anaerobic respiration is too low to maintain activities for more than a few minutes.

The first stages of anaerobic respiration and aerobic respiration share an enzymatic pathway called glycolysis (glī-kol'-ī-sis). In glycolysis, a glucose molecule is broken down into two molecules of pyruvic acid. Two molecules of ATP are used in this process, but four molecules of ATP are produced, resulting in a net gain of two ATP molecules for each glucose molecule metabolized. In anaerobic respiration, the pyruvic acid is then converted to lactate.

Anaerobic respiration is less efficient than aerobic respiration, but it is much faster, especially when insufficient oxygen is available for aerobic respiration. By using many glucose molecules, anaerobic respiration can rapidly produce ATP for a short time. During short periods of intense exercise, such as sprinting, anaerobic respiration combined with the breakdown of creatine phosphate provides enough ATP to support intense muscle contraction for up to 3 minutes. However, ATP formation from creatine phosphate and anaerobic respiration is limited by the depletion of creatine phosphate and glucose and by the brief time anaerobic respiration can produce ATP.

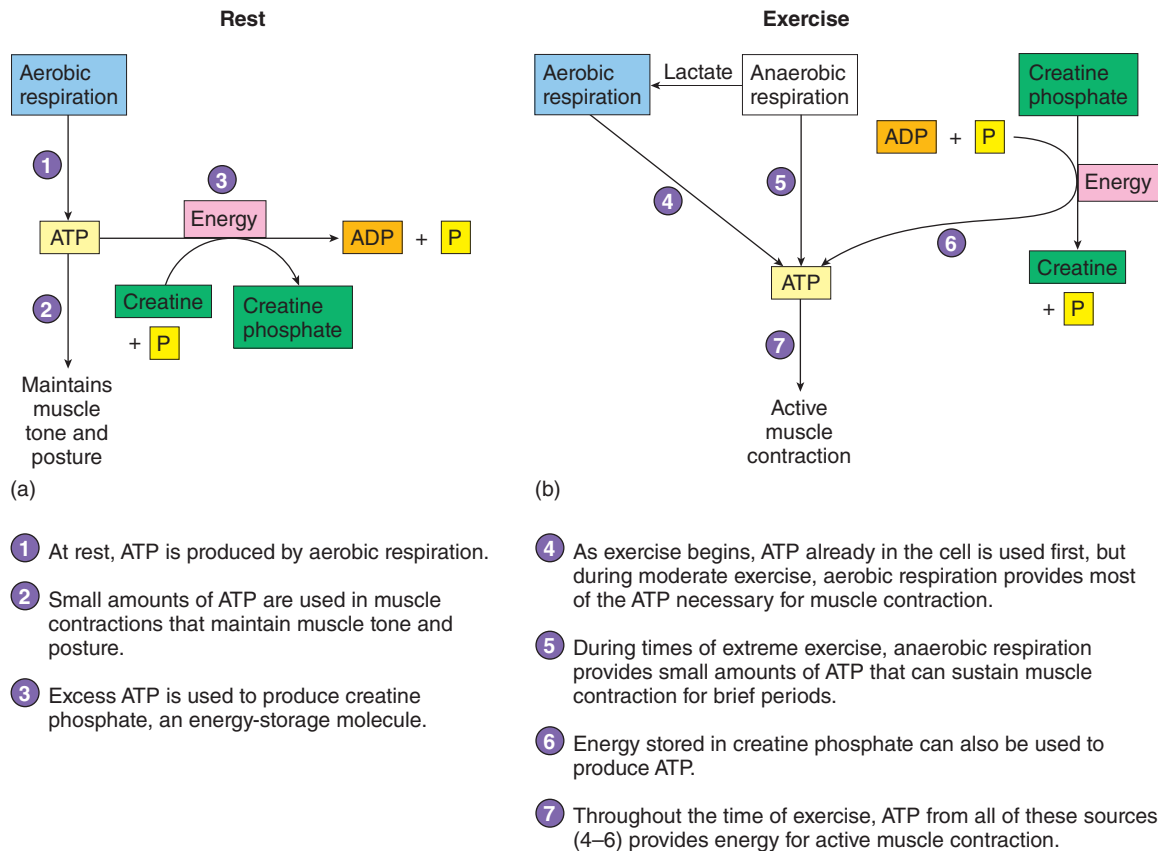

Increased breathing and elevated aerobic respiration after exercise partially result from the oxygen deficit that occurs during such exercise. The increased aerobic respiration pays back a portion of the oxygen deficit by converting creatine to creatine phosphate and converting the excess lactate to glucose, which is once again stored as glycogen in muscles and in the liver. The magnitude of the oxygen deficit depends on the intensity of the exercise, the length of time it was sustained, and the individual's physical condition. People who are in poor physical condition do not have as great a capacity to perform aerobic respiration as that of well-trained athletes.

Creatine Phosphate

Because muscle cells cannot store ATP, how do they generate enough ATP at a rate to keep pace with their high-energy demand? They store a different high-energy molecule, called creatine phosphate. Creatine phosphate provides a means of storing energy that can be rapidly used to help maintain adequate ATP in contracting muscle fibers. During periods of rest, as excess ATP is produced, the excess ATP is used to synthesize creatine phosphate. During exercise, especially at the onset of exercise, the small ATP reserve is quickly depleted. Creatine phosphate is then broken down to directly synthesize ATP.

Some of this ATP is immediately used, and some is used to restore ATP reserves. The reaction, catalyzed by the enzyme creatine kinase, occurs very rapidly and is able to maintain ATP levels as long as creatine phosphate is available in the fiber. However, during intense muscular contraction, creatine phosphate levels are quickly exhausted. ATP and creatine phosphate

PROCESS FIGURE 9.23 ATP Production in Resting and Exercising Muscle

present in the cell provide enough energy to sustain maximum contractions for about 8–10 seconds. Figure 9.23 summarizes how aerobic and anaerobic respiration, lactate fermentation, and creatine phosphate production interact to produce a continuous supply of ATP in resting and exercising muscle.

When a muscle cell is working too strenuously for ATP stores and creatine phosphate to be able to provide enough ATP, anaerobic respiration predominates. Typically, the type II fibers are the primary anaerobic fibers. The type II fibers break down glucose into the intermediate lactate, which can be shuttled to adjacent type I fibers to make ATP or be secreted into the blood for uptake by other tissues, such as the liver, to make new glucose. Thus, in skeletal muscle, the type II fiber (anaerobic) pathways and the type I fiber (aerobic) pathways are not mutually exclusive. Rather, they work together, with lactate being the product of the type II fiber pathways, which then serves as the starting point of the type I fiber pathways.

Recycling of ADP

Ultimately, if the use of ATP is greater than the production of ATP, the ATP:ADP ratio decreases, which interferes with the functioning of all the major ATP-dependent enzymes in the muscle fibers. The ATP-dependent enzymes include the myosin head, the sarcoplasmic reticulum Ca^{2+} re-uptake pump, and the

Na^+/K^+ pump for the resting membrane potential maintenance, all of which are required for proper muscle functioning. If the ATP:ADP ratio declines, an enzyme transfers one phosphate from one ADP to another ADP, generating one ATP and one AMP (adenosine monophosphate). The presence of AMP triggers a switch from anaerobic respiration to aerobic respiration of blood glucose and fatty acids. If this switch did not occur, the muscles could not maintain their activity and could ultimately fail (see “Fatigue” in the next section). Table 9.4 provides a summary of creatine phosphate, anaerobic respiration, and aerobic respiration as sources of ATP in skeletal muscle.

Predict 8

A condition called McArdle disease is due to a deficiency of an enzyme necessary for the breakdown of the stored form of glucose, called glycogen. Predict how the disease affects a person’s ability to exercise.

Muscle Fatigue

Fatigue (fă-tēg’) is a temporary state of reduced work capacity. Without fatigue, muscle fibers would be worked to the point of structural damage to them and their supportive tissues. Historically, it was thought that build-up of lactate and the corresponding drop in pH (acidosis) was the major cause of fatigue.

However, it is now established that there are multiple mechanisms underlying muscular fatigue:

1. Acidosis and ATP depletion due to either an increased ATP consumption or a decreased ATP production
2. Oxidative stress, which is characterized by the build-up of excess reactive oxygen species (ROS; free radicals)
3. Local inflammatory reactions

Acidosis and ATP Depletion

Anaerobic respiration results in the breakdown of glucose to lactate and protons accounting for lowered pH. Lowered pH has several cellular effects, including decreased effectiveness of Ca^{2+} on actin and overall less Ca^{2+} release from the sarcoplasmic reticulum. Lactic acidosis can also result when liver dysfunction results in reduced clearance of lactate (such as using it to produce glucose). Usually, increased lactate levels are due to increased anaerobic respiration production of ATP when aerobic respiration production of ATP is reduced. Increases in lactate are also seen in patients with mitochondrial disorders and chronic obstructive pulmonary disease (COPD).

However, to what extent ATP reductions are responsible for muscular fatigue is still not clear. Recent studies have demonstrated that cytoplasmic ATP levels stay relatively constant even in the face of decreasing muscle force production. But decreased ATP does cause fatigue. More specifically, it is the *localized* decreases in ATP levels or those associated with specific transport systems that are correlated with muscle fatigue.

Oxidative Stress

During intense exercise, increases in ROS production cause the breakdown of proteins, lipid, or nucleic acids. In addition, ROS trigger an immune system chemical called interleukin-6 (IL-6). IL-6 is a mediator of inflammation, which is the most likely cause of muscle soreness.

Inflammation

In addition to the stimulation of IL-6 by ROS, which causes inflammation, the immune system is directly activated by exercise. T-lymphocytes, a type of white blood cell, migrate into heavily worked muscles. The presence of immune system intermediates increases the perception of pain, which most likely serves as a signal to protect those tissues from further damage.

An example of muscle fatigue occurs when a runner collapses on the track and must be helped off. The runner's muscle can no longer function, regardless of how determined the runner is. Under conditions of extreme muscular fatigue, muscle may become incapable of either contracting or relaxing. This condition, called **physiological contracture** (kon-trak'choor), occurs when there is too little ATP to bind to myosin myofilaments. Because binding of ATP to the myosin heads is necessary for cross-bridge release between the actin and myosin, the cross-bridges between the actin and myosin myofilaments cannot be broken, and the muscle cannot relax.

Rigor mortis (rig'er mōr'tīs), the development of rigid muscles several hours after death, is similar to physiological

contracture. Shortly after death, ATP production stops, and ATP levels within muscle fibers decline. Because of low ATP levels, active transport of Ca^{2+} into the sarcoplasmic reticulum stops, and Ca^{2+} leaks from the sarcoplasmic reticulum into the sarcoplasm. Calcium ions can also leak from the sarcoplasmic reticulum as its membrane breaks down after cell death. As Ca^{2+} levels increase in the sarcoplasm, cross-bridges form. However, too little ATP is available to bind to the myosin molecules, so the cross-bridges are unable to release and re-form in a cyclic fashion to produce contractions. As a consequence, the muscles remain stiff until tissues begin to degenerate.

The most common type of fatigue, **psychological fatigue**, involves the central nervous system rather than the muscles themselves. The muscles are still capable of contracting, but the individual "perceives" that continued muscle contraction is impossible. A determined burst of activity in a tired runner in response to pressure from a competitor is an example of how psychological fatigue can be overcome.

Although fatigue reduces power output, the overall benefit is that it prevents complete exhaustion of ATP reserves, which could otherwise lead to severe damage of the muscle fibers.

Muscle Soreness

Following vigorous exercise, people sometimes experience muscle pain, which can last for several days. The pain is more common in untrained people. In addition, highly repetitive eccentric muscle contractions produce pain more readily than concentric contractions do. The pain is related to inflammatory chemical influx into the muscle fibers. In people with exercise-induced muscle soreness, enzymes that are normally found inside muscle fibers can be detected in the extracellular fluid. These enzymes are able to leave the muscle fibers because injury has increased the permeability of plasma membranes, or has even ruptured them. Also found in the extracellular fluid of muscles are fragments of collagen, indicating that both muscle fibers and the connective tissue of muscles have been injured. Exercise schedules that alternate exercise with periods of rest, such as lifting weights every other day, provide time for the repair of muscle tissue.

ASSESS YOUR PROGRESS

51. What is fatigue? List the three locations where fatigue can develop.
52. Describe what occurs to produce each type of fatigue.
53. Explain the causes of physiological contracture and rigor mortis.

Oxygen Deficit and Recovery Oxygen Consumption

There is a lag time between when a person begins to exercise and when he or she begins to breathe more heavily because of the exercise. After exercise stops, there is another lag time before breathing returns to its preexercise rate. These changes in breathing patterns reflect muscles' need for more oxygen to produce

TABLE 9.4 Sources of ATP in Skeletal Muscle

Pathway	Creatine Phosphate	Anaerobic Respiration	Aerobic Respiration
Energy source	Creatine phosphate	Glucose	Glucose, fatty acids, amino acids
Oxygen required	No	No	Yes
ATP yield	1 per creatine phosphate	2 per glucose molecule	Up to 36 per glucose molecule
Duration of energy supply	Up to 10 seconds	Up to 3 minutes	Hours
Type of work supported	Moderate exercise and extreme exercise	Extreme exercise	Resting and all exercise

ATP through aerobic respiration. The insufficient oxygen consumption relative to increased activity at the onset of exercise creates an **oxygen deficit**. This deficit must be repaid during and after exercise once oxygen consumption catches up with the increased activity level. At the onset of exercise, muscles primarily acquire the ATP they need from the creatine phosphate system and anaerobic respiration—two systems that can supply ATP relatively quickly and without requiring oxygen (table 9.4). The ability of aerobic respiration to supply ATP at the onset of exercise lags behind that of the creatine phosphate system and anaerobic respiration. This explains the lag between the onset of exercise and the need for increased oxygen.

The elevated oxygen consumption that occurs after exercise has ended is called **recovery oxygen consumption**. A portion of the recovery oxygen is used to “repay” the oxygen deficit incurred at the onset of exercise, but most of the recovery oxygen is used to support metabolic processes that restore homeostasis after it was disturbed during exercise. Such disturbances include exercise-related increases in body temperature, changes in intra- and extracellular ion concentrations, and changes in metabolite and hormone levels. Recovery oxygen consumption generally lasts minutes to hours, depending on the individual’s physical conditioning and on the length and intensity of the exercise session. In extreme cases, such as following a marathon, recovery oxygen consumption can last as long as 15 hours.

Predict 9

Eric is a highly trained cross-country runner, and his brother John is a computer programmer who almost never exercises. While the two brothers were working on a remodeling project in the basement of their house, the doorbell rang upstairs: A package they were both very excited about was being delivered. They raced each other up the stairs to the front door to see who could get the package first. When they reached the door, both were breathing heavily. However, John continued to breathe heavily for several minutes while Eric was opening the package. Why did John breathe heavily longer than Eric, even though they had both run the same distance?

ASSESS YOUR PROGRESS

54. List the energy sources used to synthesize ATP for muscle contraction.

- 55.** What is the function of creatine phosphate, and when is it used?
- 56.** Contrast the efficiency of anaerobic and aerobic respiration. When is each type used by cells?
- 57.** When does lactate increase in a muscle fiber?
- 58.** What is the difference between oxygen deficit and recovery oxygen consumption? Explain the factors that contribute to an oxygen deficit.

9.8 Smooth Muscle

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the structural features of smooth muscle cells and contrast them with skeletal muscle fibers.**
- Explain the steps of smooth muscle contraction and how the contraction differs from skeletal muscle contraction.**
- Compare the two types of smooth muscle as to their action and locations.**
- Describe the electrical and functional properties of smooth muscle.**
- Explain how smooth muscle activities are regulated.**

Smooth muscle is distributed widely throughout the body and is more variable in function than other muscle types. Smooth muscle cells (figure 9.24) are smaller than skeletal muscle fibers, ranging from 15 to 200 μm in length and from 5 to 8 μm in diameter. They are spindle-shaped, with a single nucleus in the middle of the cell. Compared with skeletal muscle, fewer total myofilaments are present, but, in smooth muscle, there are more actin than myosin myofilaments. The actin and myosin myofilaments overlap, but they are organized as loose bundles instead of sarcomeres. Consequently, smooth muscle does not have a striated appearance. Actin myofilaments are attached to structures called **dense bodies**, which are scattered through the cell cytoplasm, and to **dense areas**, which are in the plasma membrane. Dense bodies and dense areas are considered equivalent to the Z disks in skeletal muscle. Noncontractile **intermediate filaments** also attach to the dense

Nuclei of smooth muscle cells

FIGURE 9.24 Smooth Muscle Histology

Smooth muscle tissue is made up of sheets or bundles of spindle-shaped cells, with a single nucleus in the middle of each cell. **APR**

bodies. The intermediate filaments and dense bodies form an intracellular cytoskeleton, which has a longitudinal or spiral organization. The smooth muscle cells shorten when the actin and myosin slide over one another during contraction (figure 9.25).

Sarcoplasmic reticulum is present in smooth muscle cells, but no T tubule system exists. Some shallow, invaginated areas called **caveolae** (kav-ē-ō'lē) lie along the surface of the plasma membrane. The function of caveolae is not well known, but it may be similar to that of both the T tubules and the sarcoplasmic reticulum of skeletal muscle.

Other differences exist between smooth muscle and skeletal muscle. In particular, smooth muscle has a slower contraction speed than skeletal muscle. This difference is due to several factors. In smooth muscle, some of the Ca^{2+} required to initiate contractions enters the cell from the extracellular fluid and from the sarcoplasmic reticulum. Therefore, it is the greater distance that Ca^{2+} must diffuse, the slower rate at which action potentials are propagated between smooth muscle cells, and the slower rate of cross-bridge formation between actin and myosin myofilaments that are all responsible for the slower contraction of smooth muscle.

Smooth muscle contraction is stimulated both neurally and hormonally. Regardless of the stimulus source, however, calcium ions are the key to smooth muscle contraction.

FIGURE 9.25 Actin and Myosin Proteins in a Smooth Muscle Cell

Bundles of contractile myofilaments containing actin and myosin are anchored at one end to dense areas in the plasma membrane and at the other end, through dense bodies, to intermediate filaments. The contractile myofilaments are oriented with the long axis of the cell; when actin and myosin slide over one another during contraction, the cell shortens.

Although calcium ions regulate contraction in smooth muscle cells (figure 9.26), the role of Ca^{2+} in smooth muscle differs from that in skeletal muscle cells because there are no troponin molecules associated with actin fibers of smooth muscle cells. Instead, Ca^{2+} that enter the cytoplasm bind to a protein called **calmodulin** (kal-mod'ū-lin). Calmodulin molecules bound to Ca^{2+} activate an enzyme called **myosin kinase** (kī'nās), which transfers a phosphate group from ATP to light myosin molecules on the heads of myosin molecules. Cross-bridge formation occurs when myosin myofilaments have phosphate groups bound to them. The enzymes responsible for cross-bridge cycling are slower than the enzymes in skeletal muscle, resulting in slower cross-bridge formation. Once activated, cross-bridge formation has energy requirements very similar to those of cross-bridge formation in skeletal muscle fibers.

Relaxation of smooth muscle results because of the activity of another enzyme, called **myosin phosphatase** (fos'fā-tās). This enzyme removes the phosphate group from the myosin molecules (figure 9.26). If the phosphate is removed from myosin while the cross-bridges are attached to actin, the cross-bridges release very slowly. This explains how smooth muscle is able to sustain tension for long periods and without extensive energy expenditure. This period of sustained tension is often called the **latch state** of smooth muscle contraction. If myosin phosphatase removes the phosphate from myosin molecules while the cross-bridges are not attached, relaxation occurs much more rapidly.

In summary, elevated Ca^{2+} levels in the sarcoplasm of smooth muscle cells result in the activation of myosin molecules and the formation of cross-bridges. Also, the action of myosin phosphatase results in a high percentage of myosin molecules having their phosphates removed while bound to actin. This process favors

1 A hormone combines with a hormone receptor and activates a G protein mechanism, or depolarization of the plasma membrane occurs.

2 An α subunit opens the Ca^{2+} channel in the plasma membrane, or depolarization opens Ca^{2+} channels. Calcium ions diffuse through the Ca^{2+} channels and combine with calmodulin.

3 Calmodulin with a Ca^{2+} bound to it binds with myosin kinase and activates it.

4 Activated myosin kinase attaches phosphate from ATP to myosin heads to activate the contractile process.

5 A cycle of cross-bridge formation, movement, detachment, and cross-bridge formation occurs.

6 Relaxation occurs when myosin phosphatase removes phosphate from myosin.

PROCESS FIGURE 9.26 Smooth Muscle Contraction

sustained contractions, or the latch state, and a low rate of energy consumption because of the slow release of cross-bridges. As long as Ca^{2+} is present, cross-bridges re-form quickly after being released. Consequently, many cross-bridges are intact at any given time in contracted smooth muscle.

Calcium ion levels in the sarcoplasm of smooth muscle are reduced as Ca^{2+} is actively transported across the plasma membrane, including the plasma membrane of caveolae, and into the sarcoplasmic reticulum. Muscles relax in response to lower intracellular levels of Ca^{2+} .

Types of Smooth Muscle

There are two types of smooth muscle, visceral and multiunit. **Visceral** (vis'er-äl) **smooth muscle** is the more common of the two types. It occurs in sheets and includes the smooth muscle of the digestive, reproductive, and urinary tracts. Visceral smooth muscle has numerous gap junctions (see chapter 4), which allow action potentials to pass directly from one cell to another. As a consequence, sheets of smooth muscle cells function as a unit, and a wave of contraction traverses the entire smooth muscle sheet. Visceral smooth muscle is often autorhythmic but in some areas it contracts only when stimulated. For example, visceral smooth muscle in the digestive tract contracts spontaneously and at relatively regular intervals, whereas visceral smooth muscle in the urinary bladder contracts only when stimulated by the nervous system.

Multiunit smooth muscle occurs in various configurations: sheets, as in the walls of blood vessels; small bundles, as in the arrector pili muscles and the iris of the eye; and single cells, as in the capsule of the spleen. Multiunit smooth muscle has fewer gap junctions than visceral smooth muscle, and cells or groups of cells act as independent units. It normally contracts only when stimulated by nerves or hormones.

In visceral smooth muscle tissue, the arrangement between neurons and smooth muscle fibers differs from that in skeletal muscle tissue. The synapses are more diffuse than in skeletal muscle. Axons of neurons terminate in a series of dilations along the branching axons within the connective tissue among the smooth muscle cells. These dilations have vesicles containing neurotransmitter molecules that, once released, diffuse among the smooth muscle cells and bind to receptors on their surfaces. Multiunit smooth muscle has synapses more like those found in skeletal muscle tissue.

Electrical Properties of Smooth Muscle

The resting membrane potential of smooth muscle cells is usually not as negative as that of skeletal muscle fibers. It normally ranges between -55 and -60 mV, compared with approximately -85 mV in skeletal muscle fibers. Furthermore, the resting membrane

potential of many visceral smooth muscle cells fluctuates, with slow depolarization and repolarization phases. These slow waves of depolarization and repolarization are propagated from cell to cell for short distances (figure 9.27a). More “classic” action potentials can be triggered by the slow waves of depolarization and usually are propagated for longer distances (figure 9.27b). In addition, some smooth muscle types have action potentials with a plateau, or prolonged depolarization (figure 9.27c). The slow waves in the resting membrane potential may result from a spontaneous and progressive increase in the permeability of the plasma membrane to Na^+ and Ca^{2+} , or they may be controlled by neurons. Sodium ions and Ca^{2+} diffuse into the cell through their respective channels and produce the depolarization.

Smooth muscle does not respond in an all-or-none fashion to action potentials. A series of action potentials in smooth muscle can result in a single, slow contraction followed by slow relaxation instead of individual contractions in response to each action potential, as occurs in skeletal muscle. A slow wave of depolarization that has one to several more classic-appearing action potentials superimposed on it is common in many types of smooth muscle. After the wave of depolarization, the smooth muscle contracts. Action potentials with plateaus are common in smooth muscle that exhibits periods of sustained contraction.

Spontaneously generated action potentials that lead to contractions are characteristic of visceral smooth muscle in the uterus, the ureter, and the digestive tract. Certain smooth muscle cells in these organs function as **pacemaker cells**, which tend to develop action potentials more rapidly than other cells.

The nervous system can regulate smooth muscle contractions by increasing or decreasing action potentials carried by neuron axons to smooth muscle. Responses of smooth muscle cells result in depolarization and increased contraction or hyperpolarization and decreased contraction. The nervous system can also regulate the pacemaker cells.

Hormones and ligands produced locally in tissues can bind to receptors on some smooth muscle plasma membranes. The combination of a hormone or other ligands with a receptor causes

FIGURE 9.27 Membrane Potentials in Smooth Muscle

Duchenne Muscular Dystrophy

Background Information

Duchenne muscular dystrophy (DMD) is usually identified in children around 3 years of age, when their parents notice slow motor development with progressive weakness and muscle wasting (atrophy). Typically, muscular weakness begins in the hip muscles, which causes a waddling gait. Temporary enlargement of the calf muscles is apparent in 80% of cases. The enlargement is paradoxical because the muscle fibers are actually getting smaller, but the amount of fibrous connective tissue and fat between the muscle fibers is increasing (figures 9A and 9B). The protein that normally protects muscle against mechanical stress is not functional in patients with DMD. This is thought to be the primary cause of the muscle weakness and other symptoms. Rising from the floor by using the hands and arms is characteristic and is caused by weakness of the lumbar and hip muscles (figure 9C). Within 3 to 5 years, the muscles of the shoulder girdle become involved. The replacement of muscle with connective tissue contributes to muscular atrophy and shortened, inflexible muscles called contractures. The contractures limit movements and can cause severe deformities of the skeleton. By 10 to 12 years of age, people with DMD are usually unable to

Figure 9A Normal Muscle Tissue

Figure 9B DMD Muscle Tissue

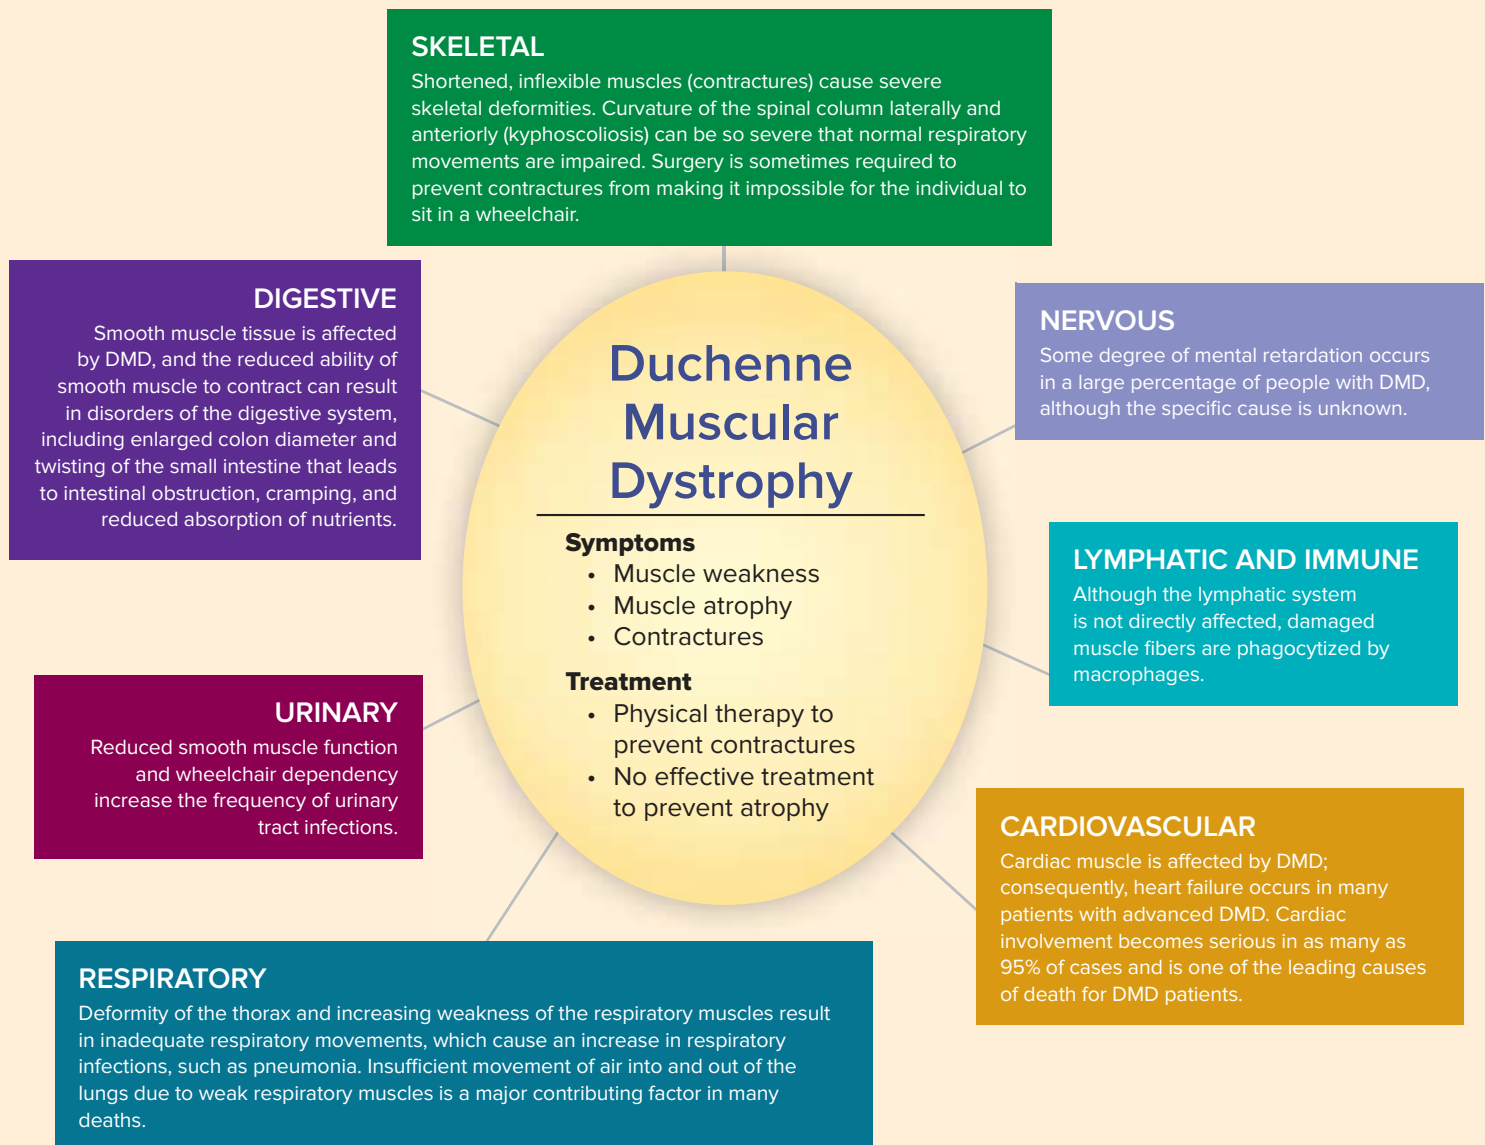

Figure 9C A DMD Patient

ligand-gated Ca^{2+} channels in the plasma membrane to open (see figure 9.26, *step 2*). Calcium ions then enter the cell and cause smooth muscle contractions to occur without a major change in the membrane potential. For example, some smooth muscles contract when exposed to the hormone epinephrine, which combines with epinephrine receptors to activate G proteins in the plasma membrane (see figure 9.26, *step 2*). The α subunit of the G complex can produce intracellular mediator molecules, which

open the ligand-gated Ca^{2+} channels in the plasma membrane or sarcoplasmic reticulum.

► Predict 10

Explain how a ligand can bind to a membrane-bound receptor in a smooth muscle cell and cause sustained contraction for a prolonged period without a large increase in ATP breakdown.

walk, and few live beyond age 20. DMD is genetic, but because of its inheritance pattern, mostly males are affected. There is no effective treatment to prevent the progressive deterioration of muscles in DMD. Therapy primarily involves exercises to help strengthen muscles and prevent contractures.

➤ Predict 11

A boy with advanced Duchenne muscular dystrophy developed pulmonary edema (accumulation of fluid in the lungs) and pneumonia caused by a bacterial infection. His physician diagnosed the condition in the following way: The pulmonary edema was the result of heart failure, and the increased fluid in the lungs provided a site where bacteria could invade and grow. The fact that the boy could not breathe deeply or cough effectively made the condition worse. How would the muscle tissues in a boy with advanced DMD differ from the muscle tissues in a boy with less advanced DMD?

Functional Properties of Smooth Muscle

Smooth muscle has four functional properties not seen in skeletal muscle: (1) Some visceral smooth muscle exhibits autorhythmic contractions; (2) smooth muscle tends to contract in response to being stretched, but a slow increase in length produces less response than a more rapid increase in length; (3) smooth muscle exhibits a relatively constant tension, called **smooth muscle tone**, over a long period and maintains that

tension in response to a gradual increase in the smooth muscle length; (4) the amplitude of contraction produced by smooth muscle also remains constant, although the muscle length varies. Smooth muscle is therefore well adapted for lining the walls of hollow organs, such as the stomach and the urinary bladder. As the volume of the stomach or urinary bladder increases, the tension applied to its contents increases only slightly. Also, as the volume of the large and small intestines

increases, the contractions that move food through them do not dramatically change in amplitude.

Regulation of Smooth Muscle

The autonomic nervous system innervates smooth muscle, whereas the somatic motor nervous system innervates skeletal muscle (see chapter 11). The regulation of smooth muscle is therefore involuntary, and the regulation of skeletal muscle is voluntary.

The most important neurotransmitters released from the nerves that innervate smooth muscle cells are acetylcholine and norepinephrine. Acetylcholine stimulates some smooth muscle types to contract and inhibits others.

Hormones are also important in regulating smooth muscle. Epinephrine, a hormone from the adrenal medulla, stimulates some smooth muscles, such as those in the blood vessels of the small intestine, and inhibits other smooth muscles, such as those in the intestinal wall. Oxytocin stimulates contractions of uterine smooth muscle, especially during childbirth. These and other hormones are discussed more thoroughly in chapters 17 and 18. Other chemical substances produced locally by surrounding tissues—such as histamine, prostaglandins, and by-products of metabolism—also influence smooth muscle function. For example, blood flow through capillaries is dramatically influenced by these substances (see chapter 21).

The type of receptors present on the plasma membrane to which the neurotransmitters or hormones bind determines the response of the smooth muscle. Some smooth muscle types have receptors to which acetylcholine binds, and the receptor responds by stimulating contractions; other smooth muscle types have receptors to which acetylcholine binds, and the receptor responds by inhibiting contractions. A similar relationship exists for smooth muscle receptors for norepinephrine and certain hormones.

The receptor molecules that stimulate smooth muscle contractions often open either Na^+ or Ca^{2+} channels. When these channels open, Na^+ and Ca^{2+} pass through their respective channels into the cell and cause depolarization of the plasma membrane. It is also possible for the receptor to open Ca^{2+} channels in the plasma membrane and sarcoplasmic reticulum. As a result, Ca^{2+} can diffuse into the cytoplasm of the smooth muscle cells without depolarization of the membrane potential to its threshold level and therefore not produce action potentials.

The receptor molecules that inhibit smooth muscle contractions often close Na^+ and Ca^{2+} channels or open K^+ channels. The result is hyperpolarization (membrane potential below resting) of the smooth muscle cells and inhibition. It is also possible for the receptors to increase the activity of the Ca^{2+} pump that transports Ca^{2+} out of the cell or into the sarcoplasmic reticulum. As a result, relaxation may occur without a change in the resting membrane potential.

The response of specific smooth muscle types to either neurotransmitters or hormones is presented in the chapters dealing with the smooth muscle types.

ASSESS YOUR PROGRESS

59. Describe a typical smooth muscle cell. How do its structure and its contraction process differ from those of skeletal muscle fibers?
60. What ion is key to smooth muscle contraction? What are the functions of this ion?
61. What is the role of calmodulin? Of myosin phosphatase?
62. Compare visceral smooth muscle and multiunit smooth muscle as to locations and structure.
63. Explain why visceral smooth muscle contracts as a single unit.
64. How do smooth muscle cells differ from skeletal muscle fibers in their electrical properties?
65. How are spontaneous contractions produced in smooth muscle?
66. List four functional properties of smooth muscle that are not seen in skeletal muscle. Can smooth muscle develop an oxygen deficit?
67. How do the nervous system and hormones regulate smooth muscle contraction?
68. How are ion channels affected by receptors that stimulate smooth muscle contractions? That inhibit smooth muscle contractions?

9.9 Cardiac Muscle

LEARNING OUTCOME

After reading this section, you should be able to

- A. Discuss the structural and functional characteristics of cardiac muscle.

Cardiac muscle, which is found only in the heart, is discussed in detail in chapter 20. Like skeletal muscle tissue, cardiac muscle tissue is striated, but each cell usually contains one nucleus located near the center. Adjacent cells join to form branching fibers by specialized cell-to-cell attachments called **intercalated** (in-ter'käl-lā-ted) **disks**, which have gap junctions that allow action potentials to pass from cell to cell. Some cardiac muscle cells are autorhythmic, and one part of the heart normally acts as the pacemaker. The action potentials of cardiac muscle are similar to those of nerve and skeletal muscle but have a much longer duration and refractory (unresponsive) period. The depolarization of cardiac muscle results from the influx of both Na^+ and Ca^{2+} across the plasma membrane. The regulation of contraction in cardiac muscle by Ca^{2+} is similar to that of skeletal muscle.

ASSESS YOUR PROGRESS

69. Compare the structural and functional characteristics of cardiac muscle with those of skeletal muscle.
70. How is cardiac muscle similar to smooth muscle?

9.10 Effects of Aging on Skeletal Muscle

LEARNING OUTCOME

After reading this section, you should be able to

A. Describe the changes that occur in aging skeletal muscle.

A primary consequence of aging is **sarcopenia**, or muscle atrophy, the age-related reduction in muscle mass and regulation of muscle function. Aging skeletal muscle undergoes several changes that reduce muscle mass, increase the time muscle takes to contract in response to nervous stimuli, reduce stamina, and increase recovery time. Loss of muscle fibers begins as early as 25 years of age and, by age 80, the muscle mass has been reduced by approximately 50%, due primarily to the loss of muscle fibers. An important component of age-related loss of muscle mass is maintenance of independence in elderly people. In order to help delay sarcopenia, weight-lifting exercises are helpful to slow the loss of muscle mass but do not prevent the loss of muscle fibers. In addition, fast-twitch muscle fibers decrease in number more rapidly than slow-twitch fibers. Most of the lost strength and speed is due to the loss of fast-twitch muscle fibers.

In addition, the surface area of the neuromuscular junction decreases; as a result, action potentials in neurons stimulate action potentials in muscle fibers more slowly, so fewer action potentials are produced in muscle fibers. The number of motor neurons also decreases. Some of the muscle fibers that lose their innervation when a neuron dies are reinnervated by a branch of another motor neuron. This makes motor units in skeletal muscle fewer in number, with a greater number of muscle fibers for each neuron, which may result in less precise muscle control. Aging is also associated with decreased density of capillaries in skeletal muscles, so that a longer recovery period is required after exercise.

Many of the age-related changes in skeletal muscle can be slowed dramatically if people remain physically active instead of assuming a sedentary lifestyle. Studies show that elderly people who are sedentary can become stronger and more mobile in response to exercise. The effects of aging on people with large muscle mass are further discussed in Chapter 10 (see Clinical Impact, “Bodybuilding”).

ASSESS YOUR PROGRESS

71. Describe the changes in muscle mass and response time that occur in aging skeletal muscle.

Diseases and Disorders

TABLE 9.5

Muscular System

Condition	Description
Cramps	Painful, spastic contractions of skeletal muscle; due to multiple causes such as dehydration and ion imbalance
Fibromyalgia (fī-brō-mī-al'ja)	Non-life-threatening, chronic, widespread pain in skeletal muscles with no known cure; also known as chronic muscle pain syndrome
Hypertrophy	Enlargement of skeletal muscle due to an increased number of myofibrils, as occurs with increased muscle use; in cardiac muscle, usually a result of other diseases, commonly hypertension
Atrophy	Decrease in muscle size due to a decreased number of myofilaments; can occur due to disuse of a muscle, as in paralysis; can also occur in cardiac muscle due to certain pathologies such as chronic heart failure
Muscular dystrophy	Group of genetic disorders in which muscles degenerate and atrophy; usually affects skeletal muscle and sometimes cardiac muscle
Duchenne muscular dystrophy	See Systems Pathology
Myotonic muscular dystrophy	Skeletal muscles are weak and fail to relax following forceful contractions; affects the hands most severely; dominant trait in 1/20,000 births
Myasthenia gravis	See Clinical Impact, “The Effect of Blocking Acetylcholine Receptors and Acetylcholinesterase,” earlier in this chapter
Tendinitis (ten-di-nī'tis)	Inflammation of a tendon or its attachment point due to overuse of a skeletal muscle
Fibrosis	Scarring of damaged cardiac or skeletal muscle due to deposition of connective tissue
Fibrositis	Inflammation of fibrous connective tissue, resulting in soreness after prolonged skeletal muscle tension; not progressive

Answer

Learn to Predict ◀ From page 268

We must address three issues: (1) Identify the bones involved when Bob is performing the exercise, (2) describe the joint movements involved, and (3) explain how Bob's muscles lift and lower the weight slowly. We know that Bob's movement engages the bones and muscles of the arm and forearm and that Bob is actively controlling the movement of the weight as he lifts the weight and lowers it.

Chapter 7 explained that the bones of the arm and forearm are the humerus, the radius, and the ulna. These are the bones involved in the exercise. In chapter 8 we learned that these bones articulate at the elbow. Chapter 8 also described the different types of joint movements, including flexion and extension. Flexion of his elbow causes Bob to lift the weight, and extension of his elbow allows him to lower it.

We learned in this chapter that muscle tension can vary depending on the number of motor units stimulated. Lifting the weight requires recruitment of motor units. As the number of stimulated motor units increases, the amount of tension produced by the muscle also increases until sufficient force is produced to lift the weight (multiple-motor-unit summation). The speed of the contraction depends on the rate of motor unit recruitment. Because the rate of recruitment is slow, Bob lifts the weight slowly. If the rate of motor unit recruitment were increased, Bob would lift the weight faster (multiple-wave summation). As Bob lowers the weight, the total tension in the arm is reduced as fewer motor units contract.

Answers to the rest of this chapter's Predict questions are in appendix G.

9.1 Functions of the Muscular System (p. 269)

Muscles are responsible for movement of the arms, legs, heart, and other parts of the body; maintenance of posture; respiration; production of body heat; communication; constriction of organs and vessels; and heartbeat.

Types of Muscle Tissue

1. The three types of muscle are skeletal, smooth, and cardiac.
2. Skeletal muscle is responsible for most body movements; smooth muscle is found in the walls of hollow organs and tubes and moves substances through them; and cardiac muscle is in the heart and pumps blood.

9.2 General Properties of Muscle Tissue (p. 270)

1. Muscle exhibits contractility (shortens forcefully), excitability (responds to stimuli), extensibility (can be stretched and still contract), and elasticity (recoils to resting length).
2. Muscle tissue shortens forcefully but lengthens passively.

9.3 Skeletal Muscle Anatomy (p. 270)

Skeletal muscle fibers are associated with connective tissue, blood vessels, and nerves.

Whole Skeletal Muscle Anatomy

1. Muscle fascicles, bundles of muscle fibers, are covered by the connective tissue layer called the perimysium.
2. The entire muscle is surrounded by a connective tissue layer called the epimysium.
3. Motor neurons extend together with arteries and veins through the connective tissue of skeletal muscles.

Summary

4. At the level of the perimysium, axons of motor neurons branch, and each branch projects to a muscle fiber to form a neuromuscular junction.

Skeletal Muscle Fiber Anatomy

1. A muscle fiber is a single cell consisting of a plasma membrane (sarcolemma), cytoplasm (sarcoplasm), several nuclei, and myofibrils.
2. Myofibrils are composed of two major protein fibers: actin and myosin.
 - Actin myofilaments consist of a double helix of F actin (composed of G actin monomers), tropomyosin, and troponin.
 - Myosin molecules, consisting of two globular heads and a rodlike portion, constitute myosin myofilaments.
 - A cross-bridge forms when the myosin binds to the actin.
3. Actin and myosin are organized to form sarcomeres.
 - Sarcomeres are bound by Z disks that hold actin myofilaments.
 - Six actin myofilaments (thin filaments) surround a myosin myofilament (thick filament).
 - Myofibrils appear striated because of A bands and I bands.

9.4 Skeletal Muscle Fiber Physiology (p. 277)

Excitability of Muscle Fibers

1. Plasma membranes are polarized, which means that a charge difference, called the resting membrane potential, exists across the plasma membrane.
2. The membrane becomes polarized because the tendency for K^+ to diffuse out of the cell is resisted by the negative charges of ions and molecules inside the cell.
3. Ion channels are responsible for membrane permeability and the resting membrane potential.

- Two types of membrane channels produce action potentials: ligand-gated and voltage-gated channels.
- Ion channels are responsible for producing action potentials.

Action Potentials

- The charge difference across the plasma membrane of cells is the resting membrane potential.
- Depolarization results from an increase in the permeability of the plasma membrane to Na^+ .
- An all-or-none action potential is produced if depolarization reaches threshold.
- The depolarization phase of the action potential results when many Na^+ channels open in an all-or-none fashion.
- The repolarization phase of the action potential occurs when the Na^+ channels close and the K^+ channels open briefly.
- Action potentials propagate along the plasma membranes of neurons and skeletal muscle fibers in an all-or-none fashion.
- A synaptic cleft separates the presynaptic terminal of the axon from the postsynaptic membrane of the muscle fiber.
- Acetylcholine released from the presynaptic terminal binds to receptors of the postsynaptic membrane, thereby changing membrane permeability and producing an action potential.
- After an action potential occurs, acetylcholinesterase splits acetylcholine into acetic acid and choline. Choline is reabsorbed into the presynaptic terminal to re-form acetylcholine.

Excitation-Contraction Coupling

- Invaginations of the sarcolemma form T tubules, which wrap around the sarcomeres.
- A triad is a T tubule and two terminal cisternae (an enlarged area of sarcoplasmic reticulum).
- Action potentials move into the T tubule system, causing Ca^{2+} channels to open and release Ca^{2+} from the sarcoplasmic reticulum.
- Calcium ions diffuse from the sarcoplasmic reticulum to the myofilaments and bind to troponin, causing tropomyosin to move and expose active sites on actin to myosin.
- Contraction occurs when myosin heads bind to active sites on actin, myosin changes shape, and actin is pulled past the myosin.
- Relaxation occurs when calcium is taken up by the sarcoplasmic reticulum, ATP binds to myosin, and tropomyosin moves back so that active sites on actin are no longer exposed to myosin.

Cross-Bridge Movement

- ATP is required for the cycle of cross-bridge formation, movement, and release.
- ATP is also required to transport Ca^{2+} into the sarcoplasmic reticulum and to maintain normal concentration gradients across the plasma membrane.

Muscle Relaxation

- Calcium ions are transported into the sarcoplasmic reticulum.
- Calcium ions diffuse away from troponin, preventing further cross-bridge formation.

9.5 Whole Skeletal Muscle Physiology (p. 288)

The Muscle Twitch

- A muscle twitch is the contraction of a single muscle fiber or a whole muscle in response to a stimulus.
- A muscle twitch has lag, contraction, and relaxation phases.

Motor Units

- A motor unit is one motor neuron and all the muscle fibers it controls.
- Precise movements use small motor units. Gross movements use large motor units.

Stimulus Strength and Motor Unit Response

- A stimulus of increasing magnitude results in graded contractions of increased force through either summation or recruitment.
- Treppe is an increase in the force of contraction during the first few contractions of a rested muscle.
- The force of contraction of a whole muscle increases with increased frequency of stimulation because of an increasing concentration of Ca^{2+} around the myofibrils and because of complete stretching of muscle elastic elements.

Stimulus Frequency and Whole Muscle Contraction

- Incomplete tetanus is partial relaxation between contractions; complete tetanus is no relaxation between contractions.
- A stimulus of increasing frequency increases the force of contraction (multiple-wave summation).

Muscle Length Versus Tension

- Muscle contracts with less than maximum force if its initial length is shorter or longer than optimum.
- Isometric contractions cause a change in muscle tension but no change in muscle length.
- Isotonic contractions cause a change in muscle length but no change in muscle tension.
- Concentric contractions cause muscles to shorten and tension to increase.
- Eccentric contractions cause muscle to lengthen and tension to decrease gradually.
- Muscle tone is the maintenance of steady tension for long periods.
- Asynchronous contractions of motor units produce smooth, steady muscle contractions.

9.6 Muscle Fiber Types (p. 294)

Slow-Twitch Muscle Fibers

Slow-twitch muscle fibers break down ATP slowly and have a well-developed blood supply, many mitochondria, and myoglobin.

Fast-Twitch Muscle Fibers

Fast-twitch muscle fibers break down ATP rapidly.

- Type IIa fibers have a well-developed blood supply, more mitochondria, and more myoglobin.
- Type IIb fibers have large amounts of glycogen, a poor blood supply, fewer mitochondria, and little myoglobin.

Distribution of Fast-Twitch and Slow-Twitch Muscle Fibers

People who are good sprinters have a greater percentage of fast-twitch muscle fibers in their leg muscles, and people who are good long-distance runners have a higher percentage of slow-twitch muscle fibers.

Effects of Exercise

- Muscles increase (hypertrophy) or decrease (atrophy) in size because of a change in the size of muscle fibers.
- Anaerobic exercise develops type IIb fibers. Aerobic exercise develops type I fibers and changes type IIb fibers into type IIa fast-twitch fibers.

Heat Production

1. Heat is a by-product of chemical reactions in muscles.
2. Shivering produces heat to maintain body temperature.

9.7 Energy Sources for Muscle Contraction (p. 296)

Energy for muscle contraction comes from ATP.

Aerobic and Anaerobic Respiration

1. The ATP synthesized by aerobic respiration produces energy for muscle contractions under resting conditions or during exercises such as long-distance running. Although ATP is produced more efficiently, it is produced more slowly.
2. The ATP synthesized by anaerobic respiration provides energy for a short time during intense exercise. Anaerobic respiration produces ATP less efficiently but more rapidly than aerobic respiration. Lactate levels increase because of anaerobic respiration.

Creatine Phosphate

ATP synthesized when ADP reacts with creatine phosphate provides energy for a short time during intense exercise.

Recycling of ADP

Two ADP are converted to one ATP and one AMP during intense exercise.

Muscle Fatigue

1. Fatigue, the decreased ability to do work, can be caused by the central nervous system, depletion of ATP in muscles, or depletion of acetylcholine in the neuromuscular junction.
2. Physiological contracture (the inability of muscles to contract or relax) and rigor mortis (stiff muscles after death) result from inadequate amounts of ATP.

Muscle Soreness

Soreness is caused by inflammation in the muscle.

Oxygen Deficit and Recovery Oxygen Consumption

After anaerobic respiration, aerobic respiration is higher than normal, as the imbalances of homeostasis that occurred during exercise become rectified.

9.8 Smooth Muscle (p. 300)

1. Smooth muscle cells are spindle-shaped with a single nucleus. They have actin myofilaments and myosin myofilaments but are not striated.
2. The sarcoplasmic reticulum is poorly developed, and caveolae may function as a T tubule system.
3. Calcium ions enter the cell to initiate contraction; calmodulin binds to Ca^{2+} and activates an enzyme that transfers a phosphate group from ATP to myosin. When phosphate groups are attached to myosin, cross-bridges form.

4. Relaxation results when myosin phosphatase removes a phosphate group from the myosin molecule.
 - If phosphate is removed while the cross-bridges are attached, relaxation occurs very slowly, and this is referred to as the latch state.
 - If phosphate is removed while the cross-bridges are not attached, relaxation occurs rapidly.

Types of Smooth Muscle

1. Visceral smooth muscle fibers contract slowly, have gap junctions (and thus function as a single unit), and can be autorhythmic.
2. Multiunit smooth muscle fibers contract rapidly in response to stimulation by neurons and function independently.

Electrical Properties of Smooth Muscle

1. Spontaneous contractions result from Na^+ and Ca^{2+} leakage into cells; Na^+ and Ca^{2+} movement into the cell is involved in depolarization.
2. The autonomic nervous system, hormones, and chemicals produced locally can inhibit or stimulate action potentials (and thus contractions). Hormones can also stimulate or inhibit contractions without affecting membrane potentials.

Functional Properties of Smooth Muscle

1. Smooth muscle can contract autorhythmically in response to stretch or when stimulated by the autonomic nervous system or hormones.
2. Smooth muscle maintains a steady tension for long periods.
3. The force of smooth muscle contraction remains nearly constant, despite changes in muscle length.
4. Smooth muscle does not develop an oxygen deficit.

Regulation of Smooth Muscle

1. Smooth muscle is innervated by the autonomic nervous system and is involuntary.
2. Hormones are important in regulating smooth muscle. Certain hormones can increase the Ca^{2+} permeability of some smooth muscle membranes and therefore cause contraction without a change in the resting membrane potential.

9.9 Cardiac Muscle (p. 306)

Cardiac muscle fibers are striated, have a single nucleus, are connected by intercalated disks (and thus function as a single unit), and are capable of autorhythmicity.

9.10 Effects of Aging on Skeletal Muscle (p. 307)

Aging skeletal muscle is associated with reduced muscle mass, increased time that muscle takes to contract in response to nervous stimuli, less precise muscle control, and a longer recovery period.

REVIEW AND COMPREHENSION

1. Which of these is true of skeletal muscle?
 - a. spindle-shaped cells
 - b. under involuntary control
 - c. many peripherally located nuclei per muscle fiber
 - d. forms the walls of hollow internal organs
 - e. may be autorhythmic
2. Which of these is *not* a major property of muscle?
 - a. contractility
 - b. elasticity
 - c. excitability
 - d. extensibility
 - e. secretability

3. Given these structures:

- (1) whole muscle
- (2) muscle fiber (cell)
- (3) myofilament
- (4) myofibril
- (5) muscle fasciculus

Choose the arrangement that lists the structures in the correct order from largest to smallest.

- a. 1,2,5,3,4 c. 1,5,2,3,4 e. 1,5,4,2,3
b. 1,2,5,4,3 d. 1,5,2,4,3

4. Each myofibril

- a. is made up of many muscle fibers.
- b. contains sarcoplasmic reticulum.
- c. is made up of many sarcomeres.
- d. contains T tubules.
- e. is the same thing as a muscle fiber.

5. Myosin myofilaments are

- a. attached to the Z disk.
- b. found primarily in the I band.
- c. thinner than actin myofilaments.
- d. absent from the H zone.
- e. attached to filaments that form the M line.

6. Which of these statements about the molecular structure of myofilaments is true?

- a. Tropomyosin has a binding site for Ca^{2+} .
- b. The head of the myosin molecule binds to an active site on G actin.
- c. ATPase is found on troponin.
- d. Troponin binds to the rodlike portion of myosin.
- e. Actin molecules have a hingelike portion, which bends and straightens during contraction.

7. The part of the sarcolemma that invaginates into the interior of skeletal muscle fibers is the

- a. T tubule system. c. myofibrils. e. mitochondria.
b. sarcoplasmic reticulum. d. terminal cisternae.

8. During the depolarization phase of an action potential, the permeability of the plasma membrane to

- a. Ca^{2+} increases. c. K^+ increases. e. Na^+ decreases.
b. Na^+ increases. d. Ca^{2+} decreases.

9. During repolarization of the plasma membrane,

- a. Na^+ moves to the inside of the cell.
- b. Na^+ moves to the outside of the cell.
- c. K^+ moves to the inside of the cell.
- d. K^+ moves to the outside of the cell.

10. Given these events:

- (1) Acetylcholine is broken down into acetic acid and choline.
- (2) Acetylcholine diffuses across the synaptic cleft.
- (3) An action potential reaches the terminal branch of the motor neuron.
- (4) Acetylcholine combines with a ligand-gated ion channel.
- (5) An action potential is produced on the muscle fiber's plasma membrane.

Choose the arrangement that lists the events in the order they occur at a neuromuscular junction.

- a. 2,3,4,1,5 c. 3,4,2,1,5 e. 5,1,2,4,3
b. 3,2,4,5,1 d. 4,5,2,1,3

11. Acetylcholinesterase is an important molecule in the neuromuscular junction because it

- a. stimulates receptors on the presynaptic terminal.
- b. synthesizes acetylcholine from acetic acid and choline.
- c. stimulates receptors within the postsynaptic membrane.

d. breaks down acetylcholine.

e. causes the release of Ca^{2+} from the sarcoplasmic reticulum.

12. Given these events:

- (1) The sarcoplasmic reticulum releases Ca^{2+} .
- (2) The sarcoplasmic reticulum takes up Ca^{2+} .
- (3) Calcium ions diffuse into the sarcoplasm.
- (4) An action potential moves down the T tubule.
- (5) The sarcomere shortens.
- (6) The muscle relaxes.

Choose the arrangement that lists the events in the order they occur following a single stimulation of a skeletal muscle fiber.

- a. 1,3,4,5,2,6 c. 4,1,3,5,2,6 e. 5,1,4,3,2,6
b. 2,3,5,4,6,1 d. 4,2,3,5,1,6

13. Given these events:

- (1) Calcium ions combine with tropomyosin.
- (2) Calcium ions combine with troponin.
- (3) Tropomyosin pulls away from actin.
- (4) Troponin pulls away from actin.
- (5) Tropomyosin pulls away from myosin.
- (6) Troponin pulls away from myosin.
- (7) Myosin binds to actin.

Choose the arrangement that lists the events in the order they occur during muscle contraction.

- a. 1,4,7 c. 1,3,7 e. 2,3,7
b. 2,5,6 d. 2,4,7

14. With stimuli of *increasing strength*, which of these is capable of a graded response?

- a. neuron axon c. motor unit
b. muscle fiber d. whole muscle

15. Considering the force of contraction of a skeletal muscle fiber, multiple-wave summation occurs because of

- a. increased strength of action potentials on the plasma membrane.
- b. a decreased number of cross-bridges formed.
- c. an increase in Ca^{2+} concentration around the myofibrils.
- d. an increased number of motor units recruited.
- e. increased permeability of the sarcolemma to Ca^{2+} .

16. Which of these events occurs during the lag (latent) phase of muscle contraction?

- a. cross-bridge movement
- b. active transport of Ca^{2+} into the sarcoplasmic reticulum
- c. Ca^{2+} binding to troponin
- d. sarcomere shortening
- e. breakdown of ATP to ADP

17. A weight lifter attempts to lift a weight from the floor, but the weight is so heavy that he is unable to move it. The type of muscle contraction the weight lifter is using is mostly

- a. isometric. c. isokinetic. e. eccentric.
b. isotonic. d. concentric.

18. Which of these types of fatigue is the most common?

- a. muscular fatigue c. synaptic fatigue
b. psychological fatigue d. army fatigue

19. Given these conditions:

- (1) low ATP levels
- (2) little or no transport of Ca^{2+} into the sarcoplasmic reticulum
- (3) release of cross-bridges
- (4) Na^+ accumulation in the sarcoplasm
- (5) formation of cross-bridges

- Choose the conditions that occur in both physiological contracture and rigor mortis.
- a. 1,2,3 c. 1,2,3,4 e. 1,2,3,4,5
b. 1,2,5 d. 1,2,4,5
20. Jerry Jogger's 3-mile run every morning takes about 30 minutes. Which of these sources provides most of the energy for his run?
a. aerobic respiration c. creatine phosphate
b. anaerobic respiration d. stored ATP
21. Which of these conditions would you expect to find within the leg muscle fibers of a world-class marathon runner?
a. myoglobin-poor c. primarily anaerobic
b. contract very quickly d. numerous mitochondria
22. Which of these increases the least as a result of muscle hypertrophy?
a. number of sarcomeres d. blood vessels and mitochondria
b. number of myofibrils e. connective tissue
c. number of fibers
23. Relaxation in smooth muscle occurs when
a. myosin kinase attaches phosphate to the myosin head.
b. Ca^{2+} binds to calmodulin.
- c. myosin phosphatase removes phosphate from myosin.
d. Ca^{2+} channels open.
e. Ca^{2+} is released from the sarcoplasmic reticulum.
24. Compared with skeletal muscle, visceral smooth muscle
a. has the same ability to be stretched.
b. loses the ability to contract forcefully when stretched.
c. maintains about the same tension, even when stretched.
d. cannot maintain long, steady contractions.
e. can accumulate a substantial oxygen deficit.
25. Which of these statements concerning aging and skeletal muscle is correct?
a. A loss of muscle fibers occurs with aging.
b. Slow-twitch fibers decrease in number faster than fast-twitch fibers.
c. The loss of strength and speed is due mainly to loss of neuromuscular junctions.
d. The density of capillaries in skeletal muscle increases.
e. The number of motor neurons remains constant.

Answers in appendix E

CRITICAL THINKING

- Bob Canner improperly canned some homegrown vegetables. After eating the vegetables, he contracted botulism poisoning with symptoms that included difficulty swallowing and breathing. Eventually, he died of respiratory failure (his respiratory muscles relaxed and would not contract). Assuming that botulism toxin affects the neuromuscular junction, propose the ways that the toxin produces the observed symptoms.
- A patient is thought to be suffering from either muscular dystrophy or myasthenia gravis. How would you distinguish between the two conditions?
- Design an experiment to test the following hypothesis: Muscle A has the same number of motor units as muscle B. (Assume that you can stimulate the nerves that innervate skeletal muscles with an electronic stimulator and monitor the tension produced by the muscles.)
- Explain what is happening at the level of individual sarcomeres when a person is using his or her biceps brachii muscle to hold a weight in a constant position. Contrast this with what is happening at the level of individual sarcomeres when a person lowers the weight, as well as when he or she raises the weight.
- Predict the shape of an active tension curve for visceral smooth muscle. How does it differ from the active tension curve for skeletal muscle?
- A researcher is investigating the composition of muscle tissue in the gastrocnemius muscles (in the calf of the leg) of athletes. She takes a needle biopsy from the muscle and determines the concentration (or enzyme activity) of several substances. Describe the major differences this researcher sees when comparing the muscles of athletes who perform in the following events: 100-meter dash, weight lifting, and 10,000-meter run.
- Shorty McFleet noticed that his rate of respiration was elevated after running a 100-meter race but was not as elevated after running slowly for a much longer distance. How would you explain this?
- High blood K^+ concentrations cause depolarization of the resting membrane potential. Predict and explain the effect of high blood K^+ levels on smooth muscle function.
- Predict and explain the response if the ATP concentration in a muscle that was exhibiting rigor mortis could be instantly increased.
- A hormone stimulates the smooth muscle of a blood vessel to contract. Although the hormone causes a small change in membrane potential, the smooth muscle contracts substantially. Explain.
- Experiments were performed in an anatomy and physiology laboratory. First, the rate and depth of respiration for a resting student were determined. In experiment A, students ran in place for 30 seconds, immediately sat down and relaxed, and then had their respiration rate and depth measured. Experiment B was conducted in the same manner as experiment A, except that the students held their breath while running in place. What differences in respiration would you expect for the two experiments? Explain the basis for your predictions.
- After learning about muscle fiber types in his anatomy and physiology class, Alex started to notice differences in the color of the turkey meat he ate for lunch. Some of the meat was very white and some of it was much darker. From the color of the meat, Alex guessed which muscles the bird used for maintenance of posture and/or slow movements, such as walking, and which muscles it used for quicker movements, such as running or flying. What type of muscle fiber predominates in white meat? In dark meat? Explain how the color of the meat relates to the function of the muscle.

Answers in appendix F

Muscular System

GROSS ANATOMY

Without muscles, we humans would be little more than department store mannequins—unable to walk, talk, blink our eyes, or even hold this book. But none of these inconveniences would bother us for long because we would also not be able to breathe.

One of the major characteristics of living human beings is our ability to move about. But we also use our skeletal muscles when we are not “moving.” Postural muscles are constantly contracting to keep us sitting or standing upright. Respiratory muscles are constantly functioning to keep us breathing, even while we are asleep. Communication of all kinds requires skeletal muscles, whether for writing, typing, or speaking. Even silent communication using hand signals or facial expressions requires skeletal muscle function.

This chapter focuses on the anatomy of the major named skeletal muscles; cardiac muscle is considered in more depth in later chapters. The physiology of skeletal and smooth muscle is described in chapter 9, including the effects of aging on skeletal muscle.

Learn to Predict

While weight training, Pedro strained his back and damaged a vertebral disk. The bulged disk placed pressure on the left side of the spinal cord, compressing the third lumbar spinal nerve, which innervates the following muscles: psoas major, iliacus, pectineus, sartorius, vastus major, iliacus, pectineus, sartorius, vastus lateralis, vastus medius, vastus intermedius, and rectus femoris. As a result, action potential conduction to these muscles was reduced. **Using your new knowledge about the histology and physiology of the muscular system from chapter 9 and combining it with the information about gross muscle anatomy in this chapter, predict Pedro’s symptoms and which movements of his lower limb were affected, other than walking on a flat surface. What types of daily tasks would be difficult for Pedro to perform?**

Photo: The man in this photo has clearly defined muscles. Which muscles can you identify?

10.1 General Principles of Skeletal Muscle Anatomy

LEARNING OUTCOMES

After reading this section, you should be able to

- Define the following and give an example of each: **origin**, **insertion**, **agonist**, **antagonist**, **synergist**, **fixator**, and **prime mover**.
- Explain how fasciculus orientation determines muscle shape and list examples of muscles that demonstrate each shape.
- Recognize muscle names based on specific nomenclature rules.
- Explain each of the three classes of levers in the body and give a specific example of each class.

Most skeletal muscles are attached to bones. They extend from bone to bone across the linking joint. Everyday movements involve skeletal muscles contracting to pull one bone of a joint toward another bone of the same joint. However, not all muscles are attached to bone at both ends. For example, some facial muscles attach to the skin, moving it as the muscles contract. One such movement is easily recognized as a smile.

The two points of attachment of each muscle to the bone are called the origin and the insertion. The **origin**, also called the *fixed end*, is usually the most stationary, proximal end of the muscle. Some muscles have more than one origin. For example, the triceps brachii has three origins that join together to form one muscle. In the case of multiple origins, each origin is called a **head**. The **insertion**, or *mobile end*, is usually the distal end of the muscle attached to the bone being pulled toward the other bone of the joint. The part of the muscle between the origin and the insertion is the **belly** (figure 10.1). At the attachment point, **tendons** connect each muscle to the bone. Tendons are composed of dense connective tissue and can be long and ropelike, broad and sheetlike (called **aponeuroses**; ap'ō-noo-rō'sēz), or very short.

The specific body movement a muscle contraction causes is called the muscle's **action**. Muscles are typically studied in groups called **agonists** (ag'ō-nists) and **antagonists** (an-tag'ō-nists). The action of a single muscle or group of muscles (agonist) is opposed by that of another muscle or group of muscles (antagonist). For example, the biceps brachii flexes (bends) the elbow, and the triceps brachii extends the elbow. In the example of elbow flexion, the biceps brachii is the agonist (flexes), whereas the triceps brachii is the antagonist (extends). When extending the elbow, the muscles' roles are reversed; the triceps brachii is the agonist and the biceps brachii is the antagonist. Most joints in the body have agonist and antagonist groups or pairs.

Muscles also tend to function in groups to accomplish specific movements. The muscles of the group are called **synergists** (sin'er-jistz; *syn-*, together). For example, the deltoid, biceps brachii, and pectoralis major all help flex the shoulder. Furthermore,

FIGURE 10.1 Muscle Attachment

Muscles are attached to bones by tendons. The biceps brachii has two heads, which originate on the scapula. The triceps brachii has three heads, which originate on the scapula and the humerus. The biceps brachii inserts onto the radial tuberosity and onto nearby connective tissue. The triceps brachii inserts onto the olecranon process of the ulna.

many muscles are members of more than one group, depending on the type of movement being produced. For example, the anterior part of the deltoid muscle functions with the flexors of the shoulder, whereas the posterior part functions with the extensors of the shoulder. In elbow flexion, the biceps brachii and the brachialis are synergists. However, the brachialis muscle is more important for elbow flexion than the biceps brachii. In a group of synergists, the muscle that contributes most to the movement is called the **prime mover**. The brachialis is the prime mover in elbow flexion. In some groups of synergists, the prime mover needs to be stabilized. The stabilizers of prime movers are called **fixators**. Usually, a fixator holds one bone in place relative to the body while a more distal bone is moved. For example, the origin of a prime mover is often stabilized by fixators, so that its action occurs at its point of insertion. When moving the humerus, the muscles of the scapula act as fixators to hold the scapula in place.

Muscle Shapes

The shape and size of any given muscle greatly influence the degree to which it can contract and the amount of force it can generate. Most of us are familiar with the common names of many of our muscles, such as “pecs” or “biceps.” In this chapter, you will learn that muscles can be classified based on their shape. The shape of the muscle determines the type of movement it has. There are five classes of muscle shapes as determined by the arrangement of its fascicles. Recall from chapter 9 that fascicles are

TABLE 10.1 Fascicle Arrangement

Pattern of Fascicle Arrangement	Shape of Muscle	Examples	Pattern of Fascicle Arrangement	Shape of Muscle	Examples
<p>Circular</p> <p>Fascicles are arranged in a circle around an opening and act as sphincters to close the opening.</p>		<p>Orbicularis oris Orbicularis oculi</p>	<p>Pennate</p> <p>Fascicles originate from a tendon that runs the length of the entire muscle. There are three different patterns.</p>		
<p>Convergent</p> <p>Broadly distributed fascicles converge at a single tendon.</p>	 <p>Triangular</p>	<p>Pectoralis major Pectoralis minor</p>	<p><i>Unipennate</i></p> <p>Fascicles are on only one side of the tendon.</p>		<p>Palmar interosseus Semimembranosus</p>
<p>Parallel</p> <p>Fascicles lie parallel to one another and to the long axis of the muscle.</p>	 <p>Trapezium</p>	<p>Trapezius</p>	<p><i>Bipennate</i></p> <p>Fascicles are on both sides of the tendon.</p>		<p>Rectus femoris</p>
	 <p>Rhomboidal</p>	<p>Rhomboideus</p>	<p><i>Multipennate</i></p> <p>Fascicles are arranged at many places around the central tendon. They are spread out at angles to many smaller tendons.</p>		<p>Deltoid</p>
	 <p>Quadrated</p>	<p>Rectus abdominis</p>	<p>Fusiform</p> <p>Fascicles lie parallel to the long axis of the muscle. The belly of the muscle is larger in diameter than the ends.</p>		<p>Biceps brachii (two-headed; shown) Triceps brachii (three-headed)</p>

groups of cells that make up a given muscle. The five classes are circular, convergent, parallel, pennate, and fusiform. Within some of the classes, there are different patterns based on the shape of the particular muscle, including triangular, trapezium, rhomboidal, and quadrate (table 10.1).

Circular muscles have their fascicles arranged in a circle around an opening and act as sphincters (constrictors) to close the opening. Examples of circular muscles are those that surround the eyes, called the orbicularis oculi, and those that surround the mouth, called the orbicularis oris.

Convergent muscles have fascicles that join at one common tendon from a wide area, which creates muscles that are triangular in shape. Having fibers that lie side by side can result in muscles with less strength if the total number of fibers is low. However, if the fibers are long, these muscles can have a large range of motion. One example of convergent muscles with many long fibers is the pectoralis muscles of the chest.

Parallel muscles, similarly to convergent muscles, have fascicles that are organized parallel to the long axis of the muscle, but they terminate on a flat tendon that spans the width of the entire muscle. As a consequence, parallel muscles can shorten to a large degree because the fascicles are in a direct line with the tendon; however, they contract with less force because fewer total fascicles are attached to the tendon. The hyoid muscles in the neck are examples of parallel muscles.

Pennate (pen'āt; *pennatus*, feather) muscles have fascicles that emerge like the barbs on a feather from a common tendon that runs the length of the entire muscle. The location of the fascicles relative to the tendon is the basis for different types of pennate muscles. In **unipennate** muscles, the fascicles are on one side of the tendon. **Bipennate** muscles have fascicles arranged on two sides of the tendon. **Multipennate** muscles are those with fascicles arranged at many places around the central tendon. The long tendons of pennate muscles can extend for some distance between a muscle belly and its insertion. The pennate arrangement allows a large number of fascicles to attach to a single tendon, with the force of contraction concentrated at the tendon. The muscles that extend the knee are multipennate muscles.

Fusiform muscles are those whose fascicles run the length of the entire muscle and taper at each end to terminate at tendons. Fusiform muscles have a wider belly than the ends of the muscle. Because their fibers are long, but are commonly numerous, these muscles generally tend to be stronger than other muscles with parallel fascicle arrangements. The muscle that flexes the forearm is an example of a fusiform muscle.

In summary, muscle strength is primarily related to total fascicle number in the muscle, whereas range of motion is correlated to fascicle arrangement. Muscles with parallel fibers have the largest range of motion.

Muscle Names

The name of a specific muscle is based on at least seven characteristics: location, size, shape, orientation of fascicles, origin and insertion, number of heads, and function. Recognizing the descriptive nature of muscle names makes learning those names much easier.

1. **Location.** A pectoralis (*chest*) muscle is located in the chest, a gluteus (*buttock*) muscle is in the buttock, and a brachial (*arm*) muscle is in the arm.
2. **Size.** The gluteus maximus (*large*) is the largest muscle of the buttock, and the gluteus minimus (*small*) is the smallest. A longus (*long*) muscle is longer than a brevis (*short*) muscle. In addition, a second part to the name immediately tells us there is more than one related muscle. For example, if there is a brevis muscle, most likely a longus muscle is present in the same area.
3. **Shape.** The deltoid (*triangular*) muscle is triangular in shape, a quadratus (*quadrate*) muscle is rectangular, and a teres (*round*) muscle is round.
4. **Orientation of fascicles.** A rectus (*straight, parallel*) muscle has muscle fascicles running in the same direction as the structure with which the muscle is associated, whereas the fascicles of an oblique muscle lie at an angle to the length of the structure.
5. **Origin and insertion.** The sternocleidomastoid has its origin on the sternum and clavicle and its insertion on the mastoid process of the temporal bone. The brachioradialis originates in the arm (*brachium*) and inserts onto the radius.
6. **Number of heads.** A biceps muscle has two heads (origins), and a triceps muscle has three heads (origins).
7. **Function.** Recall from chapter 8 that body movements have names, for example, abduction and adduction. Abductors and adductors are the muscles that cause that type of movement. Abduction moves a structure away from the midline, and adduction moves a structure toward the midline.

Muscle Movements

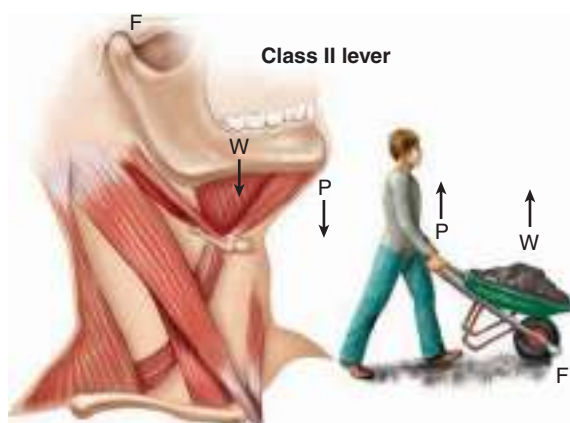

Muscles and their bones perform work together through levers. **Levers** are machines that consist of a rigid pole or beam that can pivot, or move, at a stationary hinge. The hinge is called a **fulcrum (F)**. The lever moves at the hinge and can apply force to a **weight (W)**. There are three classes, or types, of levers based on the location of the fulcrum, weight, and force along the lever. In the body, the joints function as fulcrums, the bones function as levers, and muscles provide the force. When muscles contract, the **pull (P)**, or force, of muscle contraction is applied to the levers (bones), causing them to move a body part (the weight). In figure 10.2, you can see that the three classes of levers are classes I, II, and III.

Class I Lever

In a **class I lever system**, the fulcrum is between the pull and the weight (figure 10.2a). A child's seesaw is this type of lever. The children on the seesaw alternate between being the weight and being the pull across a fulcrum in the center of the board. In the body, the head is this type of lever; the atlantooccipital joint in the neck is the fulcrum, the posterior neck muscles provide the pull depressing the back of the head, and the face, which is elevated, is the weight. With the weight balanced over the fulcrum, only a small amount of pull is required to lift the weight. For example, only a very small shift in weight is needed for one child to lift the other on a seesaw. However, a class I lever is

(a) **Class I:** The fulcrum (F) is located between the weight (W) and the pull (P), or force. The pull is directed downward, and the weight, on the opposite side of the fulcrum, is lifted. In the body, the fulcrum extends through several cervical vertebrae.

(b) **Class II:** The weight (W) is located between the fulcrum (F) and the pull (P), or force. The upward pull lifts the weight. The movement of the mandible is easier to compare to a wheelbarrow if the head is considered upside down.

(c) **Class III:** The pull (P), or force, is located between the fulcrum (F) and the weight (W). The upward pull lifts the weight.

FIGURE 10.2 Classes of Levers

quite limited as to how much weight can be lifted and how high it can be lifted. For example, consider what happens when the child on one end of the seesaw is much larger than the child on the other end.

Class II Lever

In a **class II lever system**, the weight is located between the fulcrum and the pull (figure 10.2b). An example is a wheelbarrow; the wheel is the fulcrum, and the person lifting on the handles provides the pull. The weight, or load, carried in the wheelbarrow is placed between the wheel and the operator. In the body, there are relatively few examples of class II levers. Depressing the mandible when you open your mouth is one example. Another is your entire body when doing push-ups—your toes are the fulcrum, your body is the weight, and your arms provide the pull (force).

Class III Lever

In a **class III lever system**, the most common type in the body, the pull is between the fulcrum and the weight (figure 10.2c). An example is a person using a shovel. The hand placed on the part of the handle closest to the blade provides the pull to lift the weight, such as a shovelful of dirt, and the hand placed near the end of the handle acts as the fulcrum. In the body, the action of the biceps brachii muscle (force) pulling on the radius (lever) to flex the elbow (fulcrum) and elevate the hand (weight) is a class III lever. This type of lever system does not allow as great a weight to be lifted, but it can be lifted a greater distance.

Muscle Anatomy

An overview of the superficial skeletal muscles appears in figure 10.3. Muscles of the head and neck, trunk, and limbs are described in the following sections.

ASSESS YOUR PROGRESS

1. Distinguish between the origin and the insertion of a muscle. In which direction is movement?
2. Describe the roles of the following in muscle action: agonist, antagonist, synergist, fixator, and prime mover.
3. Describe the different orientations of muscle fascicles, give an example of each, and explain how a muscle's shape is related to its force of contractions and the range of movement the contraction produces.
4. What geometric shapes can muscles have?
5. List the criteria used to name muscles, and give an example of each.
6. Using the terms fulcrum, lever, and force, explain how contraction of a muscle results in movement.
7. Describe the three classes of levers, and give an example of each type in the body.

FIGURE 10.3 Overview of the Superficial Body Musculature

(b) Posterior view

FIGURE 10.3 (continued)

10.2 Head and Neck Muscles

LEARNING OUTCOMES

After reading this section, you should be able to

- Name the muscles in the neck and list the origin, insertion, and action of each.
- Describe movements of the head and give the muscles responsible for each movement.
- List the muscles used to create various facial expressions.
- Describe mastication, tongue movement, and swallowing and list the muscles or groups of muscles involved in each.
- List the hyoid muscles and define the action of each.
- Name the muscles responsible for movement of the eyeball and describe each movement.

Neck Muscles

The muscles that move the head and neck are listed in table 10.2. The anterior neck muscles are illustrated in figure 10.4. These function primarily in lateral head movement. Most of the flexors of the head and neck lie deep within the neck along the anterior margins of the vertebral bodies (not illustrated). Extension of the neck is accomplished by the posterior neck muscles that attach to the occipital bone and mastoid process of the temporal bone (figures 10.5 and 10.6), functioning as a class I lever system. These muscles also rotate and laterally flex the neck.

The muscular ridge seen superficially in the posterior part of the neck and lateral to the midline is composed of the trapezius muscle overlying the splenius capitis (see figures 10.4*b* and 10.5*b*). The fascicles of the trapezius muscles are shorter at the base of the neck and leave a diamond-shaped area over the inferior cervical and superior thoracic vertebral spines (see figure 10.5*b*).

Rotation and lateral flexion of the neck are accomplished by muscles of both the lateral and posterior groups (table 10.2). The **sternocleidomastoid** (ster'nō-klī'dō-mas'toyd) muscle is the prime mover of the lateral group. It is easily seen on the anterior and lateral sides of the neck, especially if the head is extended slightly and rotated to one side (see figure 10.4*b*). If the sternocleidomastoid muscle on only one side of the neck contracts, the neck is rotated toward the opposite side. If both contract together, they flex the neck (chin to chest). The scalene muscles, which are deep and lateral on the neck, assist the sternocleidomastoid in neck flexion. Lateral flexion of the neck (moving the head back to the midline after it has been tilted to one side) is accomplished by the lateral flexors of the opposite side.

Facial Expression

The skeletal muscles of the face (table 10.3; figure 10.7) are cutaneous muscles attached to the skin. Many animals have cutaneous muscles over the trunk that allow the skin to twitch to remove irritants, such as insects. In humans, facial expressions are important components of nonverbal communication, and the cutaneous muscles are confined primarily to the face and neck.

Several muscles act on the skin around the eyes and eyebrows (figures 10.7 and 10.8). The **occipitofrontalis** (ok-sip'i-tō-frūn-tā'lis) raises the eyebrows and furrows the skin of the forehead. The **orbicularis oculi** (ōr-bik'ū-lā'ris ok'ū-lī) closes the eyelids and causes “crow’s-feet” wrinkles in the skin at the lateral corners of the eyes. The **levator palpebrae** (le-vā'ter, lē-vā'tōr pal-pē'brē) **superioris** raises the upper lids (figure 10.8*a*). A droopy eyelid on one side, called **ptosis** (tō'sis), usually indicates that the nerve to the levator palpebrae superioris, or the part of the brain controlling that nerve, has been damaged. The **corrugator supercilii** (kōr'ū-gā'ter, kōr'ū-gā'tōr soo'per-sil'ē-ī) draws the eyebrows inferiorly and medially, producing vertical corrugations (furrows) in the skin between the eyes (figure 10.8*c*; see figure 10.7).

Several muscles function in moving the lips and the skin surrounding the mouth (figure 10.8; see figure 10.7). The **orbicularis oris** (ōr-bik'ū-lā'ris ōr'is) and **buccinator** (buk'si-nā-tōr), the kissing muscles, pucker the mouth. Smiling is accomplished by the **zygomaticus** (zī'gō-mat'i-kūs) **major** and **minor**, the **levator anguli** (ang'gū-lī) **oris**, and the **risorius** (rī-sōr'ē-ūs). Sneering is accomplished by the **levator labii superioris** and frowning or pouting by the **depressor anguli oris**, the **depressor labii inferioris**, and the **mentalis** (men-tā'lis). If the mentalis muscles are well developed on each side of the chin, a chin dimple, where the skin is tightly attached to the underlying bone or other connective tissue, may appear between the two muscles.

ASSESS YOUR PROGRESS

- Name the major movements of the head caused by contraction of the anterior, posterior, and lateral neck muscles.
- What is unusual about the insertion (and sometimes the origin) of facial muscles?
- Which muscles are responsible for moving the ears, the eyebrows, the eyelids, and the nose?
- What usually causes ptosis on one side? Which muscles are responsible for puckering the lips, smiling, sneering, and frowning? What causes a dimple of the chin?

Mastication

Chewing, or **mastication** (mas-ti-kā'shūn), involves forcefully closing the mouth (elevating the mandible: temporalis, masseter, and medial pterygoid) and grinding food between the teeth (medial and lateral excursion (to one side) of the mandible; involving all muscles of mastication). The **muscles of mastication** and the **hyoid muscles** move the mandible (tables 10.4 and 10.5; figures 10.9 and 10.10). The elevators of the mandible are some of the strongest muscles of the body; they bring the mandibular teeth forcefully against the maxillary teeth to crush food. Slight mandibular depression involves relaxation of the mandibular elevators and the pull of gravity. Opening the mouth wide requires the action of the depressors of the mandible (lateral pterygoid, digastric, geniohyoid, mylohyoid). Even though the muscles of the tongue and the buccinator (table 10.6; see table 10.3) are not involved in chewing, they help move the food in the mouth and hold it in place between the teeth.

TABLE 10.2*

Muscles Moving the Head and Neck (see figures 10.4–10.6)

Muscle	Origin	Insertion	Nerve	Action
Anterior				
Longus capitis (lon'gūs ka'pi-tis; not illustrated)	C3–C6	Occipital bone	C1–C3	Flexes neck
Rectus capitis anterior (rek'tūs ka'pi-tis; not illustrated)	Atlas	Occipital bone	C1–C2	Flexes neck
Posterior				
Longissimus capitis (lon-gis't-mūs ka'pi-tis)	Upper thoracic and lower cervical vertebrae	Mastoid process	Dorsal rami of cervical nerves	Extends, rotates, and laterally flexes neck
Oblique capitis superior (ka'pi-tis)	Atlas	Occipital bone (inferior nuchal line)	Dorsal ramus of C1	Extends and laterally flexes neck
Rectus capitis posterior (rek'tūs ka'pi-tis)	Axis, atlas	Occipital bone	Dorsal ramus of C1	Extends and rotates neck
Semispinalis capitis	C4–T6	Occipital bone	Dorsal rami of cervical nerves	Extends and rotates neck
Splenius capitis	C4–T6	Superior nuchal line and mastoid process	Dorsal rami of cervical nerves	Extends, rotates, and laterally flexes neck
Trapezius	Occipital protuberance, nuchal ligament, spinous processes of C7–T12	Clavicle, acromion process, and scapular spine	Accessory (cranial nerve XI)	Extends and laterally flexes neck
Lateral				
Rectus capitis lateralis (not illustrated)	Atlas	Occipital bone	C1	Laterally flexes neck
Sternocleidomastoid (ster'nō-klī'dō-mas'toyd)	Manubrium and medial clavicle	Mastoid process and superior nuchal line	Accessory (cranial nerve XI)	One contracting alone: laterally flexes head and neck to same side and rotates head and neck to opposite side Both contracting together: flex neck
Scalene (skā'lēn) muscles	C2–C6	First and second ribs	Cervical and brachial plexuses	Flex, laterally flex, and rotate neck

*The tables in this chapter are to be used as references. As you study the muscular system, first locate the muscle on the figure, and then find its description in the corresponding table.

TABLE 10.3 Muscles of Facial Expression (see figures 10.7 and 10.8)

Muscle	Origin	Insertion	Nerve	Action
Auricularis (aw-rik'ū-lār'is)				
Anterior	Aponeurosis over head	Cartilage of auricle	Facial	Draws auricle superiorly and anteriorly
Posterior	Mastoid process	Posterior root of auricle	Facial	Draws auricle posteriorly
Superior	Aponeurosis over head	Cartilage of auricle	Facial	Draws auricle superiorly and posteriorly
Buccinator (buk'sī-nā'tōr)	Mandible and maxilla	Orbicularis oris at angle of mouth	Facial	Retracts angle of mouth; flattens cheek
Corrugator supercillii (kōr'ū'gā'ter soo'per-sil'ē-ī)	Nasal bridge and orbicularis oculi	Skin of eyebrow	Facial	Depresses medial portion of eyebrow; draws eyebrows together, as in frowning
Depressor anguli oris (dē-pres'ōr ang'gū-lī ōr'is)	Lower border of mandible	Skin of lip near angle of mouth	Facial	Depresses angle of mouth
Depressor labii inferioris (dē-pres'ōr lā'bē-ī in-fēr'ē-ōr-is)	Lower border of mandible	Skin of lower lip and orbicularis oris	Facial	Depresses lower lip
Levator anguli oris (lē-vā'tor, le-vā'ter ang'gū-lī ōr'is)	Maxilla	Skin at angle of mouth and orbicularis oris	Facial	Elevates angle of mouth
Levator labii superioris (lē-vā'tor, le-vā'ter lā'bē-ī sū-pēr'ē-ōr-is)	Maxilla	Skin and orbicularis oris of upper lip	Facial	Elevates upper lip
Levator labii superioris alaeque nasi (lē-vā'tor, le-vā'ter lā'bē-ī sū-pēr'ē-ōr-is ā-lak'ā nā'zī)	Maxilla	Ala at nose and upper lip	Facial	Elevates ala of nose and upper lip
Levator palpebrae superioris (lē-vā'tor, le-vā'ter pal-pē'brē sū-pēr'ē-ōr-is)	Lesser wing of sphenoid	Skin of eyelid	Oculomotor	Elevates upper eyelid
Mentalis (men-tā'lis)	Mandible	Skin of chin	Facial	Elevates and wrinkles skin over chin; protrudes lower lip
Nasalis (nā'zā-lis)	Maxilla	Bridge and ala of nose	Facial	Dilates nostril
Occipitofrontalis (ok-sip'i-tō-frūn'tā'lis)	Occipital bone	Skin of eyebrow and nose	Facial	Moves scalp; elevates eyebrows
Orbicularis oculi (ōr-bik'ū-lā'ris ok'ū-lī)	Maxilla and frontal bones	Circles orbit and inserts near origin	Facial	Closes eye
Orbicularis oris (ōr-bik'ū-lā'ris ōr'is)	Nasal septum, maxilla, and mandible	Fascia and other muscles of lips	Facial	Closes lips
Platysma (plā-tiz'mā)	Fascia of deltoid and pectoralis major	Skin over inferior border of mandible	Facial	Depresses lower lip; wrinkles skin of neck and upper chest
Procerus (prō-sē'rūs)	Bridge of nose	Frontalis	Facial	Creates horizontal wrinkles between eyes, as in frowning
Risorius (ri-sōr'ē-ūs)	Platysma and masseter fascia	Orbicularis oris and skin at corner of mouth	Facial	Abducts angle of mouth
Zygomaticus major (zī'gō-mat'i-kūs)	Zygomatic bone	Angle of mouth	Facial	Elevates and abducts upper lip
Zygomaticus minor (zī'gō-mat'i-kūs)	Zygomatic bone	Orbicularis oris of upper lip	Facial	Elevates and abducts upper lip

Tongue Movements

The tongue is important in mastication and speech in several ways: (1) It moves food around in the mouth; (2) with the buccinator, it holds food in place while the teeth grind it; (3) it pushes food up to the palate and back toward the pharynx to initiate swallowing; and (4) it changes shape to modify sound during speech. The tongue

consists of a mass of **intrinsic muscles** (entirely within the tongue), which are involved in changing the shape of the tongue, and **extrinsic muscles** (outside of the tongue but attached to it), which help change the shape and move the tongue (figure 10.11; table 10.6). The intrinsic muscles are named for their fascicle orientation in the tongue. The extrinsic muscles are named for their origin and insertion.

(b) Anterior view

FIGURE 10.7 Muscles of Facial Expression

(Bold terms denote the muscles involved in facial expression.)

FIGURE 10.8 Surface Anatomy, Muscles of Facial Expression

TABLE 10.4

Muscles of Mastication (see figures 10.7 and 10.9)

Muscle	Origin	Insertion	Nerve	Action
Temporalis (tem-pō-rā'lis)	Temporal fossa	Anterior portion of mandibular ramus and coronoid process	Mandibular division of trigeminal	Elevates and retracts mandible; involved in excursion
Masseter (ma'se-ter)	Zygomatic arch	Lateral side of mandibular ramus	Mandibular division of trigeminal	Elevates and protracts mandible; involved in excursion
Pterygoids (ter'i-goydz)				
Lateral	Lateral side of lateral pterygoid plate and greater wing of sphenoid	Condylar process of mandible and articular disk	Mandibular division of trigeminal	Protracts and depresses mandible; involved in excursion
Medial	Medial side of lateral pterygoid plate and tuberosity of maxilla	Medial surface of mandible	Mandibular division of trigeminal	Protracts and elevates mandible; involved in excursion

➤ Predict 2

While driving to school on slick roads and talking on her cell phone, Rachel lost control of her car. The car left the road and hit a tree. Rachel was not wearing a seat belt, and her head slammed into the steering wheel, causing a fractured left mandible, as well as nerve damage. On examination, Rachel's tongue deviated toward the injured side of her face when she tried to stick out her tongue, and the left side of her tongue was paralyzed. The nerve damage affected which muscles of her tongue?

Swallowing and the Larynx

The hyoid muscles (see table 10.5 and figures 10.10 and 10.11) are divided into a **suprahyoid group** superior to the hyoid bone and an **infrahyoid group** inferior to it. When the hyoid bone is fixed by the infrahyoid muscles so that the bone is stabilized from below, the suprahyoid muscles can help depress the mandible. If the suprahyoid muscles fix the hyoid and thus stabilize it from above, the thyrohyoid muscle (an infrahyoid muscle) can elevate the larynx. To observe this effect, place your hand on your larynx (Adam's apple) and swallow.

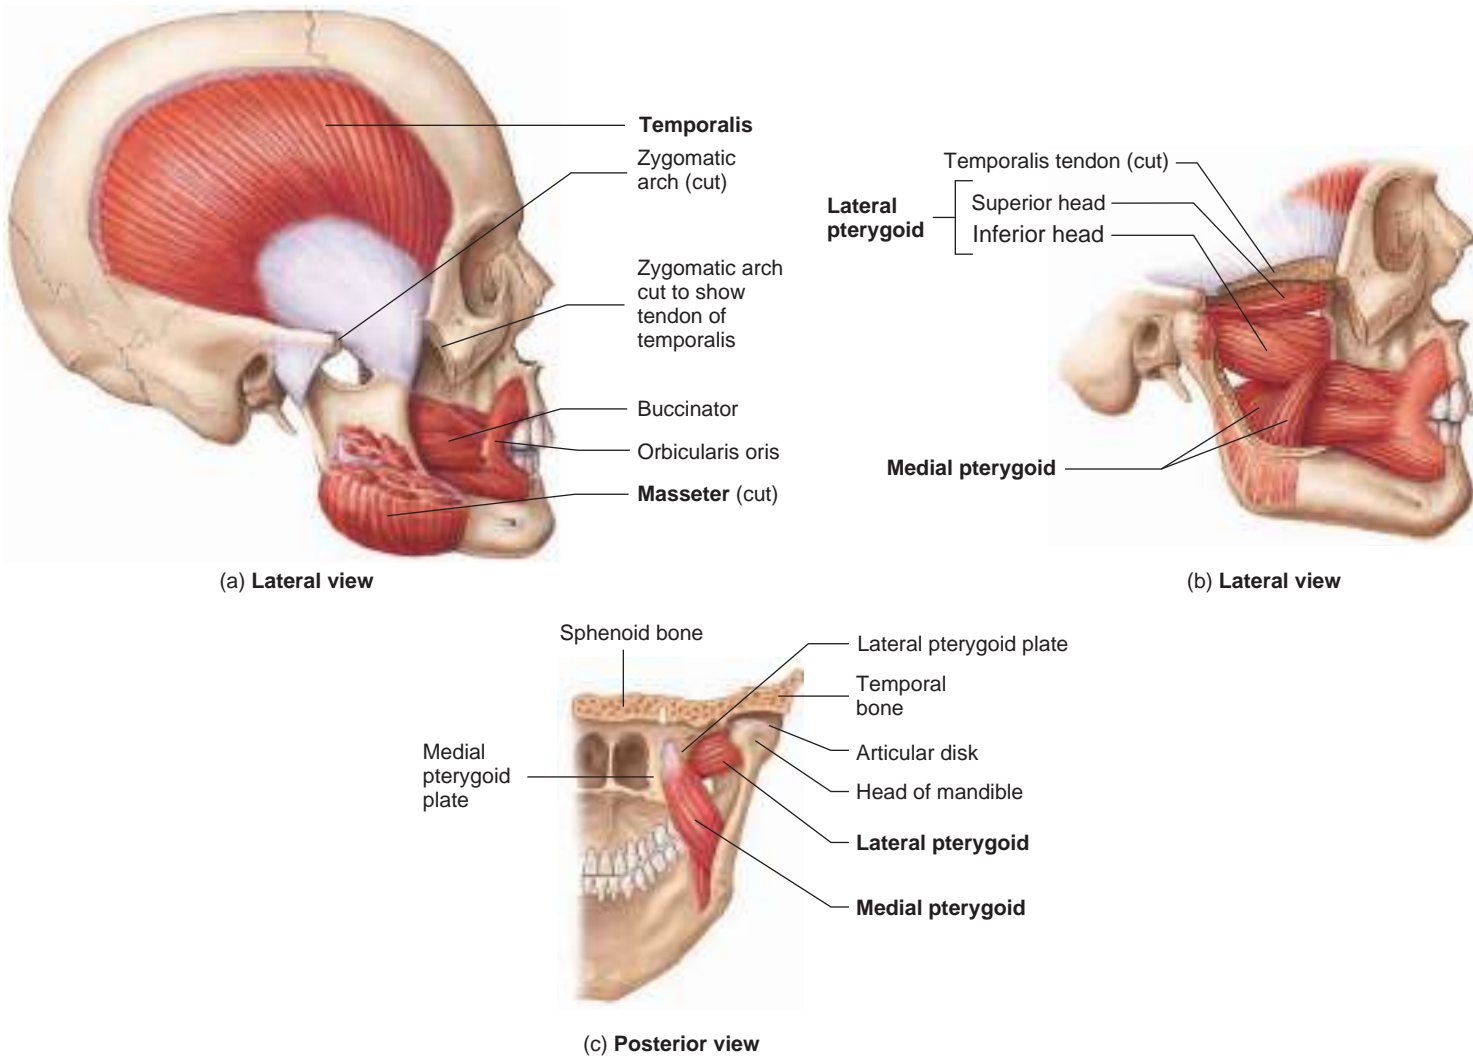

FIGURE 10.9 Muscles of Mastication

(a) The masseter and zygomatic arch are cut away to expose the temporalis. (b) The masseter and temporalis muscles are removed, and the zygomatic arch and part of the mandible are cut away to reveal the deeper muscles. (c) Frontal section of the skull, showing the pterygoid muscles. (Muscle names in bold are those involved in mastication.) **APR**

The soft palate, pharynx (throat), and larynx contain several muscles involved in swallowing and speech (table 10.7; figure 10.12). The muscles of the soft palate close the posterior opening to the nasal cavity during swallowing.

When we swallow, muscles elevate the pharynx and larynx and then constrict the pharynx (see chapter 24). Specifically, the **palatopharyngeus** (pal'ă-tō-far-in-jē'ūs) elevates the pharynx and the **salpingopharyngeus** (sal-pin'gō-far-in-jē'ūs) muscles then constrict the pharynx from superior to inferior, forcing food into the esophagus.

The salpingopharyngeus also opens the auditory tube, which connects the middle ear to the pharynx. Opening the auditory tube equalizes the pressure between the middle ear and the atmosphere; this is why it is sometimes helpful to chew gum or swallow when ascending or descending a mountain in a car or when changing altitudes in an airplane.

Clinical IMPACT

Laryngospasm

Laryngospasm is a tetanic contraction of the muscles that narrows the opening of the larynx (arytenoids, lateral cricoarytenoids) and affects speech and breathing. A typical episode lasts 30–60 seconds, but in severe cases the opening is closed completely, air can no longer pass through the larynx into the lungs, and the victim may die of asphyxiation. Laryngospasm can develop as a result of severe allergic reactions, tetanus infections, or hypocalcemia. More commonly, when food or liquid “goes down the wrong pipe,” a laryngospasm episode can occur. However, some individuals may have suffered an injury to the laryngeal nerves and experience recurrent laryngospasm. For them, an injection of botulinum toxin is an effective treatment.

TABLE 10.5 Hyoid Muscles (see figure 10.10)

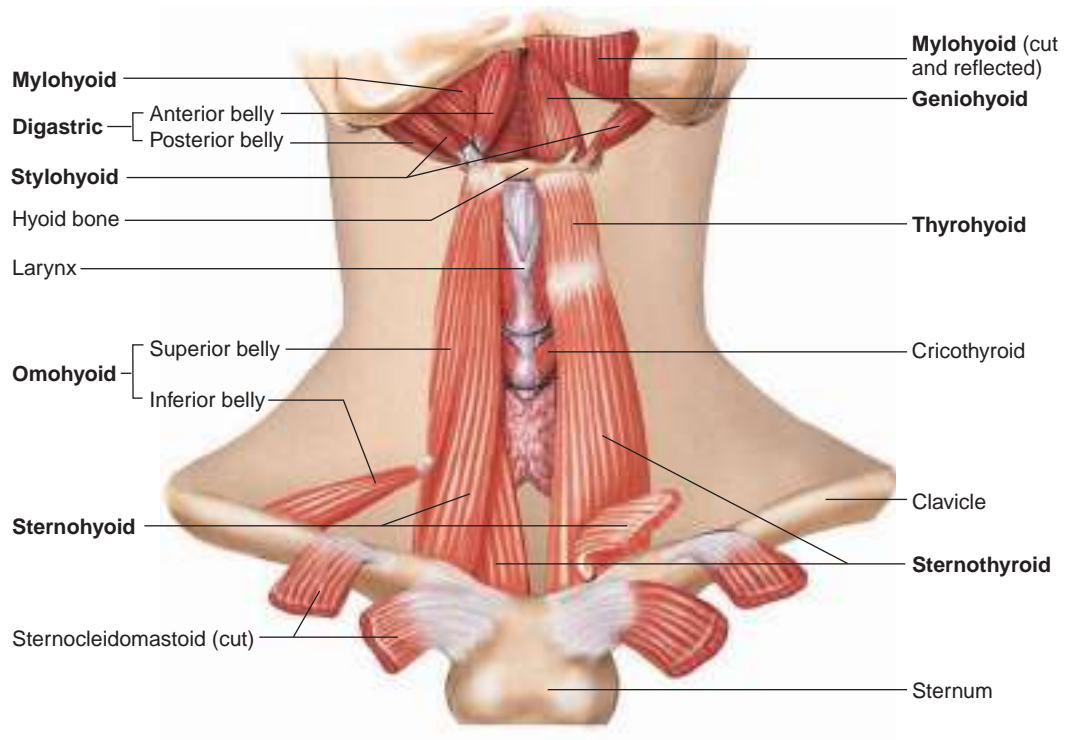

Muscle	Origin	Insertion	Nerve	Action
Suprahyoid Muscles				
Digastric (dī-gas'trik)	Mastoid process (posterior belly)	Mandible near midline (anterior belly)	Posterior belly—facial; anterior belly—mandibular division of trigeminal	Depresses and retracts mandible; elevates hyoid
Geniohyoid (jē-nī-ō-hī'oyd)	Mental protuberance of mandible	Body of hyoid	Fibers of C1 and C2 with hypoglossal	Protracts hyoid; depresses mandible
Mylohyoid (mī'lō-hī'oyd)	Body of mandible	Hyoid	Mandibular division of trigeminal	Elevates floor of mouth and tongue; depresses mandible when hyoid is fixed
Stylohyoid (stī-lō-hī'oyd)	Styloid process	Hyoid	Facial	Elevates hyoid
Infrahyoid Muscles				
Omohyoid (ō-mō-hī'oyd)	Superior border of scapula	Hyoid	Upper cervical through ansa cervicalis	Depresses hyoid; fixes hyoid in mandibular depression
Sternohyoid (ster'nō-hī'oyd)	Manubrium and first costal cartilage	Hyoid	Upper cervical through ansa cervicalis	Depresses hyoid; fixes hyoid in mandibular depression
Sternothyroid (ster'nō-thī'royd)	Manubrium and first or second costal cartilage	Thyroid cartilage	Upper cervical through ansa cervicalis	Depresses larynx; fixes hyoid in mandibular depression
Thyrohyoid (thī-rō-hī'oyd)	Thyroid cartilage	Hyoid	Upper cervical, passing with hypoglossal	Depresses hyoid and elevates thyroid cartilage of larynx; fixes hyoid in mandibular depression

FIGURE 10.10 (continued)

TABLE 10.6 Tongue Muscles (see figure 10.11)

Muscle	Origin	Insertion	Nerve	Action
Intrinsic Muscles				
Longitudinal, transverse, and vertical (not illustrated)	Within tongue	Within tongue	Hypoglossal	Change tongue shape
Extrinsic Muscles				
Genioglossus (jĕ'nĭ-ō-glos'ūs)	Mental protuberance of mandible	Tongue	Hypoglossal	Depresses and protrudes tongue
Hyoglossus (hĭ'ō-glos'ūs)	Hyoid	Side of tongue	Hypoglossal	Retracts and depresses side of tongue
Styloglossus (stī'lō-glos'ūs)	Styloid process of temporal bone	Tongue (lateral and inferior)	Hypoglossal	Retracts tongue
Palatoglossus (pal-ă-tō-glos'ūs)	Soft palate	Tongue	Pharyngeal plexus	Elevates posterior tongue

**FIGURE 10.11** Tongue Muscles

Right lateral view. (Muscle names in bold are tongue muscles.)

The muscles of the larynx are listed in table 10.7 and illustrated in figure 10.12*b*. Most of the laryngeal muscles help narrow or close the laryngeal opening, so that food does not enter the larynx when a person swallows. The remaining muscles shorten (relax) the vocal cords to lower the pitch of the voice or lengthen (tense) the vocal cords to raise the pitch of the voice.

Movements of the Eyeball

The eyeball rotates within the orbit to allow vision in a wide range of directions. The movements of each eye are accomplished by six muscles, which are named for the arrangement of their fascicles relative to the eye (table 10.8; figure 10.13).

Each rectus muscle (so named because the fibers are nearly straight with the axis of the eye) attaches to the eyeball anterior to the center of the sphere. The superior rectus rotates the anterior portion of the eyeball superiorly, so that the pupil, and thus the gaze, is directed superiorly (looking up). The inferior rectus depresses the gaze, the lateral rectus laterally deviates (abducts) the gaze (looking to the side), and the medial rectus medially deviates (adducts) the gaze (looking toward the nose). The superior rectus and inferior rectus are not completely straight in their orientation to the eye; thus, they also medially deviate the gaze as they contract.

TABLE 10.7 Muscles of Swallowing and the Larynx (see figures 10.11 and 10.12)

Muscle	Origin	Insertion	Nerve	Action
Larynx				
Arytenoids (ar-i-tē'noydz)				
Oblique (not illustrated)	Arytenoid cartilage	Opposite arytenoid cartilage	Recurrent laryngeal	Narrows opening to larynx
Transverse (not illustrated)	Arytenoid cartilage	Opposite arytenoid cartilage	Recurrent laryngeal	Narrows opening to larynx
Cricoarytenoids (krī'kō-ar-i-tē'noydz)				
Lateral (not illustrated)	Lateral side of cricoid cartilage	Arytenoid cartilage	Recurrent laryngeal	Narrows opening to larynx
Posterior (not illustrated)	Posterior side of cricoid cartilage	Arytenoid cartilage	Recurrent laryngeal	Widens opening of larynx
Cricothyroid (krī-kō-thī'royd)	Anterior cricoid cartilage	Thyroid cartilage	Superior laryngeal	Lengthens (tenses) vocal cords
Thyroarytenoid (thī'rō-ar'i-tē'noyd; not illustrated)	Thyroid cartilage	Arytenoid cartilage	Recurrent laryngeal	Shortens (relaxes) vocal cords
Vocalis (vō-kal'īs; not illustrated)	Thyroid cartilage	Arytenoid cartilage	Recurrent laryngeal	Shortens (relaxes) vocal cords
Soft Palate				
Levator veli palatini (lē-vā'tor, le-vā'ter vel'ī pal'ā-tē'nī)	Temporal bone and pharyngotympanic	Soft palate	Pharyngeal plexus	Elevates soft palate
Palatoglossus (pal-ā-tō-glos'ūs)	Soft palate	Tongue	Pharyngeal plexus	Narrows fauces; elevates posterior tongue
Palatopharyngeus (pal'ā-tō-far-in-jē'ūs)	Soft palate	Pharynx	Pharyngeal plexus	Narrows fauces; depresses palate; elevates pharynx
Tensor veli palatini (ten'sōr vel'ī pal'ā-tē'nī)	Sphenoid and auditory tube	Soft palate division of auditory tube	Mandibular, division of trigeminal	Tenses soft palate; opens auditory tube
Uvulae (ū'vū-lē)	Posterior nasal spine	Uvula	Pharyngeal plexus	Elevates uvula
Pharynx				
Pharyngeal constrictors (fā-rin'jē-āl)				
Inferior	Thyroid and cricoid cartilages	Pharyngeal raphe	Pharyngeal plexus and external laryngeal nerve	Narrows inferior portion of pharynx in swallowing
Middle	Stylohyoid ligament and hyoid	Pharyngeal raphe	Pharyngeal plexus	Narrows pharynx in swallowing
Superior	Medial pterygoid plate, mandible, floor of mouth, and side of tongue	Pharyngeal raphe	Pharyngeal plexus	Narrows superior portion of pharynx in swallowing
Salpingopharyngeus (sal-ping'gō-far-in-jē'ūs)	Auditory tube	Pharynx	Pharyngeal plexus	Elevates pharynx; opens auditory tube in swallowing
Stylopharyngeus (stī'lō-far-in-jē'ūs)	Styloid process	Pharynx	Glossopharyngeus	Elevates pharynx

The oblique muscles (so named because their fibers are oriented obliquely to the axis of the eye) insert onto the posterolateral margin of the eyeball, so that both muscles laterally deviate the gaze as they contract (see chapter 15, figure 15.11). The superior oblique elevates the posterior part of the eye, thus directing the pupil inferiorly and depressing the gaze. The inferior oblique elevates the gaze.

➤ Predict 3

Strabismus (stra-biz'mūs) is a condition in which one or both eyes deviate in a medial or lateral direction. In some cases, strabismus is caused by a weakness in either the medial or the lateral rectus muscle. If the lateral rectus of the right eye is weak, in which direction does the eye deviate?

FIGURE 10.12 Muscles of the Palate, Pharynx, and Larynx

(a) Anterior-inferior view of the palate. The palatoglossus and part of the palatopharyngeus muscles are cut on one side to reveal the deeper muscles. (b) Lateral view of the palate, pharynx, and larynx. Part of the mandible has been removed to reveal the deeper structures. (Muscle names in bold are muscles of swallowing and tongue movement.)

TABLE 10.8 Muscles Moving the Eye (see figure 10.13)

Muscle	Origin	Insertion	Nerve	Action
Oblique				
Inferior	Orbital plate of maxilla	Sclera of eye	Oculomotor	Elevates and laterally deviates gaze
Superior	Common tendinous ring	Sclera of eye	Trochlear	Depresses and laterally deviates gaze
Rectus				
Inferior	Common tendinous ring	Sclera of eye	Oculomotor	Depresses and medially deviates gaze
Lateral	Common tendinous ring	Sclera of eye	Abducens	Laterally deviates gaze
Medial	Common tendinous ring	Sclera of eye	Oculomotor	Medially deviates gaze
Superior	Common tendinous ring	Sclera of eye	Oculomotor	Elevates and medially deviates gaze

FIGURE 10.13 Muscles That Move the Right Eyeball

(Names of muscles of eye movement are in bold.)

ASSESS YOUR PROGRESS

12. Name the muscles responsible for opening and closing the jaw.
13. What muscles are used to cause lateral and medial excursion of the jaw?
14. Contrast the movements produced by the extrinsic and intrinsic tongue muscles.
15. Explain the interaction of the suprahyoid and infrahyoid muscles in swallowing.
16. Which muscles open and close the openings to the auditory tube and to the larynx?
17. Describe the muscles of the eye and the movements they produce.

Clinical IMPACT

Back Pain

Low back pain can result from injury, poor posture, being overweight, or lack of fitness; it is the primary cause of missed work and the second most common neurological affliction in the United States. In addition to chronic pain, a low back injury is often accompanied by muscle spasms, which are spontaneous, painful, uncontrolled muscle contractions. A few changes may help prevent more spasms and reduce pain. Patients should sit and stand up straight; use a low back support when sitting; lose weight; exercise, especially the back and abdominal muscles; and try to sleep on their side on a firm mattress. If lifestyle changes are not sufficient, treatment with muscle relaxants, anti-inflammatory drugs, or pain medication may be necessary.

FIGURE 10.14 Deep Neck and Back Muscles

On the right, the erector spinae group of muscles is shown. On the left, these muscles are removed to reveal the deeper back muscles. (Names of muscles of the neck and back are in bold.) **APR**

10.3 Trunk Muscles

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the muscles of the vertebral column and the actions they accomplish.
- List the muscles of the thorax and give each of their actions.
- Describe the muscles of the abdominal wall and explain their actions.
- List and describe the muscles of the pelvic floor and perineum.

Muscles Moving the Vertebral Column

The muscles that extend, laterally flex, and rotate the vertebral column are divided into superficial and deep groups (table 10.9). In general, the muscles of the superficial group connect the vertebrae to the ribs, whereas the muscles of the deep group connect vertebrae together. These back muscles are very strong to maintain erect posture. The **erector spinae** (spī'nē) group of muscles on each side of the back consists of three subgroups: the **iliocostalis** (il'ē-ō-kos-tā'lis), the **longissimus** (lon-gis'i-mūs), and the **spinalis** (spī-nā'lis). The longissimus group accounts for most of the muscle mass in the lower back (figure 10.14). The deepest muscles of the back attach between the spinous and transverse processes of individual vertebrae (figure 10.15).

TABLE 10.9

Muscles Acting on the Vertebral Column (see figures 10.5, 10.6, 10.14, and 10.15)

Muscle	Origin	Insertion	Nerve	Action
Superficial				
Erector spinae (ē-rek'tōr, ē-rek'tōr spī'nē; divides into three columns)				
Iliocostalis (il'ē-ō-kos-tā'lis)	Sacrum, ilium, and lumbar spines	Ribs and vertebrae	Dorsal rami of spinal nerves	Extends vertebral column
Cervicis (ser-vī'sis)	Superior six ribs	Transverse processes of middle cervical vertebrae	Dorsal rami of thoracic nerves	Extends, laterally flexes, and rotates vertebral column
Thoracis (thō-ra'sis)	Inferior six ribs	Superior six ribs	Dorsal rami of thoracic nerves	Extends, laterally flexes, and rotates vertebral column
Lumborum (lum-bōr'ūm)	Sacrum, ilium, and lumbar vertebrae	Inferior six ribs	Dorsal rami of thoracic and lumbar nerves	Extends, laterally flexes, and rotates vertebral column
Longissimus (lon-gis'i-mūs)				
Capitis (ka'pī-tis)	Upper thoracic and lower cervical vertebrae	Mastoid process	Dorsal rami of cervical nerves	Extends head
Cervicis (ser-vī'sis)	Upper thoracic vertebrae	Transverse processes of upper cervical vertebrae	Dorsal rami of cervical nerves	Extends neck
Thoracis (thō-ra'sis)	Ribs and lower thoracic vertebrae	Transverse processes of upper lumbar vertebrae and ribs	Dorsal rami of thoracic and lumbar nerves	Extends vertebral column
Spinalis (spī-nā'lis)				
Cervicis (ser-vī'sis; not illustrated)	C6–C7	Spinous processes of C2–C3	Dorsal rami of cervical nerves	Extends neck
Thoracis (thō-ra'sis)	T11–L2	Spinous processes of middle and upper thoracic vertebrae	Dorsal rami of thoracic nerves	Extends vertebral column
Semispinalis (sem'ē-spī-nā'lis)				
Cervicis (ser-vī'sis)	Transverse processes of T2–T5	Spinous processes of C2–C5	Dorsal rami of cervical nerves	Extends neck
Thoracis (thō-ra'sis)	Transverse processes of T5–T11	Spinous processes of C5–T4	Dorsal rami of thoracic nerves	Extends vertebral column
Splenius cervicis (splē'nē-ūs ser-vī'sis)	Spinous processes of C3–C5	Transverse processes of C1–C3	Dorsal rami of cervical nerves	Rotates and extends neck
Longus colli (lon'gūs kō'lī; not illustrated)	Bodies of C3–T3	Bodies of C1–C6	Ventral rami of cervical nerves	Flexes neck
Deep				
Interspinales (in-ter-spī-nā'lēz)	Spinous processes of all vertebrae	Next superior spinous process	Dorsal rami of spinal nerves	Extends back and neck
Intertransversarii (in-ter-trans'ver-sār'ē-ī)	Transverse processes of all vertebrae	Next superior transverse process	Dorsal rami of spinal nerves	Laterally flexes vertebral column
Multifidus (mūl-tif'i-dūs)	Transverse processes of vertebrae; posterior surface of sacrum and ilium	Spinous processes of superior vertebrae	Dorsal rami of spinal nerves	Extends and rotates vertebral column
Psoas minor (sō'as mī'ner)	T12–L1	Pectineal line near pubic crest	L1	Flexes vertebral column
Rotatores (rō-tā'tōrz)	Transverse processes of all vertebrae	Base of spinous process of superior vertebrae	Dorsal rami of spinal nerves	Extends and rotates vertebral column

Thoracic Muscles

The muscles of the thorax are mainly involved in the control of breathing (see chapter 23). Four major groups of thoracic muscles are associated with the rib cage, which helps air flow into the lungs. Changes in the diameter of the rib cage are

important for determining airflow into and out of the lungs. (table 10.10; figure 10.16). The **scalene** (skā'lēn) muscles elevate the first two ribs during more forceful inhalation. The **external intercostals** (in-ter-kos'tälz) elevate the ribs during quiet, resting inhalation. The **internal intercostals** and

FIGURE 10.15 Deep Muscles Associated with the Vertebrae
(Muscle names are in bold.)

transversus thoracis (thō-ra'sis) muscles depress the ribs during forced exhalation.

The **diaphragm** (dī'ă-fram; figure 10.16a) is the muscle responsible for normal, quiet breathing. It is a dome-shaped muscle; when it contracts, the dome flattens slightly, causing the volume of the thoracic cavity to increase and resulting in inhalation. If this dome of skeletal muscle or the phrenic nerve controlling it is severely damaged, the amount of air moving into and out of the lungs may be so small that the individual cannot survive without the aid of an artificial respirator.

Abdominal Wall

The muscles of the anterior abdominal wall (table 10.11; figures 10.17 and 10.18) flex and rotate the vertebral column. Contraction of the abdominal muscles when the vertebral column is stationary decreases the volume of the abdominal cavity and the thoracic cavity and can aid in such functions as forced exhalation, vomiting, defecation, coughing, and childbirth. The criss-cross layering of all the abdominal muscles creates a strong anterior wall, which holds in and protects the abdominal viscera. This is especially important because the anterior wall is not supported by bone.

In a relatively muscular person with little body fat, a vertical line called the **linea alba** (lin'ē-ă al'bă), or *white line*, is visible. It extends from the xiphoid process of the sternum through the navel to the pubis. The linea alba consists of dense regular collagenous connective tissue only (see figure 10.17). On each side of the linea alba is the **rectus abdominis** (figure 10.18; see figure 10.17), surrounded

TABLE 10.10 Muscles of the Thorax (see figure 10.16)

Muscle	Origin	Insertion	Nerve	Action
Diaphragm	Interior of ribs, sternum, and lumbar vertebrae	Central tendon of diaphragm	Phrenic	Inhalation depresses floor of thorax
Intercostalis (in'ter-kos-ta'lis)				
External	Inferior margin of each rib	Superior border of next rib below	Intercostal	Quiet inhalation elevates ribs
Internal	Superior margin of each rib	Inferior border of next rib above	Intercostal	Forced exhalation depresses ribs
Scalenus (skā-lē'nūs)				
Anterior	Transverse processes of C3–C6	First rib	Cervical plexus	Elevates first rib
Medial	Transverse processes of C2–C6	First rib	Cervical plexus	Elevates first rib
Posterior	Transverse processes of C4–C6	Second rib	Cervical and brachial plexuses	Elevates second rib
Serratus posterior (sēr-ā'tūs)				
Inferior (not illustrated)	Spinous processes of T11–L2	Inferior four ribs	Ninth to eleventh intercostals and subcostal	Depresses inferior ribs and extends vertebral column
Superior (not illustrated)	Spinous processes of C6–T2	Second to fifth ribs	First to fourth intercostals	Elevates superior ribs
Transversus thoracis (trans-ver'sus thō-ra'sis; not illustrated)	Sternum and xiphoid process	Second to sixth costal cartilages	Intercostal	Decreases diameter of thorax

**FIGURE 10.16** Muscles of the Thorax(Muscle names are in bold.) **APR****TABLE 10.11****Muscles of the Abdominal Wall (see figures 10.3a, 10.17, and 10.18)**

Muscle	Origin	Insertion	Nerve	Action
Anterior				
Rectus abdominis (rek'tūs ab-dom'i-nis)	Pubic crest and symphysis pubis	Xiphoid process and inferior ribs	Branches of lower thoracic	Flexes vertebral column; compresses abdomen
External abdominal oblique	Fifth to twelfth ribs	Iliac crest, inguinal ligament, and rectus sheath	Branches of lower thoracic	Flexes and rotates vertebral column; compresses abdomen; depresses thorax
Internal abdominal oblique	Iliac crest, inguinal ligament, and lumbar fascia	Tenth to twelfth ribs and rectus sheath	Lower thoracic	Flexes and rotates vertebral column; compresses abdomen; depresses thorax
Transversus abdominis (trans-ver'sūs ab-dom'i-nis)	Seventh to twelfth costal cartilages, lumbar fascia, iliac crest, and inguinal ligament	Xiphoid process, linea alba, and pubic tubercle	Lower thoracic	Compresses abdomen
Posterior				
Quadratus lumborum (kwah-drā'tūs lūm-bōr'ūm)	Iliac crest and lower lumbar vertebrae	Twelfth rib and upper lumbar vertebrae	Upper lumbar	Laterally flexes vertebral column and depresses twelfth rib

TABLE 10.12 Muscles of the Pelvic Floor and Perineum (see figure 10.19)

Muscle	Origin	Insertion	Nerve	Action
Bulbospongiosus (bul' bō-spūn'jē-ō'sūs)	Male—central tendon of perineum and median raphe of penis	Dorsal surface of penis and bulb of penis	Pudendal	Constricts urethra; erects penis
	Female—central tendon of perineum	Base of clitoris	Pudendal	Erects clitoris
Coccygeus (kok-si'jē-ūs; not illustrated)	Ischial spine	Coccyx	S3 and S4	Elevates and supports pelvic floor
Ischiocavernosus (ish'ē-ō-kav'er-nō'sūs)	Ischial ramus	Corpus cavernosum	Perineal	Compresses base of penis or clitoris
Levator ani (lē-vā'tor, le-vā'ter ā'nī)	Posterior pubis and ischial spine	Sacrum and coccyx	Fourth sacral	Elevates anus; supports pelvic viscera
External anal sphincter (ā'nāl sfingk'ter)	Coccyx	Central tendon of perineum	Fourth sacral and pudendal	Keeps orifice of anal canal closed
External urethral sphincter (ū-rē'thrāl sfingk'ter; not illustrated)	Pubic ramus	Median raphe	Pudendal	Constricts urethra
Transverse perinei (pēr'i-nē'ī)				
	Deep	Ischial ramus	Median raphe	Pudendal
Superficial	Ischial ramus	Central perineal	Pudendal	Fixes central tendon

**FIGURE 10.19** Muscles of the Pelvic Floor and Perineum

(Muscle names are in bold.)

by a **rectus sheath**. **Tendinous intersections** (tendinous inscriptions) transect the rectus abdominis at three, or sometimes more, locations, causing the abdominal wall of a lean, well-muscled person to appear segmented (a “six-pack”). Lateral to the rectus abdominis is the **linea semilunaris** (sem-ē-loo-nar'is; a crescent- or half-moon-shaped line); lateral to it are three layers of muscle (figures 10.17 and 10.18). From superficial (outermost) to deep (innermost), these muscles are the **external abdominal oblique**, **internal abdominal oblique**, and **transversus abdominis**.

Pelvic Floor and Perineum

The pelvis is a ring of bone (see chapter 7) with an inferior opening that is closed by a muscular wall, through which the anus and the urogenital openings penetrate (table 10.12). Most of the pelvic floor is formed by the **coccygeus** (kok-si'jē-ūs) muscle and the **levator ani** (a'nī) muscle. Together, these muscles are called the **pelvic diaphragm**. The diamond-shaped area just inferior to (beneath) the pelvic floor is called the **perineum** (per'i-nē'ūm; figure 10.19). The anterior half of the diamond is the urogenital

triangle, and the posterior half is the anal triangle (see chapter 28). During pregnancy, the muscles of the pelvic diaphragm and urogenital triangle may be stretched by the extra weight of the fetus, and specific exercises are designed to strengthen them.

ASSESS YOUR PROGRESS

18. List the actions of the group of back muscles that attaches to the vertebrae or ribs (or both). What is the name of the superficial subgroup?
19. Name the muscle that is mainly responsible for respiratory movements. What other muscles aid this movement?
20. Explain the anatomical basis for the segments (“cuts”) seen on a well-muscled individual’s abdomen. What are the functions of the abdominal muscles? List the muscles of the anterior abdominal wall.
21. What openings penetrate the pelvic floor muscles? Name the area inferior to the pelvic floor.

10.4 Upper Limb Muscles

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the movements of the scapula and list the muscles associated with it.
- B. Name and locate the muscles acting on the shoulder and arm and explain their movements.
- C. List and describe the muscles and movements of the forearm, wrist, hand, and fingers.
- D. Distinguish between extrinsic and intrinsic hand muscles.

The major connection of the upper limb to the body is accomplished by muscles (table 10.13; figure 10.20). The muscles of the upper limb include those that move the scapula and those that move the arm, forearm, and hand.

Scapular Movements

The muscles that attach the scapula to the thorax include the **trapezius**, **levator scapulae** (skap’ū-lē), **rhomboideus** (rom-bō-id’ē-ūs) **major** and **rhomboideus minor**, **serratus anterior**, and **pectoralis** (pek’tō-ra’lis) **minor** (see figure 10.22). These muscles move the scapula, permitting a wide range of movements of the upper limb, or they act as fixators to hold the scapula firmly in position when the arm muscles contract. The superficial muscles that act on the scapula can easily be seen on a living person (see figure 10.5b): The trapezius forms the upper line from each shoulder to the neck, and the origin of the serratus anterior from the first eight or nine ribs can be seen along the lateral thorax. The serratus anterior inserts onto the medial border of the scapula (figure 10.20c).

Arm Movements

The arm is attached to the thorax by several muscles, including the **pectoralis major** and the **latissimus dorsi** (lă-tis’i-mūs dōr’sī; table 10.14; figures 10.20b, 10.21, and 10.22). Notice that the pectoralis major is listed in table 10.14 as both a flexor and an extensor. The muscle flexes the extended shoulder and extends the flexed shoulder. Try these movements and notice the position and action of the muscle. The **deltoid** muscle (see figure 10.21) is also listed in table 10.14 as a flexor and an extensor. The deltoid muscle is like three muscles in one: The anterior fibers flex the shoulder, the lateral fibers abduct the arm, and the posterior fibers

TABLE 10.13

Muscles Acting on the Scapula (see figure 10.20)

Muscle	Origin	Insertion	Nerve	Action
Levator scapulae (lē-vā’tor, le-vā’ter skap’ū-lē)	Transverse processes of C1–C4	Superior angle of scapula	Dorsal scapular	Elevates, retracts, and rotates scapula; laterally flexes neck
Pectoralis minor (pek’tō-ra’lis)	Third to fifth ribs	Coracoid process of scapula	Medial pectoral	Depresses scapula or elevates ribs
Rhomboideus (rom-bō-id’ē-ūs)				
Major	Spinous processes of T1–T4	Medial border of scapula	Dorsal scapular	Retracts, rotates, and fixes scapula
Minor	Spinous processes of C6–C7	Medial border of scapula	Dorsal scapular	Retracts, slightly elevates, rotates, and fixes scapula
Serratus anterior (ser-ā’tūs)	First to eighth or ninth ribs	Medial border of scapula	Long thoracic	Rotates and protracts scapula; elevates ribs
Subclavius (sūb-klā’vē-ūs)	First rib	Clavicle	Subclavian	Fixes clavicle or elevates first rib
Trapezius (tra-pē’zē-ūs)	External occipital protuberance, ligamentum nuchae, and spinous processes of C7–T12	Clavicle, acromion process, and scapular spine	Accessory and cervical plexus	Elevates, depresses, retracts, rotates, and fixes scapula; extends neck

TABLE 10.14 Muscles Acting on the Arm (see figures 10.20–10.23)

Muscle	Origin	Insertion	Nerve	Action
Coracobrachialis (kōr'ā-kō-brā-kā-ā'lis)	Coracoid process of scapula	Midshaft of humerus	Musculocutaneous	Adducts arm and flexes shoulder
Deltoid (del'toyd)	Clavicle, acromion process, and scapular spine	Deltoid tuberosity	Axillary	Flexes and extends shoulder; abducts and medially and laterally rotates arm
Latissimus dorsi (lā-tis'i-mūs dōr'sī)	Spinous processes of T7–L5; sacrum and iliac crest; inferior angle of scapula in some people	Medial crest of intertubercular groove	Thoracodorsal	Adducts and medially rotates arm; extends shoulder
Pectoralis major (pek'tō-rā'lis)	Clavicle, sternum, superior six costal cartilages, and abdominal aponeurosis	Lateral crest of intertubercular groove	Medial and lateral pectoral	Flexes shoulder; adducts and medially rotates arm; extends shoulder from flexed position
Teres major (ter'ēz, tēr'ēz)	Lateral border of scapula	Medial crest of intertubercular groove	Lower subscapular C5 and C6	Extends shoulder; adducts and medially rotates arm
Rotator Cuff				
Infraspinatus (in-frā-spī-nā'tūs)	Infraspinous fossa of scapula	Greater tubercle of humerus	Suprascapular C5 and C6	Laterally rotates arm; holds head of humerus in place
Subscapularis (sūb-skap-ū-lā'ris)	Subscapular fossa	Lesser tubercle of humerus	Upper and lower subscapular C5 and C6	Medially rotates arm; holds head of humerus in place
Supraspinatus (soo-prā-spī-nā'tūs)	Supraspinous fossa	Greater tubercle of humerus	Suprascapular C5 and C6	Abducts arm; holds head of humerus in place
Teres minor (ter'ēz, tēr'ēz)	Lateral border of scapula	Greater tubercle of humerus	Axillary C5 and C6	Laterally rotates and adducts arm; holds head of humerus in place

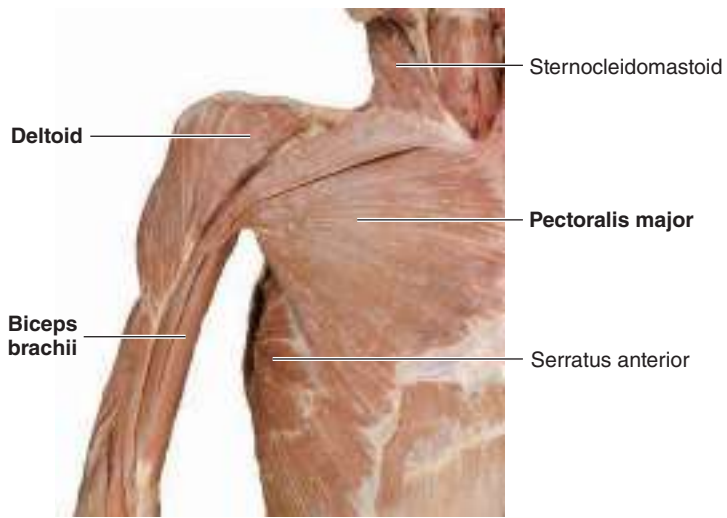

extend the shoulder. The deltoid muscle is part of the group of muscles that binds the humerus to the scapula. However, the primary muscles holding the head of the humerus in the glenoid cavity are called the **rotator cuff** muscles (table 10.14) because they form a cuff or cap over the proximal humerus (figure 10.23). The rotator cuff muscles include the **infraspinatus** (in-frā-spī-nā'tūs), **subscapularis** (sūb-skap-ū-lā'ris), **supraspinatus** (soo-prā-spī-nā'tūs), and **teres** (ter'ēz, tēr'ēz) **minor**. A rotator cuff

injury involves damage to one or more of these muscles or their tendons, usually the supraspinatus muscle. The muscles moving the arm are involved in flexion, extension, abduction, adduction, rotation, and circumduction (see chapter 8; table 10.15).

To visualize how these muscle groups work together, imagine that you want to raise your arm so that your hand is high above your head. First, you must abduct your arm from the anatomical position through 90 degrees (to the point at which the hand is level with the

**FIGURE 10.21** Anterior Muscles Attaching the Upper Limb to the Body

(Muscle names are in bold.)

shoulder); this involves moving the humerus and is accomplished by the deltoid muscle assisted by the rotator cuff muscles, which hold the head of the humerus tightly in place. In the initial phase of abduction, the deltoid is assisted by the supraspinatus. Place your hand on your deltoid, and feel it contract as you abduct 90 degrees. Next, move your arm from 90 degrees to 180 degrees, so that your hand is high above your head; this movement primarily involves rotation of the scapula, which is accomplished by the trapezius and serratus anterior muscles. Feel the inferior angle of your scapula as you abduct your arm to 90 degrees and then rotate to 180 degrees. Do you notice a big difference? Bear in mind that your arm cannot move from 90 degrees to 180 degrees unless the head of the humerus is held tightly in the glenoid cavity by the rotator cuff muscles, especially the supraspinatus. Damage to the supraspinatus muscle can prevent abduction past 90 degrees.

Clinical IMPACT

Shoulder Pain and Torn Rotator Cuff

Baseball pitchers, because they throw very hard, may tear their rotator cuffs. Such tears result in pain in the anterosuperior part of the shoulder. Older people may also develop such pain because of **degenerative tendinitis** of the rotator cuff. The supraspinatus tendon is the most commonly affected part of the rotator cuff in either trauma or degeneration, probably because it has a relatively poor blood supply. If the damage is severe, surgery is required to repair the area. During surgery, the loose tissue debris is removed, and the scapula is shaved or smoothed to make more room for the supraspinatus tendon. Finally, the torn edges of the supraspinatus tendon are sewn together and to the top of the humerus.

Pain in the shoulder can also result from **subacromial bursitis**, which is inflammation of the subacromial bursa. **Biceps tendinitis**, inflammation of the biceps brachii long head tendon, can also cause shoulder pain. This inflammation is also commonly caused by throwing a baseball or football.

Predict 4

A tennis player complains of pain in the shoulder when she abducts her arm while serving or reaching for an overhead volley (extreme abduction). In extreme abduction, the supraspinatus muscle rises superiorly and may be damaged by compression against what bony structure?

Several muscles that act on the arm can be seen very clearly in the living individual (see figures 10.21c and 10.22c). The pectoralis major forms the upper chest, and the deltoids are prominent over the shoulders. The deltoid is a common site for administering injections.

Forearm Movements

Extension and Flexion of the Elbow

The **triceps brachii** (brā'kē-ī) and the **anconeus** (ang-kō'nē-ūs) muscles extend the elbow. The **brachialis** (brā'kē-al'is), the **biceps brachii**, and the **brachioradialis** (brā'kē-ō-rā'dē-al'is) muscles flex the elbow (table 10.16; figure 10.24; see figure 10.26a).

TABLE 10.15**Summary of Muscle Actions on the Shoulder and Arm**

Flexion	Extension	Abduction	Adduction	Medial Rotation	Lateral Rotation
Deltoid	Deltoid	Deltoid	Pectoralis major	Pectoralis major	Deltoid
Pectoralis major	Teres major	Supraspinatus	Latissimus dorsi	Teres major	Infraspinatus
Coracobrachialis	Latissimus dorsi		Teres major	Latissimus dorsi	Teres minor
Biceps brachii	Pectoralis major		Teres minor	Deltoid	
	Triceps brachii		Triceps brachii	Subscapularis	
			Coracobrachialis		

TABLE 10.16 Muscles Acting on the Forearm (see figure 10.24)

Muscle	Origin	Insertion	Nerve	Action
Arm				
Biceps brachii (bī'seps brā'kē-ī)	Long head—supraglenoid tubercle Short head—coracoid process	Radial tuberosity and aponeurosis of biceps brachii	Musculocutaneous	Flexes shoulder and elbow; supinates forearm and hand
Brachialis (brā'kē-al'is)	Anterior surface of humerus	Ulnar tuberosity and coronoid process of ulna	Musculocutaneous and radial	Flexes elbow
Triceps brachii (trī'seps brā'kē-ī)	Long head—infraglenoid tubercle on lateral border of scapula Lateral head—lateral and posterior surface of humerus Medial head—posterior humerus	Olecranon process of ulna	Radial	Extends elbow; extends shoulder and adducts arm
Forearm				
Anconeus (ang-kō'nē-ūs)	Lateral epicondyle of humerus	Olecranon process and posterior ulna	Radial	Extends elbow
Brachioradialis (brā'kē-ō-rā'dē-al'is)	Lateral supracondylar ridge of humerus	Styloid process of radius	Radial	Flexes elbow
Pronator quadratus (prō-nā'ter, prō-nā'tōr kwah-drā'tūs)	Distal ulna	Distal radius	Anterior interosseous	Pronates forearm (and hand)
Pronator teres (prō-nā-tōr ter'ēz, tēr'ēz)	Medial epicondyle of humerus and coronoid process of ulna	Radius	Median	Pronates forearm (and hand)
Supinator (soo'pi-nā-ter, soo'pi-nā-tōr)	Lateral epicondyle of humerus and ulna	Radius	Radial	Supinates forearm (and hand)

The triceps brachii constitutes the main mass visible on the posterior aspect of the arm (see figures 10.22c and 10.24c). The biceps brachii is readily visible on the anterior aspect of the arm (see figures 10.21d and 10.24d). The brachialis lies deep to the biceps brachii and can be seen only as a mass on the medial and lateral sides of the arm. The brachioradialis forms a bulge on the anterolateral side of the forearm just distal to the elbow (figures 10.24b and 10.25b,d). If the elbow is forcefully flexed in the midprone position (midway between pronation and supination), the brachioradialis stands out clearly on the forearm (figure 10.25d).

Supination and Pronation

The forearm muscle, the **supinator**, and the **biceps brachii** (see figures 10.24, 10.25c, and 10.26b) supinate (turn palm up) the forearm and hand. The **pronator quadratus** (kwah-drā'tūs) and the **pronator teres** (ter'ēz, tēr'ēz; see figures 10.24a and 10.25a,c) cause pronation (palm down) of the forearm and hand.

► Predict 5

Explain the difference between doing chin-ups with the forearm supinated and doing them with it pronated. The action of which muscle predominates in each type of chin-up? Which type is easier? Why?

Wrist, Hand, and Finger Movements

The forearm muscles are divided into anterior and posterior groups (table 10.17; see figures 10.25 and 10.26). Most of the anterior forearm muscles are responsible for flexion (make a fist) of the wrist and fingers. Most of the posterior forearm muscles cause extension (open the fist) of the wrist and fingers.

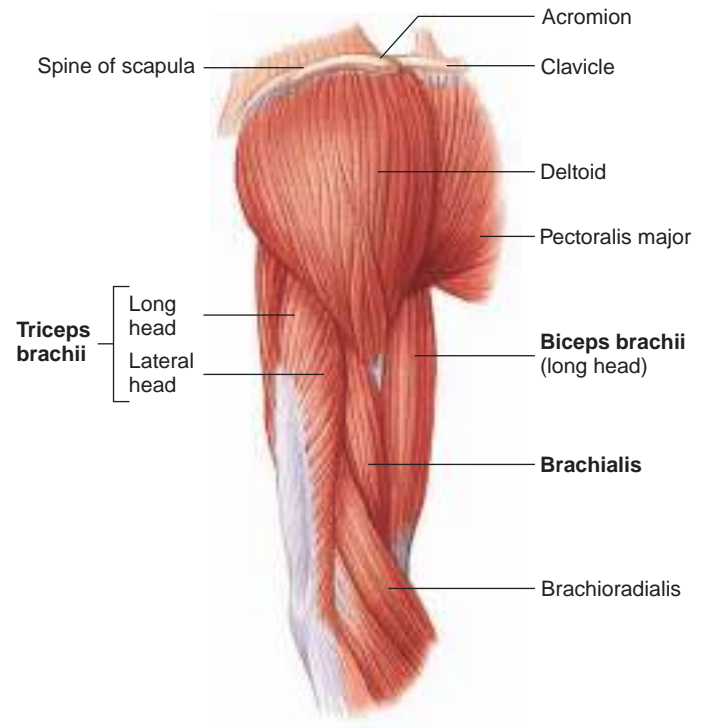

Clinical IMPACT

Tennis Elbow

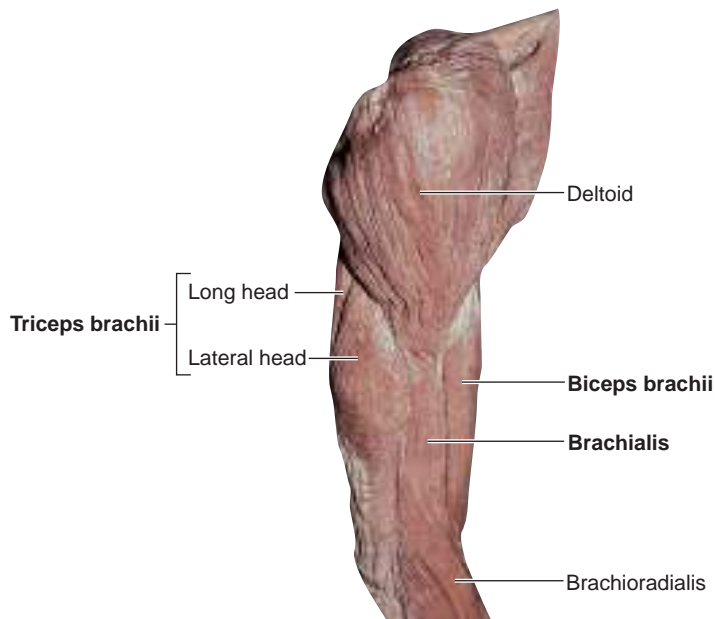

Forceful, repetitive use of the forearm extensor muscles can damage them where they attach to the lateral epicondyle. This condition is often called **tennis elbow** because it can result from playing tennis. It is also called **lateral epicondylitis** because it can result from other sports and activities, including shoveling snow. Treatment rarely requires surgery; rather, noninvasive practices, such as rest, ice, compression, and elevation (RICE) and anti-inflammatory medications, are usually effective. It is also possible to experience “golfer’s elbow,” or **medial epicondylitis**, where the medial forearm tendons attach to the medial epicondyle of the humerus.

FIGURE 10.24 Lateral Right Arm Muscles

(a, b) The right shoulder and arm. (c) The right shoulder and arm muscles of a cadaver. (d) Surface anatomy of the right shoulder and arm. (Names of arm muscles are in bold.) **APR**

Extrinsic Hand Muscles

The **extrinsic hand muscles** extend the wrist and fingers. These muscles are located in the posterior forearm but have tendons that extend into the hand. A strong ring of fibrous connective tissue,

the **extensor retinaculum** (ret-i-nak'ū-lūm; bracelet), encircles the flexor and extensor tendons to hold them in place around the wrist, so that they do not “bowstring” (pull away from the bone) during muscle contraction (figure 10.26a,c).

TABLE 10.17

Muscles of the Forearm Acting on the Wrist, Hand, and Fingers
 (see figures 10.25 and 10.26)

Muscle	Origin	Insertion	Nerve	Action
Anterior Forearm				
Flexor carpi radialis (kar'pī rā-dē-ā'lis)	Medial epicondyle of humerus	Second and third metacarpal bones	Median	Flexes and abducts wrist
Flexor carpi ulnaris (kar'pī ūl-nā'ris)	Medial epicondyle of humerus and ulna	Pisiform, hamate, and fifth metacarpal bones	Ulnar	Flexes and adducts wrist
Flexor digitorum profundus (dij'i-tōr'ūm prō-fūn'dūs)	Ulna	Distal phalanges of digits 2–5	Ulnar and median	Flexes fingers at metacarpophalangeal joints and interphalangeal joints and wrist
Flexor digitorum superficialis (dij'i-tōr'ūm soo'per-fish-ē-ā'lis)	Medial epicondyle of humerus, coronoid process, and radius	Middle phalanges of digits 2–5	Median	Flexes fingers at interphalangeal joints and wrist
Flexor pollicis longus (pol'i-sis lon'gūs)	Radius	Distal phalanx of thumb	Median	Flexes thumb
Palmaris longus (pawl-mā'r'is lon'gūs)	Medial epicondyle of humerus	Palmar fascia	Median	Tenses palmar fascia; flexes wrist
Posterior Forearm				
Abductor pollicis longus (pol'i-sis lon'gūs)	Posterior ulna and radius and interosseous membrane	Base of first metacarpal bone	Radial	Abducts and extends thumb; abducts wrist
Extensor carpi radialis brevis (kar'pī rā-dē-ā'lis brev'is)	Lateral epicondyle of humerus	Base of third metacarpal bone	Radial	Extends and abducts wrist
Extensor carpi radialis longus (kar'pī rā-dē-ā'lis lon'gus)	Lateral supracondylar ridge of humerus	Base of second metacarpal bone	Radial	Extends and abducts wrist
Extensor carpi ulnaris (kar'pī ūl-nā'ris)	Lateral epicondyle of humerus and ulna	Base of fifth metacarpal bone	Radial	Extends and adducts wrist
Extensor digiti minimi (dij'i-tī min'i-mī)	Lateral epicondyle of humerus	Phalanges of digit 5	Radial	Extends little finger and wrist
Extensor digitorum (dij'i-tōr'ūm)	Lateral epicondyle of humerus	Extensor tendon expansion over phalanges of digits 2–5	Radial	Extends fingers and wrist
Extensor indicis (in'di-sis)	Ulna	Extensor tendon expansion over digit 2	Radial	Extends forefinger and wrist
Extensor pollicis brevis (pol'i-sis brev'is)	Radius	Proximal phalanx of thumb	Radial	Extends and abducts thumb; abducts wrist
Extensor pollicis longus (pol'i-sis lon'gūs)	Ulna	Distal phalanx of thumb	Radial	Extends thumb

Two major anterior forearm muscles, the **flexor carpi radialis** (kar'pī rā-dē-ā'lis) and the **flexor carpi ulnaris** (ūl-nā'ris), flex the wrist; and three posterior forearm muscles, the **extensor carpi radialis longus**, the **extensor carpi radialis brevis**, and the **extensor carpi ulnaris**, extend the wrist. The tendon of the flexor carpi radialis serves as a landmark for locating the radial pulse, which is lateral to the tendon (see figure 10.25*d*). The wrist flexors and extensors are visible on the anterior and posterior surfaces of the forearm (see figures 10.25*d* and 10.26*d*).

Flexion of the four medial digits is a function of the **flexor digitorum** (dij'i-tor'ūm) **superficialis** and the **flexor digitorum profundus** (prō-fūn'dūs; deep). Extension is accomplished by the **extensor digitorum**. The tendons of this muscle are very visible on the dorsum of the hand (figure 10.26*d*). The little finger has an

additional extensor, the **extensor digiti minimi** (dij'i-tī min'i-mī). The index finger also has an additional extensor, the **extensor indicis** (in'di-sis).

Movement of the thumb is caused in part by the **abductor pollicis** (pol'i-sis) **longus**, the **extensor pollicis longus**, and the **extensor pollicis brevis**. These tendons form the sides of a depression on the posterolateral side of the wrist called the “anatomical snuffbox” (figure 10.26*d*). When snuff was in use, a small pinch could be placed into the anatomical snuffbox and inhaled through the nose.

Intrinsic Hand Muscles

The **intrinsic hand muscles**, which move the fingers, are entirely within the hand (table 10.18; figure 10.27). Abduction of the

TABLE 10.18 Intrinsic Hand Muscles (see figure 10.27)

Muscle	Origin	Insertion	Nerve	Action
Midpalmar Muscles				
Interossei (in'ter-os'e-ī)				
Dorsal	Sides of metacarpal bones	Proximal phalanges of digits 2, 3, and 4	Ulnar	Abducts second, third, and fourth digits
Palmar	Second, fourth, and fifth metacarpal bones	Digits 2, 4, and 5	Ulnar	Adducts second, fourth, and fifth digits
Lumbricals (lum'brā-kālz)	Tendons of flexor digitorum profundus	Digits 2–5	Two on radial side—median; two on ulnar side—ulnar	Flexes proximal and extends middle and distal phalanges
Thenar Muscles				
Abductor pollicis brevis (ab-dūk-ter, ab-dūk-tōr pol'i-sis brev'is)	Flexor retinaculum, trapezium, and scaphoid	Proximal phalanx of thumb	Median	Abducts thumb
Adductor pollicis (ā-dūk'ter, ā-dūk-tōr pol'i-sis)	Third metacarpal bone, second metacarpal bone, trapezoid, and capitate	Proximal phalanx of thumb	Ulnar	Adducts thumb
Flexor pollicis brevis (pol'i-sis brev'is)	Flexor retinaculum and first metacarpal bone	Proximal phalanx of thumb	Median and ulnar	Flexes thumb
Opponens pollicis (ō-pō'nens pol'i-sis)	Trapezium and flexor retinaculum	First metacarpal bone	Median	Opposes thumb
Hypothenar Muscles				
Abductor digiti minimi (ab-dūk-ter, ab-dūk-tōr dij'i-tī min'i-mī)	Pisiform	Base of digit 5	Ulnar	Abducts and flexes little finger
Flexor digiti minimi brevis (dij'i-tī min'i-mī brev'is)	Hamate	Base of proximal phalanx of digit 5	Ulnar	Flexes little finger
Opponens digiti minimi (ō-pō'nens dij'i-tī min'i-mī)	Hamate and flexor retinaculum	Fifth metacarpal bone	Ulnar	Opposes little finger

fingers is accomplished by the **dorsal interossei** (in'ter-os'e-ī) and the **abductor digiti minimi**, whereas adduction is a function of the **palmar interossei**.

The **flexor pollicis brevis**, the **abductor pollicis brevis**, and the **opponens pollicis** form a fleshy prominence at the base of the thumb called the **thenar** (thē'nar) **eminence** (figure 10.27a). The **abductor digiti minimi**, **flexor digiti minimi brevis**, and **opponens digiti minimi** constitute the **hypothenar eminence** on the ulnar side of the hand (figure 10.27c). The thenar and hypothenar muscles move the thumb and little finger.

ASSESS YOUR PROGRESS

- Name the seven muscles that attach the scapula to the thorax. What muscles attach the arm to the thorax?
- List the muscles forming the rotator cuff, and describe their function.
- What muscles cause flexion and extension of the shoulder? Adduction and abduction of the arm? What muscle abducts the arm to 90 degrees? Above 90 degrees?
- What muscles cause rotation of the arm?

- List the muscles that cause flexion and extension of the elbow. Where are these muscles located?
- What muscles produce supination and pronation of the forearm? Where are these muscles located?
- Describe the muscle groups that cause flexion and extension of the wrist.
- Contrast the location and actions of the extrinsic and intrinsic hand muscles. What is the retinaculum?
- Describe the muscles that move the thumb. The tendons of what muscles form the anatomical snuffbox?

10.5 Lower Limb Muscles

LEARNING OUTCOMES

After reading this section, you should be able to

- Summarize the muscles of the hip and thigh and explain their actions.
- List and describe the muscles and movements of the ankle, foot, and toes.

FIGURE 10.27 Right Hand Muscles

(a) Superficial muscles of the right hand. The abductor pollicis brevis is cut. (b) Deep muscles of the right hand. The flexor digitorum tendons are cut. (c) Surface anatomy of the palmar surface of the hand. (Muscle names are in bold.)

Hip and Thigh Movements

Several hip muscles originate on the hipbone and insert onto the femur (table 10.19; figures 10.28–10.31). These muscles are divided into three groups: anterior, posterolateral, and deep.

The anterior hip muscles, the **iliacus** (il-ī'ă-kŭs) and the **psoas** (sō'as) **major**, flex the hip (see figure 10.28). Because these muscles share an insertion and produce the same movement, they are often referred to collectively as the **iliopsoas** (il'ē-ō-sō'as). When the thigh is fixed, the iliopsoas flexes the trunk on the thigh. For example, the iliopsoas does most of the work when a person does sit-ups.

The posterolateral hip muscles consist of the gluteal muscles and the **tensor fasciae latae** (fash'ē-ē lā'tē). The **gluteus** (gloo-tē'ŭs) **maximus** contributes most of the mass that can be seen as the buttocks (see figure 10.29c); the **gluteus medius**, a common site for injections, creates a smaller mass just superior and lateral to the gluteus maximus. The gluteus maximus functions at its maximum force in extension of the thigh when the hip is flexed at a 45-degree angle, so that the muscle is optimally stretched, which accounts for both the sprinter's stance and the bicycle racing posture.

The deep hip muscles, as well as the gluteus maximus, laterally rotate the thigh. The gluteus medius, gluteus minimus, and tensor fasciae latae medially rotate the hip (table 10.19; see figure 10.29b). The gluteus medius and minimus muscles help tilt the pelvis and maintain the trunk in an upright posture during walking, as the foot of the opposite limb is raised from the ground. Without the action of these muscles, the pelvis tends to sag downward on the unsupported side.

Leg Movements

In addition to the hip muscles, some of the muscles located in the thigh originate on the hipbone and can cause movement of the thigh (tables 10.20 and 10.21). Three groups of thigh muscles have been identified based on their location in the thigh and are organized into **compartments**: The muscles of the anterior compartment flex the hip and/or extend the knee (see figure 10.28a); the muscles of the medial compartment adduct the thigh (see figure 10.30); and the muscles of the posterior compartment extend the hip and flex the knee (see figure 10.31).

TABLE 10.19

Muscles Acting on the Hip and Thigh (see figures 10.28–10.31)

Muscle	Origin	Insertion	Nerve	Action
Anterior				
Iliopsoas (il'ē-ō-sō'as)				
Iliacus (il-ī'ă-kus)	Iliac fossa	Lesser trochanter of femur and capsule of hip joint	Lumbar plexus	Flexes hip
Psoas major (sō'as)	T12–L5	Lesser trochanter of femur	Lumbar plexus	Flexes hip
Posterior and Lateral				
Gluteus maximus (gloo-tē'ŭs mak'si-mŭs)	Posterior surface of ilium, sacrum, and coccyx	Gluteal tuberosity of femur and iliotibial tract	Inferior gluteal	Extends hip; abducts and laterally rotates thigh
Gluteus medius (gloo-tē'ŭs mē'dē-ŭs)	Posterior surface of ilium	Greater trochanter of femur	Superior gluteal	Abducts and medially rotates thigh; tilts pelvis toward supported side
Gluteus minimus (gloo-tē'ŭs min'i-mŭs)	Posterior surface of ilium	Greater trochanter of femur	Superior gluteal	Abducts and medially rotates thigh; tilts pelvis toward supported side
Tensor fasciae latae (ten'sōr fash'ē-ē lā'tē)	Anterior superior iliac spine	Through iliotibial tract to lateral condyle of tibia	Superior gluteal	Tenses lateral fascia and stabilizes femur on tibia when standing; flexes hip; abducts and medially rotates thigh; tilts pelvis
Deep Thigh Rotators				
Gemellus (jē-mel'ŭs)				
Inferior	Ischial tuberosity	Obturator internus tendon	L5 and S1	Laterally rotates and abducts thigh
Superior	Ischial spine	Obturator internus tendon	L5 and S1	Laterally rotates and abducts thigh
Obturator (ob'too-rā-tōr)				
Externus (eks-ter'nŭs)	Inferior margin of obturator foramen	Greater trochanter of femur	Obturator	Laterally rotates thigh
Internus (in-ter'nŭs)	Interior margin of obturator foramen	Greater trochanter of femur	L5 and S1	Laterally rotates thigh
Piriformis (pir'i-fōr'mis)	Sacrum and ilium	Greater trochanter of femur	S1 and S2	Laterally rotates and abducts thigh
Quadratus femoris (kwah'-drā'tŭs fem'ō-ris)	Ischial tuberosity	Intertrochanteric ridge of femur	L5 and S1	Laterally rotates thigh

					Adductor brevis

TABLE 10.21 Muscles of the Thigh (see figures 10.30 and 10.32)

Muscle	Origin	Insertion	Nerve	Action
Anterior Compartment				
Quadriceps femoris (kwah'dri-seps fem'ō-ris)	Rectus femoris—anterior inferior iliac spine Vastus lateralis—greater trochanter and linea aspera of femur Vastus intermedius—body of femur Vastus medialis—linea aspera of femur	Patella and onto tibial tuberosity through patellar ligament	Femoral	Extends knee; rectus femoris also flexes hip
Sartorius (sar-tōr'ē-ūs)	Anterior superior iliac spine	Medial side of tibial tuberosity	Femoral	Flexes hip and knee; rotates thigh laterally and leg medially
Medial Compartment				
Adductor brevis (a-dük'ter, a-dük'tōr brev'is)	Pubis	Pectineal line and linea aspera of femur	Obturator	Adducts and laterally rotates thigh; flexes hip
Adductor longus (a-dük'ter, a-dük'tōr lon'gūs)	Pubis	Linea aspera of femur	Obturator	Adducts and laterally rotates thigh; flexes hip
Adductor magnus (a-dük'ter, a-dük'tōr mag'nūs)	Adductor part: pubis and ischium Hamstring part: ischial tuberosity	Adductor part: linea aspera of femur Hamstring part: adductor tubercle of femur	Adductor part: obturator Hamstring part: tibial	Adductor part: adducts thigh and flexes hip Hamstring part: extends hip and adducts thigh
Gracilis (gras'i-lis)	Pubis near symphysis	Tibia	Obturator	Adducts thigh; flexes knee
Pectineus (pek'ti-nē'ūs)	Pubic crest	Pectineal line of femur	Femoral and obturator	Adducts thigh; flexes hip
Posterior Compartment				
Biceps femoris (bī'seps fem'ō-ris)	Long head—ischial tuberosity Short head—femur	Head of fibula	Long head—tibial Short head—common fibular	Flexes knee; laterally rotates leg; extends hip
Semimembranosus (sem'ē-mem-brā-nō'sūs)	Ischial tuberosity	Medial condyle of tibia and collateral ligament	Tibial	Flexes knee; medially rotates leg; tenses capsule of knee joint; extends hip
Semitendinosus (sem'ē-ten-di-nō'sūs)	Ischial tuberosity	Tibia	Tibial	Flexes knee; medially rotates leg; extends hip

FIGURE 10.30 Right Medial Thigh Muscles

(Muscle names are in bold.)

The anterior thigh muscles are the **quadriceps femoris** (fem'ō-ris) and the **sartorius** (sar-tōr'ē-ūs; see table 10.20 and figure 10.28a). The quadriceps femoris is actually four muscles: the **rectus femoris**, the **vastus lateralis**, the **vastus medialis**, and the **vastus intermedius**. The quadriceps group extends the knee. The rectus femoris also flexes the hip because it crosses both the hip and knee joints.

The quadriceps femoris makes up the large mass on the anterior thigh (see figure 10.28c). The vastus lateralis is sometimes used as an injection site, especially in infants who do not have well-developed deltoid or gluteal muscles. The muscles of the quadriceps femoris have a common insertion, the patellar tendon, on and around the patella. The patellar ligament is an extension of the patellar tendon onto the tibial tuberosity. The patellar ligament is the point that is tapped with a rubber hammer when testing the knee-jerk reflex in a physical examination.

The sartorius is the longest muscle of the body, crossing from the lateral side of the hip to the medial side of the knee. As the muscle contracts, it flexes the hip and knee and laterally rotates the thigh. This is the action required for crossing the legs.

The medial thigh muscles (see figure 10.30) are involved primarily in adduction of the thigh. Some of these muscles also laterally rotate the thigh and/or flex or extend the hip. The gracilis also flexes the knee.

FIGURE 10.31 Right Posterior Thigh Muscles

Hip muscles are removed. (Muscle names are in bold.)

Clinical IMPACT

Shinsplints

Shinsplints is a general term involving any one of the following conditions associated with pain in the anterior portion of the leg:

1. Excessive stress on the tibialis anterior, resulting in pain along the origin of the muscle
2. Tibial periostitis, an inflammation of the tibial periosteum
3. Anterior compartment syndrome. During hard exercise, the anterior compartment muscles may swell with blood. The overlying fascia is very tough and does not expand; thus, the nerves and vessels are compressed, causing pain.
4. Stress fracture of the tibia 2–5 cm distal to the knee

Shinsplints can occur for several reasons: running with unsupportive shoes, running on a hard surface (such as concrete), or simply increasing your activity level too quickly. This injury can be treated by employing RICE and taking anti-inflammatory medicines. Runners might consider occasionally substituting a low-impact exercise, such as swimming or cycling.

TABLE 10.22 Muscles of the Leg Acting on the Leg, Ankle, and Foot (see figures 10.34 and 10.36)

Muscle	Origin	Insertion	Nerve	Action
Anterior Compartment				
Extensor digitorum longus (dij'i-tōr-ŭm lon'gūs)	Lateral condyle of tibia and fibula	Four tendons to phalanges of four lateral toes	Deep fibular*	Extends four lateral toes; dorsiflexes and everts foot
Extensor hallucis longus (hal'i-sis lon'gūs)	Middle fibula and interosseous membrane	Distal phalanx of great toe	Deep fibular*	Extends great toe; dorsiflexes and inverts foot
Tibialis anterior (tib-ē-a'lis)	Proximal, lateral tibia and interosseous membrane	Medial cuneiform and first metatarsal bone	Deep fibular*	Dorsiflexes and inverts foot
Fibularis tertius (fib-ŭ-lā'ris ter'shē-ŭs)	Fibula and interosseous membrane	Fifth metatarsal bone	Deep fibular*	Dorsiflexes and everts foot
Lateral Compartment				
Fibularis brevis (fib-ŭ-lā'ris brev'is)	Inferior two-thirds of lateral fibula	Fifth metatarsal bone	Superficial fibular*	Everts and plantar flexes foot
Fibularis longus (fib-ŭ-lā'ris lon'gūs)	Superior two-thirds of lateral fibula	First metatarsal bone and medial cuneiform	Superficial fibular*	Everts and plantar flexes foot
Posterior Compartment				
Superficial				
Gastrocnemius (gas-trok-nē'mē-ŭs)	Medial and lateral condyles of femur	Through calcaneal (Achilles) tendon to calcaneus	Tibial	Plantar flexes foot; flexes knee
Plantaris (plan-tār'is)	Femur	Through calcaneal tendon to calcaneus	Tibial	Plantar flexes foot; flexes knee
Soleus (sō-lē'ŭs)	Fibula and tibia	Through calcaneal tendon to calcaneus	Tibial	Plantar flexes foot
Deep				
Flexor digitorum longus (dij'i-tōr'ŭm lon'gūs)	Tibia	Four tendons to distal phalanges of four lateral toes	Tibial	Flexes four lateral toes; plantar flexes and inverts foot
Flexor hallucis longus (hal'i-sis lon'gūs)	Fibula	Distal phalanx of great toe	Tibial	Flexes great toe; plantar flexes and inverts foot
Popliteus (pop-li-tē'ŭs)	Lateral femoral condyle	Posterior tibia	Tibial	Flexes knee; medially rotates leg
Tibialis posterior (tib-ē-a'lis)	Tibia, interosseous membrane, and fibula	Navicular, cuneiforms, cuboid, and second through fourth metatarsal bones	Tibial	Plantar flexes and inverts foot

*Also referred to as the peroneal nerve.

The posterior thigh muscles (see figure 10.31), collectively called the hamstring muscles, consist of the **biceps femoris**, the **semimembranosus** (sem'ē-mem-brā-nō'sŭs), and the **semitendinosus** (sem'ē-ten-di-nō'sŭs; table 10.21). Their tendons are easily seen or felt on the medial and lateral posterior aspect of a slightly bent knee (figure 10.32).

Ankle, Foot, and Toe Movements

The muscles of the leg that move the ankle and the foot are listed in table 10.22 and illustrated in figures 10.33–10.35. These **extrinsic foot muscles** are divided into three groups, each located within a separate compartment of the leg: anterior, posterior, and lateral (see figure 10.33). The anterior leg muscles (see figure 10.34a)

are extensor muscles. They cause dorsiflexion, eversion, and inversion of the foot as well as extension of the toes.

The lateral leg muscles (see figure 10.34b) primarily evert the foot, but they also help plantar flex the foot. The **fibularis brevis** inserts onto the fifth metatarsal bone and everts and plantar flexes the foot. The **fibularis longus** crosses under the lateral four metatarsal bones to insert onto the first metatarsal bone and medial cuneiform. The tendons of the fibularis muscles can be seen on the lateral side of the ankle (see figure 10.34d).

The superficial muscles of the posterior compartment of the leg, the **gastrocnemius** (gas-trok-nē'mē-ŭs) and the **soleus**, form the bulge of the calf (posterior leg; see figure 10.35a,b,d). They merge with the small **plantaris** muscle to form the

FIGURE 10.32 Surface Anatomy of the Posterior Lower Limb (Muscle names are in bold.)

common **calcaneal** (kal-kā'nē-al) **tendon**, or *Achilles tendon*. These muscles plantar flex the foot. The deep muscles of the posterior compartment plantar flex and invert the foot and flex the toes.

FIGURE 10.33 Cross Section Through the Left Leg The anterior, posterior, and lateral compartments are labeled.

Intrinsic foot muscles, located within the foot itself (table 10.23; figure 10.36), flex, extend, abduct, and adduct the toes. They are arranged in a manner similar to that of the intrinsic muscles of the hand.

Clinical IMPACT

Achilles Tendon

The Achilles tendon derives its name from a hero of Greek mythology. When Achilles was a baby, his mother dipped him into magic water, which made him invulnerable to harm everywhere the water touched his skin. However, his mother held him by the heel and failed to submerge this part of his body under the water. Consequently, his heel was vulnerable and proved to be his undoing; at the battle of Troy, he was shot in the heel with an arrow and died. Thus, saying that someone has an “Achilles heel” means that the person has a weak spot that can be attacked.

Achilles tendon injuries are often due to overexertion by doing too much too quickly or too soon after a break from exercise. The main keys to preventing an injury are wearing the appropriate footwear and performing proper warm-up and stretching exercises.

Clinical IMPACT

Plantar Fasciitis

The muscles in the plantar region of the foot are covered with thick fascia and the plantar aponeurosis. Running on a hard surface wearing poorly fitting or worn-out shoes can result in inflammation of the plantar aponeurosis, called **plantar fasciitis**. Patients experience pain in the fascia over the heel and along the medial-inferior side of the foot. Wearing supportive shoes with heel inserts is a good first step toward treating plantar fasciitis. Studies show that wearing nonsupportive shoes, such as flip-flops, for extended periods of time leads to increased pain in the feet, heels, and ankles. RICE and anti-inflammatory medicines may relieve the pain and inflammation. About 80% of people recover fully within a year.

TABLE 10.23 Intrinsic Muscles of the Foot (see figure 10.36)

Muscle	Origin	Insertion	Nerve	Action
Abductor digiti minimi (ab-dŭk'ter, ab-dŭk'tŏr dij'i-tŭ min'ŭ-mŭ)	Calcaneus	Proximal phalanx of fifth toe	Lateral plantar	Abducts and flexes little toe
Abductor hallucis (ab-dŭk'ter, ab-dŭk'tŏr hal'i-sis)	Calcaneus	Base of proximal phalanx of great toe	Medial plantar	Abducts great toe
Adductor hallucis (a-dŭk'ter, a-dŭk'tŏr hal'i-sis; not illustrated)	Lateral four metatarsal bones	Proximal phalanx of great toe	Lateral plantar	Adducts great toe
Extensor digitorum brevis (dij'i-tŏr'ŭm brev'is; not illustrated)	Calcaneus	Four tendons fused with tendons of extensor digitorum longus	Deep fibular*	Extends toes
Flexor digiti minimi brevis (dij'i-tŭ min'ŭ-mŭ brev'is)	Fifth metatarsal bone	Proximal phalanx of digit 5	Lateral plantar	Flexes little toe (proximal phalanx)
Flexor digitorum brevis (dij'i-tŏr'ŭm brev'is)	Calcaneus and plantar fascia	Four tendons to middle phalanges of four lateral toes	Medial plantar	Flexes lateral four toes
Flexor hallucis brevis (hal'i-sis brev'is)	Cuboid; medial and lateral cuneiforms	Two tendons to proximal phalanx of great toe	Medial and lateral plantar	Flexes great toe
Dorsal interossei (in'ter-os'e-tŭ; not illustrated)	Metatarsal bones	Proximal phalanges of digits 2, 3, and 4	Lateral plantar	Abduct second, third, and fourth toes
Plantar interossei (plan'tă r in'ter-os'e-tŭ)	Third, fourth, and fifth metatarsal bones	Proximal phalanges of digits 3, 4, and 5	Lateral plantar	Adduct third, fourth, and fifth toes
Lumbricales (lum'bri-kă-lĕz)	Tendons of flexor digitorum longus	Extensor expansion of digits 2–5	Lateral and medial plantar	Flex proximal and extend middle and distal phalanges
Quadratus plantae (kwah'dră'tŭs plan'tĕ)	Calcaneus	Tendons of flexor digitorum longus	Lateral plantar	Assists flexor digitorum longus in flexing lateral four toes

*Also referred to as the peroneal nerve.

Clinical IMPACT

Bodybuilding

Bodybuilding is a popular sport worldwide. Its participants combine diet and specific weight training to develop maximum muscle mass and minimum body fat, with the goal of achieving a complete, well-balanced physique. Skill, training, and concentration are required to build a well-proportioned, muscular body and to know which exercises develop a large number of muscles and which are specialized to build up certain parts of the body. An uninformed, untrained muscle builder can build some muscles and ignore others; the result is a disproportioned body.

Is the old adage “no pain, no gain” correct? Not really. Overexercising can cause soreness and small tears in muscles. Torn muscles are weaker, and it may take up to 3 weeks to repair the damage, even though the soreness may last only 5–10 days.

Historically, although bodybuilders had a lot of muscle mass, they were not “in shape.” However, today bodybuilders exercise aerobically in addition to “pumping iron.”

A current topic of discussion for modern bodybuilders is whether bodybuilding shortens their life span. For instance, scientific evidence has shown that restricted-calorie diets increase life span, yet some bodybuilders consume at least 4500 calories a day when in the “bulking” phase of training. Others claim that the training process of lifting extremely heavy weights, such as squat-lifting 500 pounds in series of repetitions, and carrying the extra poundage of their acquired muscle mass cause their heart to

work harder. However the overwhelming evidence at this time shows that the life span of active people is longer than that of sedentary people, even when the activity is extreme. As bodybuilders age and reduce the intensity of their workouts, their muscle mass decreases, but not at a proportionally higher rate than other people with a lower activity level. In chapter 9, see the section “Effects of Aging on Skeletal Muscle” for more information on the effects of reduced muscle mass as people age.

Bodybuilders also have their own language. They refer to “lats,” “traps,” and “delts” rather than latissimus dorsi, trapezius, and deltoids. The exercises have special names, such as “lat pulldowns,” “preacher curls,” and “triceps extensions.”

Photographs of bodybuilders are very useful in the study of anatomy because they allow us to identify the surface anatomy of muscles that cannot usually be seen in untrained people (figure 10A).

FIGURE 10A Bodybuilders

Learn to Predict ◀ From page 313

The description of Pedro’s injury provided specific information about the regions of the body affected: the left hip and thigh. In addition, we are told that the injury affected action potential conduction to the muscles of these regions. These facts will help us determine Pedro’s symptoms and predict the movements that may be affected by his injury.

Chapter 9 described the relationship between action potential conduction and the force of muscle contractions. The reduction in action potential conduction to the muscles of the hip and thigh reduced the stimulation of these muscles, reducing the contraction force. As a result of his injury, we can predict that Pedro experienced weakness in his left hip and thigh, limiting his activity level.

We read in this chapter that the muscles affected by Pedro’s injury (psoas major, iliacus, pectineus, sartorius, vastus lateralis, vastus medius, vastus intermedius, and rectus femoris) are involved in flexing the hip, the knee, or both. Therefore, we can conclude that movements involving hip and knee flexion, such as walking up and down stairs, would be affected. Any tasks that require Pedro to walk up and down stairs would be more difficult for him. Sitting and standing may also be affected, but the weakness in Pedro’s left hip and thigh may be compensated for by increased muscle strength on his right side.

Answers to the rest of this chapter’s Predict questions are in appendix G.

Answer

ASSESS YOUR PROGRESS

31. Name the anterior hip muscle that flexes the hip. What muscles act as synergists to this muscle?
32. How is it possible for thigh muscles to move both the thigh and the leg? Name the six muscles that can do this, and give their actions.
33. What movements are produced by the three muscle compartments of the leg? Name the muscles of each

compartment, and describe the movements for which each muscle is responsible.

34. What movement do the fibularis muscles have in common? The tibialis muscles?
35. Name the leg muscles that flex the knee. Which of them can also plantar flex the foot?
36. List the general actions performed by the intrinsic foot muscles.

Body movements result from the contraction of skeletal muscles.

10.1 General Principles of Skeletal Muscle Anatomy (p. 314)

1. The less movable end of a muscle attachment is the origin; the more movable end is the insertion.
2. An agonist causes a certain movement, and an antagonist acts in opposition to the agonist.
3. Synergists are muscles that function together to produce movement.
4. Prime movers are mainly responsible for a movement. Fixators stabilize the action of prime movers.

Muscle Shapes

Muscle shape is determined primarily by the orientation of muscle fascicles.

Muscle Names

Muscles are named according to their location, size, shape, orientation of fascicles, origin and insertion, number of heads, or function.

Muscle Movements

Contracting muscles generate a force that acts on bones (levers) across joints (fulcrums) to create movement. Three classes of levers have been identified.

Muscle Anatomy

The study of muscle anatomy is usually broken down into body regions: head and neck, trunk, upper limbs, and lower limbs.

10.2 Head and Neck Muscles (p. 320)

Neck Muscles

The origins of these muscles are mainly on the cervical vertebrae (except for the sternocleidomastoid); the insertions are on the occipital bone or mastoid process. They cause flexion, extension, rotation, and lateral flexion of the head and neck.

Facial Expression

The origins of facial muscles are on skull bones or fascia; the insertions are into the skin, causing movement of the facial skin, lips, and eyelids.

Mastication

Three pairs of muscles close the jaw; gravity opens the jaw. Forced opening is caused by the lateral pterygoids and the hyoid muscles.

Summary

Tongue Movements

Intrinsic tongue muscles change the shape of the tongue; extrinsic tongue muscles move the tongue.

Swallowing and the Larynx

1. Hyoid muscles can depress the jaw and assist in swallowing.
2. Muscles open and close the openings to the nasal cavity, auditory tubes, and larynx.

Movements of the Eyeball

Six muscles with their origins on the orbital bones insert on the eyeball and cause it to move within the orbit.

10.3 Trunk Muscles (p. 333)

Muscles Moving the Vertebral Column

1. These muscles extend, laterally flex, rotate, or flex the vertebral column.
2. A more superficial group of muscles runs from the pelvis to the skull, extending from the vertebrae to the ribs.
3. A deep group of muscles connects adjacent vertebrae.

Thoracic Muscles

1. Most respiratory movement is caused by the diaphragm.
2. Muscles attached to the ribs aid in respiration.

Abdominal Wall

Abdominal wall muscles hold and protect abdominal organs and cause flexion, rotation, and lateral flexion of the vertebral column.

Pelvic Floor and Perineum

These muscles support the abdominal organs inferiorly.

10.4 Upper Limb Muscles (p. 339)

Scapular Movements

Six muscles attach the scapula to the trunk and enable the scapula to function as an anchor point for the muscles and bones of the arm.

Arm Movements

Seven muscles attach the humerus to the scapula. Two additional muscles attach the humerus to the trunk. These muscles cause flexion

and extension of the shoulder and abduction, adduction, rotation, and circumduction of the arm.

Forearm Movements

1. Flexion and extension of the elbow are accomplished by three muscles in the arm and two in the forearm.
2. Supination and pronation are accomplished primarily by forearm muscles.

Wrist, Hand, and Finger Movements

1. Forearm muscles that originate on the medial epicondyle are responsible for flexion of the wrist and fingers. Muscles extending the wrist and fingers originate on the lateral epicondyle.
2. Extrinsic hand muscles are in the forearm. Intrinsic hand muscles are in the hand.

10.5 Lower Limb Muscles (p. 349)

Hip and Thigh Movements

1. Anterior pelvic muscles cause flexion of the hip.

2. Muscles of the buttocks are responsible for extension of the hip and abduction and rotation of the thigh.

Leg Movements

1. Some muscles of the thigh also act on the leg. The anterior thigh muscles extend the leg, and the posterior thigh muscles flex the leg.
2. The thigh can be divided into three compartments.
 - The anterior compartment muscles flex the hip and extend the knee.
 - The medial compartment muscles adduct the thigh.
 - The posterior compartment muscles extend the hip and flex the knee.

Ankle, Foot, and Toe Movements

1. The leg is divided into three compartments.
 - Muscles in the anterior compartment cause dorsiflexion, inversion, or eversion of the foot and extension of the toes.
 - Muscles of the lateral compartment plantar flex and evert the foot.
 - Muscles of the posterior compartment flex the leg, plantar flex and invert the foot, and flex the toes.
2. Intrinsic foot muscles flex or extend, and abduct or adduct, the toes.

REVIEW AND COMPREHENSION

1. Muscles that oppose one another are
 - a. synergists.
 - b. levers.
 - c. hateful.
 - d. antagonists.
 - e. fixators.
2. The most movable attachment of a muscle is its
 - a. origin.
 - b. insertion.
 - c. fascia.
 - d. fulcrum.
 - e. belly.
3. The muscle whose name means it is to the side of midline is the
 - a. gluteus maximus.
 - b. vastus lateralis.
 - c. teres major.
 - d. latissimus dorsi.
 - e. adductor magnus.
4. In a class III lever system, the
 - a. fulcrum is located between the pull and the weight.
 - b. weight is located between the fulcrum and the pull.
 - c. pull is located between the fulcrum and the weight.
5. A prominent lateral muscle of the neck that can cause flexion of the neck or rotate the head is the
 - a. digastric.
 - b. mylohyoid.
 - c. sternocleidomastoid.
 - d. buccinator.
 - e. platysma.
6. An aerial circus performer who supports her body only with her teeth while spinning around should have strong
 - a. temporalis muscles.
 - b. masseter muscles.
 - c. buccinator muscles.
 - d. Both a and b are correct.
 - e. All of these are correct.
7. The tongue's shape changes *primarily* because of the action of the
 - a. extrinsic tongue muscles.
 - b. intrinsic tongue muscles.
8. The infrahyoid muscles
 - a. elevate the mandible.
 - b. move the mandible from side to side.
 - c. fix (prevent movement of) the hyoid.
 - d. Both a and b are correct.
 - e. All of these are correct.
9. The soft palate muscles
 - a. prevent food from entering the nasal cavity.
 - b. close the auditory tube.
 - c. force food into the esophagus.
 - d. prevent food from entering the larynx.
 - e. elevate the mandible.
10. Which of these movements is *not* caused by contraction of the erector spinae muscles?
 - a. flexion of the vertebral column
 - b. lateral flexion of the vertebral column
 - c. extension of the vertebral column
 - d. rotation of the vertebral column
11. Which of these muscles is *not* involved with the inhalation of air?
 - a. diaphragm
 - b. external intercostals
 - c. scalenes
 - d. transversus thoracis
12. Given these muscles:
 - (1) external abdominal oblique
 - (2) internal abdominal oblique
 - (3) transversus abdominis
 Choose the arrangement that lists the muscles from most superficial to deepest.
 - a. 1,2,3
 - b. 1,3,2
 - c. 2,1,3
 - d. 2,3,1
 - e. 3,1,2
13. Tendinous intersections
 - a. attach the rectus abdominis muscles to the xiphoid process.
 - b. divide the rectus abdominis muscles into segments.

- c. separate the abdominal wall from the thigh.
 d. are the sites where blood vessels exit the abdomen into the thigh.
 e. are the central point of attachment for all the abdominal muscles.
14. Which of these muscles can both elevate and depress the scapula?
 a. rhomboideus major and minor d. trapezius
 b. levator scapulae e. pectoralis minor
 c. serratus anterior
15. Which of these muscles does *not* adduct the arm (humerus)?
 a. latissimus dorsi c. teres major e. coracobrachialis
 b. deltoid d. pectoralis major
16. Which of these muscles would you expect to be especially well developed in a boxer known for his powerful jab (punching straight ahead)?
 a. biceps brachii c. trapezius e. supinator
 b. brachialis d. triceps brachii
17. Which of these muscles is an antagonist of the triceps brachii?
 a. biceps brachii c. latissimus dorsi e. supinator
 b. anconeus d. brachioradialis
18. The posterior group of forearm muscles is responsible for
 a. flexion of the wrist.
 b. flexion of the fingers.
 c. extension of the fingers.
 d. Both a and b are correct.
 e. All of these are correct.
19. Which of these muscles is an intrinsic hand muscle that moves the thumb?
 a. flexor pollicis brevis
 b. flexor digiti minimi brevis
 c. flexor pollicis longus
 d. extensor pollicis longus
 e. All of these are correct.
20. Given these muscles:
 (1) iliopsoas
 (2) rectus femoris
 (3) sartorius
 Which of the muscles flex the hip?
 a. 1 c. 1,3 e. 1,2,3
 b. 1,2 d. 2,3
21. Which of these muscles is found in the medial compartment of the thigh?
 a. rectus femoris c. gracilis e. semitendinosus
 b. sartorius d. vastus medialis
22. Which of these is *not* a muscle that can flex the knee?
 a. biceps femoris c. gastrocnemius e. sartorius
 b. vastus medialis d. gracilis
23. The _____ muscles evert the foot, whereas the _____ muscles invert the foot.
 a. fibularis (longus and brevis), gastrocnemius and soleus
 b. fibularis (longus and brevis), tibialis anterior and extensor hallucis longus
 c. tibialis anterior and extensor hallucis longus, fibularis longus and brevis
 d. tibialis anterior and extensor hallucis longus, flexor digitorum longus and flexor hallucis longus
 e. flexor digitorum longus and flexor hallucis longus, gastrocnemius and soleus
24. Which of these muscles causes plantar flexion of the foot?
 a. tibialis anterior d. soleus
 b. extensor digitorum longus e. sartorius
 c. fibularis tertius

Answers in appendix E

CRITICAL THINKING

- For each of the following muscles, (1) describe the movement the muscle produces, and (2) name the muscles that act as synergists and antagonists for them: longus capitis, erector spinae, coracobrachialis.
- Consider only the effect of the brachioradialis muscle for these questions: If a weight is held in the hand and the forearm is flexed, what type of lever system is in action? If the weight is placed on the forearm? Which system can lift more weight, and how far?
- A patient was involved in a rear-end auto collision, resulting in a whiplash injury to the head (hyperextension). What neck muscles might be injured in this type of accident? What is the easiest way to prevent such an injury in an automobile accident?
- During surgery, a branch of a patient's facial nerve was accidentally cut on one side of the face. After the operation, the lower eyelid and the corner of the patient's mouth drooped on that side. What muscles were affected?
- When a person becomes unconscious, the tongue muscles relax and the tongue tends to retract, or fall back, and obstruct the airway. Which tongue muscle is responsible? How can this be prevented or reversed?
- The mechanical support of the head of the humerus in the glenoid fossa is weakest in the inferior direction. What muscles help prevent dislocation of the shoulder when a person carries a heavy weight, such as a suitcase?
- Speedy Sprinter started a 200-meter dash and fell to the ground in pain. Examination of her right leg revealed the following symptoms: inability to plantar flex the foot against resistance, normal ability to evert the foot, abnormal dorsiflexion of the foot, and abnormal bulging of the calf muscles. Explain the nature of her injury.
- What muscles are required to turn this page?

Answers in appendix F

Functional Organization of Nervous Tissue

From thinking and feeling to breathing, moving, and eating, virtually everything our body does is controlled by the nervous system. There are two major control systems in the body, the nervous system and the endocrine system. The nervous system is made up of the brain, spinal cord, nerves, and sensory receptors. We begin the study of the nervous system in this chapter by focusing on the physiology of nervous tissue. Chapters 12 and 13 discuss the anatomy of the spinal cord and spinal nerves and the brain and cranial nerves. Chapter 14 focuses on the integration of the nervous system components and discusses the effects of aging on the nervous system. Chapter 15 concentrates on the anatomy and physiology of the special senses. Finally, chapter 16 explores the autonomic nervous system anatomy and physiology. By the time you've reviewed the nervous system section, you will definitely understand why you jump out of your seat and your heart pounds when the scary movie music plays and the bad guy pops out of the shower!

Learn to Predict

Once she turned 21, Amanda expected good times ahead. So why could she barely manage to climb the two flights of steps to her chemistry class? When she started experiencing weakness in her left hand, Amanda consulted a physician. After conducting numerous tests, Amanda's physician told her she had multiple sclerosis (MS), a condition in which the myelin sheaths of motor and sensory neurons in the brain and spinal cord are gradually destroyed. **By combining what you learned about the histology, physiology, and gross anatomy of the muscular system in chapters 9 and 10 with new information about nervous tissue organization in this chapter, explain why MS made it difficult for Amanda to walk up stairs and led to her hand weakness. Also, predict how Amanda's condition is likely to change over the next several years.**

11.1 Functions of the Nervous System

LEARNING OUTCOME

After reading this section, you should be able to

A. Explain the functions of the nervous system.

The regulatory and coordinating activities of the nervous system are necessary for the human body to function normally. The nervous system allows for this in the following ways:

1. *Maintaining homeostasis.* The trillions of cells in the human body do not function independently of each other but must work together to maintain homeostasis. For example, heart cells must contract at a rate that ensures adequate delivery of blood to all tissues of the body. The nervous system can stimulate or inhibit these activities to help maintain homeostasis.
2. *Receiving sensory input.* Sensory receptors monitor numerous external and internal stimuli. We are aware of sensations from some stimuli, such as sight, hearing, taste, smell, touch, pain, body position, and temperature. Other stimuli, such as blood pH, blood gases, and blood pressure, are processed at an unconscious level.
3. *Integrating information.* The brain and spinal cord are the major organs for processing sensory input and initiating responses. The input may produce an immediate response, be stored as memory, or be ignored.
4. *Controlling muscles and glands.* Skeletal muscles normally contract only when stimulated by the nervous system; thus, the nervous system controls the major movements of the body by controlling skeletal muscle. Some smooth muscle, such as that in the walls of blood vessels, contracts only when stimulated by the nervous system or by hormones (see chapter 18). Cardiac muscle and some smooth muscle, such as that in the wall of the stomach, contract autorhythmically—that is, no external stimulation is necessary for each contraction event. Although the nervous system does not initiate contraction in these muscles, it can cause the contractions to occur more rapidly or more slowly. Finally, the nervous system controls the secretions from many glands, including sweat glands, salivary glands, and glands of the digestive system.
5. *Establishing and maintaining mental activity.* The brain is the center of mental activities, including consciousness, thinking, memory, and emotions.

ASSESS YOUR PROGRESS

1. List and give examples of the general functions of the nervous system.

11.2 Divisions of the Nervous System

LEARNING OUTCOMES

After reading this section, you should be able to

A. List the divisions of the nervous system and describe the characteristics of each.

B. Differentiate between the somatic and the autonomic nervous systems.

C. Contrast the general functions of the CNS and the PNS.

The nervous system can be divided into two major divisions: the central nervous system and the peripheral nervous system (figure 11.1). The **central nervous system (CNS)** consists of the brain and the spinal cord. The brain is located within the skull, and the spinal cord is located within the vertebral canal formed by the vertebrae (see chapter 7). The brain and spinal cord connect with each other at the foramen magnum of the skull.

The **peripheral nervous system (PNS)** consists of all the nervous tissue outside the CNS (nerves and ganglia). It links the CNS with the various parts of the body. The PNS carries information about the different tissues of the body to the CNS and carries commands from the CNS that alter body activities. Cells of the nervous system are called **neurons**. Neurons send electrical messages from their cell body to other cells with long extensions called axons. Neurons are described in more detail in the next section. **Sensory receptors** are the endings of neurons, or separate, specialized cells that detect temperature, pain, touch, pressure, light, sound, odor, and other stimuli. Sensory receptors are located in the skin, muscles, joints, internal organs, and specialized sensory organs, such as the eyes and ears. A **nerve** is a bundle of many axons that connects the CNS to sensory receptors, muscles, and glands. There are 12 pairs of nerves originating from the brain, called **cranial nerves**, and 31 pairs of nerves originating from the spinal cord, called **spinal nerves** (figure 11.1). A **ganglion** (gang'glē-on; pl. ganglia, gang'glē-ă; knot) is a collection of neuron cell bodies located outside the CNS. A **plexus** (plek'sus; braid)

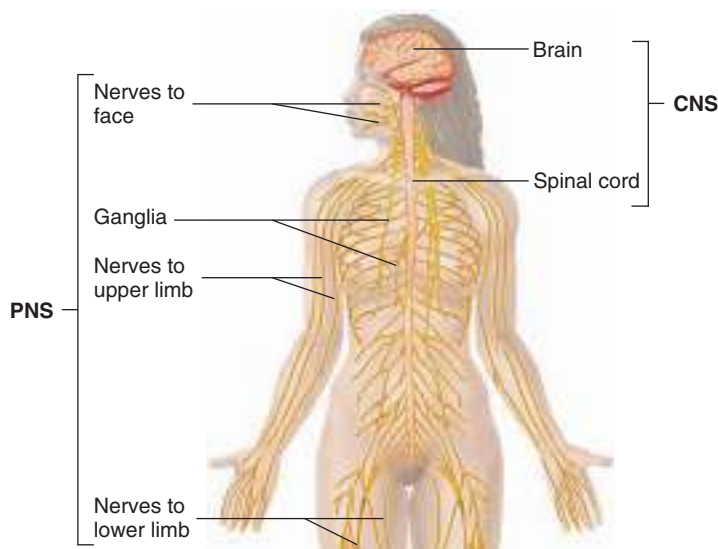

FIGURE 11.1 Nervous System

The central nervous system (CNS) consists of the brain and spinal cord. The peripheral nervous system (PNS) consists of cranial nerves, which arise from the brain, and spinal nerves, which arise from the spinal cord. The nerves, which are shown cut in the illustration, actually extend throughout the body.

is an extensive network of axons and, in some cases, neuron cell bodies, located outside the CNS.

The PNS has two subdivisions: The **sensory division**, or *afferent* (“toward”) *division*, transmits electrical signals, called **action potentials**, from sensory receptors in the body to the CNS (figure 11.2). The cell bodies of sensory neurons are located near the spinal cord in ganglia called dorsal root ganglia (figure 11.3a) or in ganglia near the origin of certain cranial nerves. The **motor division**, or *efferent* (“away”) *division*,

transmits action potentials from the CNS to effector organs, such as muscles and glands.

The sensory division of the PNS detects stimuli and transmits information in the form of action potentials to the CNS (see figure 11.2). The CNS processes information, initiates responses, and integrates thoughts, emotions, and other mental processes. It is much like a computer in its ability to receive input, process and store information, and generate responses. The motor division of the PNS conducts action potentials from the CNS to muscles and glands.

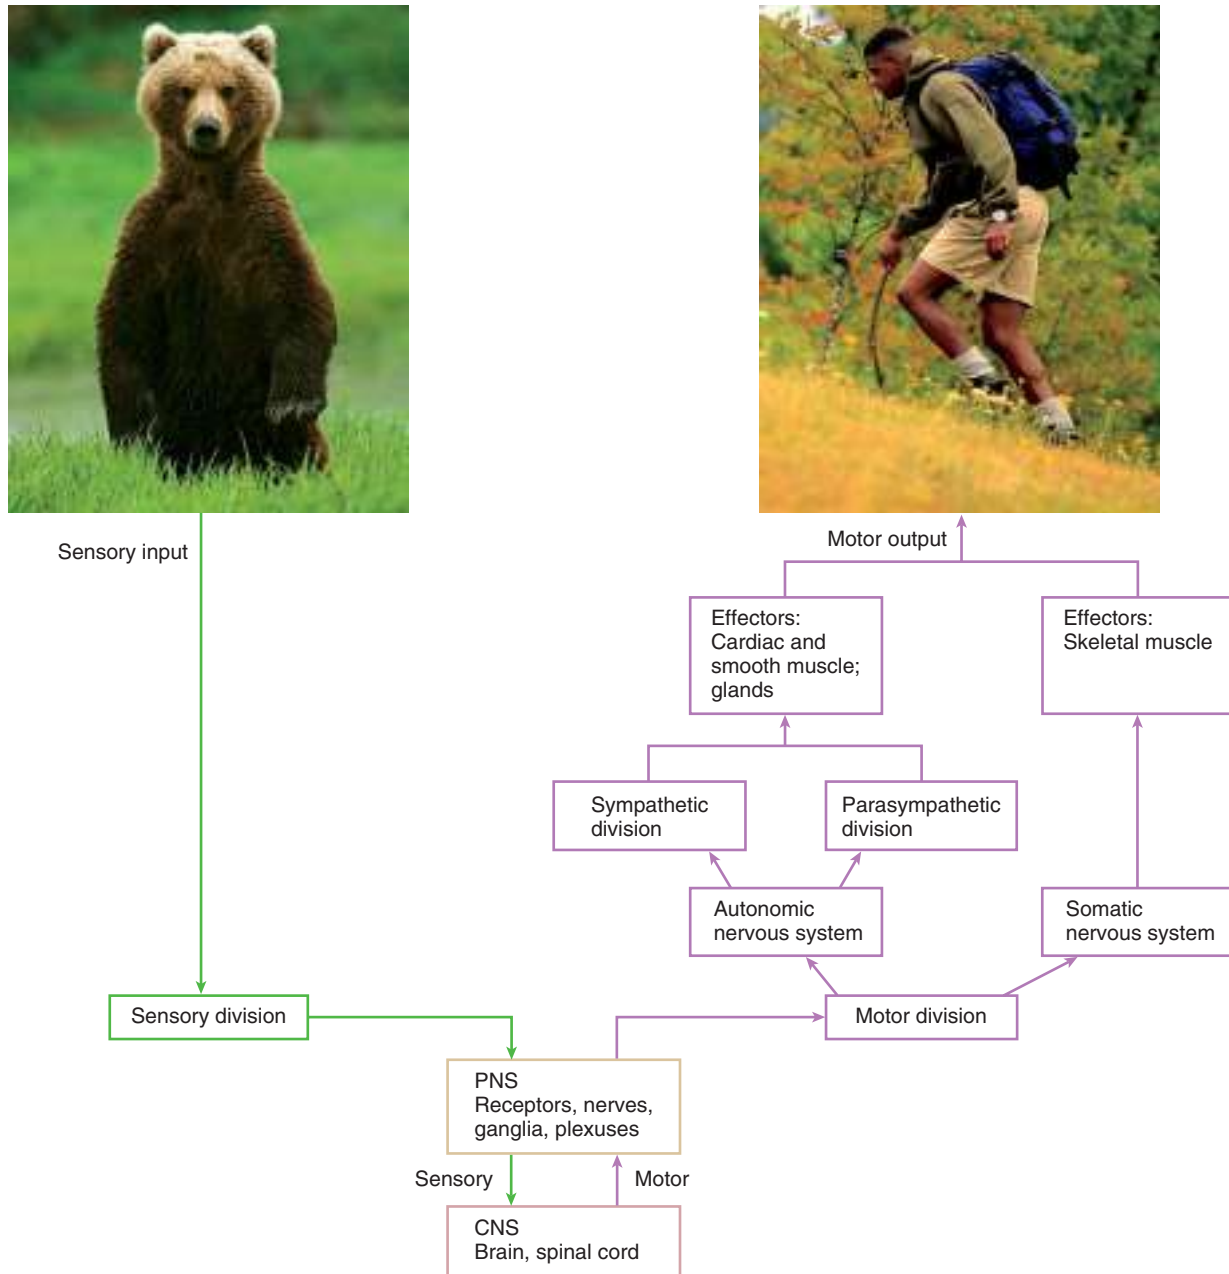

FIGURE 11.2 Organization of the Nervous System

The sensory division of the peripheral nervous system (PNS) detects stimuli and conducts action potentials to the central nervous system (CNS). The CNS interprets incoming action potentials and initiates action potentials that are conducted through the motor division to produce a response. The motor division is divided into the somatic nervous system and the autonomic nervous system. The enteric nervous system is an independent branch of the PNS and is not illustrated in this figure.

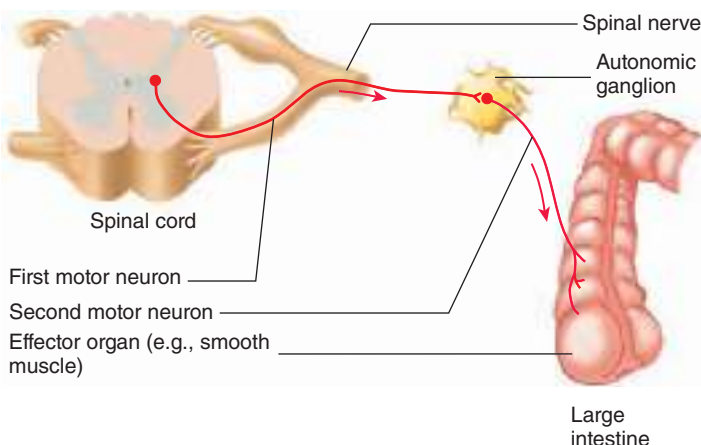

FUNDAMENTAL Figure

(a) Sensory division

(b) Somatic nervous system

(c) Autonomic nervous system

FIGURE 11.3 Divisions of the Peripheral Nervous System

(a) Sensory division. A neuron with its cell body (green dot) in a dorsal root ganglion. (b) Somatic nervous system. The neuron (purple) extends from the spinal cord (CNS) to skeletal muscle. (c) Autonomic nervous system. Two neurons are in series between the CNS and the effector organ or cells (smooth muscle or glands). The first neuron has its cell body (red dot) in the CNS, and the second neuron has its cell body in an autonomic ganglion. **AP R**

The motor division is further divided into two subdivisions: a voluntary (conscious) division called the **somatic** (sō-mat'ik; bodily) **nervous system** and an involuntary (unconscious) division called the **autonomic** (aw-tō-nom'ik; self-governing) **nervous system (ANS)**. For example, the somatic nervous system allows you to decide to move your skeletal muscles, as when you raise your hand. The CNS generates action potentials that are transmitted by the somatic nervous system to the skeletal muscles in your arm (figure 11.3b). The cell bodies of somatic motor neurons are located within the CNS, and their axons extend through nerves to form connections with skeletal muscle cells. Each of these connections, called a **synapse** (sin'aps), is the junction of a neuron with another cell. The neuromuscular junction, the synapse between a neuron and a skeletal muscle fiber, is discussed in detail in chapter 9. Neurons can also form synapses with other neurons, smooth muscle cells, cardiac muscle cells, and gland cells.

On the other hand, the ANS controls your unconscious activities, such as contractions of smooth muscle, cardiac muscle, and secretion by certain glands. The ANS has two sets of neurons in a series between the CNS and the effector organs (figure 11.3c). Cell bodies of the first neurons are within the CNS, and they send their axons to autonomic ganglia, where neuron cell bodies of the second neurons are located. Synapses exist between the first and second neurons within the autonomic ganglia, and the axons of the second neurons extend from the autonomic ganglia to the effector organs.

The ANS is subdivided into two divisions: the sympathetic division and the parasympathetic division. An easy way to remember the major functions of each division is to use the catchphrase for each. The sympathetic division is called the fight-or-flight division, while the parasympathetic division is called the rest-and-digest division. In general, the **sympathetic division** is most active during physical activity, whereas the **parasympathetic division** regulates resting functions, such as digesting food or emptying the urinary bladder.

The **enteric nervous system** (*entero-*, intestine; **ENS**) consists of plexuses within the wall of the digestive tract (see figure 24.4). A unique feature of enteric neurons is that they monitor and control the digestive tract independently of the CNS through local reflexes. However, the CNS can override enteric functions via parasympathetic and sympathetic actions. Hence, the ENS is an independent subdivision of the PNS that is integrated with the ANS. See chapters 16 and 24 for details on the enteric nervous system.

ASSESS YOUR PROGRESS

2. Name the components of the CNS and the PNS.
3. What are the following: sensory receptor, nerve, ganglion, plexus?
4. Based on the direction they transmit action potentials, what are the two subcategories of the PNS?
5. Based on the structures they supply, what are the two subcategories of the motor division?
6. Where are the cell bodies of sensory, somatic motor, and autonomic neurons located? What is a synapse?
7. What are the subcategories of the ANS?
8. Compare the general functions of the CNS and the PNS.

11.3 Cells of the Nervous System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the structure of neurons and the functions of their components.
- B. Classify neurons based on structure and function.
- C. Describe the location, structure, and functions of glial cells.
- D. Discuss the function of the myelin sheath and describe its formation in the CNS and PNS.

There are two cell types that make up the nervous system: neurons and glial cells. Neurons receive stimuli, conduct action potentials, and transmit signals to other neurons or effector organs. **Glial** (glī'äl, glē'äl) **cells** support and protect neurons and perform other functions. Glial cells account for over half of the brain's weight, and there can be 10 to 50 times more glial cells than neurons in various parts of the brain.

Neuron Structure

Neurons, or *nerve cells*, are the electrically excitable cells of the nervous system. They receive stimuli and transmit action potentials to other neurons or to effector organs. They are organized to form complex networks that perform the functions of the nervous system. There are three parts to a neuron: a cell body and two types of cellular projections. The cell body is called the **neuron cell body**, or *soma* (sō'mă; body); as with any other type of cell, the cell body's nucleus is the source of information for protein synthesis. One type of cellular projection is called a **dendrite** (den'drīt; tree), referring to its branching organization. The other type of cellular projection is called the **axon** (ak'son; axis), or *nerve fiber*, referring to the straight alignment and uniform diameter of most axons.

Neuron Cell Body

Each neuron cell body contains a single, relatively large, and centrally located nucleus with a prominent nucleolus. Extensive rough endoplasmic reticulum (ER) and the Golgi apparatuses surround the nucleus, and mitochondria and other organelles are present. Large numbers of intermediate filaments (neurofilaments) and microtubules form bundles that organize the cytoplasm into different regions. The neurofilaments separate abundant rough ER, called **Nissl** (nis'l) **bodies**, which are located primarily in the cell body and dendrites. Nissl bodies are the primary sites of protein synthesis in neurons.

► Predict 2

If an axon has been severed, so that it is no longer connected to its neuron cell body, what will be the effect on the distal and proximal portions of the axon? Explain your prediction.

Dendrites

Dendrites are extensions of the cell body and are the receiving portion of the neuron. They receive input from other neurons' axons and from the environment. Dendrites are short, often highly branched cytoplasmic extensions that are tapered from their bases at the neuron cell body to their tips (figure 11.4). Many dendrite surfaces have small extensions, called **dendritic spines**, where axons of other neurons form synapses with the dendrites. When stimulated, dendrites generate small electric currents, which are conducted toward the neuron cell body.

Axons

In most neurons, a single axon arises from a cone-shaped area of the neuron cell body called the **axon hillock**. As the axon hillock narrows, it transitions into the **initial segment**. The initial segment is the actual beginning of the axon. The combination of the axon hillock and the initial segment is called the **trigger zone**. The trigger zone is where action potentials are generated. Many axons remain as a single structure, but others branch to form collateral axons, or side branches (figure 11.4). Each axon has a constant diameter, but axons can vary in length from a few millimeters to more than 1 meter. The cytoplasm of an axon is sometimes called the **axoplasm**, and its plasma membrane can also be called the **axolemma** (*lemma*, husk). Axons terminate by branching to form small extensions with enlarged ends called **presynaptic terminals**. The presynaptic terminals store many secretory vesicles that contain signal molecules called **neurotransmitters**. Action potentials conducted along the axon to the presynaptic terminal stimulate exocytosis of the neurotransmitters from their vesicles into the synapse. Then neurotransmitters cross the synaptic cleft to stimulate or inhibit the postsynaptic cell.

Axon transport mechanisms move cytoskeletal proteins (see chapter 3), organelles (such as mitochondria), and vesicles containing neurotransmitters (see chapter 17) down the axon through the axoplasm toward the presynaptic terminals. Movement *away* from the cell body is called *anterograde*. In addition, damaged organelles, recycled plasma membrane, and substances taken in by endocytosis can be transported up the axon toward the neuron cell body. Movement *toward* the cell body is called *retrograde*. The movement of materials within the axon is necessary for its normal function, but it also provides a way for infectious agents and harmful substances to be transported from the periphery to the CNS. For example, rabies and herpes viruses can enter damaged axons in the skin and be transported within the axons to the CNS.

Types of Neurons

Neurons are classified in two different ways: functionally or structurally. The functional classification is based on the direction in which action potentials are conducted. **Sensory neurons** (*afferent neurons*) conduct action potentials toward the CNS; **motor neurons** (*efferent neurons*) conduct action potentials away from the CNS toward muscles or glands. **Interneurons** conduct action potentials within the CNS from one neuron to another.

The structural classification scheme is based on the number of dendrites. The three major structural categories are multipolar, bipolar, and pseudo-unipolar.

FIGURE 11.4 Neuron

The structural features of a neuron are a cell body and two types of cell projections: dendrites and an axon. **APR**

Multipolar neurons (*multi-*, many) have many dendrites and a single axon. The dendrites vary in number and in their degree of branching (figure 11.5a). Most of the neurons within the CNS and motor neurons are multipolar.

Bipolar neurons (*bi-*, two) have two processes: one dendrite and one axon (figure 11.5b). The dendrite is often specialized to receive the stimulus, and the axon conducts action potentials to the CNS. Bipolar neurons are located in some sensory organs, such as in the retina of the eye and in the nasal cavity.

Pseudo-unipolar neurons (*pseudo-*, false + *uni-*, one) have a single process extending from the cell body, which divides into two branches a short distance from the cell body (figure 11.5c). The two branches function as a single axon. One branch extends to the CNS, and the other extends to the periphery and has dendritelike sensory receptors. The sensory receptors respond to stimuli, producing action potentials that are transmitted to the CNS. Most sensory neurons are pseudo-unipolar. According to a strictly functional definition of dendrite, the branch of pseudo-unipolar neurons that extends from the periphery to the neuron cell body could be classified as a dendrite because it conducts action potentials toward the neuron cell body. However, this branch is usually referred to as an axon, for two reasons: It cannot be distinguished from an axon on the basis of its structure, and it conducts action potentials in the same fashion as an axon.

Glial Cells of the CNS

Glial cells are the major supporting cells in the CNS. Glial cells help form a protective permeability barrier between the blood and the brain and spinal cord, they phagocytize foreign substances, they produce cerebrospinal fluid, and they form myelin sheaths around axons. There are four types of CNS glial cells, each with unique structural and functional characteristics. Refer to table 11.1 for a description and an illustration of each glial cell type.

Astrocytes

Astrocytes (as'trō-sītz; *aster*, star) are glial cells that are star-shaped because cytoplasmic processes extend from the cell body. These extensions widen and spread out to form foot processes, which cover the surfaces of blood vessels (table 11.1), neurons, and the pia mater. (The pia mater is a membrane covering the outside of the brain and spinal cord.) Astrocytes have an extensive cytoskeleton of microfilaments (see chapter 3), which enables them to form a supporting framework for blood vessels and neurons.

Astrocytes help regulate the composition of extracellular brain fluid. They do this by releasing chemicals that promote the formation of tight junctions (see chapter 4) between the endothelial cells of capillaries. The endothelial cells with their tight junctions form the **blood-brain barrier**, which determines what substances can pass from the blood into the nervous tissue of the brain and spinal cord. The blood-brain barrier protects neurons from toxic substances in the blood, allows the exchange of nutrients and waste products between neurons and the blood, and prevents fluctuations in blood composition from affecting brain functions.

Astrocytes aid both beneficial and detrimental responses to tissue damage in the CNS. Almost all injuries to CNS tissue induce **reactive astrocytosis**, in which astrocytes wall off the injury site and help limit the spread of inflammation to the surrounding healthy tissue. Reactive scar-forming astrocytes also limit the regeneration of the axons of injured neurons.

FIGURE 11.5 Structural Classes of Neurons

Neurons are classified structurally by the number of cellular projections extending from their cell bodies. Dendrites and sensory receptors are specialized to receive stimuli, and axons are specialized to conduct action potentials.

Astrocytes also release chemicals that promote the development of synapses and help regulate synaptic activity by synthesizing, absorbing, and recycling neurotransmitters.

Ependymal Cells

Ependymal (ep-en'di-mäl) **cells** line the ventricles (cavities) of the brain and the central canal of the spinal cord (table 11.1). Specialized ependymal cells and blood vessels form structures called **choroid plexuses** (ko'royd plek'süs-ez; table 11.1), which are located within certain regions of the ventricles. The choroid plexuses secrete the cerebrospinal fluid that flows through the ventricles of the brain (see chapter 13). The ependymal cells frequently have patches of cilia that help circulate cerebrospinal fluid through the brain cavities. Ependymal cells also have long processes at their basal surfaces that extend deep into the brain and the spinal cord and seem, in some cases, to have astrocyte-like functions.

Microglia

Microglia (mī-krog'lē-ă) are CNS-specific immune cells. Microglia become mobile and phagocytic in response to inflammation. They phagocytize necrotic tissue, microorganisms, and other foreign substances that invade the CNS (table 11.1). Areas of the brain or spinal cord that have been damaged by infection, trauma, or stroke have more microglia than healthy areas. There the microglia perform phagocytosis of dead cells and pathogens. A pathologist can identify these damaged areas in the CNS during an autopsy because large numbers of microglia are found there.

Oligodendrocytes

Oligodendrocytes (ol'i-gō-den'drō-sītz) have cytoplasmic extensions that can surround axons. If the cytoplasmic extensions wrap

many times around the axons, they form an insulating material called a **myelin** (mī'ě-lin) **sheath**. One oligodendrocyte can form myelin sheaths around axons of multiple neurons (table 11.1).

Glial Cells of the PNS

There are two types of glial cells in the PNS: Schwann cells and satellite cells. **Schwann cells** form myelin sheaths. However, unlike oligodendrocytes, each Schwann cell forms a portion of the myelin sheath around only one axon (table 11.1).

Satellite cells surround neuron cell bodies in sensory and autonomic ganglia (table 11.1). Besides providing support and nutrition to the neuron cell bodies, satellite cells protect neurons from heavy-metal poisons, such as lead and mercury, by absorbing them and reducing their access to the neuron cell bodies.

Myelinated and Unmyelinated Axons

Cytoplasmic extensions of the Schwann cells in the PNS and of the oligodendrocyte extensions in the CNS surround axons to form either myelinated or unmyelinated axons. Myelin protects and electrically insulates axons from one another. In addition, action potentials travel along myelinated axons more rapidly than along unmyelinated axons (see “Propagation of Action Potentials” in section 11.5).

In **myelinated axons**, Schwann cells or oligodendrocyte extensions repeatedly wrap around a segment of an axon to form a series of tightly wrapped membranes rich in phospholipids, with little cytoplasm sandwiched between the membrane layers (figure 11.6a). One way to picture the overlapping wrappings, especially for Schwann cells, is to imagine rolling up a hot dog (axon) inside a tortilla (Schwann cell). The tightly wrapped

Clinical IMPACT

Nervous Tissue Response to Injury

When a nerve is cut, either it eventually heals or it is permanently interrupted. The final outcome depends on the severity of the injury and on its treatment.

Several degenerative changes result when a nerve is cut (figure 11A). Within about 3–5 days, the axons in the part of the nerve distal to the cut break into irregular segments and degenerate. This occurs because the neuron cell body produces the substances essential to maintain the axon, and these substances have no way of reaching parts of the axon distal to the point of damage. Eventually, the distal part of the axon completely degenerates. As the axons degenerate, the myelin part of the Schwann cells around them also degenerates, and macrophages invade the area to phagocytize the myelin. The Schwann cells then enlarge, undergo mitosis, and finally form a column of cells along the regions once

occupied by the axons. The columns of Schwann cells are essential for the growth of new axons. If the ends of the regenerating axons encounter a Schwann cell column, they grow more rapidly, and reinnervation of their target is likely. If the ends of the axons do not encounter the columns, they fail to reinnervate their target.

The end of each regenerating axon forms several axonal sprouts. It normally takes about 2 weeks for the axonal sprouts to enter the Schwann cell columns. However, only one of the sprouts from each severed neuron forms an axon. The other branches degenerate. After the axons grow through the Schwann cell columns, new myelin sheaths form and the neurons reinnervate the structures they previously supplied.

Treatment strategies that increase the probability of reinnervation involve bringing the ends of the severed nerve close together

surgically. When a section of nerve is destroyed as a result of trauma, a surgeon can perform a nerve transplant to replace the damaged segment. The transplanted nerve eventually degenerates, but it does provide Schwann cell columns through which axons can grow.

The regeneration of damaged nerve tracts within the CNS is very limited, especially when compared with the regeneration of nerves in the PNS. In part, the difference may result from the oligodendrocytes, which exist only in the CNS. An oligodendrocyte has several processes, each of which forms part of a myelin sheath. The cell bodies of the oligodendrocytes are a short distance from the axons they ensheath, and fewer oligodendrocytes than Schwann cells are present. Consequently, when the myelin degenerates following damage, no column of cells remains in the CNS to act as a guide for the growing axons.

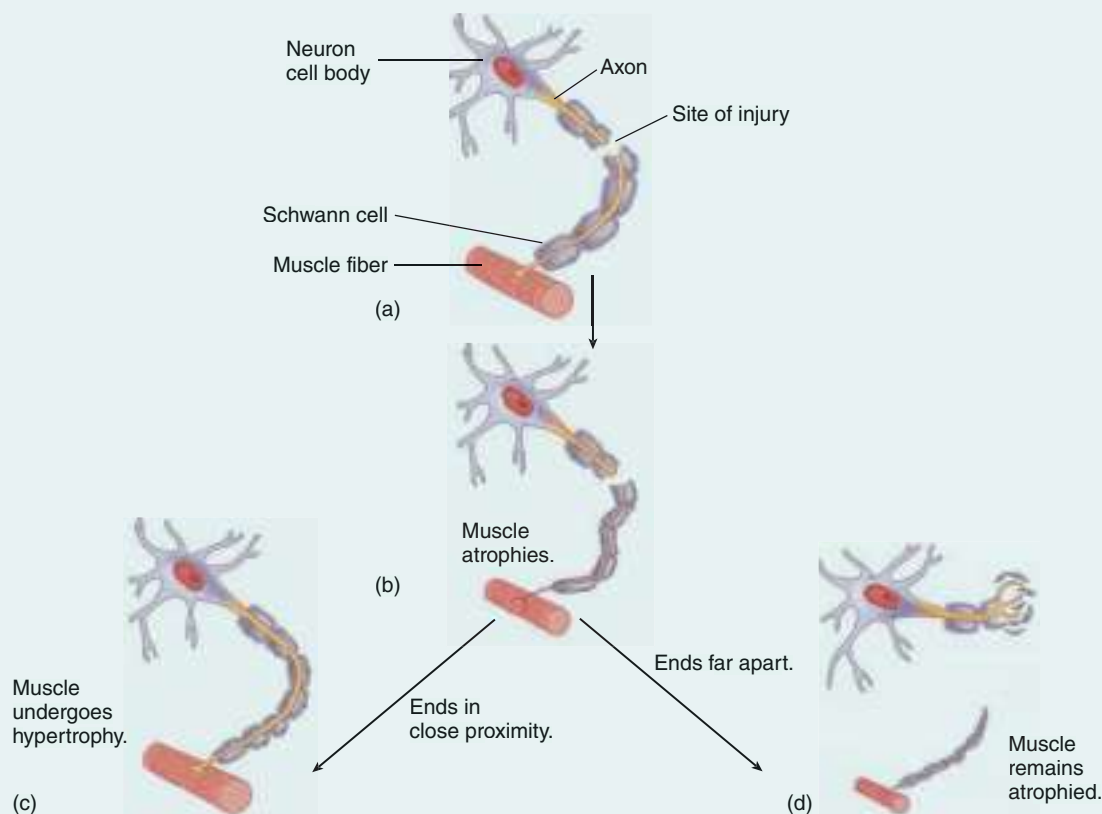

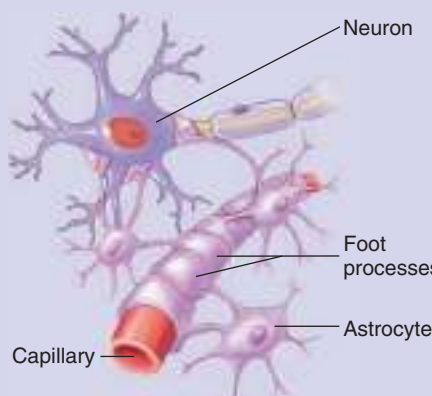

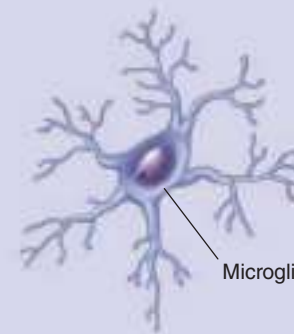

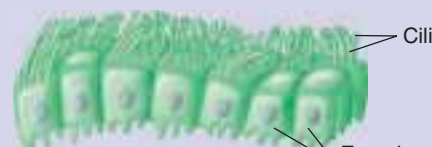

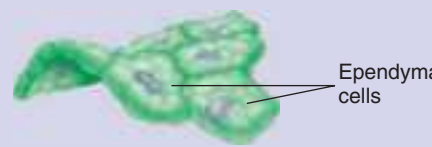

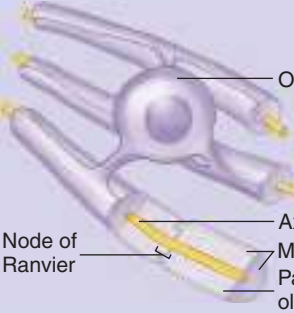

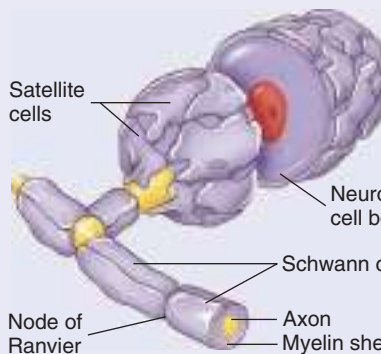

FIGURE 11A Responses to Injury in an Axon

(a) When a nerve is injured, there are two possible outcomes. Regardless, the muscle will initially atrophy (shrink in size). (b) Without stimulation from the nerve, the muscle is paralyzed and atrophies. (c) When the two ends of an injured axon are aligned in close proximity, healing and regeneration of the axon are likely to occur. After reinnervation, the muscle can become functional and hypertrophy (increase in size). (d) When the two ends of an injured axon are not aligned in close proximity, regeneration is unlikely to occur. Without innervation from the nerve, muscle function is completely lost, and the muscle remains atrophied.

membranes constitute the myelin sheath and give myelinated axons a white appearance because of the high lipid concentration. The myelin sheath is not continuous but contains gaps every 0.3–1.5 mm. At these locations are slight constrictions where the myelin sheaths of adjacent cells dip toward the axon but do not cover it, leaving an area where the myelin sheath is much thinner and about 2–3 μm in length. These gaps in the myelin sheath are the **nodes of Ranvier** (ron'vĕ-ā). Although the axon at a node of Ranvier is not wrapped in myelin, Schwann cells or oligodendrocytes extend across the node and connect to each other.

Unmyelinated axons are not devoid of myelin, as their name suggests. Instead, the axons rest in invaginations of the Schwann cells or oligodendrocytes (figure 11.6b). The glial cell's plasma membrane surrounds each axon but does not wrap around it many times. Thus, each axon is surrounded by a series of Schwann cells, and each Schwann cell can simultaneously surround more than one unmyelinated axon.

Myelin sheaths begin to form late in fetal development. The process continues rapidly until the end of the first year after birth and continues more slowly thereafter. The development of

myelin sheaths is associated with the infant's continuing development of more rapid and better coordinated responses. The importance of myelinated axons is dramatically illustrated in diseases that gradually destroy the myelin sheath, such as multiple sclerosis and some cases of diabetes mellitus. Action potential transmission is slowed, resulting in impaired control of skeletal and smooth muscles. In severe cases, action potential transmission can become completely blocked.

ASSESS YOUR PROGRESS

9. Describe and give the function of a neuron cell body, a dendrite, and an axon.
10. What is the function of the trigger zone?
11. What is the role of a neurotransmitter? Where is it stored?
12. Describe the three types of neurons based on function.
13. Explain the three types of neurons based on structure, and give an example of where each type is found.
14. What characteristic makes glial cells different from neurons?
15. Which glial cells are found in the CNS? In the PNS?
16. Which type of glial cell supports neurons and blood vessels and promotes formation of the blood-brain barrier? What is the blood-brain barrier, and what is its function?

17. Name the different kinds of glial cells that are responsible for the following functions: production of cerebrospinal fluid, phagocytosis, production of myelin sheaths in the CNS, production of myelin sheaths in the PNS, support of neuron cell bodies in the PNS.
18. What is a myelin sheath? How is it formed in the CNS? In the PNS?
19. How do myelinated axons differ from unmyelinated axons?

11.4 Organization of Nervous Tissue

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Distinguish between gray matter and white matter.
- B. Describe the components of gray matter and white matter in the CNS and PNS.

In both the CNS and the PNS, nervous tissue is organized such that axons are grouped together, forming bundles, while neuron cell bodies and dendrites are grouped together. These groupings give nervous tissue distinctive areas, called **gray matter** and **white matter**. Because gray matter consists of groups of neuron cell bodies and their dendrites, where there is very little myelin, these areas are darker in appearance. In the CNS, the **cortex** consists of gray matter on the surface of the brain. **Nuclei** are clusters of gray matter located deeper within the brain. In the PNS, gray matter consists of clusters of neuron cell bodies, each of which is called a **ganglion** (gang'glē-on; pl. ganglia; a swelling or knot). Conversely, because white matter consists of bundles of parallel myelinated axons, they are whitish in color. White matter of the CNS forms **nerve tracts**, or *conduction pathways*, which propagate action potentials from one area of the CNS to another. In the PNS, bundles of axons and their connective tissue sheaths are called nerves.

Predict 3

A 75-year-old man was found unconscious in his bathroom after falling and hitting his head. He survived for several hours but died later in the hospital. An autopsy was performed to determine the exact cause of death. Evidence indicated that the man had suffered two strokes, both due to blocked blood vessels. One had occurred a few weeks earlier; the other had occurred very recently and may have led to the fall. Autopsy findings also indicated that, when the man hit his head, some damage to his brain occurred as well. Based on what you know about inflammation and the cellular structure of the brain, describe what the pathologist found in each of the damaged areas of the brain.

ASSESS YOUR PROGRESS

20. What makes up gray matter and white matter?
21. Describe and state the location of the following: nerve tracts, nerves, the brain cortex, nuclei, ganglia.

11.5 Electrical Signals

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe a resting membrane potential and explain how it is created and maintained.
- Explain the processes that can change the resting membrane potential.
- Describe the characteristics of a graded potential.
- Describe the creation of an action potential and explain how it is propagated.
- Discuss the all-or-none principle as it applies to action potentials.
- Explain the characteristics and purpose of the refractory period.
- Explain the factors that determine action potential frequency and the five levels of stimulation.
- Describe the effect of myelination on the speed of action potential propagation, as well as other factors that affect the speed of action potential conduction.

Like computers, humans depend on electrical signals to communicate and integrate information. Electrical signals produced by specialized cells are called action potentials. Action potentials are an important means by which cells communicate with other cells in the many areas of the body. For example, stimuli—such as light, sound, and pressure—act on specialized sensory cells in the eye, ear, and skin to produce action potentials, which are conducted from these cells to the spinal cord and brain. Action potentials originating within the brain and spinal cord travel to muscles and certain glands to regulate their activities.

Our ability to perceive our environment, perform complex mental activities, and respond to stimuli depends on action potentials. For example, the brain interprets action potentials received from sensory cells as vision, hearing, or touch. Complex mental activities, such as conscious thought, memory, and emotions, result from action potentials. The contraction of muscles and the secretion of certain glands occur in response to action potentials generated within them.

A basic knowledge of the electrical properties of cells is necessary for understanding many of the normal functions and pathologies of the body. Electrical properties are due to two major characteristics:

- Ionic concentration differences across the plasma membrane
- Permeability characteristics of the plasma membrane

Ionic Concentration Differences Across the Plasma Membrane

As you learned in chapter 9, electrically excitable cells, such as muscle cells and neurons, operate through ion movements across the plasma membrane. As you will see, many of the principles you studied for skeletal muscle fibers also apply to neurons.

Cells have different concentrations of ions in the cytoplasm when compared with the extracellular fluid around the cell. It is this difference in ion concentrations that electrically excitable

TABLE 11.2

Representative Concentrations of the Principal Cations and Anions in Extracellular and Intracellular Fluids in the Human Body

cells use to carry out their functions. Table 11.2 lists the concentrations for positively charged ions (cations) and negatively charged ions (anions) in the intracellular fluid compared with the extracellular fluid. There is a higher concentration of Na⁺ and Cl⁻ outside the cell than inside the cell, while there is a higher concentration of K⁺ on the inside of the cell. We describe this distribution of ions as a concentration gradient (see chapter 3). For Na⁺, there is a steep concentration gradient from the *outside* of the cell to the *inside* of the cell. For K⁺, the concentration gradient is the opposite of the concentration gradient for Na⁺. For K⁺, there is a steep concentration gradient from the *inside* of the cell to the *outside* of the cell. In addition to a high concentration of K⁺ in the cell cytoplasm, there is also a high concentration of negatively charged molecules, such as proteins, and other molecules that contain phosphate.

Permeability Characteristics of the Plasma Membrane

Differences in intracellular and extracellular concentrations of ions result primarily from the sodium-potassium pump and the permeability characteristics of the plasma membrane.

Neurons expend energy to maintain an uneven distribution of ions across the plasma membrane. The **sodium-potassium pump** uses ATP to pump K⁺ against its concentration gradient into the cell while at the same time pumping Na⁺ against its concentration gradient out of the cell. By transporting K⁺ into the cytoplasm, the sodium-potassium pump maintains the high concentration of K⁺ in the cytoplasm. Simultaneously, the sodium-potassium pump maintains the higher concentration of extracellular Na⁺ (see figure 3.21). Three Na⁺ are transported out of the cell and two K⁺ are transported into the cell for each ATP molecule used.

As noted in chapter 3, the plasma membrane is selectively permeable, thus allowing some, but not all, substances to pass through it. Negatively charged proteins are regularly synthesized

inside the cell. Because proteins are large and relatively insoluble, they cannot easily diffuse across the plasma membrane and stay inside the cell (figure 11.7a). Because negatively charged Cl^- is repelled by the negatively charged proteins and other negatively charged ions inside the cell, Cl^- exits the cell, which results in a higher concentration of Cl^- outside the cell than inside.

Ions must pass through the plasma membrane through ion channels. The two major types of ion channels are leak ion channels and gated ion channels.

Leak Ion Channels

Leak ion channels, or *nongated ion channels*, are always open and are responsible for the permeability of the plasma membrane to ions when the plasma membrane is unstimulated, or at rest (figure 11.7a). Each ion channel is specific for one type of ion, although the specificity is not absolute. The number of each type of leak ion channel in the plasma membrane determines the permeability characteristics of the resting plasma membrane to different types of ions. The plasma membrane is more permeable to K^+ and Cl^- and much less permeable to Na^+ because the membrane has many more K^+ and Cl^- leak ion channels than Na^+ leak ion channels.

Gated Ion Channels

Gated ion channels are closed until opened by specific signals. By opening and closing, these channels can change the permeability of the plasma membrane. There are three major types of gated ion channels:

1. **Ligand-gated ion channels.** **Ligand-gated ion channels** are stimulated to open by the binding of a specific molecule to the receptor site of the ion channel. The receptor site of the ion channel is located on its extracellular side, which allows it to receive signals from the environment. The membrane-spanning part forms a channel through the phospholipid bilayer. The specific molecule that binds to the receptor site can be referred to as a ligand. Ligands could be neurotransmitters or hormones, but there is one particular ligand for each ligand-gated ion channel. When the ligand binds to the receptor site, the ion channel opens or closes. For example, the neurotransmitter acetylcholine released from the presynaptic terminal of a neuron is the ligand that binds to a ligand-gated Na^+ channel in the membrane of a muscle fiber. As a result, the Na^+ channel opens, allowing Na^+ to enter the fiber (see figure 9.12). Ligand-gated ion channels exist for Na^+ , K^+ , Ca^{2+} , and Cl^- , and these channels are common in nervous and muscle tissues, as well as in glands.
2. **Voltage-gated ion channels.** **Voltage-gated ion channels** open and close in response to a specific, small voltage change across the plasma membrane. In an unstimulated cell, the inside of the cell is negatively charged relative to the outside. This charge difference can be measured in units called **millivolts (mV; 1 mV = 1/1000 V)**. For reference, a “double-A” battery generates 1.5 V of electricity. When a cell is stimulated, the permeability of the plasma membrane changes because gated ion channels open or close. The movement of ions into or out of the cell changes the charge difference across the plasma membrane, which, in turn, can cause voltage-gated ion channels to open or close. Voltage-gated channels specific for Na^+ and K^+ are most numerous in electrically excitable

tissues, but voltage-gated Ca^{2+} channels are also important, especially in smooth muscle and cardiac muscle fibers (see chapters 9 and 20).

3. **Other gated ion channels.** Gated ion channels that respond to stimuli other than ligands or voltage changes are present in specialized electrically excitable tissues. Examples include touch receptors, which respond to mechanical stimulation of the skin, and temperature receptors, which respond to temperature changes in the skin.

ASSESS YOUR PROGRESS

22. Describe the concentration differences for Na^+ and K^+ that exist across the plasma membrane.
23. Explain how the sodium-potassium pump works to move ions.
24. Describe leak ion channels and gated ion channels. How are they responsible for the permeability of a resting versus a stimulated plasma membrane?
25. Define ligand, receptor, and receptor site.
26. What kinds of stimuli cause gated ion channels to open or close?

Establishing the Resting Membrane Potential

Intracellular fluid is electrically neutral because the number of positively charged cations is equal to the number of negatively charged anions (table 11.2). Similarly, extracellular fluid is electrically neutral. However, there is a difference in *charge* across the plasma membrane because of the uneven distribution of positive and negative ions across it. For simplicity, we can say that the inside of the cell is negative compared with the outside of the cell (figure 11.7b). Because there are opposite charges, or poles, across the membrane, the plasma membrane is referred to as being **polarized**.

This electrical charge difference across the plasma membrane is called a **potential difference**. In an unstimulated, or resting, cell, the potential difference is called the **resting membrane potential**. It can be measured using an oscilloscope or a voltmeter connected to microelectrodes positioned inside and outside the plasma membrane (figure 11.7). The resting membrane potential of neurons is approximately -70 mV, and that of skeletal muscle fibers is approximately -90 mV (see chapter 9). By convention, the potential difference is reported as a negative number because the inside of the plasma membrane is negative compared with the outside. The greater the charge difference across the plasma membrane, the greater the potential difference. A cell with a resting membrane potential of -90 mV has a greater charge difference between the inside of the cell membrane and the outside of the cell membrane than a cell with a resting membrane potential of -70 mV.

The resting membrane potential results from two characteristics of neurons:

1. The permeability characteristics of the resting plasma membrane
2. Differences in concentration of ions between the intracellular and the extracellular fluids

The plasma membrane is more permeable to K^+ because of a higher proportion of K^+ leak ion channels compared with leak channels for other ions. Positively charged K^+ can therefore diffuse down

FUNDAMENTAL Figure

1 In a resting cell, there is a higher concentration of K^+ (purple circles) inside the cell membrane and a higher concentration of Na^+ (pink circles) outside the cell membrane. Because the membrane is not permeable to negatively charged proteins (green) they are isolated to inside of the cell membrane.

2 There are more K^+ leak channels than Na^+ leak channels. In the resting cell, only the leak channels are opened; the gated channels (not shown) are closed. Because of the ion concentration differences across the membrane, K^+ diffuses out of the cell down its concentration gradient and Na^+ diffuses into the cell down its concentration gradient. The tendency for K^+ to diffuse out of the cell is opposed by the tendency of the positively charged K^+ to be attracted back into the cell by the negatively charged proteins.

3 The sodium-potassium pump helps maintain the differential levels of Na^+ and K^+ by pumping three Na^+ out of the cell in exchange for two K^+ into the cell. The pump is driven by ATP hydrolysis. The resting membrane potential is established when the movement of K^+ out of the cell is equal to the movement of K^+ into the cell.

(a)

its concentration gradient from inside to outside the cell (figure 11.7). Negatively charged proteins and other molecules cannot diffuse through the plasma membrane with the K^+ . As K^+ diffuses out of the cell, the loss of positive charges makes the inside of the plasma

K^+ concentration gradient
 Na^+ concentration gradient

(b)

FIGURE 11.7 Resting Membrane Potential

(a) In a resting cell, there is a higher concentration of K^+ inside the cell and a higher concentration of Na^+ outside the cell. In a resting cell, only the leak ion channels are open; the gated ion channels are closed. There are many more K^+ leak ion channels than Na^+ leak ion channels. As a result, K^+ diffuses out of the cell down its concentration gradient. The membrane is not permeable to the negatively charged proteins inside the cell. The tendency for the K^+ to diffuse to the outside of the cell down its concentration gradient is opposed by the tendency for the positively charged K^+ to be attracted back into the cell by the negatively charged proteins. A small amount of Na^+ diffuses into the cell (not shown). The sodium-potassium pump helps maintain the differential levels of Na^+ and K^+ by pumping three Na^+ out of the cell in exchange for two K^+ into the cell. The pump is driven by ATP hydrolysis. (b) The recording electrode is inside the cell; the reference electrode is outside. A potential difference of about -70 mV is recorded, with the inside of the plasma membrane negative with respect to the outside of the membrane. **APR**

membrane more negative. Because opposite charges attract, K^+ is attracted back toward the cell. The accumulation of K^+ outside the plasma membrane makes the outside of the plasma membrane positive relative to the inside. The resting membrane potential is an equilibrium

that is established when the tendency for K^+ to diffuse out of the cell, because of the K^+ concentration gradient, is equal to the tendency for K^+ to move into the cell because of the attraction of the positively charged K^+ to negatively charged proteins and other molecules.

► Predict 4

Given that tissue A has significantly more K^+ leak ion channels than tissue B, which tissue has the larger resting membrane potential?

Other ions, such as Na^+ , Cl^- , and Ca^{2+} , have a minor influence on the resting membrane potential, but the major influence is from K^+ . The resting plasma membrane is not very permeable to Na^+ . In fact, because the resting plasma membrane is 50–100 times less permeable to Na^+ than to K^+ , very little Na^+ can diffuse into the resting cell. The resting plasma membrane is not very permeable to Ca^{2+} , either. The plasma membrane is relatively permeable to Cl^- , but these negatively charged ions are repelled by the negative charge inside the cell.

The resting membrane potential is proportional to the tendency for K^+ to diffuse out of the cell, not to the actual rate of flow for K^+ . At equilibrium, very few of these ions pass through the plasma membrane because their movement out of the cell is opposed by the negative charge inside the cell. Still, some Na^+ and K^+ diffuse continuously across the plasma membrane, although at a low rate. The large concentration gradients for Na^+ and K^+ would eventually disappear without the continuous activity of the sodium-potassium pump.

As already noted, the sodium-potassium pump maintains the uneven distribution of Na^+ and K^+ across the plasma membrane. The pump is also responsible for a small portion of the resting membrane potential, usually less than 15 mV, because it transports approximately three Na^+ out of the cell and two K^+ into the cell for each ATP molecule used (see figure 3.21). The outside of the plasma membrane becomes more positively charged than the inside, because more positively charged ions are pumped out of the cell than are pumped into it.

The characteristics responsible for the resting membrane potential are summarized in table 11.3.

Changing the Resting Membrane Potential

The resting membrane potential can become more positive or more negative. The charge difference across a particular area of membrane is changed when ions move across the plasma membrane due to a change in the ion concentration gradients or ion permeability of the plasma membrane. **Depolarization** (dē-pō'lä-r-i-zā'shŭn) occurs when the membrane potential becomes more positive and is the movement of the membrane potential closer to zero (figure 11.8a). On the other hand, **hyperpolarization** (hī'pē-pō'lä-r-i-zā'shŭn) occurs when the membrane potential becomes more negative and is the movement of the membrane potential further away from zero (figure 11.8b). We will further discuss specific situations in which depolarization or hyperpolarization occurs in the “Graded Potentials” section.

Potassium Ions

We will now consider some scenarios where the resting membrane potential is influenced by K^+ . Under normal action potential

TABLE 11.3

Characteristics Responsible for the Resting Membrane Potential

1. The concentration of K^+ is higher inside the cell than outside, and the concentration of Na^+ is higher outside the cell than inside.
2. Due to the K^+ leak channels, the plasma membrane is 50–100 times more permeable to K^+ than to other positively charged ions, such as Na^+ .
3. The plasma membrane is impermeable to large, intracellular, negatively charged molecules, such as proteins. In other words, these anions are “trapped” inside the cell.
4. Potassium ions tend to diffuse across the plasma membrane from the inside to the outside of the cell.
5. Because negatively charged molecules cannot follow the positively charged K^+ , a small negative charge develops inside the plasma membrane.
6. The negative charge inside the cell attracts positively charged K^+ . When the negative charge inside the cell is great enough to prevent additional K^+ from diffusing out of the cell through the plasma membrane, an equilibrium is established.
7. The charge difference across the plasma membrane at equilibrium is reflected as a difference in potential, which is measured in millivolts (mV).
8. The resting membrane potential is proportional to the potential for K^+ to diffuse out of the cell but not to the actual rate of flow for K^+ .
9. At equilibrium, very little movement of K^+ or other ions takes place across the plasma membrane.

conditions, K^+ diffuses out of the cell; however, changes in the K^+ concentration gradient and permeability could change the resting membrane potential. An increase in the extracellular concentration of K^+ decreases its concentration gradient because the concentration of K^+ is normally lower outside than inside a cell. Thus, K^+ tends to stay inside the cell. In addition, because there is less “pull” on K^+ to leave the cell, the negative charge inside the cell does not need to be as large to attract K^+ back into the cell. At this new equilibrium, the smaller charge difference across the plasma membrane changes the resting membrane potential to a more positive level than normal because more positive charge is inside the cell. Thus, we say the cell is depolarized.

In contrast, a decrease in the extracellular concentration of K^+ increases the K^+ concentration gradient. As a result, the tendency for K^+ to diffuse out of the cell increases, and a larger negative charge inside the cell is required to resist that diffusion. At this new equilibrium, the larger charge difference across the plasma membrane changes the resting membrane potential to a more negative level than normal because less positive charge is inside the cell. Thus, we say the cell is hyperpolarized.

Although K^+ leak ion channels allow some K^+ to diffuse across the plasma membrane, the resting membrane is not completely permeable to K^+ . However, there are gated K^+ channels in the plasma membrane; if they open, membrane permeability to K^+ increases, and more K^+ diffuses out of the cell. The increased tendency for K^+ to diffuse out of the cell is opposed by the greater negative charge that develops inside the plasma membrane. Because the negative charge is greater inside the cell, the cell is now hyperpolarized.

(a)

(b)

FIGURE 11.8 Depolarization and Hyperpolarization of the Resting Membrane Potential

(a) In depolarization, the charge inside the plasma membrane becomes more positive. (b) In hyperpolarization, the charge inside the plasma membrane becomes more negative.

Sodium Ions

In a resting cell, the membrane is not very permeable to Na^+ because there are few Na^+ leak ion channels; therefore, changes in the concentration of Na^+ on either side of the plasma membrane do not influence the resting membrane potential very much. However, there are gated Na^+ channels in the plasma membrane; if they open, membrane permeability to Na^+ increases (see figure 3.10). Sodium then diffuses into the cell, down its concentration gradient. As Na^+ diffuses into the cell, the inside of the membrane becomes more positive, resulting in depolarization. This is the typical situation when a neuron responds to a stimulus.

Calcium Ions

Calcium ions alter membrane potentials in two ways: (1) by affecting voltage-gated Na^+ channels and (2) by entering cells through gated Ca^{2+} channels. Tight regulation of voltage-gated Na^+ channels is important for the synchronization of membrane permeability to Na^+ . It seems that closed voltage-gated Na^+ channels are stabilized by Ca^{2+} and thus are sensitive to changes in the extracellular

concentration of Ca^{2+} . Positively charged Ca^{2+} in the extracellular fluid is attracted to the negatively charged groups of proteins within the voltage-gated Na^+ channels. If the extracellular concentration of Ca^{2+} decreases, these ions diffuse away from the voltage-gated Na^+ channels, causing the channels to open. If the extracellular concentration of Ca^{2+} increases, it binds to voltage-gated Na^+ channels, causing them to close. Therefore, normal levels of Ca^{2+} in the extracellular fluid are crucial to keep voltage-gated Na^+ channels closed until the neuron fires an action potential.

Predict 5

Predict the effect of a decrease in the extracellular concentration of Ca^{2+} on the resting membrane potential.

Changes in the permeability of Ca^{2+} can also directly change the resting membrane potential. If the plasma membrane becomes permeable to Ca^{2+} by the opening of gated Ca^{2+} channels, Ca^{2+} diffuses into the cell, and the inside of the membrane becomes more positive, resulting in depolarization. This role of Ca^{2+} is important at the axon terminal (see section 11.6).

Chloride Ions

Changes in the permeability of Cl^- can change the resting membrane potential. If the plasma membrane becomes more permeable to Cl^- by the opening of gated Cl^- channels, then Cl^- diffuses into the cell, and the inside of the membrane becomes more negative, resulting in hyperpolarization.

Effects of Abnormal Membrane Potentials

Several medical conditions can alter the physiology of membrane potentials. Hypokalemia (hī-pō-ka-lē'mē-ă) is a lower-than-normal concentration of K^+ in the blood or extracellular fluid. Reduced extracellular K^+ concentrations cause hyperpolarization of the resting membrane potential (see figure 11.8b). Thus, a greater-than-normal stimulus is required to depolarize the membrane to its threshold level and to initiate action potentials in neurons, skeletal muscle, and cardiac muscle. As the excitable tissues become less sensitive to stimulation, symptoms such as muscular weakness, an abnormal electrocardiogram, and sluggish reflexes result. The causes of hypokalemia include potassium depletion during starvation, alkalosis, and certain kidney diseases.

Hypocalcemia (hī-pō-kal-sē'mē-ă) is a lower-than-normal concentration of Ca^{2+} in the blood or extracellular fluid. Symptoms of hypocalcemia include nervousness and uncontrolled contraction of skeletal muscles, called tetany (tet'ă-nē). The symptoms are due to an increased membrane permeability to Na^+ that results because low blood levels of Ca^{2+} cause voltage-gated Na^+ channels in the membrane to open. Sodium ions diffuse into the cell, causing depolarization of the plasma membrane to threshold and initiating action potentials. The tendency for action potentials to occur spontaneously in nervous tissue and muscles accounts for the symptoms. Conditions that cause hypocalcemia include a lack of dietary calcium or vitamin D and a reduced secretion rate of a parathyroid gland hormone.

ASSESS YOUR PROGRESS

27. What is the resting membrane potential? What does it result from? Is the outside of the plasma membrane positively or negatively charged relative to the inside?
28. What ion is the major influence on the resting membrane potential? Explain its role.
29. How does the resting membrane establish an equilibrium?
30. What happens to cause depolarization and hyperpolarization? How do alterations in the K^+ concentration gradient; changes in membrane permeability to K^+ , Na^+ , or Cl^- ; and changes in extracellular Ca^{2+} concentration affect depolarization and hyperpolarization?

Graded Potentials

A **graded potential** is a relatively small change in the membrane potential that is localized to one area of the plasma membrane. Often, graded potentials lead to development of action potentials. These local disturbances in the membrane potential are called graded potentials (or local potentials) because the potential change can vary from small to large. Graded potentials can result from (1) chemical signals binding to their receptors, (2) changes in the voltage across the plasma membrane, (3) mechanical stimulation, (4) temperature changes, or (5) spontaneous opening of ion channels. Graded potentials often occur in the dendrites or cell body of a neuron.

A graded potential can be either a depolarization or a hyperpolarization (figure 11.8). A change in membrane permeability to Na^+ , K^+ , or other ions produces graded potentials. For example, if a stimulus causes gated Na^+ channels to open, the diffusion of Na^+ into the cell results in depolarization. If a stimulus causes gated K^+ channels to open, the diffusion of K^+ out of the cell results in hyperpolarization.

The magnitude of graded potentials can vary from small to large, depending on the stimulus strength or on summation. For example, a weak stimulus can cause only a few gated Na^+ channels to open. A small amount of Na^+ diffuses into the cell and causes a small depolarization. A stronger stimulus can cause a greater number of gated Na^+ channels to open. A greater amount of Na^+ diffusing into the cell causes a larger depolarization (figure 11.9a).

Summation of graded potentials occurs when the effects produced by one graded potential combine with the effects produced by a different graded potential elsewhere on the plasma membrane, which could lead to an action potential (figure 11.9b). For example, if a second stimulus is applied before the graded potential produced by the first stimulus has returned to the resting membrane potential, a larger depolarization results than would result from a single stimulus. The first stimulus causes gated Na^+ channels to open, and the second stimulus causes additional Na^+ channels to open. As a result, more Na^+ diffuses into the cell, producing a larger graded potential. Summation is discussed in greater detail in section 11.6.

Graded potentials spread, or are conducted, over the plasma membrane in a *decremental* fashion. That is, they rapidly decrease in magnitude as they spread over the surface of the plasma membrane, much as a teacher's voice spreads through a large lecture hall. At the front of the class, the teacher's voice can be heard easily but, the farther away a student sits, the harder it is to hear the teacher. Normally, a graded potential cannot be detected more than a few millimeters from the site of stimulation. As a

(a)

(b)

FIGURE 11.9 Graded Potentials

(a) Graded potentials are proportional to the stimulus strength. A weak stimulus applied briefly causes a small depolarization, which quickly returns to the resting membrane potential (-70). Progressively stronger stimuli result in larger depolarizations (2–4). (b) A stimulus applied to a cell causes a small depolarization. When a second stimulus is applied before the depolarization disappears, the depolarization caused by the second stimulus is added to the depolarization caused by the first to result in a larger depolarization.

consequence, a graded potential cannot transfer information over long distances from one part of the body to another.

Graded potentials are important because they can summate to generate action potentials. The characteristics of graded potentials are summarized in table 11.4.

Action Potentials

How do graded potentials summate to produce an action potential? Let's consider the bigger picture. Recall that graded potentials result from the detection of stimulus input to the neuron. For simplicity, let's follow a chemical stimulus to a neuron as it arrives at the dendrite. There, binding of a chemical stimulus quite often results in the

TABLE 11.4 Characteristics of Graded Potentials

1. A stimulus causes ion channels to open, increasing the permeability of the membrane to Na^+ , K^+ , or Cl^- .
2. Increased permeability of the membrane to Na^+ results in depolarization. Increased permeability of the membrane to K^+ or Cl^- results in hyperpolarization.
3. The size of the graded potential is proportional to the strength of the stimulus. Graded potentials can also summate. Thus, a graded potential produced in response to several stimuli is larger than one produced in response to a single stimulus.
4. Graded potentials are conducted in a *decremental* fashion, meaning that their magnitude decreases as they spread over the plasma membrane. Graded potentials cannot be measured a few millimeters from the point of stimulation.
5. Depolarizing graded potentials can combine (summate) to cause an action potential.

opening of ligand-gated ion channels. If these channels are Na^+ channels, the receiving cell experiences a depolarizing graded potential. If enough Na^+ enters, the graded potentials can summate at the trigger zone in the axon hillock (figure 11.10). When the graded potentials summate to a level called **threshold**, an action potential results (figure 11.11). Threshold is the membrane potential at which voltage-gated Na^+ channels open. Because the trigger zone contains a much higher proportion of voltage-gated channels than other parts of the cell body, action potentials are initiated there.

An action potential has a **depolarization phase**, in which the membrane potential moves away from the resting state and becomes more positive, and a **repolarization phase**, in which the membrane potential returns toward the resting state and becomes more negative. After the repolarization phase, the plasma membrane may be slightly hyperpolarized for a short period, called the **afterpotential**. An action potential is a large change in the membrane potential that propagates, without changing its magnitude, over long distances along the plasma membrane. Thus, action potentials can transfer information from one part of the body to another. It generally takes 1–2 milliseconds (ms; 1 ms = 0.001 s)

**FIGURE 11.11** Action Potential

The action potential consists of a depolarization phase and a repolarization phase, often followed by a short period of hyperpolarization, called the afterpotential.

for an action potential to occur. The characteristics of action potentials are summarized in table 11.5.

Depolarizing graded potentials that summate to threshold produce an action potential, but hyperpolarizing graded potentials can never reach threshold and do not produce action potentials. Thus, depolarizing graded potentials are stimulatory by triggering an action potential, whereas hyperpolarizing graded potentials are inhibitory by preventing an action potential.

The magnitude of a depolarizing graded potential affects the likelihood of generating an action potential. For example, a weak stimulus can produce a small depolarizing graded potential that does

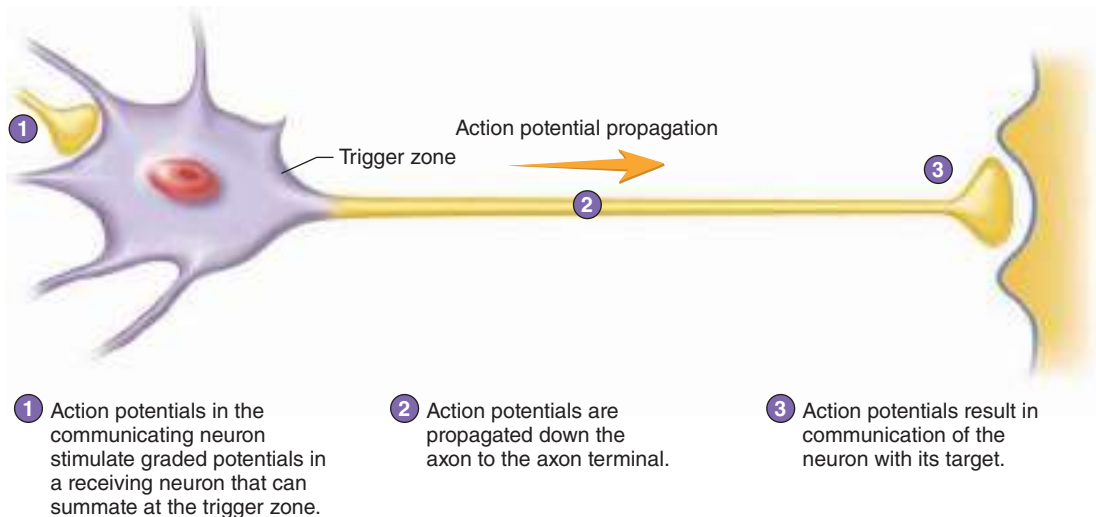

TABLE 11.5 Characteristics of Action Potentials

1.	Action potentials are produced when a graded potential reaches threshold.
2.	Action potentials are all-or-none.
3.	Depolarization is a result of increased membrane permeability to Na^+ and movement of Na^+ into the cell. Activation gates of the voltage-gated Na^+ channels open.
4.	Repolarization is a result of decreased membrane permeability to Na^+ and increased membrane permeability to K^+ , which stops Na^+ movement into the cell and increases K^+ movement out of the cell. The inactivation gates of the voltage-gated Na^+ channels close, and the voltage-gated K^+ channels open.
5.	During the absolute refractory period, no action potential is produced by a stimulus, no matter how strong. During the relative refractory period, a stronger-than-threshold stimulus can produce an action potential.
6.	Action potentials are propagated and, for a given axon or muscle fiber, the magnitude of the action potential is constant.
7.	Stimulus strength determines the frequency of action potentials.

not reach threshold and therefore does not cause an action potential. A stronger stimulus, however, can produce a larger depolarizing graded potential that reaches threshold, resulting in an action potential.

All-or-None Principle

Action potentials occur according to the **all-or-none principle**. If a stimulus produces a depolarizing graded potential that is large enough to reach threshold, all the permeability changes responsible for an action potential proceed without stopping and are constant in magnitude (the “all” part). If a stimulus is so weak that the depolarizing graded potential does not reach threshold, few of the permeability changes occur. The membrane potential returns to its resting level after a brief period without producing an action potential (the “none” part). An action potential can be compared to the starter in a car. Once the ignition switch is pressed (reaches threshold), the car starts (an action potential is produced) and, each time, the engine runs the same as the previous time the car started (the “all” part). If the ignition switch is pressed, but not fully (does not reach threshold), the car does not start (the “none” part).

Depolarization Phase

The increase in positive charge inside the plasma membrane caused by a depolarizing graded potential causes increasing numbers of voltage-gated Na^+ channels to open rapidly. As soon as a threshold depolarization is reached (usually at the axon hillock), many voltage-gated Na^+ channels are stimulated to open. Sodium ions then diffuse into the cell, and the resulting depolarization causes additional voltage-gated Na^+ channels to open. As a consequence, more Na^+ diffuses into the cell, causing a greater depolarization of the membrane, which in turn causes still more voltage-gated Na^+ channels to open. This is an example of a positive-feedback cycle, and it continues until most of the voltage-gated Na^+ channels in the plasma membrane are open.

Each voltage-gated Na^+ channel has two voltage-sensitive gates, called **activation gates** and **inactivation gates**. When the

plasma membrane is at rest, the activation gates of the voltage-gated Na^+ channel are closed, and the inactivation gates are open (figure 11.12, *step 1*). Because the activation gates are closed, Na^+ cannot diffuse through the channels. When the graded potential reaches threshold, the change in the membrane potential causes many of the activation gates to open, and Na^+ can diffuse through the Na^+ channels into the cell.

When the plasma membrane is at rest, voltage-gated K^+ channels, which have one gate, are closed (figure 11.12, *step 1*). When the graded potential reaches threshold, the voltage-gated K^+ channels start to open at the same time as the voltage-gated Na^+ channels, but they open significantly more slowly than the voltage-gated Na^+ channels (figure 11.12, *step 2*). At this stage, because the voltage-gated K^+ channels open so slowly, only a small number of them are open, compared with the number of voltage-gated Na^+ channels. Depolarization occurs because more Na^+ diffuses into the cell than K^+ diffuses out of it.

Predict 6

Predict the effect of a reduced extracellular concentration of Na^+ on the magnitude of the action potential in an electrically excitable cell.

Repolarization Phase

As the membrane potential approaches its maximum depolarization, the inactivation gates of the voltage-gated Na^+ channels are triggered to close by the specific membrane potential. Thus, the permeability of the plasma membrane to Na^+ decreases. During the repolarization phase, the voltage-gated K^+ channels, which started to open slowly along with the voltage-gated Na^+ channels, continue to open (figure 11.12, *step 3*). Consequently, the permeability of the plasma membrane to Na^+ decreases, and the permeability to K^+ increases. The decreased diffusion of Na^+ into the cell and the increased diffusion of K^+ out of the cell cause repolarization.

At the end of repolarization, the return toward resting membrane potential causes the activation gates in the voltage-gated Na^+ channels to close and the inactivation gates to open. Although this change does not affect the diffusion of Na^+ , it does return the voltage-gated Na^+ channels to their resting state (figure 11.12, *step 4*).

Afterpotential

In many cells, a period of hyperpolarization, called afterpotential, follows each action potential. The afterpotential occurs because the voltage-gated K^+ channels open and close more slowly than the voltage-gated Na^+ channels and remain open for a slightly longer time than it takes to bring the membrane potential back to its original resting level. This allows extra K^+ to leave the cell (figure 11.12, *step 4*). As the voltage-gated K^+ channels close, the original resting membrane potential is reestablished by the sodium-potassium pump (figure 11.12, *step 5*).

During an action potential, a small amount of Na^+ diffuses into the cell and a small amount of K^+ diffuses out of the cell. The sodium-potassium pump restores normal resting ion concentrations by transporting these ions in the opposite direction of their movement during the action potential. That is, Na^+ is pumped out of the cell and K^+ is pumped into the cell. The sodium-potassium pump is too slow to have an effect on either the depolarization or the repolarization phase

1 Resting membrane potential. Na^+ channels (pink) and most, but not all, K^+ channels (purple) are closed. The outside of the plasma membrane is positively charged compared to the inside.

Open inactivation gate

2 Depolarization. Na^+ channels open. K^+ channels begin to open. Depolarization results because the inward movement of Na^+ makes the inside of the membrane more positive.

3 Repolarization. Na^+ channels close and additional K^+ channels open. Na^+ movement into the cell stops, and K^+ movement out of the cell increases, causing repolarization.

4 End of repolarization and afterpotential. Voltage-gated Na^+ channels are closed. Closure of the activation gates and opening of the inactivation gates reestablish the resting condition for Na^+ channels (see step 1). Diffusion of K^+ through voltage-gated channels produces the afterpotential.

5 Resting membrane potential. The resting membrane potential is reestablished after the voltage-gated K^+ channels close.

PROCESS FIGURE 11.12 Voltage-Gated Ion Channels and the Action Potential

Step 1 illustrates the status of voltage-gated Na^+ and K^+ channels in a resting cell. Steps 2–5 show how the channels open and close to produce an action potential. Next to each step (far right), a graph shows in red the membrane potential resulting from the condition of the ion channels.

of individual action potentials. As long as the Na^+ and K^+ concentrations remain unchanged across the plasma membrane, all the action potentials produced by a cell are identical. They all take the same amount of time, and they all exhibit the same magnitude.

ASSESS YOUR PROGRESS

31. What is a graded potential, and what four events can cause it?
32. What does it mean to say a graded potential can summate and then spread in a decremental fashion?
33. How does an action potential differ from a local potential? How do depolarizing and hyperpolarizing graded potentials affect the likelihood of generating an action potential?
34. Explain the “all” and the “none” parts of the all-or-none principle of action potentials.
35. What are the depolarization and repolarization phases of an action potential?
36. What happens when the activation gates in the voltage-gated Na^+ channels open and the inactivation gates close?
37. Describe the afterpotential and its cause.

Refractory Period

Once an action potential is produced at a given point on the plasma membrane, that area becomes less sensitive to further stimulation. This time period is called the **refractory** (rē-frak'tōr-ē) **period**. The first part of the refractory period, during which complete insensitivity exists to another stimulus, is called the **absolute refractory period**. In many cells, it occurs from the beginning of the action potential until near the end of repolarization (figure 11.13). At the beginning of the action potential, depolarization occurs when the activation gates in the voltage-gated Na^+ channel open. At this time, the inactivation gates in the voltage-gated Na^+ channels are already open (see figure 11.12, *step 2*). Depolarization ends as the inactivation gates close (see figure 11.12, *step 3*). As long as the inactivation gates are closed, further depolarization cannot occur. Near the end of repolarization when the inactivation gates open and the activation gates close (see figure 11.12, *step 4*), it is possible, once again, to stimulate another action potential if the activation gates re-open.

The existence of the absolute refractory period guarantees that, once an action potential is begun, both the depolarization and the repolarization phases will be completed, or nearly completed, before another action potential can begin and that a strong stimulus cannot lead to prolonged depolarization of the plasma membrane. The absolute refractory period has important consequences for the rate at which action potentials can be generated and for the propagation of action potentials.

The second part of the refractory period, called the **relative refractory period**, follows the absolute refractory period. A very strong stimulus, or a stronger-than-threshold stimulus, can initiate another action potential during the relative refractory period. Thus, after the absolute refractory period, but before the relative refractory period is completed, a sufficiently strong stimulus can produce another action potential. During the relative refractory period, the membrane is more permeable to K^+ because many voltage-gated K^+ channels are open (see figure 11.12, *step 4*). The relative refractory period ends when the voltage-gated K^+

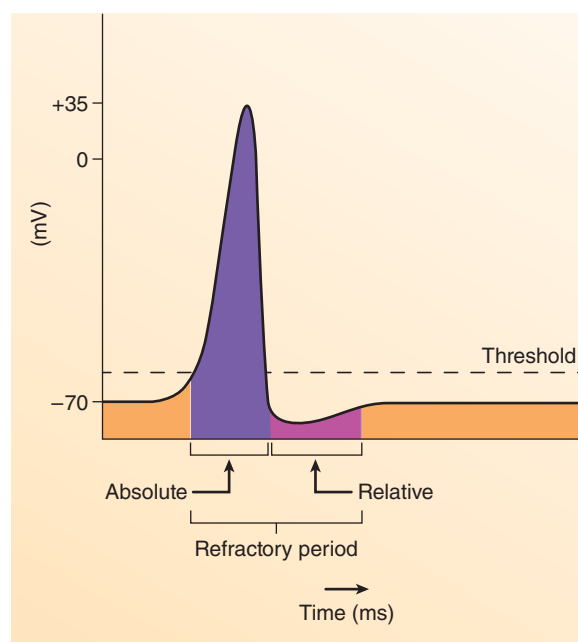

FIGURE 11.13 Refractory Period

The absolute and relative refractory periods of an action potential. In some cells, the absolute refractory period ends during the repolarization phase of the action potential.

channels close and the membrane potential has returned to the resting level (see figure 11.12, *step 5*).

Predict 7

Which produces the most action potentials: a prolonged threshold stimulus or a prolonged, stronger-than-threshold stimulus of the same duration? Explain.

Action Potential Frequency

The **action potential frequency** is the number of action potentials produced per unit of time in response to a stimulus. Recall that the size of the graded potential is dependent on the strength of a stimulus. A small stimulus results in a small graded potential and, as stimulus strength increases, the size of the graded potentials increases. Thus, action potential frequency is directly proportional to stimulus strength and to the size of the graded potential. For example, a **subthreshold stimulus** is any stimulus not strong enough to produce a graded potential that reaches threshold. Therefore, no action potential is produced (figure 11.14). A **threshold stimulus** produces a graded potential that is just strong enough to reach threshold and cause the production of a single action potential. A **maximal stimulus** is just strong enough to produce a maximum frequency of action potentials. A **submaximal stimulus** includes all stimuli between threshold and the maximal stimulus strength. For submaximal stimuli, the action potential frequency increases in proportion to the strength of the stimulus because the size of the graded potential increases with stimulus strength. A **supramaximal stimulus** is any stimulus stronger than a maximal stimulus. Because an axon's ability to produce action potentials is limited, these stimuli cannot produce a greater frequency of action potentials than a maximal stimulus.

FIGURE 11.14 Stimulus Strength and Action Potential Frequency

From left to right, each stimulus in the figure is stronger than the previous one. As stimulus strength increases, the frequency of action potentials increases until a maximal rate is produced. Thereafter, increasing stimulus strength does not increase action potential frequency due to the refractory period.

The duration of the absolute refractory period determines the maximum frequency of action potentials generated in an excitable cell. During the absolute refractory period, a second stimulus, no matter how strong, cannot stimulate an additional action potential. However, as soon as the absolute refractory period ends, it is possible for a second stimulus to cause the production of an action potential.

► Predict 8

If the duration of the absolute refractory period of a neuron is 1 millisecond (ms), how many action potentials are generated by a maximal stimulus in 1 second?

Communication regarding the strength of stimuli cannot depend on the magnitudes of action potentials because, according to the all-or-none principle, the magnitudes of action potentials produced by weak and strong stimuli are always the same. Instead, the frequency of action potentials provides information about the strength of a stimulus. For example, a weak pain stimulus generates a low frequency of action potentials, whereas a stronger pain stimulus generates a higher frequency of action potentials. The ability to interpret a stimulus as mildly painful versus very painful depends, in part, on the frequency of action potentials generated by individual pain receptors.

The ability to stimulate muscle or gland cells also depends on action potential frequency. A low frequency of action potentials produces a weaker muscle contraction or less secretion than does a higher frequency. For example, a low frequency of action potentials in a muscle results in incomplete tetanus, and a high frequency results in complete tetanus (see chapter 9).

In addition to the frequency of action potentials, how long the action potentials are produced provides important information. For example, a pain stimulus of 1 second is interpreted differently than a pain stimulus applied for 30 seconds.

Propagation of Action Potentials

A single action potential occurs in one very small area of the plasma membrane and does not occur over the entire membrane at one time. Additionally, the same action potential does not travel down the entire length of an axon. Movement of action potentials down an axon is like a row of toppling dominoes. A single domino does not travel along the entire row. Rather, each domino must trigger the next domino to fall over, and so on. The row of dominoes represents the axon, and each domino represents an individual action potential. Thus, we see that action potentials can **propagate**, or spread, across the plasma membrane. An action potential produced at one point on the plasma membrane stimulates the production of an action potential at the adjacent point of the same plasma membrane.

In a neuron, action potentials are normally produced at the trigger zone and propagate in one direction along the axon (figure 11.15, *step 1*). The location at which the next action potential is generated is different for unmyelinated and myelinated axons (see figure 11.6). In an unmyelinated axon, the next action potential is generated in the membrane immediately adjacent to the previous action potential. When an action potential is produced, the inside of the membrane becomes more positive than the outside (figure 11.15, *step 2*). On the outside of the membrane, positively charged ions from the adjacent area are attracted to the negative charges at the site of the action

PROCESS FIGURE 11.15 Action Potential Propagation in an Unmyelinated Axon

potential. On the inside of the plasma membrane, positively charged ions at the site of the action potential are attracted to the adjacent negatively charged part of the membrane. The movement of positively charged ions is called a **local current**, or an **ionic current**. As a result of the local current, the part of the membrane immediately adjacent to the action potential depolarizes. That is, the outside of the membrane immediately next to the action potential becomes more negative because of the loss of positive charges, and the inside becomes more positive because of the gain of positive charges (depolarization). When the depolarization reaches threshold, an action potential is produced (figure 11.15, *step 3*). This type of action potential conduction in unmyelinated axons is called **continuous conduction**.

If an action potential is initiated at one end of an axon, it is propagated in one direction down the axon. The absolute refractory period ensures one-way propagation of an action potential because it prevents the local current from stimulating the production of an action potential in the reverse direction (figure 11.15, *step 4*).

In a myelinated axon, an action potential is conducted from one node of Ranvier to another in a process called **saltatory**

conduction (*saltare*, to leap). An action potential at one node of Ranvier generates local currents that flow toward the next node of Ranvier (figure 11.16, *step 1*). The lipids within the membranes of the myelin sheath act as a layer of insulation, forcing the local currents to flow from one node of Ranvier to the next. The action potentials seem to jump from node to node. In addition, voltage-gated Na^+ channels are highly concentrated at the nodes of Ranvier. Therefore, the local current quickly flows to a node and stimulates the voltage-gated Na^+ channels to open, resulting in the production of an action potential (figure 11.16, *step 2*).

The speed of action potential conduction along an axon depends on the myelination of the axon. Action potentials are conducted more rapidly in myelinated than unmyelinated axons because they are formed quickly at each successive node of Ranvier (figure 11.16, *step 3*), instead of being propagated more slowly through every part of the axon's membrane, as in unmyelinated axons (see figure 11.15). Action potential conduction in a myelinated axon is like a child skipping across the floor; in an unmyelinated axon, it is like a child walking heel to toe across the floor. The child (action potential) moves

PROCESS FIGURE 11.16 Saltatory Conduction: Action Potential Propagation in a Myelinated Axon

The gaps between the Schwann cells are exaggerated for clarity.

more rapidly by skipping. The generation of action potentials at nodes of Ranvier occurs so rapidly that as many as 30 successive nodes of Ranvier are simultaneously in some phase of an action potential.

The speed of action potential conduction is also affected by the thickness of the myelin sheath, which is determined by how many times oligodendrocytes or Schwann cells wrap around the axon. Heavily myelinated axons have a thicker myelin sheath and conduct action potentials more rapidly than lightly myelinated axons.

In addition to myelination, the diameter of an axon affects the speed of action potential conduction. Large-diameter axons conduct action potentials more rapidly than small-diameter axons because large-diameter axons have a greater surface area. Consequently, at a given site on an axon, more voltage-gated Na^+ channels open during depolarization, resulting in a greater local current flow, which more rapidly stimulates adjacent membrane areas.

Nerve fibers (axons) are classified according to their size and degree of myelination. It is not surprising that the structure of nerve fibers reflects their functions. Type A fibers are large-diameter, myelinated axons that conduct action potentials at 15–120 m/s. Motor neurons supplying skeletal muscles and most sensory neurons have type A fibers. Rapid response to the external environment is possible because of the rapid input of sensory information to the CNS and the rapid output of action potentials to skeletal muscles.

Type B fibers are medium-diameter, lightly myelinated axons that conduct action potentials at 3–15 m/s, and type C fibers are small-diameter, unmyelinated axons that conduct action potentials at 2 m/s or less. Types B and C fibers are primarily part of the ANS, which stimulates internal organs, such as the stomach, intestines, and heart. The responses necessary to maintain internal homeostasis, such as digestion, need not be as rapid as responses to the external environment.

11.6 The Synapse

LEARNING OUTCOMES

After reading this section, you should be able to

- A.** Describe the general structure and function of a synapse.

- B. Distinguish between electrical and chemical synapses as to mode of operation and types of tissues where they are found.**
- C. Describe the release of a neurotransmitter in a chemical synapse, then its removal from the synapse.**
- D. Explain the effects of neurotransmitter binding to receptors in a chemical synapse.**
- E. Discuss the effects of neuromodulators in a chemical synapse.**
- F. Contrast excitatory and inhibitory postsynaptic potentials.**
- G. Explain the roles of presynaptic inhibition and of facilitation.**
- H. Describe the processes of spatial and temporal summation.**

Just as the fire from one lit torch can light another torch, action potentials in one cell can stimulate action potentials in another cell, thereby allowing communication between the cells. For example, if your finger touches a hot pan, the heat is a stimulus that produces action potentials in sensory nerve fibers. The action potentials are propagated along the sensory fibers from the finger toward the CNS. For the CNS to get this information, the action potentials of the sensory neurons must produce action potentials in CNS neurons. After the CNS has received the information, it

produces a response. One response is the contraction of the appropriate skeletal muscles that causes the finger to move away from the hot pan. CNS action potentials cause motor neurons to produce action potentials that are then transmitted by the motor neurons toward skeletal muscles. The action potentials of the motor neuron produce skeletal muscle action potentials, which are the stimuli that cause muscle fibers to contract (see chapter 9).

As stated in section 11.2, the synapse is the junction between two cells where they communicate with each other. The cell that transmits a signal toward the synapse is called the **presynaptic cell** (before the synapse), and the target cell receiving the signal is called the **postsynaptic cell** (after the synapse).

The average presynaptic neuron synapses with about 1000 other neurons, but the average postsynaptic neuron has up to 10,000 synapses. Some postsynaptic neurons in the part of the brain called the cerebellum have up to 100,000 synapses. There are two types of synapses: electrical and chemical.

Electrical Synapses

Electrical synapses occur between cells connected by gap junctions (see chapter 4). The gap junctions allow a local current to flow directly from one cell to a neighboring cell (figure 11.17).

- 1 Electrical synapses connect cardiac muscle cells.
- 2 An electrical synapse is a gap junction where the membranes of two cells are separated by a gap but connected by proteins called connexons.
- 3 An action potential (*orange arrow*) in the plasma membrane generates local currents (*black arrows*) that flow to adjacent parts of the plasma membrane and through the gap junction.
- 4 A local current stimulates the production of another action potential. Thus, the action potential propagates along the plasma membrane.
- 5 A local current flows through a gap junction and stimulates the production of an action potential in the adjacent cardiac muscle cell. Thus, the action potential propagates to the adjacent cell.

PROCESS FIGURE 11.17 Electrical Synapse

- 1 Action potentials arriving at the presynaptic terminal cause voltage-gated Ca^{2+} channels to open.
- 2 Ca^{2+} diffuses into the cell and causes synaptic vesicles to release neurotransmitter molecules.
- 3 Neurotransmitter molecules diffuse from the presynaptic terminal across the synaptic cleft.
- 4 Neurotransmitter molecules combine with their receptor sites and cause ligand-gated Na^+ channels to open. Na^+ diffuses into the cell (shown in illustration) or out of the cell (not shown) and causes a change in membrane potential.

PROCESS FIGURE 11.18 A Chemical Synapse

A synapse consists of the end of a neuron (presynaptic terminal), a small space (synaptic cleft), and the postsynaptic membrane of another neuron or an effector cell, such as a muscle or gland cell. **APR**

At these gap junctions, the membranes of adjacent cells are separated by a 2 nm gap spanned by structures called **connexons**. The connexons are groups of six tubular proteins, each called a connexin. The movements of ions through the connexons are local currents. Thus, an action potential in one cell produces a

local current that generates an action potential in the adjacent cell almost as if the two cells had the same membrane. As a result, action potentials are conducted rapidly between cells, allowing the cells' activity to be synchronized. Electrical synapses are not common in the nervous system of vertebrates, but some do exist in humans, such as between adjacent cardiac muscle cells. Electrical synapses are also important in many types of smooth muscle. Coordinated contractions of these muscle cells occur when action potentials in one cell propagate to adjacent cells because of electrical synapses (see chapters 9 and 20).

Chemical Synapses

A chemical synapse occurs where a chemical messenger, called a neurotransmitter, is used to communicate a message to an effector. The essential components of a **chemical synapse** are the presynaptic terminal, the synaptic cleft, and the postsynaptic membrane (figure 11.18). The **presynaptic terminal** consists of the end of an axon of the presynaptic cell. The space separating the axon ending and the cell with which it synapses is the **synaptic cleft**. The membrane of the postsynaptic cell associated with the presynaptic terminal is the **postsynaptic membrane**. Postsynaptic cells are typically other neurons, muscle cells, or gland cells.

Neurotransmitter Release

In chemical synapses, action potentials do not pass directly from the presynaptic terminal to the postsynaptic membrane. Instead, the action potentials in the presynaptic terminal cause the release of neurotransmitters from its terminal.

Presynaptic terminals are specialized to produce and release neurotransmitters. The major cytoplasmic organelles within presynaptic terminals are mitochondria and numerous membrane-bound **synaptic vesicles**, which contain neurotransmitters, such as acetylcholine (figure 11.18). Each action potential arriving at the presynaptic terminal initiates a series of specific events, which result in the release of neurotransmitters. In response to an action potential, voltage-gated Ca^{2+} channels open in the presynaptic cell's axon terminal. Next, Ca^{2+} diffuses into the presynaptic terminal. These ions cause synaptic vesicles to fuse with the presynaptic membrane and to release their neurotransmitters by exocytosis into the synaptic cleft.

Once neurotransmitters are released from the presynaptic terminal, they diffuse rapidly across the synaptic cleft, which is about 20 nm wide, and bind reversibly to specific receptors, such as ligand-gated ion channels, in the postsynaptic membrane (figure 11.18). Depending on the ion channel type, this binding produces a depolarizing or hyperpolarizing graded potential in the postsynaptic membrane. For example, the binding of acetylcholine to ligand-gated Na^+ channels causes them to open, allowing Na^+ to diffuse into the postsynaptic cell. If the resulting depolarizing graded potential reaches threshold, an action potential is produced. On the other hand, the opening of K^+ or Cl^- channels results in a hyperpolarizing graded potential.

- 1 Acetylcholine molecules bind to their receptors.
- 2 Acetylcholine molecules unbind from their receptors.
- 3 Acetylcholinesterase splits acetylcholine into choline and acetic acid, which prevents acetylcholine from again binding to its receptors. Choline is taken up by the presynaptic terminal.
- 4 Choline is used to make new acetylcholine molecules that are packaged into synaptic vesicles.

(a)

- 1 Norepinephrine binds to its receptor.
- 2 Norepinephrine unbinds from its receptor.
- 3 Norepinephrine is taken up by the presynaptic terminal, which prevents norepinephrine from again binding to its receptor.
- 4 Norepinephrine is repackaged into synaptic vesicles or broken down by monoamine oxidase (MAO).

PROCESS FIGURE 11.19 Removal of Neurotransmitters from the Synaptic Cleft

(a) In some synapses, neurotransmitters are broken down by enzymes and recycled into the presynaptic terminal. (b) In other synapses, neurotransmitters are taken up whole into the presynaptic terminal.

Predict 9

Is an action potential transmitted faster between cells connected by an electrical synapse or by a chemical synapse? Explain.

Neurotransmitter Removal

The interaction between a neurotransmitter and a receptor represents an equilibrium:

When the neurotransmitter concentration in the synaptic cleft is high, many of the receptor molecules have neurotransmitter molecules bound to them; when the neurotransmitter concentration declines, the neurotransmitter molecules diffuse away from the receptor molecules.

Neurotransmitters have short-term effects on postsynaptic membranes because the neurotransmitter is rapidly destroyed or removed from the synaptic cleft. For example, in the neuromuscular junction (see chapter 9), the neurotransmitter acetylcholine is broken

down by the enzyme **acetylcholinesterase** (as'e-til-kō-lin-es'ter-ās) to acetic acid and choline (figure 11.19a). Choline is then transported back into the presynaptic terminal and combines with acetyl-CoA to re-form acetylcholine. Acetyl-CoA is synthesized by mitochondria as foods are metabolized to produce ATP (see chapter 25). Acetic acid can be absorbed from the synaptic cleft into the presynaptic terminal, or it can diffuse out of the synaptic cleft and be taken up by a variety of cells. Acetic acid can be used to synthesize acetyl-CoA.

When the neurotransmitter norepinephrine is released into the synaptic cleft, most of it is transported back into the presynaptic terminal, where it is repackaged into synaptic vesicles for later use (figure 11.19b). The enzyme **monoamine oxidase (MAO; mon-ō-am'in ok'si-dās)** breaks down some of the norepinephrine.

Diffusion of neurotransmitter molecules away from the synapse and into the extracellular fluid also limits the length of time the neurotransmitter molecules remain bound to their receptors. Norepinephrine in the circulation is taken up primarily by liver and kidney cells, where the enzymes monoamine oxidase and

catechol-O-methyltransferase (kat'ě-kol-ō-meth-il-trans'fer-ās) convert it into inactive metabolites.

Receptor Molecules in Synapses

Receptor molecules in synapses are highly specific for particular ligands. Most of these receptors are membrane-bound, ligand-activated receptors. Consequently, only neurotransmitter molecules or very closely related substances normally bind to their receptors. For example, acetylcholine binds to acetylcholine receptors but not to norepinephrine receptors, whereas norepinephrine binds to norepinephrine receptors but not to acetylcholine receptors. Any given cell does not have all possible receptors. Therefore, a neurotransmitter affects only the cells with receptors for that neurotransmitter.

A neurotransmitter can stimulate some cells but inhibit others. More than one type of receptor molecule exists for some neurotransmitters. Different cells respond differently to a neurotransmitter when these cells have different receptors. For example, norepinephrine can bind to one type of norepinephrine receptor to cause depolarization in one synapse and to another type of norepinephrine receptor to cause hyperpolarization in another synapse. Thus, norepinephrine is either stimulatory or inhibitory, depending on the type of norepinephrine receptor to which it binds and on the effect that receptor has on the permeability of the postsynaptic membrane.

Although neurotransmitter receptors are in greater concentrations on postsynaptic membranes, some receptors exist on presynaptic membranes. For example, norepinephrine released from the presynaptic membrane binds to receptors on both presynaptic and postsynaptic membranes. Its binding to the receptors of the presynaptic membrane decreases the release of additional synaptic vesicles. Norepinephrine can therefore modify its own release by binding to presynaptic receptors. A high frequency of presynaptic action potentials results in the release of fewer synaptic vesicles in response to later action potentials.

Neurotransmitters and Neuromodulators

Several substances have been identified as neurotransmitters, and others are suspected neurotransmitters. Scientists once thought that each neuron contained only one type of neurotransmitter; however, they now know that some neurons can secrete more than one type. If a neuron does produce more than one neurotransmitter, it secretes all of them from each of its presynaptic terminals. The physiological significance of presynaptic terminals that secrete more than one type of neurotransmitter has not been clearly established.

Neuromodulators are substances released from neurons that influence the likelihood of an action potential being produced in the postsynaptic cell. For example, a neuromodulator that inhibits the release of an excitatory neurotransmitter from a presynaptic terminal reduces the likelihood of the postsynaptic cell producing an action potential. Drugs can modulate the action of neurotransmitters at the synapse in ways that can be either beneficial or harmful. For example, cocaine and amphetamines increase the release and block the reuptake of norepinephrine, which increases norepinephrine levels in a synapse. This results in overstimulation

of postsynaptic neurons and deleterious effects on the body. On the other hand, drugs that block serotonin reuptake are particularly effective at treating depression and behavioral disorders. A list of neurotransmitters and neuromodulators is presented in table 11.6.

50. Why does a given type of neurotransmitter affect only certain types of cells? How can a neurotransmitter stimulate one type of cell but inhibit another type?
51. What is a neuromodulator? Give some examples of how drugs can modulate the action of neurotransmitters.

Excitatory and Inhibitory Postsynaptic Potentials

The combination of neurotransmitters with their specific receptors causes either depolarization or hyperpolarization of the postsynaptic membrane. When depolarization of the postsynaptic cell occurs, the response is stimulatory, and the resulting graded potential is called an **excitatory postsynaptic potential (EPSP)**; figure 11.20a). EPSPs are important because the depolarization might reach threshold, thereby producing an action potential and a response from the cell. Neurons releasing neurotransmitter substances that cause EPSPs are **excitatory neurons**. In general, an EPSP occurs because the membrane has become more permeable to Na^+ . For example, glutamate in the brain and acetylcholine in skeletal muscle can bind to their receptors, causing Na^+ channels to open. Because the concentration gradient is large for Na^+ and because the negative charge inside the cell attracts the positively charged Na^+ , it diffuses into the cell and causes depolarization. If EPSPs cause a depolarizing graded potential that reaches threshold, an action potential is produced. For example, awareness of pain can occur only if action potentials generated by sensory neurons stimulate the production of action potentials in CNS neurons. Local anesthetics, such as procaine (novocaine), act at their site of application to prevent pain sensations. They do so by blocking voltage-gated Na^+ channels, which prevents action potentials from propagating along sensory neurons. Consequently, neurotransmitters are not released from the presynaptic terminals of the sensory neurons, and EPSPs are not produced in CNS neurons.

When the combination of a neurotransmitter with its receptor results in hyperpolarization of the postsynaptic membrane, the response is inhibitory because no action potentials are generated. This local hyperpolarization is called an **inhibitory postsynaptic potential (IPSP)**; figure 11.20b). IPSPs are important because they move the membrane potential farther from threshold, which decreases the likelihood of an action potential being generated. Neurons releasing neurotransmitter substances that cause IPSPs are called **inhibitory neurons**. The IPSP results from an increase in the permeability of the plasma membrane to Cl^- or K^+ , resulting in hyperpolarization of the postsynaptic cell. For example, in

TABLE 11.6 Clinical Examples of Synaptic Function

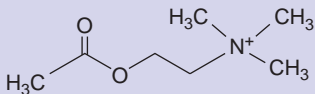

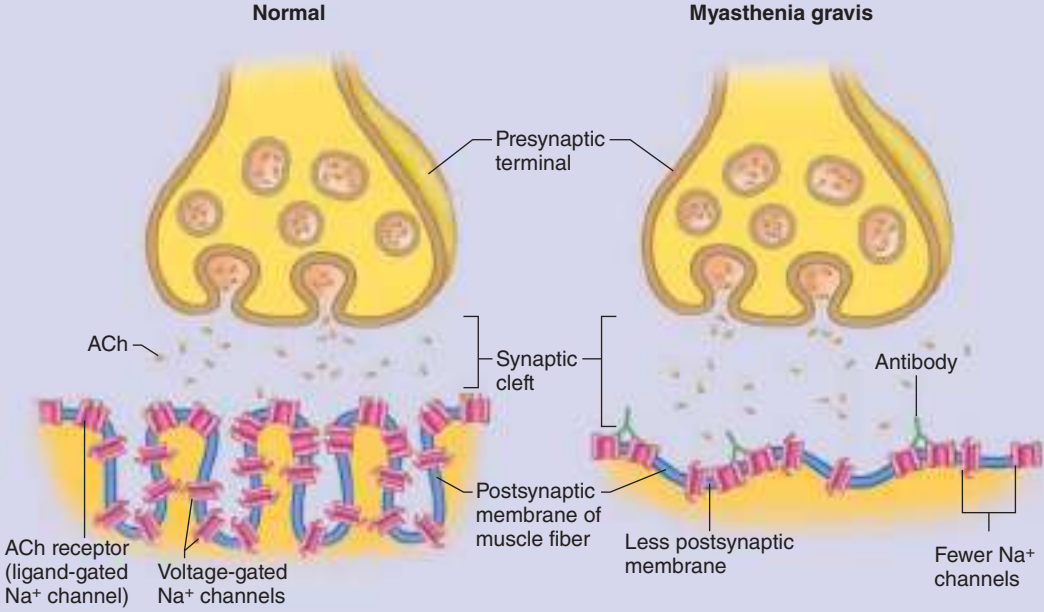

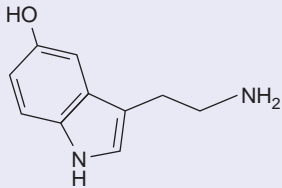

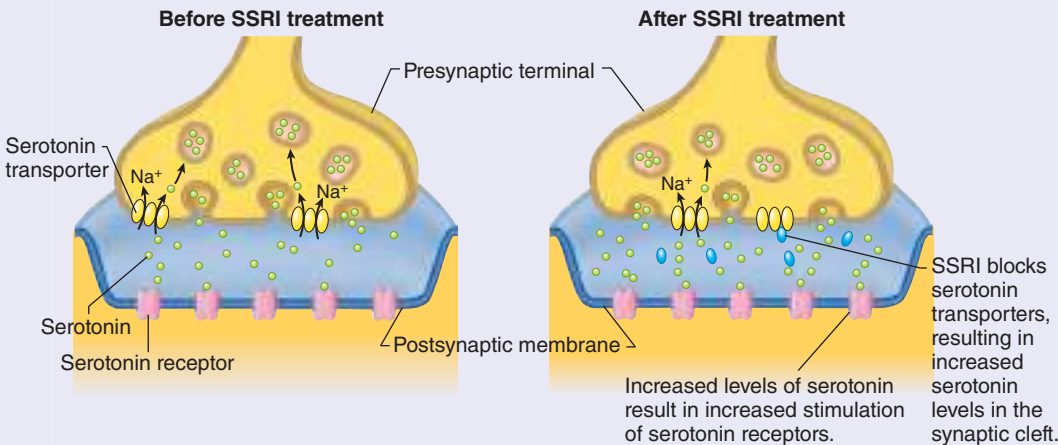

Neurotransmitter/Neuromodulator	Clinical Examples
<p>Acetylcholine</p> <p>Structure:</p>  <p>Site of release: CNS synapses, ANS synapses, and neuromuscular junctions</p> <p>Effect: excitatory in the CNS and neuromuscular junctions; inhibitory or excitatory in ANS synapses</p>	<p>Myasthenia Gravis</p> <p>In the disease myasthenia gravis, the ability of skeletal muscle to respond to nervous system stimulation decreases, resulting in muscle weakness and even paralysis. Antibodies, proteins produced by the immune system, can attach to foreign substances, such as bacteria (see chapter 22). In myasthenia gravis, antibodies inappropriately attach to acetylcholine receptors. The antibodies link the receptors together, causing them to be removed from the plasma membrane faster than normal and decreasing the number of receptors. The antibodies also stimulate immune responses that lead to destruction of the postsynaptic membrane, which decreases the number of Na⁺ channels in the synapse. Thus, the ability of ACh to stimulate action potential production decreases because there are fewer ligand-gated ACh receptors, and the ability to generate an action potential is reduced because there are fewer voltage-gated Na⁺ channels.</p> 
<p>Biogenic Amines</p> <p><i>Serotonin</i></p> <p>Structure:</p>  <p>Site of release: CNS synapses</p> <p>Effect: both inhibitory and excitatory</p>	<p>Antidepressant Therapy</p> <p>Selective serotonin reuptake inhibitors (SSRIs), such as Prozac (fluoxetine hydrochloride) and Zoloft (sertraline HCl), are drugs commonly used to treat depression. They temporarily block serotonin transporters (symporters), which decreases serotonin transport back into presynaptic terminals, resulting in increased serotonin levels in synaptic clefts. In some people, the increased stimulation of the postsynaptic neuron by serotonin relieves depression.</p>  <p>Anxiety Disorders</p> <p>SSRIs are also used to treat panic disorders, such as obsessive-compulsive disorder (OCD), leading researchers to believe that OCD might be linked to abnormalities in serotonin function.</p>

TABLE 11.6 Clinical Examples of Synaptic Function—Continued

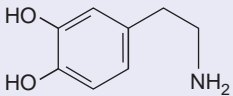

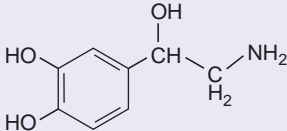

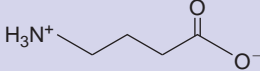

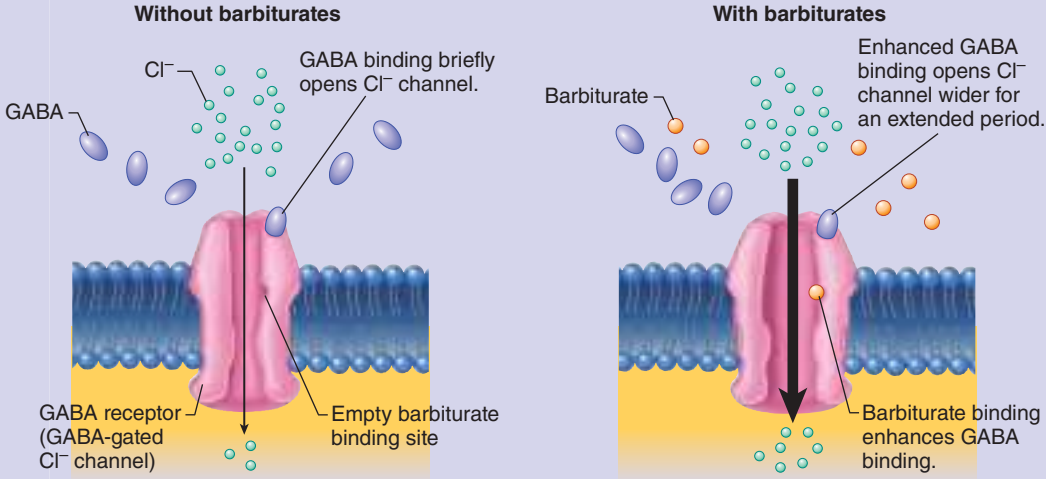

Neurotransmitter/Neuromodulator	Clinical Examples
<p><i>Serotonin (continued)</i></p>	<p>Hallucinogens</p> <p>The hallucinogenic drug D-lysergic acid diethylamide (LSD) blocks serotonin transporters in specific areas of the brain and produces hallucinogenic effects. Other drugs, such as ecstasy, are also hallucinogens that block serotonin transporters.</p>
<p><i>Dopamine</i></p> <p>Structure:</p>  <p>Site of release: selected CNS synapses; also found in some ANS synapses</p> <p>Effect: excitatory or inhibitory</p>	<p>Drug Addiction</p> <p>Cocaine blocks dopamine transporters (symporters), which increases dopamine levels in synaptic clefts, resulting in overstimulation of postsynaptic neurons. Although moderate levels of dopamine can cause euphoria, high levels of dopamine can produce psychotic effects.</p> <p>Parkinson Disease</p> <p>Parkinson disease results from the destruction of dopamine-producing neurons, and it is characterized by tremors and decreased voluntary motor control. Parkinson disease is treated with the drug L-Dopa, which increases the production of dopamine in the presynaptic terminals of remaining neurons. Another treatment option involves drugs that mimic the action of dopamine.</p>
<p><i>Norepinephrine</i></p> <p>Structure:</p>  <p>Site of release: selected CNS synapses and some ANS synapses</p> <p>Effect: excitatory</p>	<p>Attention-Deficit Hyperactivity Disorder (ADHD)</p> <p>ADHD is often treated with drugs that increase the level of excitatory neurotransmitters, such as norepinephrine, in the synaptic clefts. This is achieved by using selective norepinephrine reuptake inhibitors (SNRIs) that block norepinephrine transporters (symporters) and increase the levels of norepinephrine in the synaptic clefts. Additionally, simultaneously increasing the levels of dopamine in the synaptic cleft is a common treatment. The most familiar of the ADHD medications, Ritalin®, prevents reuptake of both norepinephrine and dopamine. The most recent information suggests that enhancing the nicotinic cholinergic pathways is also an effective treatment for ADHD.</p> <p>Amphetamines</p> <p>Amphetamines are drugs with excitatory effects on the CNS. They increase the levels of norepinephrine and dopamine in synaptic clefts by either blocking the reuptake of these neurotransmitters or promoting their release from synaptic vesicles. The CNS effects of amphetamines include decreased appetite, increased alertness, and enhanced ability to concentrate and perform physical tasks. Amphetamines are used to treat ADHD, clinical depression, narcolepsy, and chronic fatigue syndrome. An overdose of amphetamines can cause insomnia, tremors, anxiety, and panic.</p>
<p>Amino Acids</p> <p><i>Gamma-Amino Butyric Acid (GABA)</i></p> <p>Structure:</p> 	<p>Barbiturates</p> <p>Certain GABA receptors are ligand-gated channels that permit the inflow of Cl⁻ when stimulated. GABA produces an inhibitory (or a hyperpolarizing) effect by binding to these receptors and promoting Cl⁻ inflow. Barbiturates enhance the binding of GABA to their receptors, resulting in the prolonged inhibition of postsynaptic neurons. These drugs are used as sedatives and anesthetics and as a treatment for epilepsy, which is characterized by excessive neuronal discharge.</p>
<p>Site of release: CNS synapses</p> <p>Effect: inhibitory effect on postsynaptic neurons; some presynaptic inhibition in the spinal cord</p>	 <p>Without barbiturates</p> <p>GABA binding briefly opens Cl⁻ channel.</p> <p>GABA receptor (GABA-gated Cl⁻ channel)</p> <p>Empty barbiturate binding site</p> <p>The inflow of Cl⁻ causes inhibition of the postsynaptic neuron.</p> <p>With barbiturates</p> <p>Enhanced GABA binding opens Cl⁻ channel wider for an extended period.</p> <p>Barbiturate binding enhances GABA binding.</p> <p>Greater inflow of Cl⁻ causes prolonged inhibition of the postsynaptic neuron.</p>

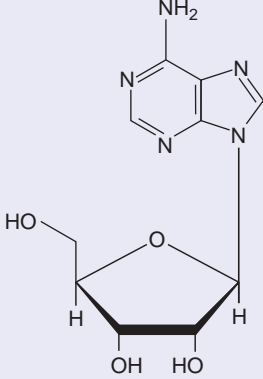

TABLE 11.6 Clinical Examples of Synaptic Function—Continued

Neurotransmitter/Neuromodulator	Clinical Examples
<p>Amino Acids</p> <p><i>Gamma-Amino Butyric Acid (GABA)</i> (continued)</p>	<p>Benzodiazepines</p> <p>Benzodiazepines that are used in antianxiety drugs also have binding sites on certain GABA receptors. Their action is similar to that of barbiturates in that they enhance the binding of GABA to its receptor, producing an inhibitory effect.</p> <p>Alcohol Dependence</p> <p>Alcohol acts similarly to barbiturates to enhance the effect of GABA. As a result, the ligand-gated Cl^- channel becomes more permeable to Cl^-, producing an inhibitory effect. Chronic consumption of alcohol renders the GABA receptor less sensitive to both alcohol and GABA, resulting in increased alcohol dependence and alcohol withdrawal symptoms, such as anxiety, tremors, and insomnia. Alcohol withdrawal symptoms are often treated with benzodiazepines.</p>
<p><i>Glycine</i></p> <p>Structure:</p> <chem>NC(=O)O</chem> <p>Site of release: CNS synapses Effect: inhibitory</p>	<p>Strychnine Poisoning</p> <p>Glycine receptors are similar to GABA receptors in that they act as ligand-gated channels permitting the inflow of Cl^-. The poison strychnine blocks glycine receptors, which increases the excitability of certain neurons by preventing their inhibition. Strychnine poisoning results in powerful muscle contractions and convulsions. Tetanus of respiratory muscles can cause death.</p>
<p><i>Glutamate</i></p> <p>Structure:</p> <chem>NC(CC(=O)O)C(=O)O</chem> <p>Site of release: CNS synapses; in areas of the brain involved in learning and memory Effect: excitatory</p>	<p>Stroke and Excitotoxicity</p> <p>Glutamate is the major excitatory neurotransmitter of the CNS. Some glutamate receptors are ligand-gated Ca^{2+} channels. When stimulated, Ca^{2+} channels open, causing depolarization of postsynaptic membranes. Some glutamate is removed from the synapse by transporters in presynaptic terminals, whereas the bulk of it is removed by transporters (symporters) in neighboring astrocytes. When a person suffers a stroke, brain tissue is deprived of oxygen, and ATP levels decrease. This causes the secondary active transport of glutamate by the glutamate transporters to fail temporarily. As a result, glutamate accumulates in the synaptic clefts and causes excessive stimulation of postsynaptic neurons. Excessive movement of Ca^{2+} into neurons activates a variety of destructive processes, which can cause cell death.</p>

**Cognition**

Glutamate is implicated in learning and memory. Drugs, such as Namenda (memantine), that target specific glutamate receptors are often used to treat Alzheimer disease.

TABLE 11.6 Clinical Examples of Synaptic Function—Continued

Neurotransmitter/Neuromodulator	Clinical Examples
<p>Purines</p> <p><i>Adenosine</i></p> <p>Structure:</p>  <p>Site of release: CNS synapses; in the areas of the brain involved in learning and memory</p> <p>Effect: inhibitory</p>	<p>Neuroprotective Agent</p> <p>Adenosine acts as both a neurotransmitter and a neuromodulator. Adenosine receptors are linked to G proteins (see figure 3.11). As a neurotransmitter, adenosine stimulates the opening of Cl⁻ and K⁺ channels on postsynaptic membranes, thereby producing a hyperpolarizing effect. Acting as a neuromodulator, adenosine stimulates the closing of Ca²⁺ channels on presynaptic neurons, inhibiting neurotransmitter release. Adenosine production greatly increases during a stroke. It prevents the release of glutamate from presynaptic vesicles, which reduces the level of glutamate in synaptic clefts. It also hyperpolarizes the postsynaptic membranes of glutamate synapses, thereby countering the excitatory effects of glutamate. As a result, the damaging effects of glutamate during a stroke are diminished. The possibility of using adenosine as an antistroke agent is being investigated.</p> <p>Caffeine</p> <p>Adenosine produces drowsiness. Caffeine counters that effect by blocking adenosine receptors and promoting alertness. Caffeine also promotes cognition by blocking adenosine's inhibitory effect on glutamate function.</p>
<p>Neuropeptides</p> <p><i>Substance P</i></p> <p>Structure: polypeptide (10 amino acids)</p> <p>Site of release: descending pain pathways</p> <p>Effect: excitatory</p> <p><i>Endorphins</i></p> <p>Structure: polypeptide (30 amino acids)</p> <p>Site of release: descending pain pathways</p> <p>Effect: inhibitory</p>	<p>Pain Therapy</p> <p>Substance P acts as a neurotransmitter and neuromodulator. The receptor for substance P is called a neurokinin receptor, which is linked to a G protein complex (see figure 3.11). Drugs such as morphine reduce pain by blocking the release of substance P.</p> <p>Opiates</p> <p>Endorphins bind to endorphin receptors on presynaptic neurons and reduce pain by blocking the release of substance P. Endorphins also produce feelings of euphoria. Opiates such as morphine and heroin also bind to endorphin receptors, resulting in similar effects.</p>
<p>Gases</p> <p><i>Nitric Oxide (NO)</i></p> <p>Structure: N=O</p> <p>Site of release: CNS, nerves supplying the adrenal gland, penis</p> <p>Effect: excitatory</p>	<p>Stroke Damage</p> <p>During a stroke, rising glutamate levels act on postsynaptic neurons and cause the release of NO, which in high concentrations can be toxic to cells. Nitric oxide also diffuses out of postsynaptic neurons, enters neighboring cells, and damages them.</p> <p>Treatment of Erectile Dysfunction</p> <p>During sexual arousal, nerves release NO, causing the vasodilation of the blood vessels supplying the penis. Viagra (sildenafil citrate), which is used to treat erectile dysfunction, acts by prolonging the effect of NO on these blood vessels (see chapter 28).</p>

the spinal cord, glycine binds to its receptors, directly causing Cl⁻ channels to open. Because Cl⁻ is more concentrated outside the cell than inside, when the membrane's permeability to Cl⁻ increases, it diffuses into the cell, causing the inside of the cell to become more negative and resulting in hyperpolarization. Acetylcholine can bind to its receptors in the heart, causing G protein-mediated opening of K⁺ channels (see chapter 3). The concentration of K⁺ is greater inside the cell than outside, and increased permeability of the membrane to K⁺ allows K⁺ to diffuse out of the cell. Consequently, the outside of the cell becomes more positive than the inside, resulting in hyperpolarization.

Presynaptic Inhibition and Facilitation

Many of the synapses of the CNS are **axoaxonic synapses**, meaning that the axon of one neuron synapses with the presynaptic terminal (axon) of another (figure 11.21a). Through axoaxonic synapses, one neuron can release a neuromodulator that influences the release of a neurotransmitter from the presynaptic terminal of another neuron.

In **presynaptic inhibition**, the amount of neurotransmitter released from the presynaptic terminal is reduced. For example, sensory neurons for pain can release neurotransmitters from their presynaptic terminals and stimulate the postsynaptic membranes of neurons in the brain or spinal cord. Awareness of pain occurs only if action

(a) Excitatory postsynaptic potential (EPSP)

(b) Inhibitory postsynaptic potential (IPSP)

FIGURE 11.20 Postsynaptic Potentials

- (a) An excitatory postsynaptic potential (EPSP) is closer to threshold.
 (b) An inhibitory postsynaptic potential (IPSP) is farther from threshold.

potentials are produced in the postsynaptic membranes of the CNS neurons. Enkephalins and endorphins released from inhibitory neurons of axoaxonic synapses can reduce or eliminate pain sensations by inhibiting the release of neurotransmitter from the presynaptic terminals of sensory neurons (figure 11.21*b*). Enkephalins and endorphins can block voltage-gated Ca^{2+} channels. Consequently, when action potentials reach the presynaptic terminal, the influx of Ca^{2+} that normally stimulates neurotransmitter release is blocked.

In **presynaptic facilitation**, the amount of neurotransmitter released from the presynaptic terminal is elevated. For example, serotonin, released in certain axoaxonic synapses, functions as a neuromodulator that increases the release of neurotransmitter from the presynaptic terminal by causing voltage-gated Ca^{2+} channels to open.

Spatial and Temporal Summation

Depolarizations produced in postsynaptic membranes are graded potentials. Within the CNS and in many PNS synapses, a single presynaptic action potential does not cause a graded potential in the postsynaptic membrane sufficient to reach threshold and produce an action potential. Instead, many presynaptic action potentials cause many graded potentials in the postsynaptic neuron. The graded potentials combine in summation at the trigger zone of the postsynaptic neuron, which is the normal site of action potential generation for most neurons. If summation results in a graded potential that

**FIGURE 11.21 An Axoaxonic Synapse**

- (a) The inhibitory neuron of the axoaxonic synapse is inactive and has no effect on the release of neurotransmitter from the presynaptic terminal. (b) The inhibitory neuron of the axoaxonic synapse releases a neuromodulator, which reduces the amount of neurotransmitter released from the presynaptic terminal.

exceeds threshold at the trigger zone, an action potential is produced. Action potentials are readily produced at the trigger zone because the concentration of voltage-gated Na^+ channels is approximately seven times greater there than at the rest of the neuron cell body.

Two types of summation are possible: spatial summation and temporal summation. **Spatial summation** occurs when multiple action potentials from separate neurons arrive simultaneously at the same postsynaptic neuron. In the postsynaptic neuron, each action potential causes a depolarizing graded potential that undergoes summation at the trigger zone. If the summated depolarization reaches threshold, an action potential is produced (figure 11.22*a*).

Temporal summation results when two or more action potentials arrive very close together at the postsynaptic cell from the presynaptic terminal of a particular neuron. The first action potential causes a depolarizing graded potential in the postsynaptic membrane that remains for a few milliseconds before it disappears, although its magnitude decreases through time. Temporal summation in the postsynaptic cell results when the second action potential from the presynaptic neuron initiates a second graded depolarization before the postsynaptic cell's membrane potential returns to its resting value (see figure 11.9*b*). Subsequent action potentials cause depolarizations that summate with previous depolarizations. If the summated depolarizing graded potentials reach threshold at the trigger zone, an action potential is produced in the postsynaptic neuron (figure 11.22*b*).

Predict 10

Excitatory neurons A and B both synapse with neuron C. Neuron A releases a neurotransmitter, and neuron B releases the same type and amount of neurotransmitter plus a neuromodulator that produces EPSPs in neuron C. Action potentials produced in neuron A alone can result in action potential production in neuron C. Action potentials produced in neuron B alone also can cause action potential production in neuron C. Which results in more action potentials in neuron C, stimulation by only neuron A or stimulation by only neuron B? Explain.

- (a) **Spatial summation.** Action potentials 1 and 2 cause the production of graded potentials at two different dendrites. These graded potentials summate at the trigger zone to produce a graded potential that exceeds threshold, resulting in an action potential.

- (b) **Temporal summation.** Two action potentials arrive in close succession at the postsynaptic cell from the presynaptic terminal. The first action potential causes the production of a graded potential in the postsynaptic cell that does not reach threshold at the trigger zone. The second action potential results in the production of a second graded potential that summates with the first to reach threshold, resulting in the production of an action potential.

- (c) **Combined spatial and temporal summation with both excitatory postsynaptic potentials (EPSPs) and inhibitory postsynaptic potentials (IPSPs).** An action potential is produced at the trigger zone when the graded potentials produced as a result of the EPSPs and IPSPs summate to reach threshold.

FIGURE 11.22 Summation

Excitatory and inhibitory neurons can synapse with the same postsynaptic neuron. Spatial summation of EPSPs and IPSPs occurs in the postsynaptic neuron, and whether a postsynaptic action potential is initiated or not depends on which type of graded potential has the greatest influence on the postsynaptic membrane potential (figure 11.22c). If the EPSPs (local depolarizations) cancel the IPSPs (local hyperpolarizations) and summate to threshold, an action potential is produced. If the IPSPs prevent the EPSPs from summing to threshold, no action potential is produced.

The synapse is an essential structure for the integration carried out by the CNS. For example, action potentials propagated along axons from sensory organs to the CNS can allow the brain to perceive, or not perceive, a sensory stimulus. To produce the perception of a sensation, action potentials must be transmitted across synapses as they travel through the CNS to the cerebral cortex, where information is interpreted. Stimuli that do not result in action potential transmission across synapses are not perceived because the information never reaches the cerebral cortex. The brain doesn't perceive a large amount of sensory information as a result of complex integration.

56. How do EPSPs and IPSPs affect the likelihood that summation will result in an action potential?

11.7 Neuronal Pathways and Circuits

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Contrast convergent and divergent neuron pathways.
- B. Describe a reverberating circuit.
- C. Explain a parallel after-discharge circuit.

The organizational patterns of neurons within the CNS vary from relatively simple to extremely complex. The simplest organization is a **serial** pathway, where the input travels along only one pathway. However, most pathways are more complex and are called **parallel** pathways, where the input travels along several pathways. The axon of a neuron can branch repeatedly to form synapses with many other neurons, and hundreds or even thousands of axons can

synapse with the cell body and dendrites of a single neuron. Although their complexity varies, four basic patterns of parallel pathways can be recognized: convergent pathways, divergent pathways, reverberating circuits, and parallel after-discharge circuits.

In **convergent pathways**, multiple neurons converge upon and synapse with a smaller number of neurons (figure 11.23a). Convergence allows different parts of the nervous system to activate or inhibit the activity of neurons. For example, one part of the nervous system can stimulate the neurons responsible for making a muscle contract, whereas another part can inhibit those neurons. Through summation, muscle contraction can be activated if more converging neurons stimulate the production of EPSPs than converging neurons stimulate the production of IPSPs. Conversely, muscle contraction is inhibited if the converging neurons stimulate the production of more IPSPs than EPSPs.

In **divergent pathways**, a smaller number of presynaptic neurons synapse with a larger number of postsynaptic neurons to allow information transmitted in one neuronal pathway to diverge into two or more pathways (figure 11.23b). Diverging pathways allow one part of the nervous system to affect more than one other part of the nervous system. For example, sensory input to the central nervous system can go to both the spinal cord and the brain.

Reverberating circuits have a chain of neurons with synapses with previous neurons in the chain, making a positive-feedback loop. This allows action potentials entering the circuit to cause a neuron farther along in the circuit to produce an action potential more than once (figure 11.23c). This response, called **after-discharge**, prolongs the response to a stimulus. Once a reverberating circuit is stimulated, it continues to discharge until the synapses involved become fatigued or are inhibited by other neurons. Reverberating circuits play a role in neuronal circuits that control rhythmic

FIGURE 11.23 Neuronal Pathways and Circuits

The direction of action potential propagation is represented by the orange arrows. (a) General model of a convergent pathway; many neurons converge and synapse with a smaller number of neurons. (b) General model of a divergent pathway; a few neurons synapse with a larger number of neurons. (c) Simple model of a reverberating circuit; input action potentials result in the production of a larger number of output action potentials because neurons within the circuit are repeatedly stimulated to produce action potentials. (d) Simple model of a parallel after-discharge circuit; several neurons in parallel that integrate complex processes stimulate a common output cell.

activities. Respiration appears to be controlled by a reverberating circuit. In addition, neurons that spontaneously produce action potentials are common in the CNS and may activate reverberating circuits, which remain active awhile and include the sleep-wake cycle.

Parallel after-discharge circuits have neurons that stimulate several neurons in parallel organization, which all converge upon a common output cell (figure 11.23*d*). These circuits are involved in complex neuronal processes, including mathematics

and chemical conversions. The intricate functions carried out by the CNS are affected by the numerous circuits operating together and influencing the activity of one another.

- 57.** Diagram a convergent pathway, a divergent pathway, a reverberating circuit, and a parallel after-discharge circuit, and describe what is accomplished in each.

Answer

Learn to Predict ◀ From page 365

Multiple sclerosis results from the destruction of myelin sheaths around axons of CNS neurons. As a result of her condition, Amanda is experiencing muscle weakness in her legs and left hand. In chapter 9 we learned that skeletal muscle contractions are stimulated by the nervous system and that the amount of muscle tension produced is determined by the frequency of the stimulation. This chapter explained that myelin sheaths increase the rate of action potential conduction in neurons and therefore increase the frequency of muscle stimulation. We can then conclude that the destruction of the myelin sheaths reduced the ability of Amanda's brain and spinal cord to communicate with the motor neurons supplying her leg and hand muscles. Because the brain and spinal cord neurons were conducting action potentials more slowly, the motor neurons were not being stimulated as quickly as normal. Therefore, Amanda's muscles could not produce as much tension as they could

before the damage to the brain and spinal cord neurons occurred. Amanda's difficulty with climbing the steps suggests that the damaged spinal cord neurons include those that stimulate neurons that innervate muscles of her hip, thigh, and leg.

As the degeneration of myelin sheaths continues, Amanda is likely to experience increasing muscle weakness. Some muscle groups may become so weak that they cannot support Amanda's weight. She may have to use crutches, a cane, or eventually a wheelchair. Other muscle groups, including those involved in swallowing and breathing, will probably be compromised. In addition to motor functions, if Amanda's sensory neurons in her brain and spinal cord are affected, she may experience numbness, pain, and vision problems.

Answers to the rest of this chapter's Predict questions are in appendix G.

11.1 Functions of the Nervous System (p. 366)

The nervous system detects external and internal stimuli (sensory input), processes and responds to sensory input (integration), controls body movements through skeletal muscles, maintains homeostasis by regulating other systems, and is the center for mental activities.

11.2 Divisions of the Nervous System (p. 366)

- The nervous system has two anatomical divisions.
 - The central nervous system (CNS) consists of the brain and spinal cord and is encased in bone.
 - The peripheral nervous system (PNS), the nervous tissue outside of the CNS, consists of sensory receptors, nerves, ganglia, and plexuses.
- The PNS has two divisions.
 - The sensory division transmits action potentials to the CNS and usually consists of single neurons that have their cell bodies in ganglia.
 - The motor division carries action potentials away from the CNS in cranial or spinal nerves.
- The motor division has two subdivisions.
 - The somatic nervous system innervates skeletal muscle and is mostly under voluntary control. It consists of single neurons that have their cell bodies located within the CNS.
 - The autonomic nervous system (ANS) innervates cardiac muscle, smooth muscle, and glands. It has two sets of neurons between the CNS and effector organs. The first set has its cell bodies within the CNS, and the second set has its cell bodies within autonomic ganglia.
 - The ANS is subdivided into the sympathetic division, which is most active during physical activity, and the parasympathetic division, which regulates resting functions.
 - The enteric nervous system controls the digestive system.
- The anatomical divisions perform different functions.
 - The PNS detects stimuli and transmits information to and receives information from the CNS.
 - The CNS processes, integrates, stores, and responds to information from the PNS.

Summary

11.3 Cells of the Nervous System (p. 369)

Neuron Structure

1. Neurons receive stimuli and transmit action potentials.
2. Neurons have three components.
 - The cell body is the primary site of protein synthesis.
 - Dendrites are short, branched cytoplasmic extensions of the cell body that usually conduct electrical signals toward the cell body.
 - An axon is a cytoplasmic extension of the cell body that transmits action potentials to other cells.

Types of Neurons

1. Multipolar neurons have several dendrites and a single axon. Interneurons and motor neurons are multipolar.
2. Bipolar neurons have a single axon and dendrite and are components of sensory organs.
3. Pseudo-unipolar neurons have a single axon. Most sensory neurons are pseudo-unipolar.

Glial Cells of the CNS

1. Glial cells are supportive cells that support and aid the neurons of the CNS and PNS.
2. Astrocytes provide structural support for neurons and blood vessels. Astrocytes influence the functioning of the blood-brain barrier and process substances that pass through it. Astrocytes isolate damaged tissue and limit the spread of inflammation. Astrocytes also help maintain synaptic function.
3. Ependymal cells line the ventricles and the central canal of the spinal cord. Some are specialized to produce cerebrospinal fluid.
4. Microglia phagocytize microorganisms, foreign substances, and necrotic tissue.
5. An oligodendrocyte forms myelin sheaths around the axons of several CNS neurons.

Glial Cells of the PNS

1. A Schwann cell forms a myelin sheath around part of the axon of a PNS neuron.
2. Satellite cells support and nourish neuron cell bodies within ganglia.

Myelinated and Unmyelinated Axons

1. Myelinated axons are wrapped by several layers of plasma membrane from Schwann cells (PNS) or oligodendrocytes (CNS). Spaces between the wrappings are the nodes of Ranvier. Myelinated axons conduct action potentials rapidly.
2. Unmyelinated axons rest in invaginations of Schwann cells (PNS) or oligodendrocytes (CNS). They conduct action potentials slowly.

11.4 Organization of Nervous Tissue (p. 374)

1. Nervous tissue can be grouped into white matter and gray matter.
 - White matter consists of myelinated axons; it propagates action potentials.
 - Gray matter consists of collections of neuron cell bodies or unmyelinated axons. Axons synapse with neuron cell bodies, which are functionally the site of integration in the nervous system.
2. White matter forms nerve tracts in the CNS and nerves in the PNS. Gray matter forms cortex and nuclei in the CNS and ganglia in the PNS.

11.5 Electrical Signals (p. 375)

Electrical properties of cells result from the ionic concentration differences across the plasma membrane and from the permeability characteristics of the plasma membrane.

Ionic Concentration Differences Across the Plasma Membrane

1. The sodium-potassium pump moves ions by active transport. Potassium is moved into the cell, and Na^+ is moved out of it.
2. The concentrations of K^+ and negatively charged proteins and other molecules are higher inside the cell, and the concentrations of Na^+ and Cl^- are higher outside the cell.
3. Negatively charged proteins and other negatively charged ions are synthesized inside the cell and cannot diffuse out of it; they repel negatively charged Cl^- .

Permeability Characteristics of the Plasma Membrane

1. The permeability of the plasma membrane to ions is determined by leak ion channels and gated ion channels.
 - Potassium ion leak channels are more numerous than Na^+ leak channels; thus, the plasma membrane is more permeable to K^+ than to Na^+ when at rest.
 - Gated ion channels in the plasma membrane include ligand-gated ion channels, voltage-gated ion channels, and other gated ion channels.

Establishing the Resting Membrane Potential

1. The resting membrane potential is a charge difference across the plasma membrane when the cell is in an unstimulated condition. The inside of the plasma membrane is negatively charged compared with the outside of the plasma membrane.
2. The resting membrane potential is due mainly to the tendency of positively charged K^+ to diffuse out of the cell, which is opposed by the negative charge that develops inside the plasma membrane.

Changing the Resting Membrane Potential

1. Depolarization, when the inside of the plasma membrane becomes more positive, can result from a decrease in the K^+ concentration gradient, a decrease in membrane permeability to K^+ , an increase in membrane permeability to Na^+ , an increase in membrane permeability to Ca^{2+} , or a decrease in extracellular Ca^{2+} concentration.
2. Hyperpolarization, when the inside of the plasma membrane becomes more negative, can result from an increase in the K^+ concentration gradient, an increase in membrane permeability to K^+ , an increase in membrane permeability to Cl^- , a decrease in membrane permeability to Na^+ , or an increase in extracellular Ca^{2+} concentration.

Effects of Abnormal Membrane Potentials

1. Hypokalemia is a lower-than-normal concentration of K^+ in the blood or extracellular fluid. This can cause hyperpolarization of the resting membrane potential. Causes include potassium depletion during starvation, alkalosis, and certain kidney diseases.
2. Hypocalcemia is a lower-than-normal concentration of Ca^{2+} in the blood or extracellular fluid. This can cause nervousness and uncontrolled contraction of skeletal muscles, called tetany. Causes include lack of dietary calcium or vitamin D and low parathyroid gland hormone.

Graded Potentials

1. A graded potential is a small change in the resting membrane potential that is confined to a small area of the plasma membrane.

2. An increase in membrane permeability to Na^+ can cause graded depolarization, and an increase in membrane permeability to K^+ or Cl^- can result in graded hyperpolarization.
3. The term *graded potential* is used because a stronger stimulus produces a greater potential change than a weaker stimulus.
4. Graded potentials can summate, or add together.
5. A graded potential decreases in magnitude as the distance from the stimulation increases.

Action Potentials

1. An action potential is a larger change in the resting membrane potential that spreads over the entire surface of the cell.
2. Threshold is the membrane potential at which a graded potential depolarizes the plasma membrane sufficiently to produce an action potential.
3. Action potentials occur in an all-or-none fashion. If action potentials occur, they are of the same magnitude, no matter how strong the stimulus.
4. Depolarization occurs as the inside of the membrane becomes more positive because Na^+ diffuses into the cell through voltage-gated ion channels.
5. Repolarization is a return of the membrane potential toward the resting state. It occurs because voltage-gated Na^+ channels close and Na^+ diffusion into the cell slows to resting levels and because voltage-gated K^+ channels continue to open and K^+ diffuses out of the cell.
6. The afterpotential is a brief period of hyperpolarization following repolarization.

Refractory Period

1. The absolute refractory period is the time during an action potential when a second stimulus, no matter how strong, cannot initiate another action potential.
2. The relative refractory period follows the absolute refractory period and is the time during which a stronger-than-threshold stimulus can evoke another action potential.

Action Potential Frequency

1. The strength of stimuli affects the frequency of action potentials.
 - A subthreshold stimulus produces only a graded potential.
 - A threshold stimulus causes a graded potential that reaches threshold and results in a single action potential.
 - A submaximal stimulus is greater than a threshold stimulus and weaker than a maximal stimulus. The action potential frequency increases as the strength of the submaximal stimulus increases.
 - A maximal or a supramaximal stimulus produces a maximum frequency of action potentials.
2. A low frequency of action potentials represents a weaker stimulus than a high frequency.

Propagation of Action Potentials

1. An action potential generates local currents, which stimulate voltage-gated Na^+ channels in adjacent regions of the plasma membrane to open, producing a new action potential.
2. In an unmyelinated axon, action potentials are generated immediately adjacent to previous action potentials.
3. In a myelinated axon, action potentials are generated at successive nodes of Ranvier.
4. Reversal of the direction of action potential propagation is prevented by the absolute refractory period.
5. Action potentials propagate most rapidly in myelinated, large-diameter axons.

11.6 The Synapse (p. 387)

Electrical Synapses

1. Electrical synapses are gap junctions in which tubular proteins called connexons allow local currents to move between cells.
2. At an electrical synapse, an action potential in one cell generates a local current that causes an action potential in an adjacent cell.

Chemical Synapses

1. Anatomically, a chemical synapse has three components.
 - The enlarged ends of the axon are the presynaptic terminals containing synaptic vesicles.
 - The postsynaptic membranes contain receptors for the neurotransmitter.
 - The synaptic cleft is a space separating the presynaptic and postsynaptic membranes.
2. An action potential arriving at the presynaptic terminal causes the release of a neurotransmitter, which diffuses across the synaptic cleft and binds to the receptors of the postsynaptic membrane.
3. The effect of the neurotransmitter on the postsynaptic membrane is stopped in several ways.
 - The neurotransmitter is broken down by an enzyme.
 - The neurotransmitter is taken up by the presynaptic terminal.
 - The neurotransmitter diffuses out of the synaptic cleft.
4. Neurotransmitters are specific for their receptors. A neurotransmitter can be stimulatory in one synapse and inhibitory in another, depending on the type of receptor present.
5. Neuromodulators influence the likelihood that an action potential in a presynaptic terminal will result in an action potential in the membrane of a postsynaptic cell.
6. An excitatory postsynaptic potential (EPSP) is a depolarizing graded potential of the postsynaptic membrane. It can be caused by an increase in membrane permeability to Na^+ .
7. An inhibitory postsynaptic potential (IPSP) is a hyperpolarizing graded potential of the postsynaptic membrane. It can be caused by an increase in membrane permeability to K^+ or Cl^- .
8. Presynaptic inhibition decreases neurotransmitter release. Presynaptic facilitation increases neurotransmitter release.

Spatial and Temporal Summation

1. Presynaptic action potentials through neurotransmitters produce graded potentials in postsynaptic neurons. The graded potential can summate to produce an action potential at the trigger zone.
2. Spatial summation occurs when two or more presynaptic terminals simultaneously stimulate a postsynaptic neuron.
3. Temporal summation occurs when two or more action potentials arrive in succession at a single presynaptic terminal.
4. Inhibitory and excitatory presynaptic neurons can converge on a postsynaptic neuron. The activity of the postsynaptic neuron is determined by the integration of the EPSPs and IPSPs produced in the postsynaptic neuron.

11.7 Neuronal Pathways and Circuits (p. 398)

1. Convergent pathways have many neurons synapsing with a few neurons.
2. Divergent pathways have a few neurons synapsing with many neurons.
3. Reverberating circuits have collateral branches of postsynaptic neurons synapsing with presynaptic neurons.
4. Parallel after-discharge circuits have neurons that stimulate several neurons arranged in parallel that stimulate a common output.

REVIEW AND COMPREHENSION

- The part of the nervous system that controls smooth muscle, cardiac muscle, and glands is the
 - somatic nervous system.
 - autonomic nervous system.
 - skeletal division.
 - sensory division.
- Motor neurons and interneurons are _____ neurons.
 - pseudo-unipolar
 - bipolar
 - multipolar
 - afferent
- Cells found in the choroid plexuses that secrete cerebrospinal fluid are
 - astrocytes.
 - microglia.
 - ependymal cells.
 - oligodendrocytes.
 - Schwann cells.
- Glial cells that are phagocytic within the central nervous system are
 - oligodendrocytes.
 - microglia.
 - ependymal cells.
 - astrocytes.
 - Schwann cells.
- Action potentials are conducted more rapidly
 - in small-diameter axons than in large-diameter axons.
 - in unmyelinated axons than in myelinated axons.
 - along axons that have nodes of Ranvier.
 - All of these are correct.
- Clusters of neuron cell bodies within the peripheral nervous system are
 - ganglia.
 - fascicles.
 - nuclei.
 - laminae.
- Gray matter contains primarily
 - myelinated fibers.
 - neuron cell bodies.
 - Schwann cells.
 - oligodendrocytes.
- Concerning concentration differences across the plasma membrane, there is
 - more K^+ and Na^+ outside the cell than inside.
 - more K^+ and Na^+ inside the cell than outside.
 - more K^+ outside the cell than inside and more Na^+ inside the cell than outside.
 - more K^+ inside the cell than outside and more Na^+ outside the cell than inside.
- Compared with the inside of the resting plasma membrane, the outside surface of the membrane is
 - positively charged.
 - electrically neutral.
 - negatively charged.
 - continuously reversing, so that it is positive one second and negative the next.
 - negatively charged whenever the sodium-potassium pump is operating.
- Leak ion channels
 - open in response to small voltage changes.
 - open when a chemical signal binds to its receptor.
 - are responsible for the ion permeability of the resting plasma membrane.
 - allow substances to move into the cell but not out.
 - All of these are correct.
- The resting membrane potential results when the tendency for _____ to diffuse out of the cell is balanced by its attraction to opposite charges inside the cell.
 - Na^+
 - K^+
 - Cl^-
 - negatively charged protein
- If the permeability of the plasma membrane to K^+ increases, the resting membrane potential difference _____. This is called _____.
 - increases, hyperpolarization
 - increases, depolarization
 - decreases, hyperpolarization
 - decreases, depolarization
- Decreasing the extracellular concentration of K^+ affects the resting membrane potential by causing
 - hyperpolarization.
 - depolarization.
 - no change.
- Which of these terms is correctly matched with its definition or description?
 - depolarization: membrane potential becomes more negative
 - hyperpolarization: membrane potential becomes more negative
 - hypopolarization: membrane potential becomes more negative
- Which of these statements about ion movement through the plasma membrane is true?
 - Movement of Na^+ out of the cell requires energy (ATP).
 - When Ca^{2+} binds to proteins in ion channels, the diffusion of Na^+ into the cell is inhibited.
 - Specific ion channels regulate the diffusion of Na^+ through the plasma membrane.
 - All of these are true.
- The *major* function of the sodium-potassium pump is to
 - pump Na^+ into and K^+ out of the cell.
 - generate the resting membrane potential.
 - maintain the concentration gradients of Na^+ and K^+ across the plasma membrane.
 - oppose any tendency of the cell to undergo hyperpolarization.
- Graded potentials
 - spread over the plasma membrane in decremental fashion.
 - are not propagated for long distances.
 - are confined to a small region of the plasma membrane.
 - can summate.
 - All of these are correct.
- During the depolarization phase of an action potential, the permeability of the membrane
 - to K^+ is greatly increased.
 - to Na^+ is greatly increased.
 - to Ca^{2+} is greatly increased.
 - is unchanged.
- During repolarization of the plasma membrane,
 - Na^+ diffuses into the cell.
 - Na^+ diffuses out of the cell.
 - K^+ diffuses into the cell.
 - K^+ diffuses out of the cell.
- The absolute refractory period
 - limits how many action potentials can be produced during a given period of time.

- b. prevents an action potential from starting another action potential at the same point on the plasma membrane.
 - c. is the period of time when a strong stimulus can initiate a second action potential.
 - d. Both a and b are correct.
 - e. All of these are correct.
21. A subthreshold stimulus
 - a. produces an afterpotential.
 - b. produces a graded potential.
 - c. causes an all-or-none response.
 - d. produces more action potentials than a submaximal stimulus.
 22. Neurotransmitter substances are stored in vesicles located in specialized portions of the

a. neuron cell body.	c. dendrite.
b. axon.	d. postsynaptic membrane.
 23. In a chemical synapse,
 - a. action potentials in the presynaptic terminal cause voltage-gated Ca^{2+} channels to open.
 - b. neurotransmitters can cause ligand-gated Na^+ channels to open.
 - c. neurotransmitters can be broken down by enzymes.
 - d. neurotransmitters can be taken up by the presynaptic terminal.
 - e. All of these are correct.
 24. An inhibitory presynaptic neuron can affect a postsynaptic neuron by
 - a. producing an IPSP in the postsynaptic neuron.
 - b. hyperpolarizing the plasma membrane of the postsynaptic neuron.
 - c. causing K^+ to diffuse out of the postsynaptic neuron.
 - d. causing Cl^- to diffuse into the postsynaptic neuron.
 - e. All of these are correct.
 25. Summation
 - a. is caused by combining two or more graded potentials.
 - b. occurs at the trigger zone of the postsynaptic neuron.
 - c. results in an action potential if it reaches the threshold potential.
 - d. can occur when two action potentials arrive in close succession at a single presynaptic terminal.
 - e. All of these are correct.
 26. In convergent pathways,
 - a. the response of the postsynaptic neuron depends on the summation of EPSPs and IPSPs.
 - b. a smaller number of presynaptic neurons synapse with a larger number of postsynaptic neurons.
 - c. information transmitted in one neuronal pathway can go into two or more pathways.
 - d. All of these are correct.

Answers in appendix E

CRITICAL THINKING

1. A child eats a whole bottle of salt (NaCl) tablets. What effect does this have on action potentials?
2. Some smooth muscle has the ability to contract spontaneously—that is, it contracts without any external stimulation. Propose an explanation for this ability based on what you know about membrane potentials. Assume that an action potential in a smooth muscle cell causes it to contract.
3. Assume that two nerve fibers have the same diameter, but one is myelinated and the other is unmyelinated. The conduction of an action potential is most energy-efficient along which type of fiber? (*Hint:* Think about the required ATP.)
4. Explain the consequences when an inhibitory neuromodulator is released from a presynaptic terminal and a stimulatory neurotransmitter is released from another presynaptic terminal, both of which synapse with the same neuron.
5. The speed of action potential propagation and synaptic transmission decreases with aging. List possible explanations.
6. Students in a veterinary school are given the following hypothetical problem: A dog ingests organophosphate poison, and the students are responsible for saving the animal's life. Organophosphate poisons bind to and inhibit acetylcholinesterase. Several substances the students could inject include the following: acetylcholine, curare (which blocks acetylcholine receptors), and potassium chloride. If you were a student in the class, what would you advise to save the animal?
7. Strychnine blocks receptor sites for inhibitory neurotransmitter substances in the CNS. Explain how strychnine can produce tetanus in skeletal muscles.
8. Alcohol affects the central nervous system by enhancing the effect of GABA at its receptor. GABA binds to GABA receptors and opens ligand-gated Cl^- channels. However, chronic consumption of alcohol makes the GABA receptor less sensitive to both alcohol and GABA, which increases alcohol dependence as well as alcohol withdrawal symptoms, such as anxiety, tremors, and insomnia. Benzodiazepines enhance the binding of GABA molecules to their receptors and thus are sometimes used to treat people with alcohol withdrawal symptoms. For synapses involving GABA, predict the effect of alcohol on the postsynaptic membranes; compare the effect of chronic alcohol consumption on the postsynaptic membranes in these synapses; and predict the effect of benzodiazepine treatment on the degree of polarization of postsynaptic membranes in people who are experiencing alcohol withdrawal symptoms.
9. The venom of many cobras contains a potent neurotoxin that binds to ligand-gated Na^+ channels, causing them to open. Unlike ACh, which binds to and then rapidly unbinds from ligand-gated Na^+ channels, the neurotoxin tends to remain bound to ligand-gated Na^+ channels. How does this neurotoxin affect the nervous system's ability to stimulate skeletal muscle contraction? How does it affect the ability of skeletal muscle fibers to respond to stimulation?
10. Epilepsy is a chronic disorder characterized by seizures that result when neurons in the brain produce excessive action potentials. Channelopathies are genetic disorders caused by mutations in ion channel genes, which result in ion channels that do not function normally. What kind of Na^+ or Ca^{2+} channelopathies might contribute to epilepsy?

Learn to Predict

How many times had Javier told his kids not to leave their toys lying around on the floor? While walking down a dark hallway in the middle of the night, Javier stepped on a tiny race car with his right foot. He immediately withdrew his foot from the painful stimulus but then stepped on a second car with his left foot. Fortunately, he was able to shift his weight back to his other foot, therefore preventing a fall. **After reading this chapter and using your knowledge of nervous system organization from chapter 11, explain the spinal reflexes that kept Javier on his feet.**

Module 07
Nervous System

Spinal Cord and Spinal Nerves

Each year, over 10,000 people, usually males in their late teens and twenties, suffer spinal cord injuries. As we learn more about the spinal cord, there is growing hope for improved therapies for these injuries. The spinal cord and the associated spinal nerves play a central role in communication between the brain and the rest of the body.

Before focusing on the functions of the spinal cord and spinal nerves, it is important to understand their relationship to the nervous system as a whole. Recall from chapter 11 that the central nervous system (CNS) consists of the brain and spinal cord, whereas the peripheral nervous system (PNS) consists of the nerves and ganglia outside the CNS. The PNS includes 12 pairs of cranial nerves and 31 pairs of spinal nerves and their ganglia. The spinal cord is part of the CNS, and the spinal nerves are part of the PNS, so in this chapter we begin to see how the two systems work together. The PNS collects information from numerous sources, both inside and outside the body, and relays it through axons of sensory neurons to the CNS. The CNS receives this sensory information, integrates and evaluates the information, stores some information, and initiates reactions. Axons of motor neurons in the PNS relay information from the CNS to various parts of the body, primarily to muscles and glands, thereby regulating activity in those structures.

The spinal cord and spinal nerves are described in this chapter. The brain and cranial nerves are covered in chapter 13.

Posterior view

FIGURE 12.1 Spinal Cord and Spinal Nerve Roots 

12.1 Spinal Cord

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the general structure of the spinal cord.**
- B. Name the meninges (sing. meninx) and their related spaces surrounding the spinal cord.**
- C. Draw and label a cross section of the spinal cord with its dorsal and ventral nerve roots.**

The **spinal cord** is the major communication link between the brain and the PNS inferior to the head. It integrates incoming information and produces responses through reflex mechanisms.

General Structure

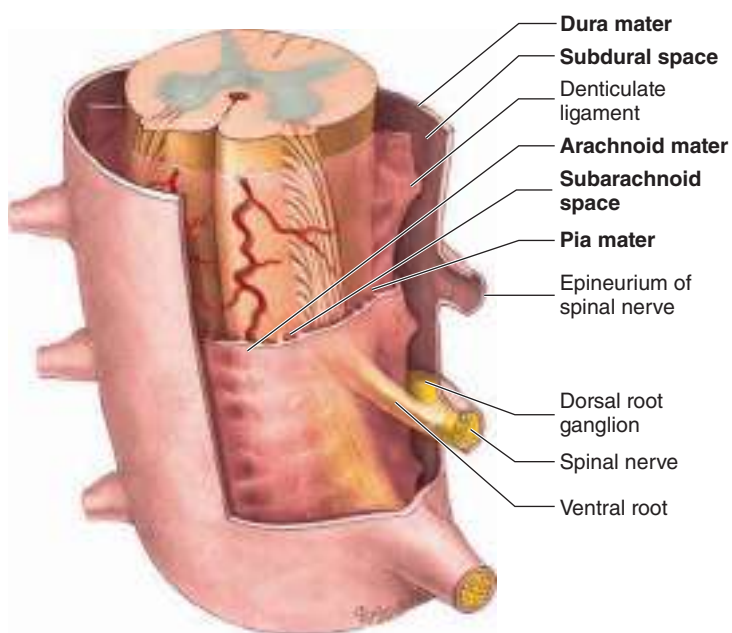

The spinal cord extends from the brain at the level of the foramen magnum down to the level of the second lumbar vertebra (figure 12.1). It is considerably shorter than the vertebral column because it does not grow as rapidly during development. The spinal cord is composed of cervical, thoracic, lumbar, and sacral segments, named according to the portion of the vertebral column from which their nerves enter and exit. The spinal cord gives rise to 31 pairs of **spinal nerves**, which exit the vertebral column through intervertebral and sacral foramina (see figure 7.13). Each spinal nerve is a bundle of axons, Schwann cells, and connective tissue sheaths. The nerves from the lower segments descend some distance in the vertebral canal before they exit because the spinal cord is shorter than the vertebral column.

The spinal cord is larger in diameter at its superior end, and it gradually decreases in diameter toward its inferior end. Two enlargements occur where nerves supplying the upper and lower limbs enter and leave the spinal cord. The **cervical enlargement** in the inferior cervical region corresponds to the location where nerve fibers that supply the upper limbs enter and leave the spinal cord (figure 12.1). The **lumbo-sacral enlargement** in the inferior thoracic, lumbar, and superior sacral regions is the site where the nerve fibers supplying the lower limbs enter or leave the spinal cord.

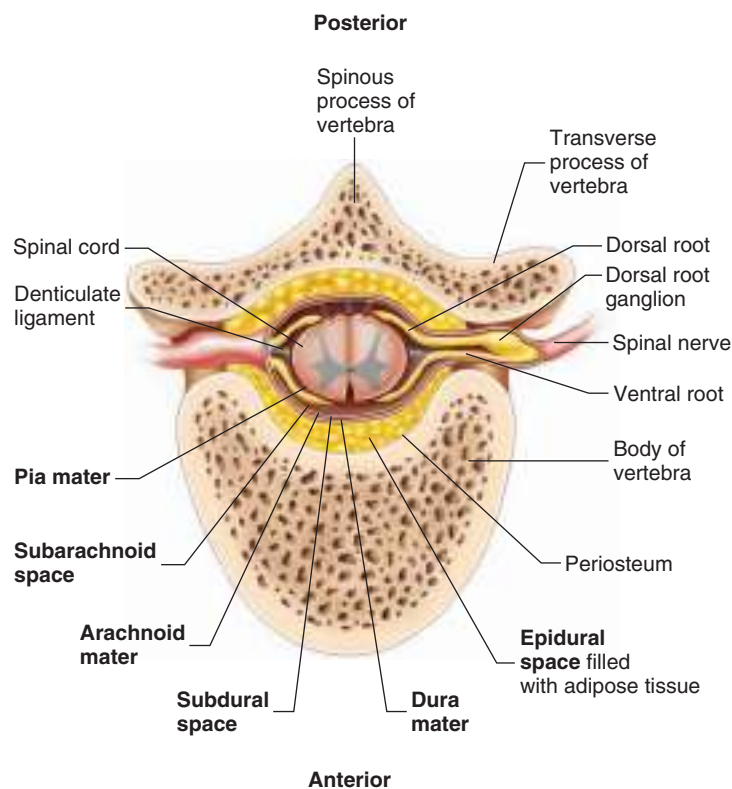

Immediately inferior to the lumbo-sacral enlargement, the spinal cord tapers to form a conelike region called the **conus medullaris** (figure 12.1). Its tip is the inferior end of the spinal cord and extends to the level of the second lumbar vertebra. The nerves supplying the lower limbs and other inferior structures of the body arise from the lumbar and sacral regions. They exit the lumbo-sacral enlargement and conus medullaris, course inferiorly through the vertebral canal, and exit through the intervertebral and sacral foramina from the second lumbar to the fifth sacral vertebrae. The numerous roots (origins) of spinal nerves extending inferiorly from the lumbo-sacral enlargement and conus medullaris resemble a horse's tail and are therefore called the **cauda** (kaw'dā; tail) **equina** (ē-kwī'nā; horse; figure 12.1).

Meninges of the Spinal Cord

The **meninges** (mě-nin'jēz) are connective tissue membranes that surround the spinal cord and brain (figure 12.2). The most superficial and thickest membrane is the **dura mater** (doo'rā mā'ter; tough mother). The dura mater forms a sac, often called the **thecal** (the'kal) **sac**, which surrounds the spinal cord. The thecal sac attaches to the rim of the foramen magnum and ends at the level of the second sacral vertebra. The spinal dura mater is continuous with the dura mater surrounding the brain and the connective tissue surrounding the spinal nerves. The dura mater around the spinal cord is separated from the periosteum of the vertebral canal by the **epidural space**. This is a true space between the walls of the vertebral canal and the dura mater of the spinal cord that contains spinal nerve roots, blood vessels, areolar connective tissue, and adipose tissue.

(a) Anterolateral view

(b) Superior view

FIGURE 12.2 Meningeal Membranes Surrounding the Spinal Cord **APR**

In contrast, the epidural space around the brain is only a potential space. **Epidural anesthesia** of the spinal nerves is often induced in women during childbirth by injecting anesthetics into the epidural space of the spinal cord.

The next deepest meningeal membrane is a very thin, wispy **arachnoid** (ă-rak'noyd; spiderlike—i.e., cobwebs) **mater**. The space between this membrane and the dura mater is the **subdural space**; it contains only a very small amount of serous fluid.

The third, deepest meningeal layer, the **pia** (pī'ă; affectionate) **mater** is bound very tightly to the surface of the spinal cord. Holding the spinal cord in place within the thecal sac are the denticulate ligaments and the filum terminale. The paired **denticulate** (den-tik'ū-lăt) **ligaments** are connective tissue septa extending from the lateral sides of the spinal cord to the dura mater (figure 12.2b). The term *denticulate* refers to having small teeth, and the denticulate ligaments attach to the dura mater by toothlike processes between the exits of the cervical and thoracic spinal nerves. The denticulate ligaments limit the lateral movement of the spinal cord. The **filum terminale** (fī'lūm ter'mi-nal'ē) is a connective tissue strand that anchors the conus medullaris and the thecal sac to the first coccygeal vertebra, limiting their superior movement.

Between the arachnoid mater and the pia mater is the **subarachnoid space**, which contains weblike strands of the arachnoid mater, blood vessels, and **cerebrospinal** (ser'ē-brō-spī-nāl, sē-rē'brō-spī-nal) **fluid (CSF)**, which is described in chapter 13.

Clinical IMPACT

Introduction of Needles into the Subarachnoid Space

Several clinical procedures involve inserting a needle into the subarachnoid space at either the L3/L4 or L4/L5 level. The needle does not puncture the spinal cord because the cord extends only approximately to the second lumbar vertebra of the vertebral column, but the subarachnoid space extends to level S2 of the vertebral column. Nor does the needle damage the nerve roots of the cauda equina located in the subarachnoid space because the needle quite easily pushes them aside. In **spinal anesthesia**, or spinal block, drugs that block action potential transmission are introduced into the subarachnoid space to prevent pain sensations in the lower half of the body. There are advantages and disadvantages to spinal versus epidural anesthesia. In spinal anesthesia, the drugs are delivered directly to the CSF, so the anesthesia is generally stronger and takes effect faster than epidural anesthesia. With epidural anesthesia, the needle does not penetrate the dura mater, so the drugs must first diffuse into the CSF. However, an advantage is that the drugs can be readministered via a catheter (flexible tube) to maintain longer anesthesia. In some instances, a combination of spinal and epidural anesthesia is used. In a **lumbar puncture**, or *spinal tap*, CSF is removed from the subarachnoid space in order to examine it for infectious agents (meningitis) or for the presence of blood (hemorrhage) or to measure the CSF pressure. Sometimes clinicians inject a radiopaque substance into this area and take a **myelogram** (radiograph of the spinal cord) to visualize spinal cord defects or damage.

FUNDAMENTAL Figure

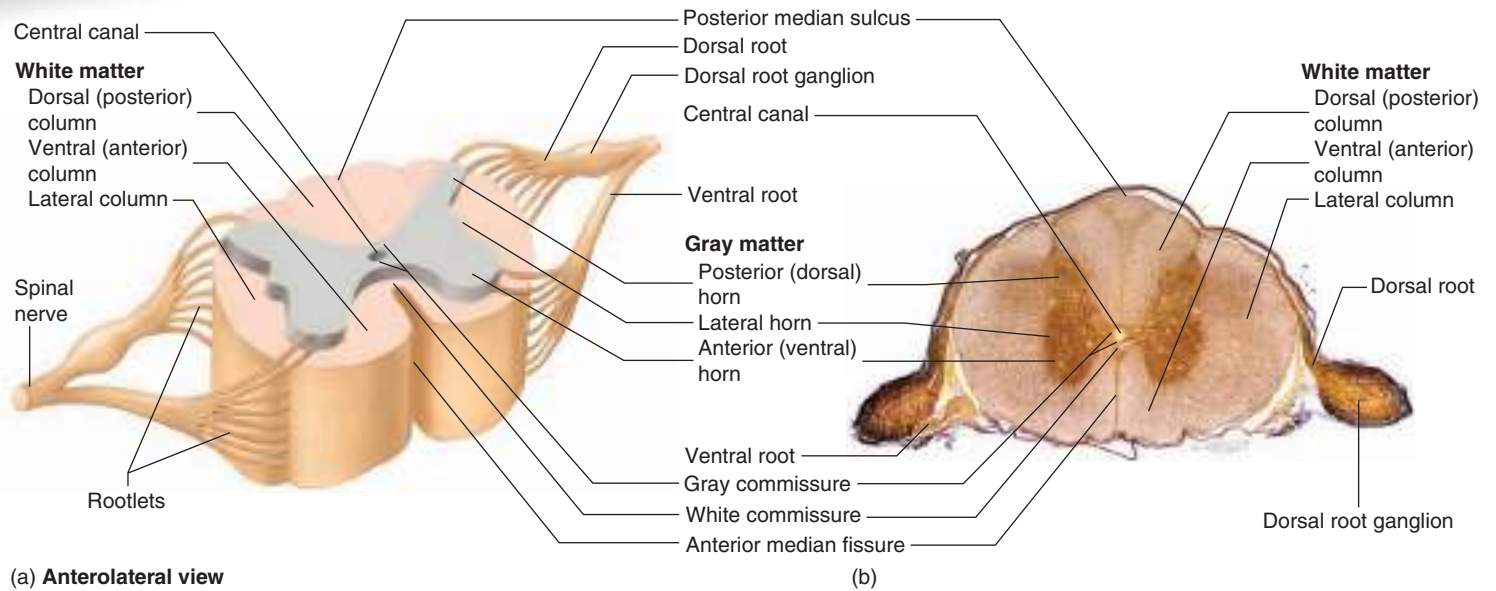

FIGURE 12.3 Cross Section of the Spinal Cord

(a) A segment of the spinal cord showing one dorsal and one ventral root on each side and the rootlets that form them. (b) Photograph of a cross section through the midlumbar region. The *lighter tan areas* are white matter, where myelinated tracts are located. The *darker area* is gray matter, where neuron cell bodies are located. (c) Ascending and descending tracts in the spinal cord. Ascending nerve tracts are *green*; descending nerve tracts are *purple*. The arrows indicate the direction of action potential propagation in each pathway. **AP R**

Cross Section of the Spinal Cord

A cross section reveals that the spinal cord consists of a superficial, white portion and a deep, gray portion (figure 12.3a,b). The white matter consists of myelinated axons, which form nerve tracts, and the gray matter consists of neuron cell bodies, dendrites, and axons. An **anterior median fissure** and a **posterior median sulcus** are deep clefts partially separating the two halves of the cord. The white matter in each half of the spinal cord is organized into three **columns**, or *funiculi* (fū-nik'ū-lī), called the **ventral** (anterior), **dorsal** (posterior), and **lateral columns**. Each column of the spinal cord is subdivided into **tracts**, or *fascicles*, also referred to as *pathways*. A collection of axons *inside* the CNS is called a tract, whereas *outside* the CNS it is called a *nerve*. Tracts have different myelination than nerves and lack the extensive connective tissue of nerves. Individual

axons ascending to the brain or descending from the brain are usually grouped together within the tracts (figure 12.3c). Axons within a given tract carry basically the same type of information, although they may overlap to some extent. For example, one ascending tract carries action potentials related to pain and temperature sensations, whereas another carries action potentials related to light touch.

The central gray matter is organized into horns. Each half of the central gray matter of the spinal cord consists of a relatively thin **posterior** (dorsal) **horn** and a larger **anterior** (ventral) **horn**. Small **lateral horns** exist in the levels of the cord associated with the autonomic nervous system (see chapter 16). The two halves of the spinal cord are connected by structures called the **gray** and **white commissures** (figure 12.3a,b). The gray and white commissures contain axons that cross from one side of the spinal cord to

FIGURE 12.4 Relationship of Sensory and Motor Neurons to the Spinal Cord

the other. The **central canal**, located in the center of the gray commissure, helps circulate CSF associated with the ventricular system (see chapter 13).

Spinal nerves arise from numerous rootlets along the dorsal and ventral surfaces of the spinal cord (figure 12.3a). Six to eight of these rootlets combine to form a **ventral root** on the ventral (anterior) side of the spinal cord, and another six to eight form a **dorsal root** on the dorsal (posterior) side of the cord at each segment. The ventral and dorsal roots extend laterally from the spinal cord, passing through the subarachnoid space, piercing the arachnoid mater and dura mater, and joining one another to form a spinal nerve.

The dorsal roots contain axons of sensory neurons. Sensory neuron cell bodies are contained within the **dorsal root ganglion**, or *spinal ganglion* (gang'glē-on; a swelling or knot; figure 12.4). The axons of these pseudo-unipolar sensory neurons extend from various parts of the body and pass through spinal nerves to the dorsal root ganglia. The axons do not synapse in the dorsal root ganglion but pass through the dorsal root into the posterior horn of the spinal cord gray matter. The axons either synapse with interneurons in the posterior horn or pass into the white matter and ascend or descend in the spinal cord.

The ventral roots contain the axons of motor neurons. Motor neurons innervate muscles and glands. Unlike the sensory neurons, the cell bodies of the motor neurons are located in the spinal cord gray matter (figure 12.4). The cell bodies of multipolar somatic motor neurons are in the anterior horn, also called the motor horn. Autonomic motor neuron cell bodies are in the lateral horn. Axons of the motor neurons form the ventral roots and pass into the spinal nerves. Thus, dorsal roots contain sensory axons, ventral roots contain motor axons, and spinal nerves have both sensory and motor axons.

Predict 2

Explain why the dorsal root ganglia are larger in diameter than the dorsal roots, and describe the direction of action potential propagation in the spinal nerves, dorsal roots, and ventral roots.

ASSESS YOUR PROGRESS

1. Where does the spinal cord begin and end? How many pairs of spinal nerves exit the spinal cord?
2. Name the meninges surrounding the spinal cord. What is found within each of these spaces: the epidural space, the subdural space, and the subarachnoid space?
3. What is the thecal sac? What two structures hold the thecal sac in the vertebral canal?
4. Describe the arrangement of gray and white matter in the spinal cord. What are the divisions of the gray matter and white matter? What are commissures?
5. Where are the cell bodies of somatic motor and autonomic motor neurons located in the gray matter?
6. What kinds of neurons are in the dorsal roots, in the ventral roots, and in the spinal nerves? What is found in the dorsal root ganglion?

12.2 Reflexes

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the components of a monosynaptic and a polysynaptic reflex arc.
- B. Compare and contrast the features of a stretch reflex, a Golgi tendon reflex, a withdrawal reflex, and a crossed extensor reflex.

The basic *structural unit* of the nervous system is the **neuron** (see section 11.3). The basic *functional unit* of the nervous system is the **reflex arc** because it is the smallest, simplest portion capable of receiving a stimulus and producing a response. Therefore, it is possible to learn much about nervous system functions by examining how reflex arcs receive stimuli and produce responses. The reflex arc generally has five basic components: (1) a sensory receptor, (2) a sensory neuron, (3) an interneuron, (4) a motor neuron, and (5) an effector organ (figure 12.5). The simplest reflex arcs do not involve interneurons.

FUNDAMENTAL Figure

- 1 A sensory receptor detects a stimulus.
- 2 A sensory neuron conducts action potentials through the nerve and dorsal root to the spinal cord.
- 3 In the spinal cord, the sensory neuron synapses with an interneuron. (An interneuron is not involved in a monosynaptic reflex arc.)
- 4 The interneuron synapses with a motor neuron.
- 5 A motor neuron axon conducts action potentials through the ventral root and spinal nerve to an effector organ.

PROCESS FIGURE 12.5 Reflex Arc

The parts of a reflex arc are labeled in the order in which action potentials pass through them. A polysynaptic reflex arc containing an interneuron is shown. **APR**

A **reflex** is an automatic response to a stimulus produced by a reflex arc. That means it occurs without conscious thought. Action potentials initiated in sensory receptors are transmitted along the axons of sensory neurons to the CNS, where the axons usually synapse with interneurons. Interneurons synapse with motor neurons, which send axons out of the spinal cord and through the PNS to muscles or glands, where the action potentials of the motor neurons cause these effector organs to respond.

Reflexes are homeostatic. For example, a number of reflexes, called autonomic reflexes, are responsible for maintaining relatively constant blood pressure, blood carbon dioxide levels, and water intake. Other reflexes, called somatic reflexes, remove the body from painful stimuli that would cause tissue damage or keep the body from suddenly falling or moving because of external forces.

Individual reflexes vary in complexity. **Monosynaptic reflexes** involve simple neuronal pathways in which sensory neurons synapse directly with motor neurons. **Polysynaptic reflexes** involve more complex pathways involving multiple synapses with interneurons between the sensory and motor neurons (figure 12.5).

Many reflexes are integrated within the spinal cord, and others are integrated within the brain. Some reflexes involve excitatory neurons and result in a response, as when a muscle contracts (see chapter 11). Other reflexes involve inhibitory neurons and result in the inhibition of a response, as when a muscle relaxes. In addition, higher brain centers influence

reflexes by either suppressing or exaggerating them. The subsequent discussion describes three major spinal cord reflexes: the stretch reflex, the Golgi tendon reflex, and the withdrawal reflex.

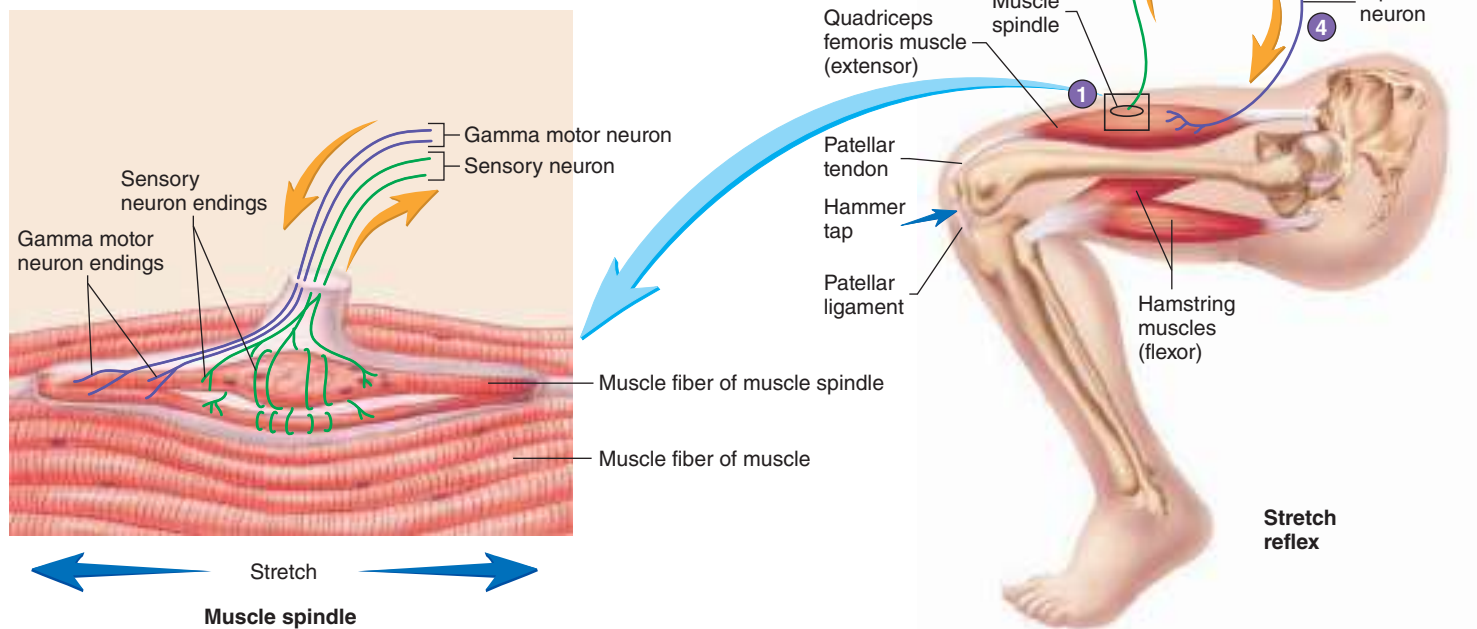

Stretch Reflex

The simplest reflex is the **stretch reflex** (figure 12.6). The stretch reflex occurs when muscles contract in response to a stretching force. The classic example of a stretch reflex is the **knee-jerk reflex**, or **patellar reflex**, that happens when a clinician taps the patellar ligament. When the patellar ligament is tapped, the tendons and muscles of the quadriceps femoris muscle group stretch. Sensory receptors within the muscles stretch, which activates the stretch reflex, leading to the characteristic knee-jerk response. The sensory receptor of this reflex is the **muscle spindle**, which consists of 3–10 small, specialized skeletal muscle fibers that are contractile only at their ends. Sensory neurons innervate the non-contractile centers of the muscle spindle cells. Axons of these sensory neurons extend to the spinal cord, where they synapse directly with **alpha motor neurons**. Alpha motor neurons then innervate the muscle in which the muscle spindle is embedded. The stretch reflex is a monosynaptic reflex because there is no interneuron between the sensory neuron and the alpha motor neuron.

Thus, stretching a muscle stretches muscle spindles located among the muscle fibers. This stretch stimulates the sensory neurons that innervate the center of each of the muscle spindles.

Sudden stretch of a muscle results in:

- 1 Muscle spindles detect stretch of the muscle.
 - 2 Sensory neurons conduct action potentials to the spinal cord.
 - 3 Sensory neurons synapse directly with alpha motor neurons.
 - 4 Alpha motor neurons conduct action potentials to the muscle, causing it to contract and resist being stretched.
- Note: The muscle that contracts is the muscle that is stretched.

PROCESS FIGURE 12.6 Stretch Reflex

The increased frequency of action potentials carried to the spinal cord by sensory neurons stimulates the alpha motor neurons in the spinal cord. The alpha motor neurons transmit action potentials to skeletal muscle, causing a rapid contraction of the stretched muscle, which opposes the stretch of the muscle. The postural muscles demonstrate the adaptive nature of this reflex. If a person is standing upright and then begins to tip slightly to one side, the postural muscles associated with the vertebral column on the other side are stretched. As a result, stretch reflexes are initiated in those muscles, which cause them to contract and reestablish normal posture.

Collateral axons from the sensory neurons of the muscle spindles also synapse with neurons whose axons contribute to ascending nerve tracts, which enable the brain to perceive that a muscle has been stretched (see figure 12.3c). Descending neurons within the spinal cord synapse with the neurons of the stretch reflex modifying their activity. This activity is important in maintaining posture and in coordinating muscle actions.

In addition to the alpha motor neurons, **gamma motor neurons** innervate the ends of the muscle spindles. The term *gamma* refers to the small-diameter axons of these neurons compared to the large-diameter axons of alpha motor neurons. The gamma motor

neurons originate in the spinal cord and control the sensitivity of the muscle spindle cells. As a skeletal muscle contracts, the tension on the centers of muscle spindles within the muscle decreases because the muscle spindles passively shorten as the muscle shortens. The decrease in tension in the centers of the muscle spindles causes them to be less sensitive to stretch. Sensitivity is maintained because, while alpha motor neurons are stimulating the muscle to contract, gamma motor neurons are stimulating the muscle spindles to contract. The contraction of the muscle fibers at the ends of the muscle spindles pulls on the center part of the muscle spindles and maintains the proper tension. The activity of the muscle spindles helps control posture, muscle tension, and muscle length.

Clinicians use the knee-jerk stretch reflex to determine whether the higher CNS centers that normally influence this reflex are functional. A greatly exaggerated stretch reflex indicates that the neurons within the brain that innervate the gamma motor neurons and enhance the stretch reflex are overly active. On the other hand, if the neurons that innervate the gamma motor neurons are depressed, the stretch reflex may be suppressed or absent. Absence of the stretch reflex may also indicate that the reflex pathway is not intact.

Intense stretch of a skeletal muscle results in:

- 1 Golgi tendon organs detect tension applied to a tendon.
- 2 Sensory neurons conduct action potentials to the spinal cord.
- 3 Sensory neurons synapse with inhibitory interneurons that synapse with alpha motor neurons.
- 4 Inhibition of the alpha motor neurons causes muscle relaxation, relieving the tension applied to the tendon. *Note:* The muscle that relaxes is attached to the tendon to which tension is applied.

Golgi tendon organ

PROCESS FIGURE 12.7 Golgi Tendon Reflex

Golgi Tendon Reflex

The **Golgi tendon reflex** prevents contracting muscles from applying excessive tension to tendons. **Golgi tendon organs** are encapsulated nerve endings that have at their ends numerous branches with small swellings adjacent to bundles of collagen fibers in tendons. Golgi tendon organs are located near the muscle-tendon junction (figure 12.7). As a muscle contracts, the attached tendons stretch, resulting in increased tension in the tendon. The increased tension stimulates action potentials in the sensory neurons from the Golgi tendon organs. Golgi tendon organs have a high threshold and are sensitive only to intense stretch.

The sensory neurons of the Golgi tendon organs pass through the dorsal root to the spinal cord and enter the posterior gray matter, where they branch and synapse with inhibitory interneurons. The interneurons synapse with alpha motor neurons that innervate the muscle to which the Golgi tendon organ is attached. Applying a great amount of tension to the tendon stimulates the sensory neurons of the Golgi tendon organs. The key feature of the Golgi tendon reflex is that the sensory neurons stimulate the interneurons to release *inhibitory* neurotransmitters that inhibit the alpha motor neurons of the associated muscle and cause it to relax. The sudden relaxation of the muscle reduces the tension applied to the muscle and tendons. This reflex protects muscles and tendons from damage

caused by excessive tension. For example, a weight lifter who suddenly drops a heavy weight after straining to lift it does so, in part, because of the effect of the Golgi tendon reflex.

The muscles and tendons of the legs sustain tremendous amounts of tension, particularly in athletes. Frequently, an athlete's Golgi tendon reflex is inadequate to protect muscles and tendons from excessive tension. For example, the large muscles and sudden movements of football players and sprinters can make them vulnerable to relatively frequent hamstring pulls and calcaneal (Achilles) tendon injuries.

Withdrawal Reflex

The function of the **withdrawal reflex**, or *flexor reflex*, is to remove a limb or another body part from a painful stimulus. The sensory receptors are pain receptors (see chapter 14). Following painful stimuli, sensory neurons conduct action potentials through the dorsal root to the spinal cord, where the sensory neurons synapse with excitatory interneurons, which in turn synapse with alpha motor neurons (figure 12.8). The alpha motor neurons stimulate muscles, usually flexor muscles, that remove the limb from the source of the painful stimulus. Collateral branches of the sensory neurons synapse with ascending fibers to the brain, providing conscious awareness of the painful stimuli.

Stimulation of pain receptors results in:

- 1 Pain receptors detect a painful stimulus.
- 2 Sensory neurons conduct action potentials to the spinal cord.
- 3 Sensory neurons synapse with excitatory interneurons that synapse with alpha motor neurons.
- 4 Excitation of the alpha motor neurons results in contraction of the flexor muscles and withdrawal of the limb from the painful stimulus.

Withdrawal reflex

PROCESS FIGURE 12.8 Withdrawal Reflex

Reciprocal innervation

- 1 During the withdrawal reflex, sensory neurons conduct action potentials from pain receptors to the spinal cord.
- 2 Sensory neurons synapse with excitatory interneurons that are part of the withdrawal reflex.
- 3 Collateral branches of the sensory neurons also synapse with inhibitory interneurons that are part of reciprocal innervation.
- 4 The inhibitory interneurons synapse with alpha motor neurons supplying the extensor muscles. The reduced stimulation (indicated by dashed line) causes them to relax and not oppose the flexor muscles of the withdrawal reflex, which are contracting.

Withdrawal reflex

PROCESS FIGURE 12.9 Withdrawal Reflex with Reciprocal Innervation

Reciprocal Innervation

Reciprocal innervation is a phenomenon that allows opposing muscles to reinforce the efficiency of the withdrawal reflex (figure 12.9). Reciprocal innervation allows the coordinated contraction of flexor muscles and relaxation of the opposing extensor muscles.

Collateral axons of sensory neurons that carry action potentials from pain receptors synapse with inhibitory interneurons in the dorsal horn of the spinal cord. The inhibitory interneurons synapse with and inhibit alpha motor neurons of extensor (antagonist) muscles. When the withdrawal reflex is initiated, flexor muscles

contract and reciprocal innervation causes the extensor muscles to relax. This reduces the resistance to movement that the extensor muscles would otherwise generate.

Reciprocal innervation is also involved in the stretch reflex. When the stretch reflex causes a muscle to contract, reciprocal innervation causes opposing muscles to relax. In the patellar reflex, for example, the quadriceps femoris muscle contracts and the hamstring muscles relax.

Crossed Extensor Reflex

The **crossed extensor reflex** is another reflex associated with the withdrawal reflex (figure 12.10). The crossed extensor reflex occurs on the opposite side of the body from the stimulus. When the withdrawal reflex occurs in one limb, the crossed extensor reflex causes the opposite response to occur in the other limb. This mechanism is possible because the interneurons that stimulate alpha motor neurons to cause withdrawal of a limb also have collateral axons that

extend through the white commissure to the opposite side of the spinal cord. These interneurons synapse with alpha motor neurons that innervate extensor muscles in the opposite side of the body. When a withdrawal reflex is initiated in one lower limb, the crossed extensor reflex causes extension of the opposite lower limb.

The crossed extensor reflex is adaptive in that it helps prevent falls by shifting the weight of the body from the affected to the unaffected limb. For example, when you step on a sharp object with your right foot, you withdraw your right lower limb from the stimulus (withdrawal reflex) while extending your left lower limb (crossed extensor reflex). Therefore, your body weight shifts from the right to the left lower limb. Initiating a withdrawal reflex in both legs at the same time would cause you to fall.

Interactions with Spinal Cord Reflexes

Reflexes do not operate as isolated entities. Rather, because of divergent and convergent pathways (see chapter 11), their activities are integrated with the functions of the nervous system as a whole. Diverging branches of the sensory neurons or interneurons in a reflex arc send action potentials along ascending nerve tracts to the brain (figure 12.11). A pain stimulus, for example, not only initiates a withdrawal reflex, causing you to remove the affected body part from the painful stimulus, but also enables you to perceive the pain as a result of action potentials sent to your brain.

Axons within descending tracts from the brain carry action potentials to motor neurons in the anterior horn of the spinal cord,

Crossed extensor reflex

- 1 During the withdrawal reflex, sensory neurons from pain receptors conduct action potentials to the spinal cord.
- 2 Sensory neurons synapse with excitatory interneurons that are part of the withdrawal reflex.
- 3 The excitatory interneurons that are part of the withdrawal reflex stimulate alpha motor neurons that innervate flexor muscles, causing withdrawal of the limb from the painful stimulus.
- 4 Collateral branches of the sensory neurons also synapse with excitatory interneurons that cross to the opposite side of the spinal cord as part of the crossed extensor reflex.
- 5 The excitatory interneurons that cross the spinal cord stimulate alpha motor neurons supplying extensor muscles in the opposite limb, causing them to contract and support body weight during the withdrawal reflex.

PROCESS FIGURE 12.10 Withdrawal Reflex with Crossed Extensor Reflex

FIGURE 12.11 Spinal Reflex, with Ascending and Descending Axons

A diverging branch of a sensory neuron synapses with a neuron that extends to the brain in an ascending tract (green). An axon from the brain extends to the spinal cord in a descending tract (purple) and synapses with an interneuron, influencing its action on the motor neuron.

converging with neurons of reflex arcs. The neurotransmitters released from the axons of these tracts either stimulate or inhibit the motor neurons in the anterior horn. Neurotransmitters change the sensitivity of the reflex by stimulating (EPSP) or inhibiting (IPSP) the motor neurons (see chapter 11).

ASSESS YOUR PROGRESS

- Name the parts of a monosynaptic and of a polysynaptic reflex arc. What is a reflex? Explain how reflexes are homeostatic.
- Describe the operation of a gamma motor neuron.
- Contrast and give the functions of a stretch reflex and a Golgi tendon reflex. Describe the sensory receptors for each.
- What is a withdrawal reflex? How do reciprocal innervation and the crossed extensor reflex assist the withdrawal reflex?
- How do ascending and descending pathways relate to reflexes and other neuron functions?

12.3 Spinal Nerves

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the connective tissue components of a nerve.
- List the number and locations of the 31 pairs of spinal nerves.

- Describe a dermatome and its clinical importance.
- Explain the branching of the spinal nerves into rami and plexuses.
- List the major nerves that exit each plexus and the body region they innervate.

Structure of Nerves

Nerves of the PNS, including spinal nerves, consist of axons, Schwann cells, and connective tissue (figure 12.12). There are three layers of connective tissue. Each axon, or nerve fiber, and its Schwann cell sheath are surrounded by a delicate connective tissue layer, the **endoneurium** (en-dō-noo'rē-ŭm). A heavier connective tissue layer, the **perineurium** (per-i-noo'rē-ŭm), surrounds groups of axons to form nerve **fascicles** (fas'i-klz). A third layer of dense connective tissue, the **epineurium** (ep-i-noo'rē-ŭm), binds the nerve fascicles together to form a nerve. The connective tissue of the epineurium is continuous with the dura mater surrounding the CNS. The connective tissue layers of nerves make them tougher than the tracts in the CNS.

Organization of Spinal Nerves

All of the 31 pairs of spinal nerves, except the first pair and those in the sacrum, exit the vertebral column through intervertebral foramina located between adjacent vertebrae (see figure 7.13). The first pair of spinal nerves exit between the skull and the first cervical vertebra. The nerves of the sacrum exit from the single

FIGURE 12.12 Structure of a Nerve

A nerve consists of axons surrounded by various layers of connective tissue: Epineurium surrounds the whole nerve, perineurium surrounds nerve fascicles, and endoneurium surrounds Schwann cells and axons. Loose connective tissue also surrounds the nerve fascicles.

bone of the sacrum through the sacral foramina (see chapter 7). Eight spinal nerve pairs exit the vertebral column in the cervical region, 12 in the thoracic region, 5 in the lumbar region, 5 in the sacral region, and 1 in the coccygeal region (figure 12.13). For convenience, each of the spinal nerves is designated by a letter and a number. The letter indicates the region of the vertebral column from which the nerve emerges: **C**, cervical; **T**, thoracic; **L**, lumbar; and **S**, sacral. The single coccygeal nerve is often not designated, but when it is the symbol **Co** is usually used. The number indicates the location in each region where the nerve emerges from the vertebral column, with the smallest number always representing the most superior origin. For example, the most superior nerve exiting the thoracic region of the vertebral column is designated T1. The cervical nerves are designated C1–C8, the thoracic nerves T1–T12, the lumbar nerves L1–L5, and the sacral nerves S1–S5.

The nerves arising from each region of the spinal cord and vertebral column supply specific regions of the body. A **dermatome** is the area of skin supplied with sensory innervation by a pair of spinal nerves. Each of the spinal nerves except C1 has a specific cutaneous sensory distribution. Figure 12.14 illustrates the dermatomal (der-mă-tō' mā) map for the sensory cutaneous distribution of the spinal nerves.

FIGURE 12.13 Spinal Nerves and Plexuses

The regional designations and the numbers of the spinal nerves are shown on the left. The plexuses formed by the spinal nerves are shown on the right. **APR**

► Predict 3

Loss of sensation in a dermatomal pattern can provide valuable information about the location of nerve damage. Using the dermatomal map in figure 12.14, predict the possible site of nerve damage for a patient who suffered whiplash in an automobile accident and subsequently developed anesthesia (no sensation) in the left arm, forearm, and hand.

A **ramus** (rā' mūs; branch) is a major branch of a spinal nerve. Figure 12.15a depicts an idealized section through the trunk. Each spinal nerve has a dorsal and a ventral ramus. Additional rami (rā' mī), called communicating rami, from the thoracic and upper lumbar spinal cord regions carry axons associated with the sympathetic division of the autonomic nervous system (see chapter 16).

The **dorsal rami** (rā' mī) innervate most of the deep muscles of the dorsal trunk responsible for moving the vertebral column. They also innervate the connective tissue and skin near the midline of the back.

The **ventral rami** are distributed in two ways. In the thoracic region, the ventral rami form **intercostal** (between ribs) **nerves** (figure 12.15a), which extend along the inferior margin of each rib

FIGURE 12.14 Spinal Cord and Dermatome Map

(a) Nerves of the spinal cord and their functions. The regions are color-coded. (b) Letters and numbers indicate the spinal nerves innervating a given region of skin (dermatome). **APR**

and innervate the intercostal muscles and the skin over the thorax. The ventral rami of the remaining spinal nerves form five major **plexuses** (plek'sūs-ēz; braids). A plexus is an intermingling of nerves, much like the intermingling of hair in a braid. The ventral rami of different spinal nerves, called the **roots**, join with each other to form a plexus. These roots should not be confused with the dorsal and ventral roots from the spinal cord, which are more medial. Nerves that arise from plexuses usually have axons from more than one spinal nerve and thus more than one level of the spinal cord. The ventral rami of spinal nerves C1–C4 form the cervical plexus, C5–T1 form the brachial plexus, L1–L4 form the lumbar plexus, L4–S4 form the sacral plexus, and S5 and the

coccygeal nerve (Co) form the coccygeal plexus. An important functional aspect of these plexuses is that the intermingling of nerves from multiple spinal cord levels often minimizes the loss of control and feeling to a specific area of the body following spinal cord injury.

Several smaller somatic plexuses, such as the pudendal plexus in the pelvis, are derived from more distal branches of the spinal nerves. Some of the somatic plexuses are described later in this section. Autonomic plexuses (described in chapter 16) also exist in the thorax and abdomen. In the following discussion, we investigate the five major plexuses derived from the ventral rami of spinal nerves.

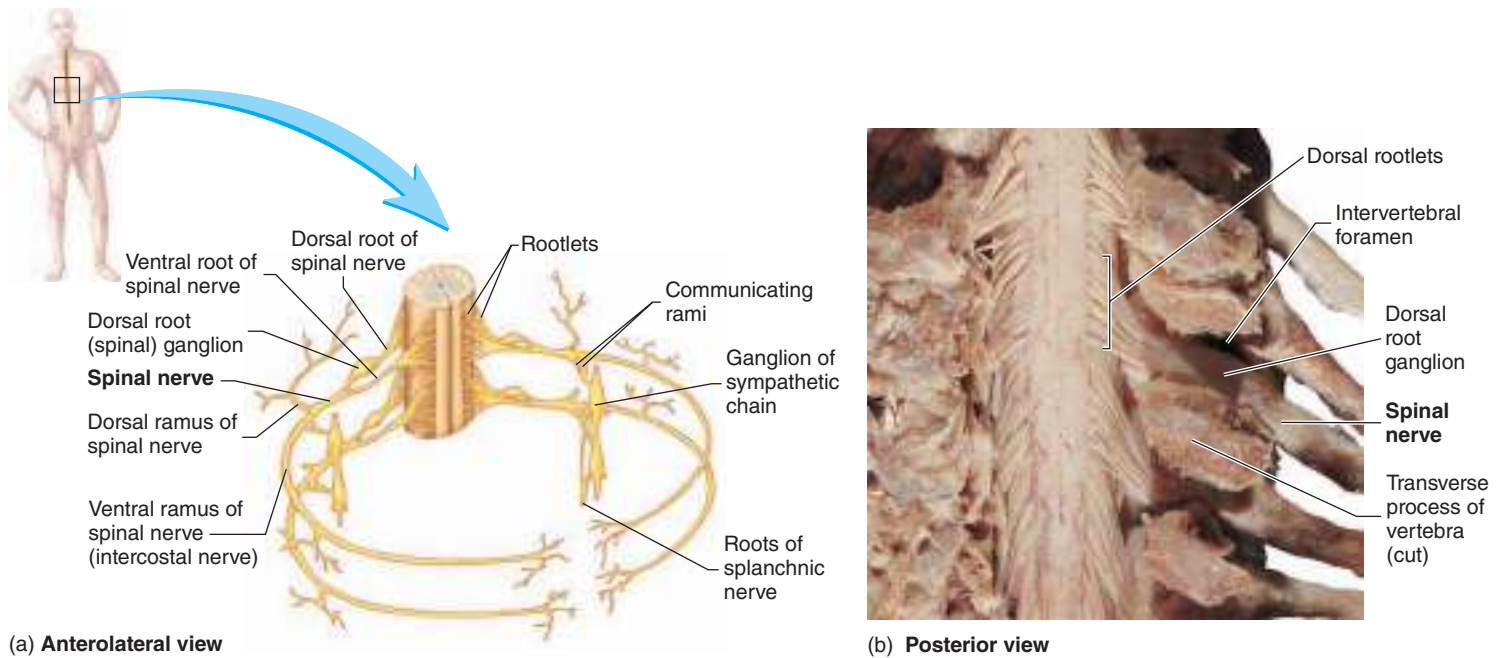

FIGURE 12.15 Spinal Nerves

(a) Typical thoracic spinal nerves have dorsal and ventral roots, as well as dorsal, ventral, and communicating rami. Communicating rami connect to the sympathetic chain (see chapter 16). (b) Photograph of four dorsal roots in place along the vertebral column. **APR**

Clinical IMPACT

Spinal Cord Injury

Damage to the spinal cord can disrupt ascending tracts to the brain, resulting in the loss of sensation. Conversely, the disruption of descending tracts from the brain to motor neurons in the spinal cord can result in the loss of motor functions. About 10,000 new cases of **spinal cord injury** occur each year in the United States. Leading causes are automobile and motorcycle accidents, followed by gunshot wounds, falls, and swimming accidents. The primary mechanisms include concussion (an injury caused by a blow), contusion (an injury resulting in hemorrhage), and laceration (a tear or cut). Spinal cord injuries often involve excessive flexion, extension, rotation, or compression of the vertebral column. Most spinal cord injuries are acute contusions of the cord due to bone or disk displacement into the cord and involve a combination of excessive directional movements, such as simultaneous flexion and compression.

Spinal cord injury is classified according to the vertebral level at which the injury occurred, whether the entire cord or only a portion is damaged at that level, and the mechanism of injury. Most spinal cord injuries occur in the cervical region or at the thoracolumbar junction and are incomplete. Injuries in the cervical region above

T1 are the most severe and can result in paralysis of all four limbs (quadriplegia or tetraplegia), with the abdominal and chest muscles also affected. Injuries at or below T1 can result in varying degrees of paralysis of the legs (paraplegia) and the abdomen, while retaining full function of the upper limbs.

At the time of spinal cord injury, two types of tissue damage occur: (1) primary, mechanical damage and (2) secondary, tissue damage extending into a much larger region of the cord than the primary damage. Secondary spinal cord damage begins within minutes of the primary damage and is caused by ischemia, edema, ion imbalances, the release of “excitotoxins” (such as glutamate), and inflammatory cell invasion. Secondary damage is the primary focus of current research.

Once an accident occurs, little can be done about the primary damage. On the other hand, much secondary damage can be prevented if promptly treated. Treatment with large doses of anti-inflammatory steroids, such as methylprednisolone, within 8 hours of the injury can dramatically lessen the secondary damage to the cord by reducing inflammation and edema. Additional treatments include structural realignment and stabilization of the vertebral column

and decompression of the spinal cord. Rehabilitation is based on retraining the patient to use whatever residual connections exist across the site of damage.

For a long time, researchers thought the spinal cord was incapable of regeneration following severe damage. But they have now learned that most neurons of the adult spinal cord survive the injury and begin to regenerate, growing about 1 mm into the site of damage. Unfortunately, the neurons then regress to an inactive, atrophic state. A major block to adult spinal cord regeneration is the formation of a scar, consisting mainly of myelin and astrocytes, at the site of the injury. Myelin and other inhibitory factors, such as the protein Nogo, in the scar inhibit regeneration. Implantation of stem cells or other cell types, such as olfactory ensheathing glia and Schwann cells, can partially bridge the scar and stimulate some regeneration. Certain growth factors can also stimulate regeneration, and blocking inhibitory factors may be able to prevent the formation of the glial scar to allow axon regeneration. Current research continues to look for the right combination of cells and other factors to stimulate regeneration of the spinal cord following injury.

ASSESS YOUR PROGRESS

12. List all the spinal nerves by name and number. Where do they exit the vertebral column?
13. What is a dermatome? Why are dermatomes clinically important?
14. Contrast the dorsal and ventral rami of the spinal nerves. What muscles do the dorsal rami innervate?
15. Describe the distribution of the ventral rami of the thoracic region.
16. What is a plexus? What happens to the axons of spinal nerves as they pass through a plexus? Why is this functionally important?
17. Name the five major spinal plexuses and the spinal nerves associated with each.

Cervical Plexus

The **cervical plexus** is a relatively small plexus originating from spinal nerves C1–C4 (figure 12.16). Branches derived from this plexus innervate superficial neck structures, including several of the muscles attached to the hyoid bone. The cervical plexus innervates the skin of the neck and posterior portion of the head (see figure 12.14). An unusual part of the cervical plexus, the **ansa** (an'sah; bucket handle) **cervicalis**, is a loop between C1 and C3. Nerves to the infrahyoid muscles branch from the ansa cervicalis (see chapter 10).

One of the most important derivatives of the cervical plexus is the **phrenic** (fren'ik) **nerve**, which is important for breathing. The phrenic nerve originates from spinal nerves C3–C5 and is derived from both the cervical and brachial plexuses. The phrenic nerves descend along each side of the neck to enter the thorax and then descend along the sides of the mediastinum to reach the diaphragm, which they innervate. Contraction of the diaphragm is largely responsible for a person's ability to breathe; therefore, damage to the phrenic nerve during surgery or compression of the nerve by a tumor at the base of the lung severely limits breathing.

Predict 4

Explain how damage to or compression of the right phrenic nerve affects the diaphragm. How would breathing be affected if the spinal cord were completely severed at the level of C2 versus at the level of C6?

Brachial Plexus

The **brachial plexus** originates from spinal nerves C5–T1 (figure 12.17). The five ventral rami that constitute the brachial plexus join to form three **trunks**, which separate into six **divisions** and then join again to create three **cords** (posterior, lateral, and medial) from which five **branches**, or nerves of the upper limb, emerge.

The five major nerves emerging from the brachial plexus to supply the upper limb are the axillary, radial, musculocutaneous, ulnar, and median nerves. The axillary nerve innervates part of the shoulder; the radial nerve innervates the posterior arm, forearm,

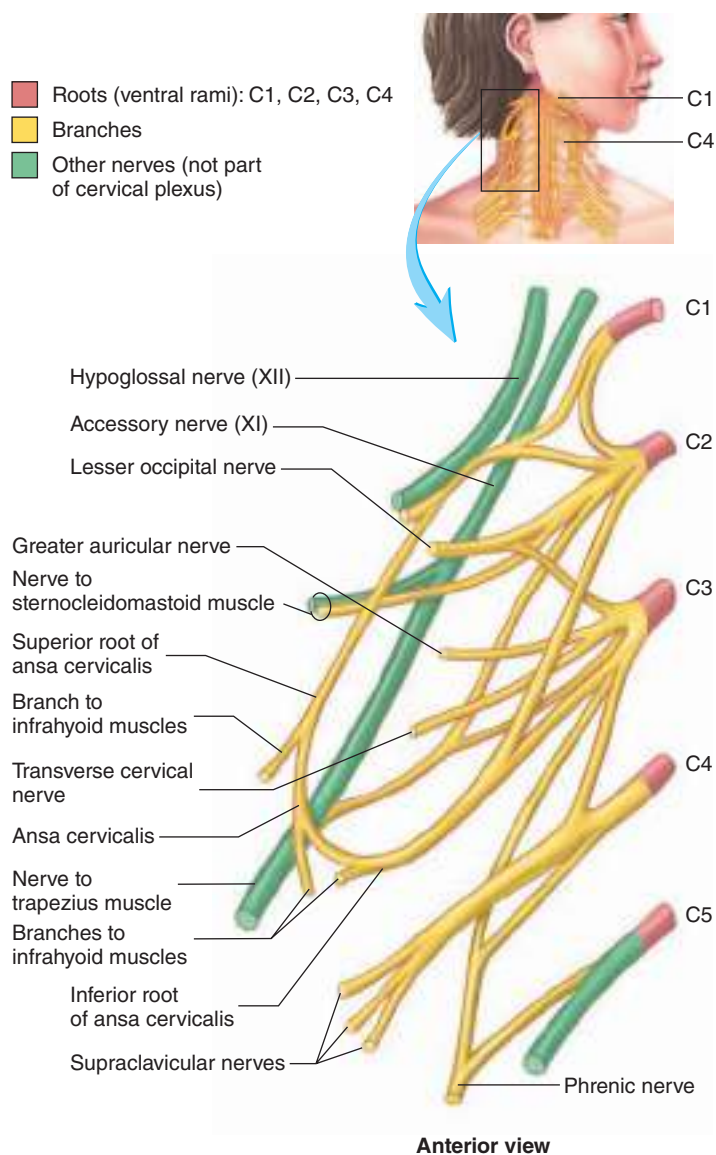

FIGURE 12.16 Cervical Plexus

The roots of the plexus are formed by the ventral rami of spinal nerves C1–C4. Branches of the cervical plexus innervate the muscles (infrahyoid) and skin of the neck. The phrenic nerve (C3–C5) innervates the diaphragm.

APR

and hand; the musculocutaneous nerve innervates the anterior arm; and the ulnar and median nerves innervate the anterior forearm and hand. Smaller nerves from the brachial plexus innervate the shoulder and pectoral muscles. Because of this anatomical organization, the entire upper limb can be anesthetized by injecting an anesthetic near the brachial plexus between the neck and the shoulder posterior to the clavicle. This is called **brachial anesthesia**.

Axillary Nerve

The **axillary** (ak'sil-ār-ē) **nerve** innervates the deltoid and teres minor muscles (figure 12.18). It also provides sensory innervation to the shoulder joint and to the skin over part of the shoulder.

FIGURE 12.17 Brachial Plexus

The roots of the plexus are formed by the ventral rami of spinal nerves C5–T1 and join to form an upper, a middle, and a lower trunk. Each trunk divides into anterior and posterior divisions. The divisions join to form the posterior, lateral, and medial cords from which the major brachial plexus nerves arise. The major brachial plexus nerves include the axillary, radial, musculocutaneous, median, and ulnar nerves, which innervate the muscles and skin of the upper limb. **APR**

Radial Nerve

The **radial nerve** innervates all of the extensor muscles of the upper limb (triceps brachii), the supinator muscle, and the brachioradialis. Its cutaneous sensory distribution is to the posterior portion of the upper limb, including the posterior surface of the hand. The nerve emerges from the posterior cord of the brachial plexus and descends within the deep aspect of the posterior arm (figure 12.19). About midway down the shaft of the humerus, it lies against the bone in the radial groove.

Musculocutaneous Nerve

The **musculocutaneous** (mūs'kū-lō-kū-tā'nē-ŭs) **nerve** provides motor innervation to the anterior muscles of the arm, as

Clinical IMPACT

Crutch Paralysis

Because the radial nerve lies near the humerus in the axilla, it can be damaged if it is compressed against the humerus. Improper use of crutches (pushing the crutch tightly into the axilla) can result in **crutch paralysis**. As the radial nerve is compressed

between the top of the crutch and the humerus, the nerve is damaged and the muscles it innervates lose their function. The major symptom of crutch paralysis is **wrist drop**, in which the elbow, wrist, and fingers are constantly flexed because the extensor muscles of the wrist and

fingers, which are innervated by the radial nerve, fail to function. There is also a loss of sensation over the back of the forearm and hand. Crutch paralysis is usually temporary as long as the patient begins to use the crutches correctly.

Musculocutaneous Nerve

Origin

Lateral cord of brachial plexus, C5–C7

Movements/Muscles Innervated

Flexes shoulder

- *Biceps brachii*
- *Coracobrachialis*

Flexes elbow and supinates forearm and hand

- *Biceps brachii*

Flexes elbow

- *Brachialis* (also small amount of innervation from radial nerve)

Cutaneous (Sensory) Innervation

Lateral surface of forearm

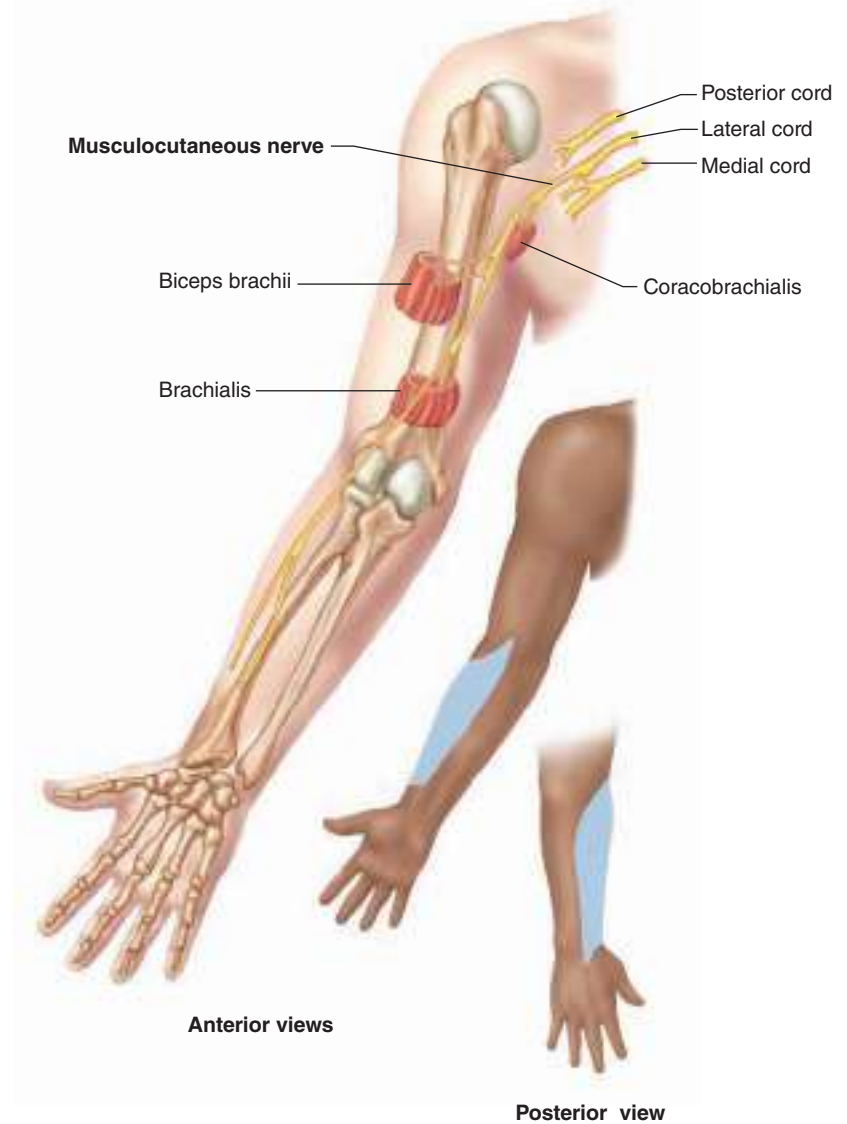

FIGURE 12.20 Musculocutaneous Nerve

The route of the musculocutaneous nerve and the muscles it innervates. The *insets* depict the cutaneous (sensory) distribution of the nerve (*blue areas*).

Median Nerve

The **median nerve** innervates all but one of the flexor muscles of the forearm and most of the hand muscles at the base of the thumb, called the thenar area of the hand. The nerve's cutaneous sensory distribution is to the radial portion of the palm of the hand (figure 12.22). Damage to the median nerve occurs most commonly where it enters the wrist through the **carpal tunnel**. This tunnel is created by the concave organization of the carpal bones and the flexor retinaculum on the anterior surface of the wrist. Compression of the median nerve in this relatively narrow tunnel produces numbness, tingling, and pain in the fingers. In addition, the function of the thenar muscles, which are innervated by the median nerve, is reduced, resulting in weakness in thumb flexion and opposition. This condition is called **carpal tunnel syndrome**. In general, anything that compresses the

Clinical IMPACT

The “Funny Bone”

The ulnar nerve is the most easily damaged of all the spinal nerves, but such damage is almost always temporary. The ulnar nerve passes posterior to the medial epicondyle of the humerus and can be felt just below the skin at this region. If the elbow is banged against a hard object, temporary ulnar nerve damage may occur, causing painful tingling to radiate down the ulnar side of the forearm and hand. Because of this sensation, we often call this area of the elbow the *funny bone* or *crazy bone*.

Ulnar Nerve

Origin

Medial cord of brachial plexus, C8–T1

Movements/Muscles Innervated

Flexes and adducts wrist

- *Flexor carpi ulnaris*

Flexes fingers

- Part of the *flexor digitorum profundus* controlling the distal phalanges of little and ring fingers

Adducts thumb

- *Adductor pollicis*

Controls hypothenar muscles

- *Flexor digiti minimi brevis*
- *Abductor digiti minimi*
- *Opponens digiti minimi*

Flexes metacarpophalangeal joints and extends interphalangeal joints

- Two medial (ulnar) lumbricales

Abducts and adducts fingers

- *Interossei*

Cutaneous (Sensory) Innervation

Medial third of hand, little finger, and medial half of ring finger

FIGURE 12.21 Ulnar Nerve

The route of the ulnar nerve and the muscles it innervates. The *insets* depict the cutaneous (sensory) distribution of the nerve (*blue areas*).

Case STUDY

Thoracic Outlet Syndrome

Sarah, age 26, noticed that over a period of time she experienced pain, tingling, and numbness in the ring finger and little finger of her right hand. She also felt pain in her elbow that radiated down the posteromedial portion of her forearm and hand, so she made an appointment with her physician. After careful examination of Sarah's upper limb, her physician ordered an x-ray of her neck. The x-ray disclosed a cervical rib on the right, which was attached to the C7 vertebra. Cervical ribs are extra ribs that occur in about 0.5% of the population, yet most people exhibit no symptoms. In Sarah's case, the extra rib was compressing the inferior roots of the brachial plexus (see figure 12.17), a condition called **thoracic outlet syndrome**. This syndrome is a group of related disorders that involve compression of the nerves

and vessels in the "thoracic outlet" region of the lower neck and upper chest. The syndrome is generally caused by compression of the brachial plexus or the subclavian artery or vein. Compression can result from an anatomical abnormality, such as Sarah's extra rib, but to become symptomatic there is often an associated injury or overuse activity, such as repetitive overhead arm motions in sports and occupations, droopy shoulders, joint pressure from heavy backpacks or obesity, joint changes during pregnancy, and trauma, such as whiplash. Thoracic outlet syndrome can also result from these injuries and activities in the absence of a cervical rib. Treatment of thoracic outlet syndrome first involves physical therapy to improve shoulder alignment, range of motion, and strength. In more severe and persistent

cases, surgery may be required to alleviate compression of the plexus or blood vessels.

Predict 5

Use figures 12.14, 12.17, and 12.19–12.21 to answer these questions:

- Name the brachial plexus nerves supplying the skin of the hand.
- Damage to which of these nerves could produce the symptoms in Sarah's hand?
- What made Sarah's physician suspect thoracic outlet syndrome rather than damage to an individual nerve?
- Thoracic outlet syndrome can also affect muscles, producing muscle weakness and paralysis. Muscles supplied by what nerves could be affected by a cervical rib?

Median Nerve

Origin

Medial and lateral cords of brachial plexus, C5–T1

Movements/Muscles Innervated

Pronates forearm and hand

- *Pronator teres*
- *Pronator quadratus*

Flexes and abducts wrist

- *Flexor carpi radialis*

Flexes wrist

- *Palmaris longus*

Flexes fingers

- Part of *flexor digitorum profundus* controlling the distal phalanx of the middle and index fingers
- *Flexor digitorum superficialis*

Controls thumb muscle

- *Flexor pollicis longus*

Controls thenar muscles

- *Abductor pollicis brevis*
- *Opponens pollicis*
- *Flexor pollicis brevis*

Flexes metacarpophalangeal joints and extends interphalangeal joints

- Two lateral (radial) *lumbricales*

Cutaneous (Sensory) Innervation

Lateral two-thirds of palm of hand, thumb, index and middle fingers, and the lateral half of ring finger and dorsal tips of the same fingers

FIGURE 12.22 Median Nerve

The route of the median nerve and the muscles it innervates. The insets depict the cutaneous (sensory) distribution of the nerve (blue areas).

APR

median nerve in the carpal tunnel can cause the syndrome (see Clinical Impact, “Carpal Tunnel Syndrome” in chapter 7).

Other Nerves of the Brachial Plexus

Several nerves, other than the five just described, arise from the brachial plexus (see figure 12.17). They supply most of the muscles acting on the scapula and arm and include the pectoral, long thoracic, thoracodorsal, subscapular, and suprascapular nerves. In addition, brachial plexus nerves innervate the skin of the medial arm and forearm.

Lumbar and Sacral Plexuses

The **lumbar plexus** originates from the ventral rami of spinal nerves L1–L4, and the **sacral plexus** originates from L4–S4. However, because of their close, overlapping relationship and similar distribution, the two plexuses are often considered together as a

single **lumbosacral plexus** (L1–S4; figure 12.23). Four major nerves exit the lumbosacral plexus and enter the lower limb: the obturator, femoral, tibial, and common fibular (peroneal). The obturator nerve innervates the medial thigh; the femoral nerve innervates the anterior thigh; the tibial nerve innervates the posterior thigh, leg, and foot; and the common fibular nerve innervates the posterior thigh, anterior and lateral leg, and foot. Other lumbosacral nerves supply the lower back, hip, and lower abdomen.

Obturator Nerve

The **obturator** (ob'too-ră-tōr) **nerve** innervates the muscles that adduct the thigh. Its cutaneous sensory distribution is to the medial side of the thigh (figure 12.24).

Femoral Nerve

The **femoral nerve** innervates the iliopsoas and sartorius muscles and the quadriceps femoris group. Its cutaneous sensory

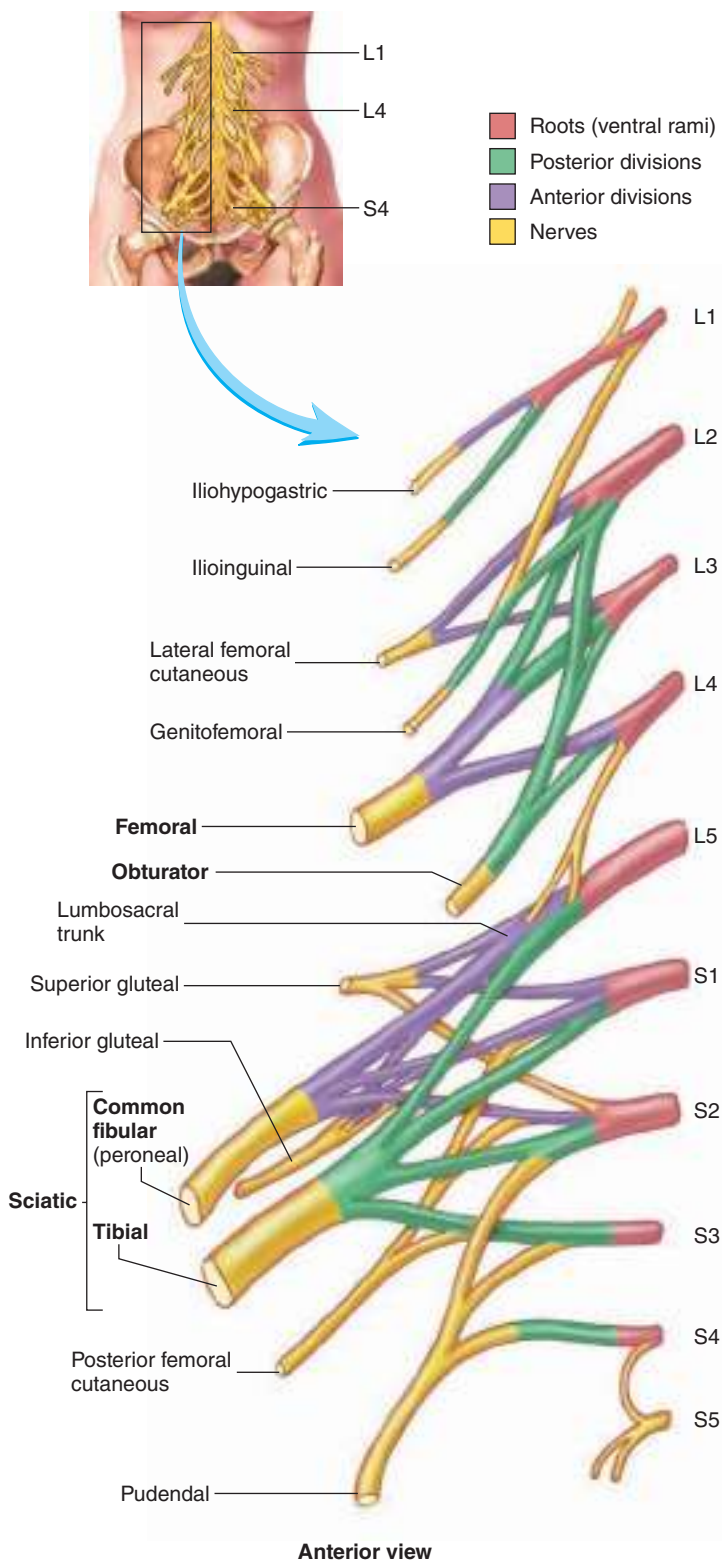

FIGURE 12.23 Lumbosacral Plexus

The roots of the plexus are formed by the ventral rami of the spinal nerves L1–S4 and form anterior and posterior divisions, which give rise to the lumbosacral nerves. The lumbosacral trunk joins the lumbar and sacral plexuses. **APR**

Clinical IMPACT

Sciatic Nerve Damage

If a person sits on a hard surface for a considerable time, the sciatic nerve may be compressed against the ischial portion of the hipbone. When the person stands up, he or she feels a tingling sensation, described as “pins and needles,” throughout the lower limb and often remarks that the limb has “gone to sleep.” This condition is temporary, but the sciatic nerve can be seriously injured in a number of ways. A ruptured intervertebral disk or pressure from the uterus during pregnancy may compress the roots of the sciatic nerve. Other causes of sciatic nerve damage include hip injury, compression of the nerve by the piriformis muscle (piriformis syndrome), and an improperly administered injection in the hip region (see Clinical Impact, “Gluteal Injections” in section 7.3).

distribution is the anterior and lateral thigh and the medial leg and foot (figure 12.25).

► Predict 6

While moving a large box in his garage, Carl hurt his back. Within hours, the pain in his back was radiating down the medial side of his left thigh and knee. It was especially difficult for Carl to flex his left hip and extend his left knee. He could not stand the pain, so he went to the emergency room. Radiographs and an MRI revealed a bulging intervertebral disk. Which spinal nerve was most likely affected, and why were Carl’s motor movements affected? Also, explain the referred pain.

Tibial and Common Fibular Nerves

The **tibial** and **common fibular nerves** (*peroneal nerves*; per-ō-nē’āl) originate from spinal segments L4–S3 and are bound together within a connective tissue sheath for the length of the thigh (figures 12.26 and 12.27; see figure 12.23). These two nerves, combined within the same sheath, are referred to jointly as the **sciatic** (sī-at’ik) **nerve**, or **ischialic** (is-kē-ad’ik) **nerve** (see figure 12.23). The sciatic nerve is by far the largest peripheral nerve in the body. It passes through the greater sciatic notch in the pelvis and descends in the posterior thigh to the popliteal fossa, where the two portions of the sciatic nerve separate.

The tibial nerve innervates most of the posterior thigh and leg muscle (see figure 12.26). It branches in the foot to form the **medial** and **lateral plantar nerves**, which innervate the plantar muscles of the foot and the skin over the sole of the foot. Another branch, the **sural** (soo’rāl) **nerve**, supplies part of the cutaneous innervation over the calf of the leg and the plantar surface of the foot.

The common fibular nerve divides into the **deep** and **superficial fibular (peroneal) nerves**. These branches innervate the anterior and lateral muscles of the leg and foot. The

Obturator Nerve

Origin

Lumbosacral plexus, L2–L4

Movements/Muscles Innervated

Rotates thigh laterally

- *Obturator externus*

Adducts thigh

- *Adductor magnus (adductor part)*
- *Adductor longus*
- *Adductor brevis*

Adducts thigh and flexes knee

- *Gracilis*

Cutaneous (Sensory) Innervation

Superior medial side of thigh

FIGURE 12.24 Obturator Nerve

The route of the obturator nerve and the muscles it innervates. The *inset* depicts the cutaneous (sensory) distribution of the nerve (*blue area*).

cutaneous distribution of the common fibular nerve and its branches is the lateral and anterior leg and the dorsum of the foot (figure 12.27).

Other Lumbosacral Plexus Nerves

In addition to the nerves just described, the lumbosacral plexus gives rise to **gluteal nerves**, which supply the hip muscles that act on the femur, and the **pubdental** (pū-den'däl) **nerve**, which supplies the muscles of the abdominal floor (see figure 12.23).

The **iliohypogastric** (il'ē-ō-hī-pō-gas'trik), **ilioinguinal** (il'ē-ō-ing'gwi-näl), **genitofemoral** (jen'i-tō-fem'ō-räl), **cutaneous femoral**, and **pubdental** nerves innervate the skin of the suprapubic area, the external genitalia, the superior medial thigh, and the posterior thigh. The pubdental nerve plays a vital role in sexual stimulation and response. Branches of the pubdental nerve are anesthetized during childbirth before a doctor performs an **episiotomy** (e-piz-ē-ot'ō-mē, epis-ē-ot'ō-mē), a cut in the perineum that enlarges the opening of the birth canal.

Femoral Nerve

Origin

Lumbosacral plexus, L2–L4

Movements/Muscles Innervated

Flexes hip

- *Psoas major*
- *Iliacus*
- *Pectineus*

Flexes hip and flexes knee

- *Sartorius*

Extends knee

- *Vastus lateralis*
- *Vastus intermedius*
- *Vastus medialis*

Extends knee and flexes hip

- *Rectus femoris*

Cutaneous (Sensory) Innervation

Anterior and lateral branches supply the anterior and lateral thigh; saphenous branch supplies the medial leg and foot

FIGURE 12.25 Femoral Nerve

The route of the femoral nerve and the muscles it innervates. The *insets* depict the cutaneous (sensory) distribution of the nerve (*blue areas*).

Coccygeal Plexus

The **coccygeal** (kok-sij'ē-äl) **plexus** is a very small plexus formed from the ventral rami of spinal nerve S5 and the coccygeal nerve (Co). This small plexus supplies motor innervation to the muscles of the pelvic floor and sensory cutaneous innervation to the skin over the coccyx. The dorsal rami of the coccygeal nerves innervate some skin over the coccyx.

ASSESS YOUR PROGRESS

18. Name the structures innervated by the cervical plexus. Describe the makeup of the phrenic nerve.
19. Name the five major nerves that emerge from the brachial plexus. List the muscles they innervate and the areas of skin they supply.

Tibial Nerve

Origin

Lumbosacral plexus, L4–S3

Movements/Muscles Innervated

Extends hip and flexes knee

- *Biceps femoris (long head)*
- *Semitendinosus*
- *Semimembranosus*

Extends hip and adducts thigh

- *Adductor magnus (hamstring part)*

Plantar flexes foot

- *Plantaris*
- *Gastrocnemius*
- *Soleus*
- *Tibialis posterior*

Flexes knee

- *Popliteus*

Flexes toes

- *Flexor digitorum longus*
- *Flexor hallucis longus*

Cutaneous (Sensory) Innervation

None

Medial and Lateral Plantar Nerves

Origin

Tibial nerve

Movements/Muscles Innervated

Flex and adduct toes

Clinical IMPACT

Bionic Sensors

Patients paralyzed by strokes or spinal cord lesions are able to regain some functions with the help of microcomputers that stimulate certain programmed activities, such as grasping and walking. The microcomputer initiates electrical impulses, which are conveyed through fine wire leads either to peripheral nerves or directly to the muscles responsible for the desired movement. The subtle movement of muscles not affected by the paralysis initiates the program. Sensors

connected to the microcomputer are attached to the skin overlying functional muscles, where they are able to detect electrical activity associated with movement of the underlying muscles. For example, a person whose legs are paralyzed may have a sensor attached to the abdomen. The abdominal muscles normally involved in stabilizing and moving the pelvis during walking are stimulated by descending tracts when CNS centers initiate walking. The resultant abdominal muscle activity is detected

by the sensor, which activates the program that stimulates the appropriate sequence of muscles in the lower limbs, and the paralyzed person walks. Similarly, a quadriplegic using subtle movements of the shoulder, neck, or face, where specific sensors can be placed, can initiate certain upper limb and grasping actions. Recent advances are now even allowing sensory feedback, so that a person can “feel” pressure and heat from an object being held by a bionic hand.

Diseases and Disorders

TABLE 12.1

Spinal Cord and Spinal Nerves

Condition	Description
SPINAL CORD DISORDERS	
Encephalitis	Inflammation of the brain caused by a virus and less often by bacteria or other agents; symptoms include fever, coma, and convulsions
Meningitis	Inflammation of meninges caused by viral or bacterial infection; symptoms include stiffness in the neck, headache, and fever; severe cases can cause paralysis, coma, or death
Rabies	Viral disease transmitted by an infected animal; brain infection results in abnormal excitability, aggression, paralysis, and death
Tetanus	Caused by bacterial neurotoxin; affects lower motor neurons in spinal cord and brainstem, leading to muscle contraction; prevents muscle relaxation; body becomes rigid, including “lockjaw”; death results from spasms in respiratory muscles
Multiple sclerosis	Autoimmune condition; may be initiated by viral infection; inflammation in brain and spinal cord with demyelination and sclerotic (hard) sheaths result in poor conduction of action potentials; symptoms include exaggerated reflexes, tremor, and speech defects
SPINAL NERVE DISORDERS	
Anesthesia	Loss of sensation; may be a pathological condition or may be induced temporarily to facilitate medical action
Neuritis	Inflammation of a nerve from a number of causes; in motor nerves, can result in loss of motor function; in sensory nerves, can result in anesthesia or neuralgia
Neuralgia	Nerve pain; involves severe spasms of throbbing or stabbing pain along the pathway of a nerve; can result from inflammation, nerve damage, or an unknown cause
Sciatica	Neuralgia of the sciatic nerve, with pain radiating down the back of the leg; most common cause is a herniated lumbar disk
Leprosy	Bacterial disease that kills skin and PNS cells; characterized by disfiguring nodules and tissue necrosis
Herpes	Family of diseases characterized by skin lesions due to herpes viruses in sensory ganglia; different viruses cause oral lesions (cold sores), sexually transmitted disease with lesions on genitalia, or chickenpox in children (shingles in adults)
Poliomyelitis	Viral infection of the CNS, but primarily damages somatic motor neurons, leaving muscles without innervation; leads to paralysis and atrophy
Diabetic neuropathy	Damage to nerves occurs in diabetic patients due to high blood sugar levels and decreased blood flow; occurs in over half of diabetics; symptoms develop slowly, often including pain or numbness in extremities but can be manifested in every organ system
Charcot-Marie-Tooth disease	One of the most common hereditary neurological disorders (named for three neurologists who described it); different forms caused by mutations that generally lead to damage of the myelin sheath; characterized primarily by muscle weakness, dysfunction, atrophy, and loss of sensation primarily in lower extremities
Neurofibromatosis	Genetic disorder; neurofibromas (benign tumors along peripheral nerve tract) occur in early childhood and result in skin growths
Myasthenia gravis	Autoimmune disorder affecting acetylcholine receptors; makes the neuromuscular junction less functional; muscle weakness and increased fatigue lead to paralysis

Answer

Learn to Predict ◀ From page 404

Javier reacted to the pain of stepping on the toy cars not once but twice. We know that each time he stepped on a toy he switched the leg that supported his weight, first from the right to the left and then from the left to the right. This chapter described the withdrawal reflex that moves a limb away from a painful stimulus. Javier demonstrated this reflex when he stepped on the toys.

Javier displayed the withdrawal reflex and the crossed extensor reflex. Both of these reflexes are polysynaptic spinal reflexes, involving sensory neurons, interneurons, and motor neurons. Chapter 11 explained the functions of each of these neuron types. The sensory neurons delivered the painful stimulus to the central nervous system; the interneurons relayed the information between sensory and motor neurons; and the motor neurons regulated skeletal muscle activity. When Javier stepped on the

toy car with his right foot, he transferred nearly all of his weight to his right leg before the withdrawal reflex was activated. The painful stimulus of stepping on the toy car activated the withdrawal reflex, causing Javier to pick up his right leg. At the same time, Javier extended his left leg because of the crossed extensor reflex. However, as Javier extended his left leg, he stepped on another toy car, activating the withdrawal reflex in his left leg and the crossed extensor reflex in his right leg. The repeated sequence of withdrawing one leg and stepping down on the other foot prevented Javier from falling down.

Answers to the rest of this chapter's Predict questions are in appendix G.

12.1 Spinal Cord (p. 405)

General Structure

1. The spinal cord gives rise to 31 pairs of spinal nerves. Nerves of the limbs enter and leave the spinal cord at the cervical and lumbosacral enlargements.
2. The spinal cord is shorter than the vertebral column. Nerves from the end of the spinal cord form the cauda equina.

Meninges of the Spinal Cord

Three meningeal layers surround the spinal cord: the dura mater, arachnoid mater, and pia mater.

Cross Section of the Spinal Cord

1. The spinal cord consists of peripheral white matter and central gray matter.
2. White matter is organized into columns, which are subdivided into nerve tracts, or fascicles, which carry action potentials to and from the brain.
3. Gray matter is divided into horns.
 - The dorsal horns contain sensory axons that synapse with interneurons. The ventral horns contain the neuron cell bodies of somatic motor neurons, and the lateral horns contain the neuron cell bodies of autonomic motor neurons.
 - The gray and white commissures connect each half of the spinal cord.
4. The dorsal root conveys sensory input into the spinal cord, and the ventral root conveys motor output away from the spinal cord.

12.2 Reflexes (p. 408)

1. A reflex arc is the functional unit of the nervous system.
 - Sensory receptors respond to stimuli and produce action potentials in sensory neurons.
 - Sensory neurons propagate action potentials to the CNS.

Summary

- Interneurons in the CNS synapse with sensory neurons and with motor neurons.
 - Motor neurons carry action potentials from the CNS to effector organs.
 - Effector organs, such as muscles or glands, respond to the action potentials.
2. Reflexes do not require conscious thought, and they produce a consistent and predictable result.
 3. Reflexes are homeostatic.
 4. Reflexes are integrated within the brain and spinal cord. Higher brain centers can suppress or exaggerate reflexes.

Stretch Reflex

Muscle spindles detect the stretch of skeletal muscles and cause the muscle to shorten reflexively.

Golgi Tendon Reflex

Golgi tendon organs respond to increased tension within tendons and cause skeletal muscles to relax.

Withdrawal Reflex

1. Activation of pain receptors causes muscles to contract and move some part of the body away from a painful stimulus.
2. Reciprocal innervation causes muscles that would oppose withdrawal to relax.
3. In the crossed extensor reflex, flexion of one limb caused by the withdrawal reflex stimulates the opposite limb to extend.

Interactions with Spinal Cord Reflexes

Convergent and divergent pathways interact with reflexes.

12.3 Spinal Nerves (p. 414)

Structure of Nerves

In the PNS, individual axons are surrounded by the endoneurium. Groups of axons, called fascicles, are bound together by the perineurium. The fascicles form the nerve and are held together by the epineurium.

Organization of Spinal Nerves

1. Eight cervical, 12 thoracic, 5 lumbar, 5 sacral pairs, and 1 coccygeal pair make up the spinal nerves.
2. Spinal nerves have specific cutaneous distributions called dermatomes.
3. Spinal nerves branch to form rami.
 - The dorsal rami supply the muscles and skin near the midline of the back.
 - The ventral rami in the thoracic region form intercostal nerves, which supply the thorax and upper abdomen. The remaining ventral rami join to form plexuses. Communicating rami supply sympathetic nerves.

Cervical Plexus

Spinal nerves C1–C4 form the cervical plexus, which supplies some muscles and the skin of the neck and shoulder. The phrenic nerves innervate the diaphragm.

Brachial Plexus

1. Spinal nerves C5–T1 form the brachial plexus, which supplies the upper limb.
2. The axillary nerve innervates the deltoid and teres minor muscles and the skin of the shoulder.
3. The radial nerve supplies the extensor muscles of the arm and forearm and the skin of the posterior surface of the arm, forearm, and hand.

4. The musculocutaneous nerve supplies the anterior arm muscles and the skin of the lateral surface of the forearm.
5. The ulnar nerve innervates most of the intrinsic hand muscles and the skin on the ulnar side of the hand.
6. The median nerve innervates the pronator and most of the flexor muscles of the forearm, most of the thenar muscles, and the skin of the radial side of the palm of the hand.
7. Other nerves supply most of the muscles that act on the arm, the scapula, and the skin of the medial arm and forearm.

Lumbar and Sacral Plexuses

1. Spinal nerves L1–S4 form the lumbosacral plexus.
2. The obturator nerve supplies the muscles that adduct the thigh and the skin of the medial thigh.
3. The femoral nerve supplies the muscles that flex the thigh and extend the leg and the skin of the anterior and lateral thigh and the medial leg and foot.
4. The tibial nerve innervates the muscles that extend the thigh and flex the leg and the foot. It also supplies the plantar muscles and the skin of the posterior leg and the sole of the foot.
5. The common fibular nerve and its branches supply the short head of the biceps femoris, the muscles that dorsiflex and plantar flex the foot, and the skin of the lateral and anterior leg and the dorsum of the foot.
6. In the thigh, the tibial nerve and the common fibular nerve are combined as the sciatic nerve.
7. Other lumbosacral nerves supply the lower abdominal muscles, the hip muscles, and the skin of the suprapubic area, external genitalia, and upper medial thigh.

Coccygeal Plexus

Spinal nerve S5 and the coccygeal nerve form the coccygeal plexus, which supplies the muscles of the pelvic floor and the skin over the coccyx.

REVIEW AND COMPREHENSION

1. The spinal cord extends from the
 - a. medulla oblongata to the coccyx.
 - b. level of the third cervical vertebra to the coccyx.
 - c. level of the axis to the lowest lumbar vertebra.
 - d. level of the foramen magnum to the second lumbar vertebra.
 - e. axis to the sacral hiatus.
2. The structure that anchors the inferior end of the spinal cord to the coccyx is the
 - a. conus medullaris.
 - b. cauda equina.
 - c. filum terminale.
 - d. lumbar enlargement.
 - e. posterior median sulcus.
3. Axons of sensory neurons synapse with the cell bodies of interneurons in the _____ of spinal cord gray matter.
 - a. anterior horn
 - b. lateral horn
 - c. posterior horn
 - d. gray commissure
 - e. lateral columns
4. Given these components of a reflex arc:
 - (1) effector organ
 - (2) interneuron
 - (3) motor neuron
 - (4) sensory neuron
 - (5) sensory receptor

Choose the correct order an action potential follows after a sensory receptor is stimulated.

- a. 5,4,3,2,1
 - b. 5,4,2,3,1
 - c. 5,3,4,1,2
 - d. 5,2,4,3,1
 - e. 5,3,2,1,4
5. A reflex response accompanied by the conscious sensation of pain is possible because of
 - a. convergent pathways.
 - b. divergent pathways.
 - c. a reflex arc that contains only one neuron.
 - d. sensory perception in the spinal cord.
 6. Several of the events that occur between the time a physician strikes a patient's patellar tendon with a rubber hammer and the time the quadriceps femoris contracts (knee-jerk reflex) are listed below:
 - (1) increased frequency of action potentials in sensory neurons
 - (2) stretch of the muscle spindles
 - (3) increased frequency of action potentials in the alpha motor neurons
 - (4) stretch of the quadriceps femoris
 - (5) contraction of the quadriceps femoris

Which of the following most closely describes the sequence of events as they normally occur?

- a. 4,1,2,3,5
- b. 4,1,3,2,5
- c. 1,4,3,2,5
- d. 4,2,1,3,5
- e. 4,2,3,1,5

7. _____ are responsible for regulating the sensitivity of the muscle spindle.
 - a. Alpha motor neurons
 - b. Sensory neurons
 - c. Gamma motor neurons
 - d. Golgi tendon organs
 - e. Inhibitory interneurons
8. Which of these events occurs when a person steps on a tack with the right foot?
 - a. The right foot is pulled away from the tack because of the Golgi tendon reflex.
 - b. The left leg is extended to support the body because of the stretch reflex.
 - c. The flexor muscles of the right thigh contract, and the extensor muscles of the right thigh relax because of reciprocal innervation.
 - d. Extensor muscles contract in both thighs because of the crossed extensor reflex.
9. Damage to the dorsal ramus of a spinal nerve results in
 - a. loss of sensation.
 - b. loss of motor function.
 - c. Both a and b are correct.
10. A collection of spinal nerves that join together after leaving the spinal cord is called a
 - a. ganglion.
 - b. nucleus.
 - c. projection nerve.
 - d. plexus.
11. A dermatome
 - a. is the area of skin supplied by a pair of spinal nerves.
 - b. exists for each spinal nerve except C1.
 - c. can be used to locate the site of spinal cord or nerve root damage.
 - d. All of these are correct.
12. Which of these nerves arises from the cervical plexus?
 - a. median
 - b. musculocutaneous
 - c. phrenic
 - d. obturator
 - e. ulnar
13. The skin on the posterior surface of the hand is supplied by the
 - a. median nerve.
 - b. musculocutaneous nerve.
 - c. ulnar nerve.
 - d. axillary nerve.
 - e. radial nerve.
14. The sciatic nerve is actually two nerves combined within the same sheath. The two nerves are the
 - a. femoral and obturator.
 - b. femoral and gluteal.
 - c. common fibular (peroneal) and tibial.
 - d. common fibular (peroneal) and obturator.
 - e. tibial and gluteal.
15. The muscles of the anterior compartment of the thigh are supplied by the
 - a. obturator nerve.
 - b. gluteal nerve.
 - c. sciatic nerve.
 - d. femoral nerve.
 - e. ilioinguinal nerve.

Answers in appendix E

CRITICAL THINKING

1. Describe how stimulation of a neuron that has its cell body in the cerebrum can inhibit a reflex that is integrated within the spinal cord.
2. A cancer patient has his left lung removed. To reduce the space remaining where the lung is removed, the diaphragm on the left side is paralyzed to allow the abdominal viscera to push the diaphragm upward. What nerve is cut? Where is a good place to cut it, and when would the surgery be done?
3. During a difficult delivery, the baby's arm delivered first. The attending physician grasped the arm and forcefully pulled it. Later, a nurse observed that the baby could not abduct or adduct the medial four fingers, and flexion of the wrist was impaired. What nerve was damaged?
4. Two patients are admitted to the hospital. According to their charts, both have herniated disks that are placing pressure on the roots of the sciatic nerve. One patient has pain in the buttocks and the posterior aspect of the thigh. The other patient experiences pain in the posterior and lateral aspects of the leg and the lateral part of the ankle and foot. Explain how the same condition, a herniated disk, can produce such different symptoms.
5. In an automobile accident, a woman suffers a crushing hip injury. For each of the following conditions, state what nerve is damaged.
 - a. unable to adduct the thigh
 - b. unable to extend the knee
 - c. unable to flex the knee
 - d. loss of sensation from the skin of the anterior thigh
 - e. loss of sensation from the skin of the medial thigh
6. A skier breaks his ankle. As part of his treatment, the ankle and leg are placed in a plaster cast. Unfortunately, the cast is too tight around the proximal portion of the leg and presses in against the neck of the fibula. Predict where the patient will experience tingling or numbness in the leg. Explain.
7. Cecil's motorcycle collided with a tree. When the ambulance arrived, he complained of loss of sensation and voluntary movement in his lower limbs, as well as impaired mobility in his upper limbs, especially his hands. Examination revealed that the accident had permanently damaged his spinal cord. Cecil was able to breathe on his own and, with exercise, movement of his upper limbs eventually improved, although the mobility of his hands was still impaired, and he never regained the use of his lower limbs. At which level was Cecil's spinal cord injured? Explain how you were able to determine your answer.

Brain and Cranial Nerves

The complexity of the human brain is mind-boggling. It contains around 100 billion neurons and another trillion glial cells. Even more amazing is that each neuron has an average of 10,000 connections with other neurons. From that complexity arises the command and control of our bodies by the spinal cord and spinal nerves, described in chapter 12, and the cranial nerves, discussed in this chapter, that connect directly to the brain. Furthermore, these connections also, importantly, generate our perception of self. Current research is adding insight into the organization and functions of the brain, yet much remains a mystery. This chapter lays the foundation by describing the structure of the brain, its functional units, and its associated cranial nerves. The integration of brain functions is discussed in chapter 14.

Learn to Predict

After mastering the mechanical bull at a local amusement park, Marvin decided he was ready to compete in an amateur rodeo. But during the very first event, a live bull threw Marvin to the dirt and kicked him in the side of the face. Clinicians in the emergency room diagnosed a broken jaw, and they noted that Marvin's tongue deviated to the right when they asked him to stick it out. A magnetic resonance imaging (MRI) scan was performed to detect the presence of brain or cranial nerve damage. **By recalling your knowledge of nervous system organization from chapter 11 and combining it with new information about the cranial nerves in this chapter, explain the results of Marvin's tongue protrusion test.**

Photo: MRI scan showing the head and brain of a patient.

13.1 Development of the CNS

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the development of the neural tube and name the embryonic pouches and the adult brain structures that they become.
- Explain the origin of the ventricles of the brain.

The brain is the part of the central nervous system (CNS) that is contained within the cranial cavity (figure 13.1). It consists of the brainstem, the cerebellum, the diencephalon, and the cerebrum (table 13.1). The brainstem includes the medulla oblongata, the pons, and the midbrain. We begin our study of the brain and the cranial nerves by examining how the CNS develops in the fetus.

The CNS forms from a flat plate of ectodermal tissue (see chapter 4), the **neural plate**, on the dorsal surface of the embryo. Just ventral to the neural plate is the **notochord**, a rod-shaped tissue that defines the axis of the embryo and eventually gives rise to the central region of the intervertebral disks (figure 13.2). The lateral sides of the neural plate become elevated as waves, forming **neural folds**. The crest of each fold is called a **neural crest**, and the center of the neural plate becomes the neural groove. The neural folds move toward each other in the midline and fuse to create a **neural tube** (figure 13.2), which gives rise to the CNS. The cephalic portion of the neural tube becomes the brain, and the caudal portion becomes the spinal cord. **Neural crest cells**

migrate away from the neural crests to give rise to all the sensory, autonomic, and enteric neurons of the peripheral nervous system. They also give rise to all the pigmented cells of the body, the adrenal medulla, the facial bones, and the dentin of the teeth.

A series of pouches develops in the anterior part of the neural tube, forming three brain regions in the early embryo (figure 13.3a): a **forebrain**, or *prosencephalon* (pros-en-sef'ă-lon); a **midbrain**, or *mesencephalon* (mez-en-sef'ă-lon); and a **hindbrain**, or *rhombencephalon* (rom-ben-sef'ă-lon). The pouch walls become the various portions of the adult brain (table 13.2). The forebrain divides into the **telencephalon** (tel-en-sef'ă-lon), which becomes the cerebrum, and the **diencephalon** (dī-en-sef'ă-lon). The midbrain remains a single structure as in the embryo, the **mesencephalon**. The hindbrain divides into the **metencephalon** (met'en-sef'ă-lon), which becomes the pons and cerebellum, and the **myelencephalon** (mī'el-en-sef'ă-lon), which becomes the medulla oblongata (figure 13.3b,c).

The pouch cavities become fluid-filled **ventricles** (ven'tri-klz). The ventricles are continuous with each other and with the **central canal** of the spinal cord. The neural tube develops flexures that cause the brain to be oriented almost 90 degrees to the spinal cord.

ASSESS YOUR PROGRESS

- Name the five pouches of the neural tube and the part of the adult brain that each division becomes.
- What do the cavities of the neural tube become in the adult brain?

13.2 Brainstem

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the parts of the brainstem and describe their structural characteristics.
- B. Explain the functions of the parts of the brainstem.

The **brainstem** connects the spinal cord to the base of the brain. The brainstem consists of three parts: the medulla oblongata, pons, and midbrain (figure 13.4). In addition to these anatomical divisions, the reticular formation is a functional unit that spans all three divisions. The brainstem is responsible for many essential functions. Damage to small areas often causes death, because many reflexes essential for survival are integrated in the brainstem, whereas relatively large areas of the cerebrum or cerebellum may be damaged without life-threatening consequences.

Medulla Oblongata

The **medulla oblongata** (ob-long-gah'tă), often called the medulla, is about 3 cm long. It is the most inferior part of the brainstem and is continuous inferiorly with the spinal cord. The medulla oblongata contains sensory and motor tracts, cranial nerve nuclei, and related nuclei. Superficially, the spinal cord blends into the medulla oblongata, but internally several differences exist. In the medulla oblongata, the gray matter is organized into discrete **nuclei** (figure 13.4b), clusters of gray matter composed mostly of neuron cell bodies. This arrangement contrasts with that of the gray matter of the spinal cord, which extends as a continuous mass in the center of the cord. Several medullary nuclei function as centers for vital reflexes, such as those involved in regulating heart rate, blood vessel diameter, respiration, swallowing, vomiting, hiccupping, coughing, and sneezing.

Two prominent enlargements on the anterior surface of the medulla oblongata are called **pyramids**, because they are broader near the pons and taper toward the spinal cord (figure 13.4a). The pyramids are formed by the large descending motor tracts involved in the conscious control of skeletal muscles. Near their inferior ends, most of the fibers of the descending tracts cross to the opposite side, or **decussate** (dē'kŭ-sāt, dē-kŭs'āt). This decussation accounts, in part, for the fact that each half of the brain controls the opposite half of the body. Its role as a conduction pathway is discussed in the description of ascending and descending tracts (see chapter 14).

Two rounded, oval structures, called **olives**, protrude from the anterior surface of the medulla oblongata just lateral to the superior ends of the pyramids (figure 13.4a,b). The olives are nuclei involved in functions such as balance, coordination, and modulation of sound from the inner ear (see chapter 15). Nuclei of cranial nerves V (trigeminal), VII (facial), IX (glossopharyngeal), X (vagus), XI (accessory), and XII (hypoglossal) are also located within the medulla oblongata (figure 13.4c). Note that some cranial nerves, such as V, VII, and X, have more than one nucleus in the brainstem and that some nuclei, such as the solitary nucleus and nucleus ambiguus, serve as nuclei for multiple cranial nerves.

Pons

The part of the brainstem just superior to the medulla oblongata is the **pons** (figure 13.4a). The pons contains ascending and descending tracts and several nuclei. The pontine nuclei, located in the anterior portion of the pons, relay information from the cerebrum to the cerebellum.

The posterior region of the pons contains nuclei for cranial nerves V (trigeminal), VI (abducens), VII (facial), and VIII (vestibulocochlear). Other important pontine areas are the pontine sleep center, which initiates rapid eye movement sleep (see chapter 14), and the pontine respiratory center, which works with the respiratory centers in the medulla oblongata to help control respiratory movements (see chapter 23).

Midbrain

The **midbrain**, or *mesencephalon*, is the smallest region of the brainstem (figure 13.4b). It is located just superior to the pons. The midbrain contains the nuclei of cranial nerves III (oculomotor), IV (trochlear), and V (trigeminal).

The **tectum** (tek'tŭm; roof; figure 13.5) of the midbrain consists of four nuclei that form mounds on the dorsal surface, collectively called **corpora** (kōr'pōr-ă; bodies) **quadrigemina** (kwah'dri-jem'i-nă; four twins). Each mound is called a **colliculus** (ko-lik'ŭ-lŭs; hill); the two superior mounds are superior colliculi, and the two inferior mounds are inferior colliculi (see figure 13.4b).

The **superior colliculi** receive sensory input from visual, auditory, and tactile sensory systems and are involved in the reflex movements of the head, eyes, and body toward these stimuli, such as loud noises, flashing lights, or startling pain. For example, when a bright object suddenly appears in a person's field of vision, a reflex turns the eyes to focus on it; when a person hears a sudden, loud noise, a reflex turns the head and eyes toward it. The superior colliculi also receive input from the inferior colliculi and the cerebrum.

The **inferior colliculi** are involved in hearing and are an integral part of the auditory pathways in the CNS. Neurons conducting action potentials from the structures of the inner ear (see chapter 15) to the brain synapse in the inferior colliculi. Collateral fibers from the inferior colliculi to the superior colliculi provide auditory input that stimulates visual reflexes.

The **tegmentum** (teg-men'tŭm) of the midbrain largely consists of ascending tracts, such as the spinothalamic tract and the medial lemniscus, that carry sensory information from the spinal cord to the brain. The tegmentum also contains the red nuclei, the cerebral peduncles, and the substantia nigra. The paired **red nuclei** (figure 13.5) are so named because in fresh brain specimens they are pinkish in color as a result of an abundant blood supply. The red nuclei aid in the unconscious regulation and coordination of motor activities. **Cerebral peduncles** (pe-dŭng'klz, pē'dŭng-klz; the foot of a column) constitute the portion of the midbrain ventral to the tegmentum. They consist primarily of descending tracts, which carry motor information from the cerebrum to the brainstem and spinal cord. The **substantia nigra** (nŭ'gră; black substance) is a nuclear mass between the tegmentum and cerebral peduncles containing cytoplasmic melanin granules that give it a dark gray or black color (figure 13.5). The substantia nigra is interconnected with other basal nuclei of the cerebrum, described in section 13.5, and it is involved in maintaining muscle tone and coordinating movements.

FIGURE 13.4 Diencephalon and Brainstem

(a) Anterior view. (b) Posterolateral view. The inset shows the location of the diencephalon (red) and the brainstem (blue). (c) Brainstem nuclei. The sensory nuclei are shown on the left (green). The motor nuclei are shown on the right (purple). Even though the nuclei are shown on only one side, each half of the brainstem has both sensory and motor nuclei. (CN = cranial nerve) **APR**

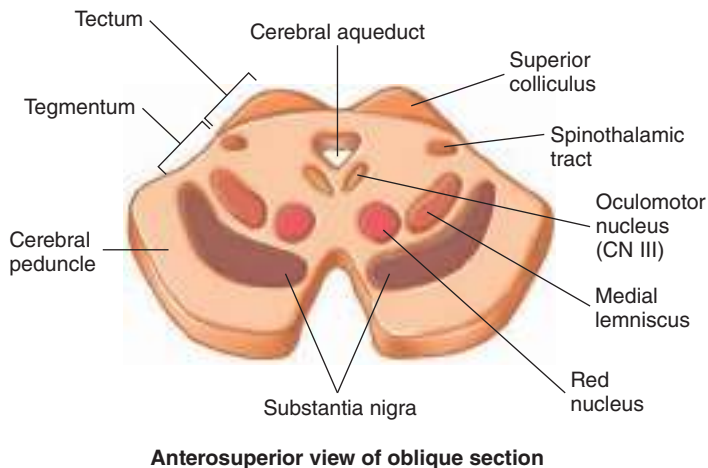

FIGURE 13.5 Oblique Section Through the Midbrain

Inset shows the level of section.

Reticular Formation

The **reticular formation** is a diffuse, but interconnected, system of loosely packed nuclei scattered throughout the brainstem. Reticular formation neurons play roles in arousal and awareness. The reticular formation receives axons from a large number of sources and especially from nerves that innervate the face. The reticular formation modulates and controls many functions mediated by the brainstem, only a few of which are listed here. Some reticular formation neurons send axons to the spinal cord in a motor tract that controls posture, whereas others send axons that reduce the transmission of pain signals from the spinal cord (see chapter 14). By modulating the activity of cranial nuclei within the brainstem, the reticular formation coordinates the rhythmic activities of swallowing, breathing, and the heart rate. Finally, the reticular formation controls the state of alertness and consciousness, including the sleep-wake cycle (see chapter 14).

Predict 2

Willy was driving his car too fast on his way to school, when the car left the road and hit a guard rail. Elizabeth saw the accident and called 911 on her cell phone. Willy's injuries resulted in extensive blood loss and, while waiting for Life Flight, his heart rate became rapid and his blood pressure fell to a very low level. Pallor (pale complexion) developed progressively, and his breathing was heavy. Which areas of Willy's brain were most important in integrating these responses?

ASSESS YOUR PROGRESS

3. What are the major functions of the medulla oblongata? What cranial nerves have nuclei in the medulla oblongata?

4. What activities do the pontine nuclei help control? What cranial nerves have nuclei in the pons?
5. What are the parts of the midbrain and their functions?
6. What is the function of the reticular formation?

13.3 Cerebellum

LEARNING OUTCOME

After reading this section, you should be able to

- A. List the major regions of the cerebellum and describe the functions of each.

The **cerebellum** (ser-e-bel'üm; little brain) is attached to the brainstem posterior to the pons (figure 13.6). It communicates with other regions of the CNS through three large tracts called **cerebellar peduncles** (see figure 13.4b). The superior, middle, and inferior cerebellar peduncles connect the cerebellum to the midbrain, pons, and medulla oblongata, respectively. The cerebellum has a gray cortex and nuclei, with white medulla in between. (*Medulla* in this case is a general term meaning “the center of a structure.”) The cerebellar cortex has ridges called **folia**. The white matter of the medulla resembles a branching tree and is called the **arbor vitae** (ar'bör vī'tē; tree of life). The **nuclei** of the cerebellum are located in the deep inferior center of the white matter.

The cerebellar cortex contains more neurons than the entire cerebral cortex. These neurons include stellate, basket, granule, Golgi, and Purkinje cells. The cerebellar cortex also contains mossy fibers, which are afferent axons that branch extensively within the cerebellum. **Purkinje** (pür-kin'jē) **cells** are the largest and probably most interesting cells in the CNS. Each Purkinje cell receives about 200,000 synapses from passing fibers. Purkinje cells are inhibitory neurons and are the only cerebellar cortex neurons that send axons to the cerebellar nuclei.

The cerebellum consists of three parts: a small, inferior part, the **flocculonodular** (flok'ū-lō-nod'ū-lār) **lobe**; a narrow, central **vermis** (worm-shaped); and two large, **lateral hemispheres** (figure 13.6b,c). The flocculonodular lobe, the simplest part of the cerebellum, helps control balance and eye movements. The vermis and the medial portion of the lateral hemispheres are involved in controlling posture, locomotion, and fine motor coordination, thereby producing smooth, flowing movements. The major portions of the lateral hemispheres of the cerebellum function in concert with the frontal lobes of the cerebral cortex in planning, practicing, and learning complex movements.

Each lateral hemisphere is divided by a **primary fissure** into an **anterior lobe** and a **posterior lobe**. The lobes are subdivided into **lobules**, which contain the folia.

ASSESS YOUR PROGRESS

7. How are the gray matter and white matter arranged in the cerebellum? What is the arbor vitae?
8. What are the major regions of the cerebellum? What are the primary functions of each?

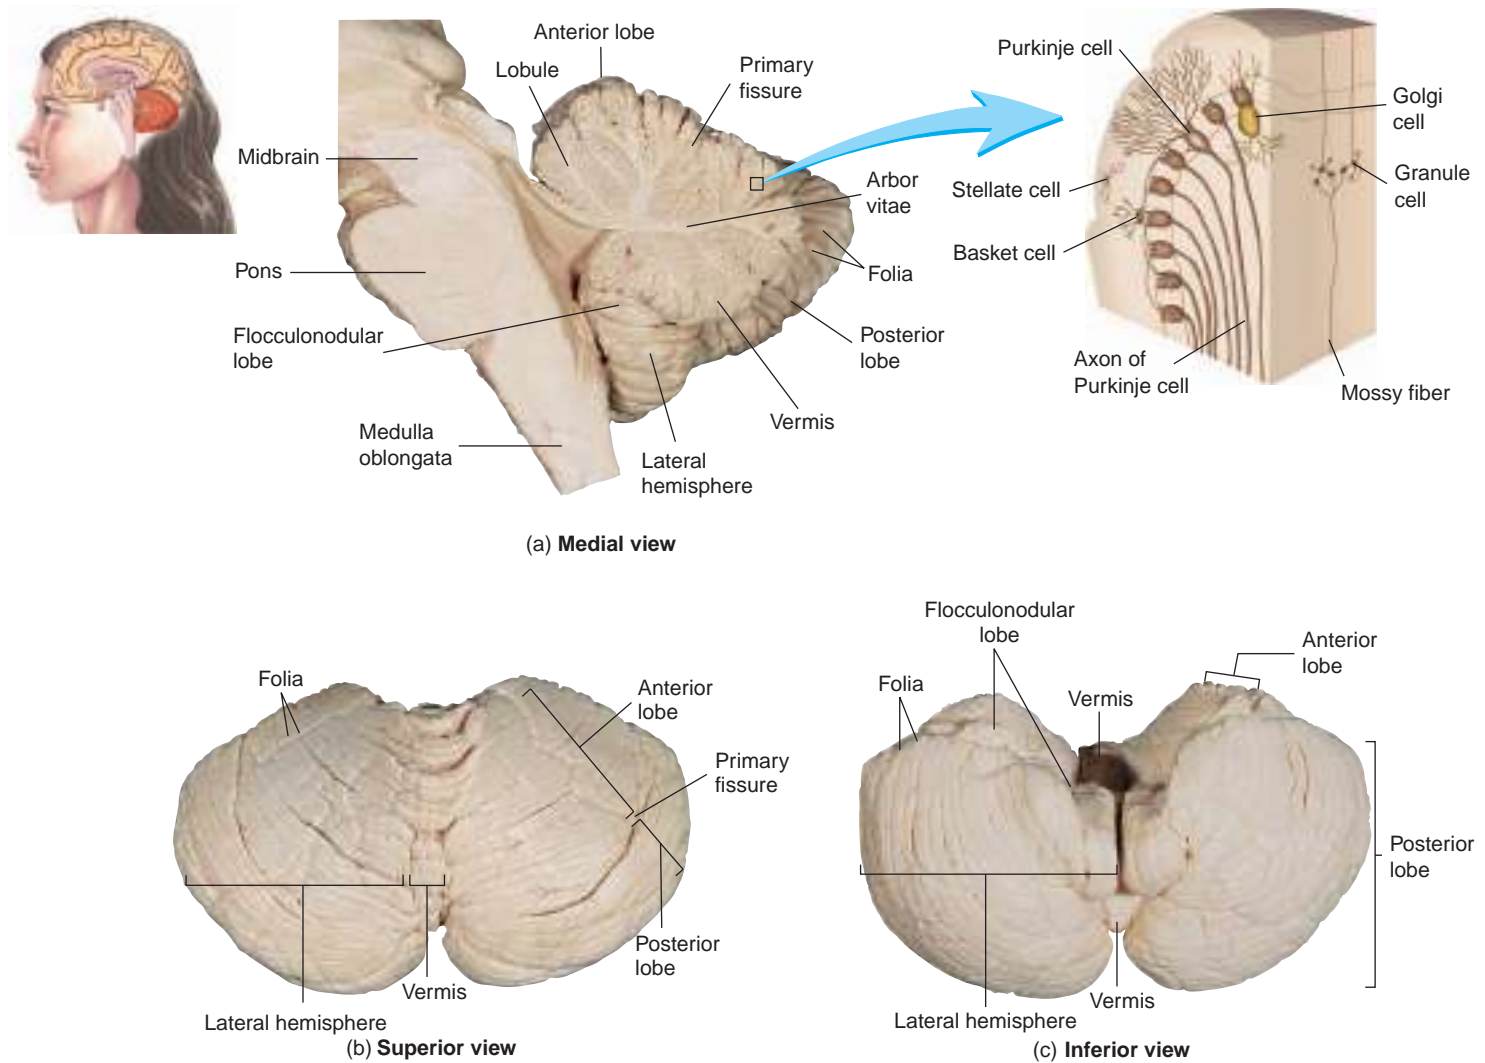

FIGURE 13.6 Cerebellum

(a) Right half of the cerebellum and brainstem as seen in a median section. Inset shows the histology of the cerebellum. (b) Superior view of the cerebellum. (c) Inferior view of the cerebellum. **APR**

13.4 Diencephalon

LEARNING OUTCOME

After reading this section, you should be able to

- A. List the parts of the diencephalon and state their functions.**

The **diencephalon** (dī-en-sef'ă-lon) is the part of the brain between the brainstem and the cerebrum (figure 13.7; see figures 13.1 and 13.4). Its main components are the thalamus, subthalamus, epithalamus, and hypothalamus.

Thalamus

The **thalamus** (thal'ă-mūs; figure 13.7*a,b*) is by far the largest part of the diencephalon, constituting about four-fifths of its weight. It consists of a cluster of nuclei shaped somewhat like a yo-yo, with two large, lateral portions connected in the center by a small stalk called the **interthalamic adhesion**, or *intermediate*

mass. The space surrounding the interthalamic adhesion and separating the two large portions of the thalamus is the third ventricle of the brain.

Except for the olfactory neurons, all sensory neurons that project to the cerebrum first synapse in the thalamus. Thalamic neurons then send projections to the appropriate areas of the cerebral cortex where sensory input is localized (see chapter 14). For this reason, the thalamus is considered the **sensory relay center** of the brain. Axons carrying auditory information synapse in the **medial geniculate** (je-nik'ū-lāt) **nucleus** of the thalamus. Axons carrying visual information synapse in the **lateral geniculate nucleus**. Most other sensory impulses synapse in the **ventral posterior nucleus**. Axons originating in the ventral posterior nucleus project to the **dorsal tier** of nuclei, which register pain (figure 13.7*b*). Other axons project to the cerebral cortex where sensory input is localized (see chapter 14). The **ventral anterior nucleus** and the **ventral lateral nucleus** are involved with motor functions, communicating among the basal nuclei, the cerebellum, and the motor cortex (areas described later in this chapter).

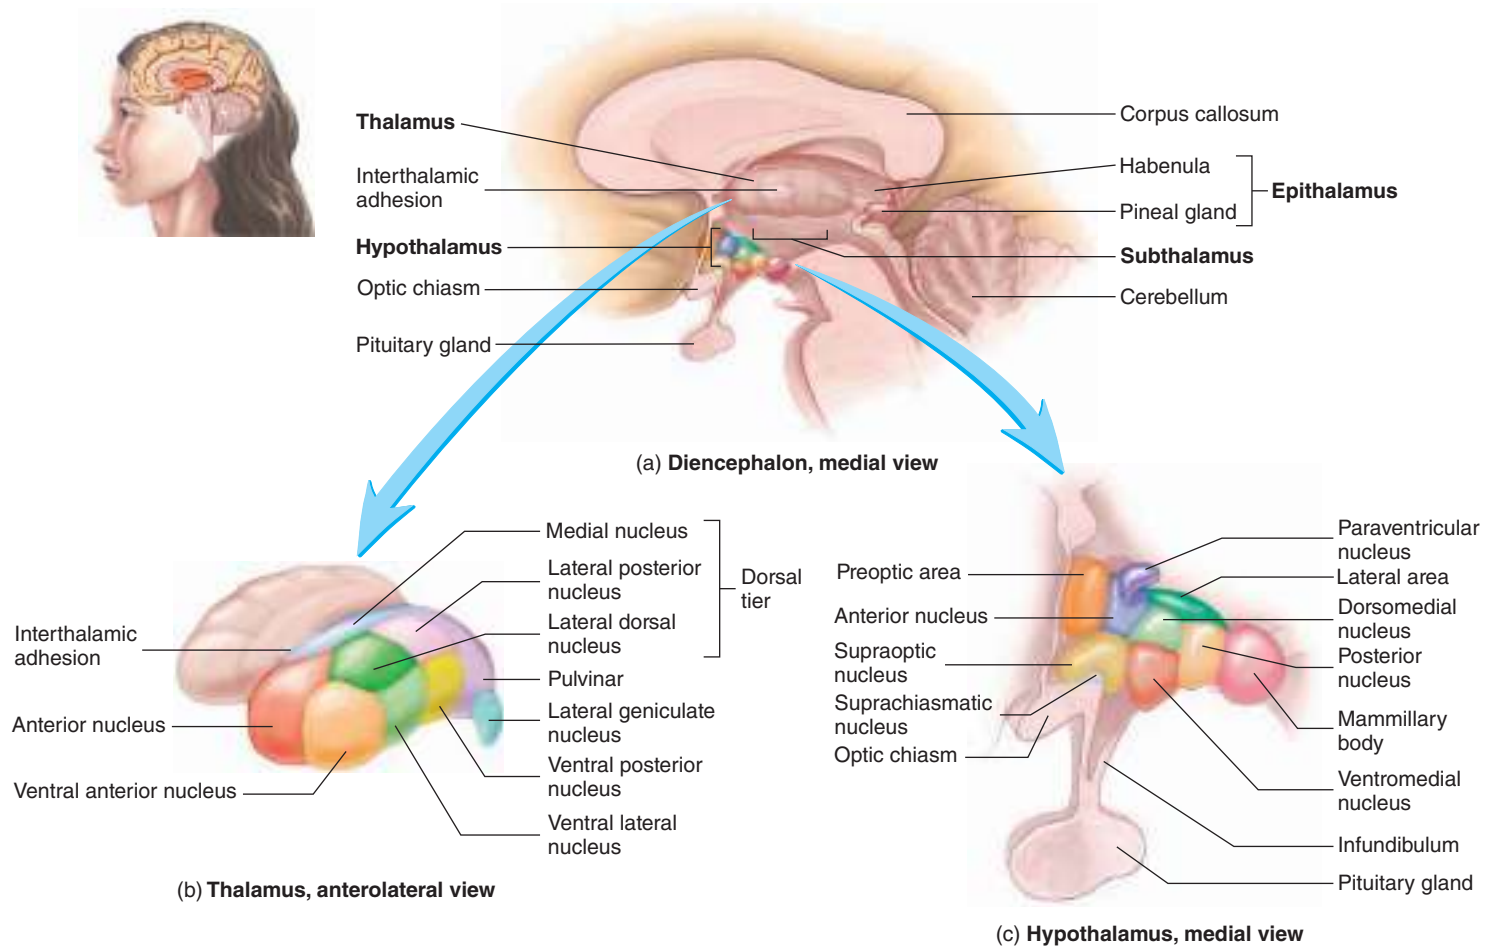

FIGURE 13.7 Diencephalon

(a) General overview of the right half of the diencephalon as seen in a median section. (b) Thalamus, showing the nuclei of the left half. (c) Hypothalamus, showing the nuclei and right half of the pituitary.

The thalamus also influences mood and actions associated with strong emotions, such as fear and rage. The **anterior** and **medial nuclei** are connected to the limbic system and to the prefrontal cortex (described later in this chapter and in chapter 14). These nuclei are involved in mood modification. The **lateral dorsal nuclei**, which are connected to other thalamic nuclei and to the cerebral cortex, are involved in regulating emotions. The **lateral posterior nuclei** and the **pulvinar** (pŭl-vī'nār) also have connections to other thalamic nuclei and are involved in sensory integration.

Subthalamus

The **subthalamus** is a small area immediately inferior to the thalamus (figure 13.7a). It contains the **subthalamic nuclei** and several ascending and descending tracts. The subthalamic nuclei are associated with the basal nuclei and are involved in controlling motor functions. Small portions of two regions of the midbrain involved in motor coordination, the red nucleus and the substantia nigra, also extend into this area.

Epithalamus

The **epithalamus** is a small area superior and posterior to the thalamus (figure 13.7a). It consists of the habenula and the pineal gland. The **habenula** (hä-ben'ū-lä) is influenced by the sense of smell and

is involved in emotional and visceral responses to odors. The **pineal** (pin'ē-äl) **gland**, or **pineal body**, is shaped somewhat like a pinecone, from which the name *pineal* is derived. Pineal gland functions in humans are not fully understood, but they involve modulation of the sleep-wake cycle and other biorhythms.

Hypothalamus

The **hypothalamus** is the most inferior portion of the diencephalon (figure 13.7a,c). It contains a cluster of small nuclei and tracts. The most conspicuous nuclei, called the **mammillary bodies**, appear as bulges on the ventral surface of the diencephalon. They are involved in olfactory reflexes and emotional responses to odors. They may also be involved in memory.

The hypothalamus is a central controller of the endocrine system. A funnel-shaped stalk, the **infundibulum** (in-fŭn-dib'ū-lŭm), extends from the floor of the hypothalamus and connects it to the pituitary gland. The hypothalamus regulates the pituitary gland's secretion of hormones, which influence functions as diverse as metabolism, reproduction, responses to stressful stimuli, and urine production (table 13.3; see chapter 18).

The hypothalamus receives and coordinates the responses to sensory input from multiple systems. Sensory neurons that terminate in the hypothalamus provide input from (1) internal

TABLE 13.3 Functions of the Hypothalamus

Function	Hypothalamic Nuclei	Description
Autonomic	Preoptic area and anterior nucleus (parasympathetic) Lateral area and posterior nucleus (sympathetic)	Helps control heart rate, urine release from the bladder, movement of food through the digestive tract, and blood vessel diameter
Endocrine	Paraventricular nucleus Supraoptic nucleus	Helps regulate pituitary gland secretions and influences metabolism, ion concentration, sexual development, and sexual functions; serves as the site of antidiuretic hormone and oxytocin production (see chapter 18)
Muscle control	Lateral area	Controls the muscles involved in swallowing; stimulates shivering
Regulation of body temperature	Preoptic area Anterior nucleus Posterior nucleus	Promotes heat loss when the hypothalamic temperature increases by increasing sweat production (anterior nucleus); promotes heat production when the hypothalamic temperature decreases by stimulating shivering (posterior nucleus); aspirin reduces fever by affecting the preoptic area
Regulation of food and water intake	Ventromedial nucleus Lateral area	Hunger center promotes eating; satiety center inhibits eating; thirst center promotes water intake
Emotions	Lateral area Medial area	Large range of emotional influences over body functions; directly involved in stress-related and psychosomatic illnesses and in feelings of fear and rage
Regulation of the sleep-wake cycle	Lateral area Suprachiasmatic nucleus	Coordinates responses to the sleep-wake cycle with the other areas of the brain (e.g., the reticular activating system); suprachiasmatic nucleus receives direct input from the eyes concerning light/dark cycles and is implicated in jet lag
Sexual development and behavior	Preoptic area Dorsomedial nucleus Ventromedial nucleus	Stimulates sexual development, sexual arousal, and sexual behavior; the preoptic area is larger in males than in females

organs; (2) taste receptors of the tongue; (3) the limbic system, which is involved in many activities, including responses to smell; (4) specific cutaneous areas, such as the nipples and external genitalia; and (5) the eyes. Efferent fibers from the hypothalamus extend into the brainstem and the spinal cord, where they synapse with neurons of the autonomic nervous system (see chapter 16). In this way, the hypothalamus serves as the major coordinating center of the autonomic nervous system. These connections regulate functions such as heart rate and digestive activities (table 13.3).

In addition to regulating autonomic functions, other hypothalamic efferent fibers extend through the infundibulum to the posterior portion of the pituitary gland (see chapter 18). Some hypothalamic fibers extend to trigeminal and facial nerve nuclei to help control the muscles involved in swallowing; and some extend to motor neurons of the spinal cord to stimulate shivering. Hypothalamic nuclei can directly control body temperature by stimulating sweating or shivering.

Hypothalamic nuclei are also involved in controlling thirst, hunger, and sex drive. In particular, they are very important in a number of functions related to mood, motivation, and emotion. Sensations such as sexual pleasure, relaxation after a meal, rage, and fear are related to hypothalamic functions. This is one reason that strong emotional experiences may affect a person's desire or ability to eat, drink, or experience sexual pleasure, and vice versa. The hypothalamus also interacts with the reticular activating system in the brainstem to coordinate the sleep-wake cycle (table 13.3).

ASSESS YOUR PROGRESS

9. What are the four main components of the diencephalon?
10. Which part serves as the sensory relay center of the brain? As the link between the nervous system and the endocrine system?
11. What is the role of the subthalamus? Name the parts of the epithalamus, and give their functions.
12. List and explain the functions of the hypothalamus.

13.5 Cerebrum

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the structure of the cerebrum, including the lobes, fissures, sulci, cerebral cortex, and cerebral medulla.**
- B. Relate the principle function of each lobe of the cerebrum.**
- C. List and describe the three types of tracts found in the cerebrum.**
- D. List the basal nuclei and explain their function.**
- E. State the parts and functions of the limbic system.**

The cerebrum (figure 13.8) is the part of the brain that most people think of when the term *brain* is mentioned. The cerebrum accounts for the largest portion of total brain weight, which is

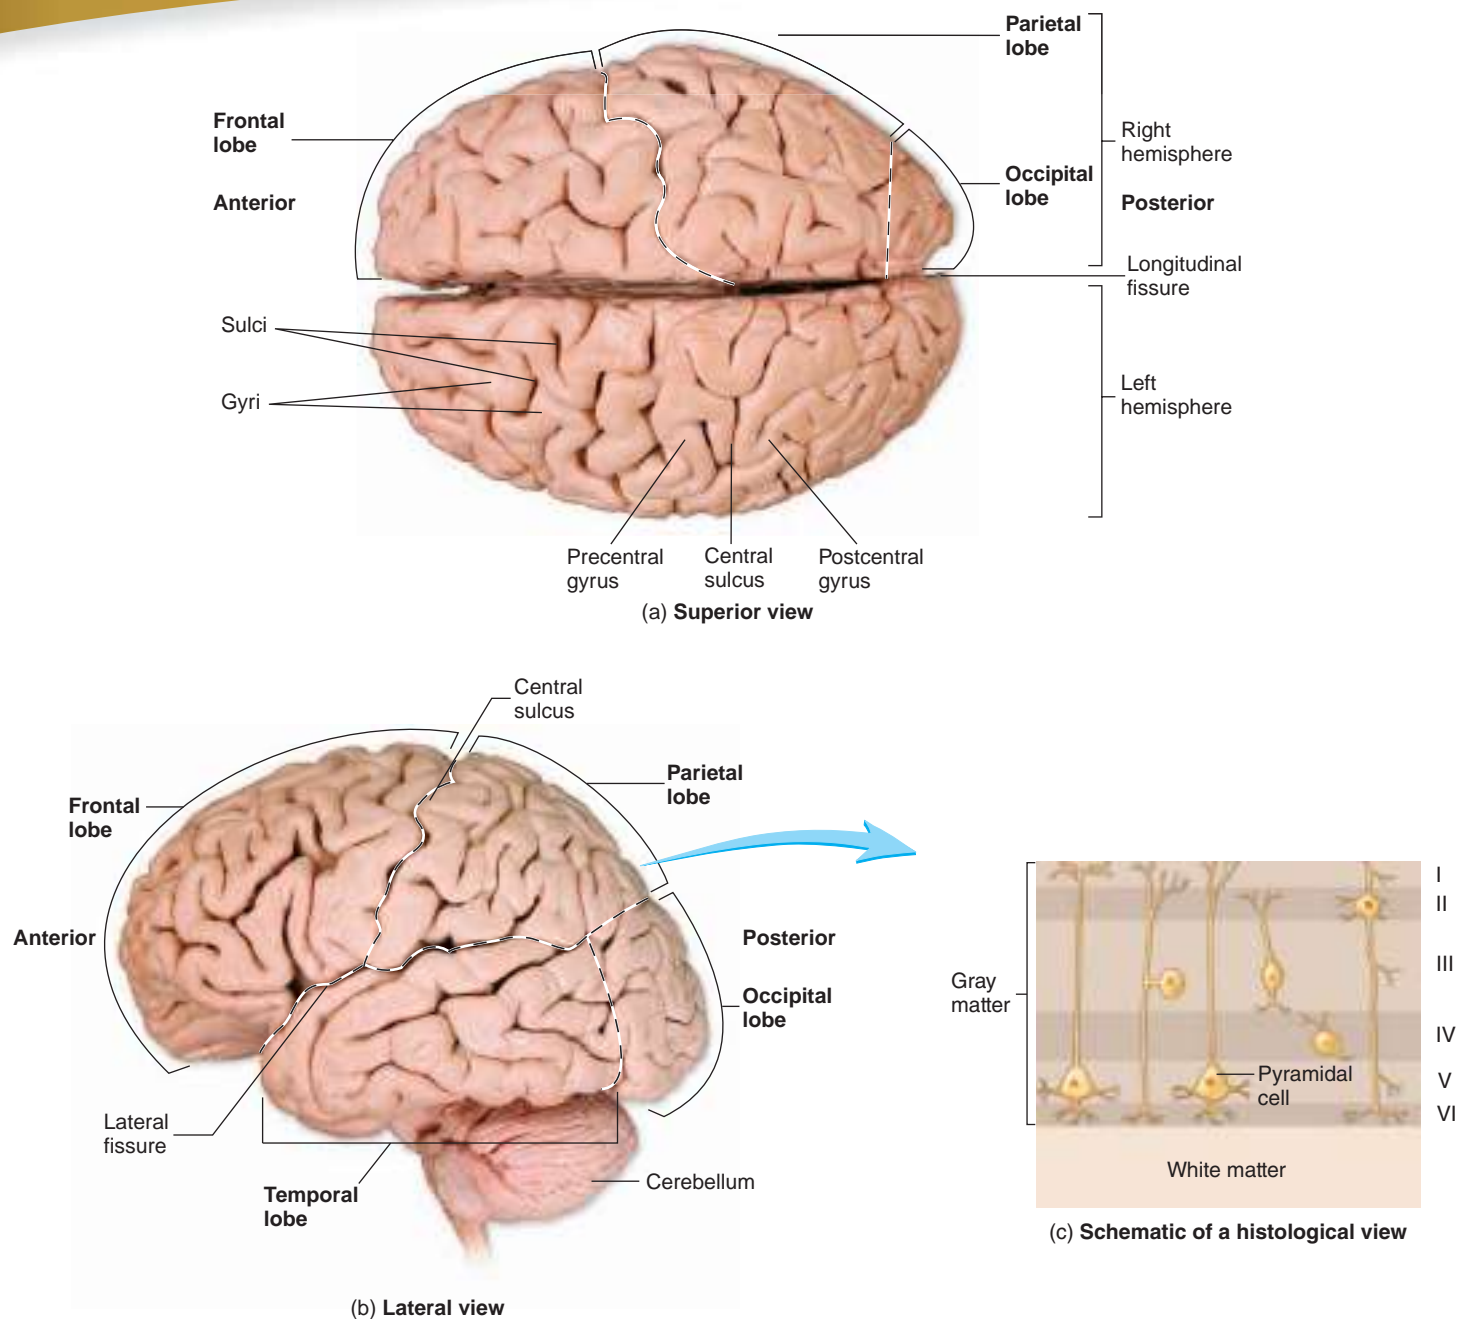

FIGURE 13.8 Cerebrum

(a) Superior view of the two hemispheres. (b) Lateral view of the left cerebral hemisphere, showing the lobes. (c) Layers and cell types of the cerebral cortex. **APR**

about 1200 g in females and 1400 g in males. Brain size is related to body size; larger brains are associated with larger bodies, not with greater intelligence.

The cerebrum is divided into left and right hemispheres by a **longitudinal fissure** (figure 13.8a). The most conspicuous features on the surface of each hemisphere are numerous folds called **gyri** (jī'ri; sing. gyrus), which greatly increase the surface area of the cortex. The grooves between the gyri, called **sulci** (sūl'sī; sing. sulcus), divide each hemisphere into lobes. The **central sulcus** is located about midway along the length of the brain. It extends

across the lateral surface of the cerebrum from superior to inferior to separate the frontal and parietal lobes. Anterior to the central sulcus is the **precentral gyrus**, which is the **primary motor cortex**. Posterior to the central sulcus is the **postcentral gyrus**, which is the **primary somatic sensory cortex** (see chapter 14). The general pattern of the gyri is similar in all normal human brains, but some variation exists between individuals and even between the two hemispheres of the same cerebrum.

Each cerebral hemisphere is divided into lobes, which are named for the skull bones overlying each of them (figure 13.8b).

The **frontal lobe** is important in voluntary motor function, motivation, aggression, the sense of smell, and mood. The anterior region, called the prefrontal cortex, is involved in personality and decision making (see chapter 14). The **parietal lobe** is the major center for receiving and evaluating most sensory information, except for smell, hearing, taste, and vision. The frontal and parietal lobes are separated by the central sulcus. The **occipital lobe** functions in receiving and integrating visual input and is not distinctly separate from the other lobes. The **temporal lobe** receives and evaluates input for smell and hearing and plays an important role in memory. Its anterior and inferior portions are associated with such brain functions as abstract thought and judgment. The temporal lobe is separated from the rest of the cerebrum by a **lateral fissure**, and deep within the fissure is the **insula** (in'soo-lă; island). The insula receives and evaluates taste information and is often referred to as a fifth lobe.

The gray matter on the outer surface of the cerebrum is the **cerebral cortex**, and clusters of gray matter deep inside the brain are nuclei. The cerebral cortex contains a number of neuron types, named largely for their shape, such as fusiform cells, stellate cells, and pyramidal cells (figure 13.8c). These cells are distributed in layers within the cerebral cortex. The thickness of the cortex is not uniform throughout the cerebrum but ranges from two or three layers in the most “primitive” parts of the cortex to six layers in the more “advanced” regions.

The white matter of the brain between the cortex and the nuclei is the **cerebral medulla**. This term should not be confused with *medulla oblongata*. The cerebral medulla consists of tracts that connect areas of the cerebral cortex to each other or to other parts of the CNS (figure 13.9). The fibers in these tracts fall into three main

categories: association, commissural, and projection. **Association fibers** connect areas of the cerebral cortex within the *same* hemisphere. **Commissural fibers** connect one cerebral hemisphere to the *other* hemisphere. Bundles of commissural fibers are often referred to as a **commissure**. The largest bundle of commissural fibers is the **corpus callosum** (kōr'pūs ka-lō'sūm; see figure 13.1). **Projection fibers** connect the cerebrum to other parts of the brain and spinal cord (figure 13.9). The projection fibers form the **internal capsule**.

Basal Nuclei

The **basal nuclei** are a group of functionally related nuclei beneath the cortex (subcortical). These nuclei are located bilaterally in the inferior cerebrum, diencephalon, and midbrain (figure 13.10). The basal nuclei are involved in controlling motor functions (see chapter 14). The basal nuclei are the largest nuclei of the brain and occupy a large part of the cerebrum. The nuclei in the cerebrum are collectively called the **corpus striatum** (kōr'pūs strī-ā'tūm) and include the **caudate** (kaw'dāt; having a tail) **nucleus** and the **lentiform** (len'ti-fōrm; lens-shaped) **nucleus**. The lentiform nucleus, in turn, is divided into a lateral **putamen** (pū-tā'men) and the medial **globus pallidus** (glō'būs pal'li-dūs; pale globe). Two additional basal nuclei are the **subthalamic nucleus** in the diencephalon and the **substantia nigra** in the midbrain. The subthalamic nucleus and substantia nigra function with the caudate and lentiform nuclei to control movement.

Limbic System

Parts of the cerebrum and diencephalon are grouped together under the title **limbic system** (figure 13.11). The limbic system plays a

central role in basic survival functions, such as memory, reproduction, and nutrition. It is also involved in interpreting sensory input and emotions in general. The term *limbic* (lim’bik; border) refers to deep portions of the cerebrum that form a ring around the diencephalon. Structurally, the limbic system consists of (1) certain cerebral cortical areas, including the **cingulate** (sin’gū-lāt; to surround) **gyrus**, located along the inner surface of the longitudinal fissure just above the corpus callosum, and the **parahippocampal gyrus**, located on the medial side of the temporal lobe; (2) various nuclei, such as anterior nuclei of the thalamus, the habenula in the epithalamus, and the **dentate gyrus** of the **hippocampus**; (3) parts of the basal nuclei, such as the **amygdala**; (4) the hypothalamus, especially the mammillary bodies; (5) the **olfactory cortex**; and (6) tracts connecting the various cortical areas and nuclei, such as the **fornix**, which connects the hippocampus to the thalamus and mammillary bodies.

ASSESS YOUR PROGRESS

13. Distinguish between gyri and sulci. What structures do the longitudinal fissure, central sulcus, and lateral fissure separate?

14. Describe the cerebral cortex and the cerebral medulla.
15. Name the five lobes of the cerebrum, and describe their locations and functions.
16. List the three categories of tracts in the cerebral medulla, and tell what each connects.
17. List the basal nuclei, and state their general function.
18. What are the parts of the limbic system? What are the functions of this system?

13.6 Meninges, Ventricles, and Cerebrospinal Fluid

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the meninges and the spaces between them.**
- B. Identify the locations of the four ventricles and the structures that connect them.**

FIGURE 13.11 Limbic System and Associated Structures of the Right Hemisphere

C. Explain how cerebrospinal fluid is formed, circulated, and returned to the blood.

D. Describe the function of cerebrospinal fluid.

Meninges

Three connective tissue membranes, the **meninges** (mě-nin'jēz), surround and protect the brain and spinal cord (figure 13.12). The most superficial and thickest membrane is the **dura mater** (doo'ra mā'ter; tough mother), which is composed of dense irregular connective tissue. Within the vertebral canal, the dura mater is distinctly separate from the vertebrae. This allows the formation of an **epidural space**, which lies between the dura and the vertebral bones. Within the cranial cavity, the dura mater tightly adheres to the cranial bones, so the epidural space of the cranial cavity is only a potential space. The dura mater within the cranial cavity consists of two layers. The outer layer, the **periosteal dura**, is the inner periosteum of the cranial bones. The inner layer, the **meningeal dura**, is continuous with the dura of the spinal cord. The meningeal dura is separated from the periosteal dura in several regions to form structures called dural folds and dural venous sinuses.

Dural folds are tough connective tissue partitions that extend into the major brain fissures. The dural folds help hold the brain in place within the skull and keep it from moving around too freely. The largest of the dural folds is the **falx cerebri** (falks se-rē'brē; sickle-shaped). The falx cerebri lies in the longitudinal fissure that separates the left and right hemispheres. It is anchored anteriorly to the ethmoid bone. Two other important dural folds are the **tentorium cerebelli** (ten-tō'rē-ŭm; tent) **cerebelli** (ser'ē-bel'ē), which lies between the

Clinical IMPACT

Traumatic Brain Injuries

Head injuries are classified as **open** (when some of the cranial cavity contents are exposed to the outside) or **closed** (when the cranial cavity remains intact). Closed injuries are more common and usually result from the head striking a hard surface or an object striking the head. Such injuries may cause brain trauma—either **coup** (kū), occurring at the site of impact, or **contrecoup** (kon'tra-kū), occurring on the opposite side of the brain from the impact as a result of the brain moving within the skull. Traumatic brain injury is three times more common in males than in females. The most common traumatic brain injury (75–90%) is a **concussion**, characterized by immediate, but transient, impairment of neural function, such as loss of consciousness or blurred vision.

Traumatic brain injury has been called the “signature wound” of the Iraq and Afghanistan wars. A large number of soldiers have suffered from blasts, often from improvised explosive devices, which in previous wars would have been lethal without current armor and helmets. Unfortunately, effective treatment of traumatic brain injury remains difficult and is even more challenging for soldiers with physical and psychiatric symptoms that overlap with posttraumatic stress disorder (PTSD). In addition, the consequences of repeated concussions in contact sports, such as football, are now being recognized as underlying long-term brain damage and dementia.

cerebrum and the cerebellum, and the **falx cerebelli**, which lies between the two cerebellar hemispheres.

Dural venous sinuses are drainage channels that form where the two layers of the dura mater are separated from each other. The dural venous sinuses are lined with endothelium and transport venous blood and cerebrospinal fluid (CSF; see “Cerebrospinal Fluid” later in this section) away from the brain. All veins draining blood from the brain empty into dural venous

sinuses. The largest of the sinuses, the superior sagittal sinus, forms between the falx cerebri and the periosteal dura and runs along the median plane (figure 13.12b). The dural sinuses subsequently drain into the internal jugular veins, which are the major veins that exit the cranial cavity to carry blood back to the heart (see chapter 21).

The next meningeal membrane is the very thin, wispy **arachnoid** (ă-rak’noyd; spiderlike, as in cobwebs) **mater**. The space between

this membrane and the dura mater is the **subdural space**; it contains only a very small amount of serous fluid. The third meningeal layer, the **pia** (pī'ă, pē'ă; affectionate) **mater** is bound very tightly to the surface of the brain. Between the arachnoid mater and the pia mater is the **subarachnoid space**, which contains weblike strands of arachnoid mater and the blood vessels supplying the brain. The subarachnoid space is filled with CSF.

Ventricles

The CNS forms as a hollow tube that may be quite reduced in some areas of the adult CNS and expanded in other areas (see section 13.1). The interior of the tube is lined with a single layer of epithelial cells called **ependymal** (ep-en'di-mäl) **cells** (see chapter 11). Each cerebral hemisphere contains a relatively large cavity, the **lateral ventricle** (figure 13.13). The lateral ventricles are separated from each other by a thin membrane called the **septum pellucidum** (sep'tüm pe-loo'si-düm; translucent walls). The septum pellucidum lies in the midline just inferior to the corpus callosum between the anterior horns of the lateral ventricles. The lateral ventricles can be thought of as the first and second ventricles, but they are not designated as such. The **third ventricle** is a smaller cavity located at the midline between the two halves of the thalamus. The two lateral ventricles are connected with the third ventricle through two **interventricular foramina**. The **fourth ventricle** is in the inferior part of the pontine region and the superior region of the medulla oblongata at the base of the cerebellum. The third ventricle is connected to the fourth ventricle through a narrow canal, the **cerebral aqueduct**, which passes through the midbrain. The fourth ventricle is continuous with the central canal of the spinal cord, which extends nearly the full length of the cord. The fourth ventricle is also continuous with the subarachnoid space through apertures to allow circulation of cerebrospinal fluid out of the CNS.

Cerebrospinal Fluid

Cerebrospinal (ser'ě-brō-spī-näl; sě-rē'brō-spī-näl) **fluid (CSF)** is a clear fluid similar to blood serum but without most of the proteins. It bathes the brain and the spinal cord and provides a protective cushion around the CNS. CSF allows the brain to float within the cranial cavity, so that it does not rest directly on the surface of the skull or dura mater. In addition, it protects the brain against the shock of rapid head movements. It also provides some nutrients to CNS tissues.

The CSF is produced by a secretory structure called the **choroid** (kō'royd; lacy) **plexus** (plek'süs). The choroid plexus consists of a layer of specialized ependymal cells surrounded by supportive loose connective tissue and associated blood vessels. The choroid plexuses are formed by invaginations of the vascular pia mater into the ventricles, thus producing a vascular connective tissue core covered by ependymal cells (figure 13.14 *inset, lower left*). There is a choroid plexus in each of the ventricles, although about 80–90% of the CSF is produced within the lateral ventricles.

CSF is formed by the transport of water and solutes from the blood through a variety of mechanisms. The majority of the fluid enters the ventricles by following a Na^+ concentration gradient.

Case STUDY

Head Trauma

The body of an 80-year-old woman was being examined by a hospital pathologist to determine the cause of death. Her medical records indicated no significant history of cardiovascular disease, stroke, Alzheimer disease, or cancer. She had been taken to the emergency room after being found not breathing, lying in her bathtub. Bleeding over the occipital region of her scalp led the pathologist to hypothesize that she had slipped and fallen while getting into the bath and had hit the back of her head on the edge of the tub. Because the pathologist suspected that a traumatic brain injury had caused her death, he focused most of his attention on the contents of the cranial cavity. The pathologist noted superficial bruising and bleeding of the scalp in the occipital region of the woman's head. He then opened the cranial cavity, where he noted a large subdural hematoma above the right frontal lobe of the woman's brain. In addition, he saw that the brain had shifted due to the extensive bleeding, so that the medulla oblongata had been pushed inferiorly (herniated) through the foramen magnum into the vertebral canal. After completing a thorough inspection of the remainder of the woman's body, the pathologist determined that a subdural hematoma resulting from traumatic brain injury had caused the woman's death.

Predict 3

- Explain why the subdural hematoma was found in the frontal region of the brain, when the blow to the head occurred over the occipital region.
- How did the herniation of the medulla oblongata into the vertebral canal affect brain function and contribute to the woman's death?

Ependymal cells of the choroid plexus actively transport Na^+ into the ventricles, and water passively follows. Large molecules are transported by pinocytosis. Glucose is transported by facilitated diffusion mediated by a specific glucose transporter (see chapter 3). Since glucose is the primary energy source for the brain, patients with mutations in this transporter (GLUT1) are severely affected with CNS disorders.

Endothelial cells of the blood vessels in the choroid plexuses, which are joined by tight junctions (see chapter 4), form the blood-brain barrier, or more correctly the blood-cerebrospinal fluid barrier (see section 13.7). Consequently, substances do not pass between the cells but must pass through the cells.

CSF fills all the open spaces of the CNS. This includes all the ventricles, the subarachnoid space of the brain and spinal cord, and the central canal of the spinal cord. The route taken by the CSF from its origin in the choroid plexuses to its return to the circulation is depicted in figure 13.14. CSF passes from the lateral ventricles through the interventricular foramina into the third ventricle and then through the cerebral aqueduct into the fourth ventricle. It can

FIGURE 13.13 Ventricles of the Brain Viewed from the Left

Clinical IMPACT

Hydrocephalus

The cerebral aqueduct may be blocked at the time of birth or may become blocked later in life because of a tumor growing in the brainstem. If the apertures of the fourth ventricle or the cerebral aqueduct are blocked, CSF can accumulate within the ventricles, resulting in a condition called **internal hydrocephalus** (*noncommunicating hydrocephalus*). The production of CSF continues, even when the passages that normally allow it to exit the brain are blocked. Consequently, fluid builds inside the brain, causing pressure, which compresses the nervous tissue and dilates the ventricles. Compression of the nervous tissue usually results in irreversible brain damage. If the skull bones are not completely ossified when the hydrocephalus occurs, the pressure may also severely enlarge the head.

Internal hydrocephalus can be treated successfully by placing a drainage tube (shunt) between the brain ventricles and the abdominal cavity to eliminate the high internal pressures. However, there is some risk of introducing infection into the brain through these shunts, and the shunts must be replaced as the person grows.

A subarachnoid hemorrhage may block the return of CSF to the circulation. If CSF accumulates in the subarachnoid space, the condition is called **external hydrocephalus** (*communicating hydrocephalus*). In this condition, pressure is applied to the brain externally, compressing neural tissues and causing brain damage. The condition usually resolves without treatment.

exit the interior of the brain only from the fourth ventricle. One **median aperture** (foramen of Magendie), which opens through the roof of the fourth ventricle, and two **lateral apertures** (foramina of Luschka), which open through the walls, allow the CSF to pass from the fourth ventricle to the subarachnoid space. Some CSF continues to flow inferiorly into the central canal of the spinal cord. However, parts of the central canal are closed off in adults, so the amount circulating there is very small. Clusters of fingerlike protusions of arachnoid tissue called **arachnoid granulations** penetrate into the dural venous sinuses, especially the superior sagittal sinus. CSF passes into the blood-filled dural venous sinuses through these granulations. From the dural venous sinuses, the blood drains into the internal jugular veins to enter the veins of the general circulation; in this way, the CSF reenters the bloodstream. The flow rate of CSF from its origin to the point at which it enters the bloodstream is about 0.4 mL/min and the entire CSF volume of about 117 ml in the subarachnoid space and 23 ml in the ventricles is replenished about 4–5 times a day.

ASSESS YOUR PROGRESS

19. Describe the three meninges that surround the brain. What are the *falx cerebri*, *tentorium cerebelli*, and *falx cerebelli*?
20. Describe the contents of the dural sinuses, subdural space, and subarachnoid space.
21. Name the four ventricles of the brain. Describe their locations and the connections between them. What are the *septum pellucidum*?
22. Describe the production and circulation of CSF. Where does the CSF return to the blood?

- 1 Cerebrospinal fluid (CSF) is produced by the choroid plexuses of each of the four ventricles (*inset, lower left*).
- 2 CSF from the lateral ventricles flows through the interventricular foramina to the third ventricle.
- 3 CSF flows from the third ventricle through the cerebral aqueduct to the fourth ventricle.
- 4 CSF exits the fourth ventricle through the lateral and median apertures and enters the subarachnoid space. Some CSF enters the central canal of the spinal cord.
- 5 CSF flows through the subarachnoid space to the arachnoid granulations in the superior sagittal sinus, where it enters the venous circulation (*inset, upper right*).

Sagittal section, medial view

PROCESS FIGURE 13.14 Choroid Plexuses and the Flow of CSF

CSF flows through the ventricles and subarachnoid space, as shown by the *white arrows*. Arrows going through the foramina in the wall and roof of the fourth ventricle represent the CSF entering the subarachnoid space. CSF passes back into the blood through the arachnoid granulations (*white and black arrows*), which penetrate the dural sinus. The *black arrows* show the direction of blood flow in the sinuses. *Yellow* indicates CSF; *blue* indicates venous blood.

13.7 Blood Supply to the Brain

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe how the brain is supplied with blood.
- B. Explain the role of the blood-brain barrier.

The brain requires a tremendous amount of blood to maintain its normal functions. The brain has a very high metabolic rate, and brain cells are not capable of storing high-energy molecules for any length of time. In addition, brain cells depend almost entirely on glucose as their energy source (see chapter 25). Thus, the brain requires a constant blood supply to meet the demands of brain cells for both glucose and oxygen. Even though the brain accounts for only about 2% of total body weight, it receives approximately 15–20% of the blood pumped by the heart. Interruption of the brain's blood supply for only seconds can cause unconsciousness, and interruption for minutes can cause irreversible brain damage.

The brain's blood supply is illustrated in chapter 21 (see figures 21.10 and 21.11). Blood reaches the brain through the **internal carotid arteries**, which ascend to the head along the anterior-lateral part of the neck, and the **vertebral arteries**, which ascend along the posterior part of the neck, through the transverse foramina of the cervical vertebrae. The internal carotid arteries enter the cranial cavity through the carotid canals, and the vertebral arteries enter through the foramen magnum. The vertebral arteries join to form the **basilar artery**, which lies on the ventral surface of the pons. The basilar artery and the internal carotid arteries contribute to the **cerebral arterial circle** (circle of Willis). Branches from this circle and from the basilar artery supply blood to the brain.

The cerebral cortex on each side of the brain is supplied by three branches that arise from the cerebral arterial circle: the **anterior, middle, and posterior cerebral arteries**. The middle cerebral artery supplies most of the lateral surface of each cerebral hemisphere. The anterior cerebral artery supplies the medial portion of the parietal and frontal lobes. The posterior cerebral artery supplies the occipital lobe and the medial surface of the temporal lobe.

The arteries to the brain and their larger branches are located in the subarachnoid space. Small cortical arterial branches leave the subarachnoid space and enter the pia mater, where they branch extensively. Precapillary branches leave the pia mater and enter the tissue of the brain. Most of these branches are short and remain in the cortex. Fewer, longer branches extend into the medulla.

Hemorrhagic brain injury is characterized by bleeding outside the dura (extradural or epidural), between the dura and the brain (subdural), or within the brain (intracerebral). A hemorrhage, which is bleeding, results in a hematoma, an accumulation of blood. Extradural or epidural hematomas occur in about 1–2% of major head injuries. They usually affect the middle cranial fossa and involve a tear in the middle meningeal artery. Subdural hematomas are much more common, occurring in 10–20% of major head injuries. They most commonly involve tears in the

cortical veins or dural venous sinuses in the superior portion of the cranial cavity. Intracerebral hematomas occur in about 2–3% of major head injuries and involve damage to small vessels within the brain itself.

The arteries within the brain tissue quickly divide into capillaries. These capillaries have a highly selective permeability barrier called the **blood-brain barrier**. The blood-brain barrier is formed by tight junctions between the capillary endothelial cells. The endothelial cells are surrounded by the foot processes of brain astrocytes (see figure 11.6). The astrocytes promote the formation of tight junctions between the endothelial cells. The blood-brain barrier regulates the movement of materials from the blood into the brain. Materials that would enter many tissues by passing between the endothelial cells of capillaries cannot pass through the blood-brain barrier because of the tight junctions. Most materials that enter the brain pass through the endothelial cells. Water-soluble molecules, such as amino acids and glucose, require specific transporters to move across the plasma membranes by mediated transport (see chapter 3). However, gases, such as O₂, and lipid-soluble substances, such as nicotine and ethanol, can freely diffuse through the plasma membranes of the endothelial cells and enter the brain.

The permeability characteristics of the blood-brain barrier are an important consideration when developing drugs to affect the CNS. For example, Parkinson disease is caused by a lack of the neurotransmitter dopamine, which is normally produced by certain neurons of the brain. Lack of dopamine results in decreased muscle control and shaky movements. However, administering dopamine is not helpful, because dopamine cannot cross the blood-brain barrier. Instead, physicians prescribe levodopa (L-dopa), a precursor to dopamine, because it can cross the blood-brain barrier. CNS neurons then convert levodopa to dopamine, which helps reduce the symptoms of Parkinson disease (see chapter 14).

ASSESS YOUR PROGRESS

23. Describe the blood supply to the brain. List the arteries supplying each part of the cerebral cortex.
24. Explain how the blood-brain barrier functions.

13.8 Cranial Nerves

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the 12 cranial nerves and give the primary sensory, somatic motor, and/or parasympathetic functions of each.
- B. Describe cranial reflexes.

Cranial nerves transmit and relay information to the brain analogous to the spinal nerves, except they do so by direct connections to the brain instead of the spinal cord.

A given cranial nerve may have one or more of three functions: (1) sensory, (2) somatic motor, and (3) parasympathetic (table 13.4). **Sensory** functions include the special senses, such as

TABLE 13.4 Functional Organization of the Cranial Nerves

Nerve Function	Cranial Nerve	
Sensory	I	Olfactory
	II	Optic
	VIII	Vestibulocochlear
Somatic motor	IV	Trochlear
	VI	Abducens
	XI	Accessory
	XII	Hypoglossal
Somatic motor and sensory	V	Trigeminal
Somatic motor and parasympathetic	III	Oculomotor
Somatic motor, sensory, and parasympathetic	VII	Facial
	IX	Glossopharyngeal
	X	Vagus

vision, and the more general senses, such as touch and pain. **Somatic** (sō-mat'ik) **motor** functions involve the control of skeletal muscles through motor neurons. The cranial nerves innervating skeletal muscles also contain proprioceptive sensory fibers, which convey action potentials to the CNS from those muscles and associated joints. **Proprioception** (prō-prē-ō-sep'shun) is the awareness of the position of your various body parts. However, because proprioception is the only sensory function of several otherwise somatic motor cranial nerves, that function is usually ignored, and the nerves are designated by convention as somatic motor only. **Parasympathetic** functions involve the regulation of glands, smooth muscles, and cardiac muscle. These functions are part of the autonomic nervous system and are discussed in chapter 16. Several of the cranial nerves have associated ganglia, and these ganglia are of two types: parasympathetic and sensory.

By convention, the 12 pairs of cranial nerves are indicated by Roman numerals (I–XII) from anterior to posterior (figure 13.15). The first 2 pairs of cranial nerves connect directly to the cerebrum (I) or the diencephalon (II). Nine pairs of cranial nerves connect to the brainstem. The remaining pair of cranial nerves (XI) is connected to the spinal cord and has no direct connection to brain structures.

Characteristics of the Cranial Nerves

It may be helpful to refer to table 13.5 while reading the following descriptions of the cranial nerves. The **olfactory (I)** and **optic (II)** nerves are exclusively sensory and are involved in the special senses of smell and vision, respectively. The functions of these nerves are discussed in chapter 15.

The **oculomotor nerve (III)** innervates four of the six muscles that move the eyeball (the superior, inferior, and medial rectus

muscles and the inferior oblique muscle; see chapter 10) and the levator palpebrae superioris muscle, which raises the superior eyelid. In addition, parasympathetic nerve fibers in the oculomotor nerve innervate smooth muscles in the eye and regulate the size of the pupil and the shape of the lens of the eye.

The **trochlear (trōk'lē-ar) nerve (IV)** is a somatic motor nerve that innervates one of the six eye muscles responsible for moving the eyeball (superior oblique).

The **trigeminal (trī-jem'i-nāl) nerve (V)** has somatic motor, proprioceptive, and cutaneous sensory functions. It supplies motor innervation to the muscles of mastication, one middle ear muscle, one palatine muscle, and two throat muscles. In addition to the proprioception associated with its somatic motor functions, the trigeminal nerve also carries proprioceptive information from the temporomandibular joint, tongue, and cheek, which allows you to chew food without biting your tongue or cheek. Damage to the trigeminal nerve may impede chewing.

The trigeminal nerve has the greatest general sensory function of all the cranial nerves and is the only cranial nerve involved in **sensory cutaneous innervation** of the head. It also provides sensory innervation of blood vessels in the meninges that are associated with the pain of migraine headaches (see chapter 14). Although the mechanisms are not fully understood, the trigeminal nerve is responsible for the pain of a headache. All other cutaneous innervation comes from spinal nerves (see figure 12.14). *Trigeminal* means “three twins,” and the sensory distribution of the trigeminal nerve in the face is divided into three regions, each supplied by a branch of the nerve. The three branches—ophthalmic (V_1), maxillary (V_2), and mandibular (V_3)—arise directly from the trigeminal ganglion, which serves the same function as the dorsal root ganglia of the spinal nerves. Only the mandibular branch contains motor axons, which bypass the trigeminal ganglion, much as the ventral root of a spinal nerve bypasses a dorsal root ganglion.

In addition to these cutaneous functions, the maxillary and mandibular branches are important in dentistry. The maxillary nerve supplies sensory innervation to the maxillary teeth, palate, and gingiva (jin'ji-vă; gum). The mandibular branch supplies sensory innervation to the mandibular teeth, tongue, and gingiva. The various nerves innervating the teeth are referred to as **alveolar nerves** (al-vē'ō-lăr; socket). The **superior alveolar nerves** to the maxillary teeth are derived from the maxillary branch of the trigeminal nerve, and the **inferior alveolar nerves** to the mandibular teeth are derived from the mandibular branch of the trigeminal nerve.

The **abducens (ab-doo'senz) nerve (VI)**, like the trochlear nerve, is a somatic motor nerve that innervates one of the six muscles responsible for moving the eyeball (lateral rectus).

Predict 4

A drooping upper eyelid on one side of the face is a sign of possible oculomotor nerve damage. Describe how a patient could be tested for this type of damage by examining other oculomotor nerve functions. Describe the eye movements that distinguish among oculomotor, trochlear, and abducens nerve damage.

FIGURE 13.15 Inferior Surface of the Brain, Showing the Origins of the Cranial Nerves **APR**

The **facial nerve (VII)** is somatic motor, sensory, and parasympathetic in function. It controls all the muscles of facial expression, a small muscle in the middle ear, and two hyoid muscles. It is sensory for the sense of taste in the anterior two-thirds of the tongue (see chapter 15). The facial nerve supplies parasympathetic innervation to the submandibular and sublingual

salivary glands of the mouth and to the lacrimal glands of the eye.

The **vestibulocochlear (ves-tīb'ū-lō-kok'lē-ār) nerve (VIII)**, like the olfactory and optic nerves, is exclusively sensory and transmits action potentials from the inner ear responsible for the special senses of hearing and balance (see chapter 15).

**Clinical
IMPACT**

Dental Anesthesia

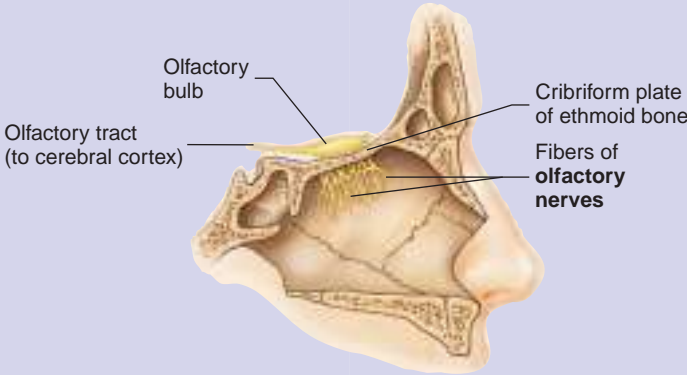

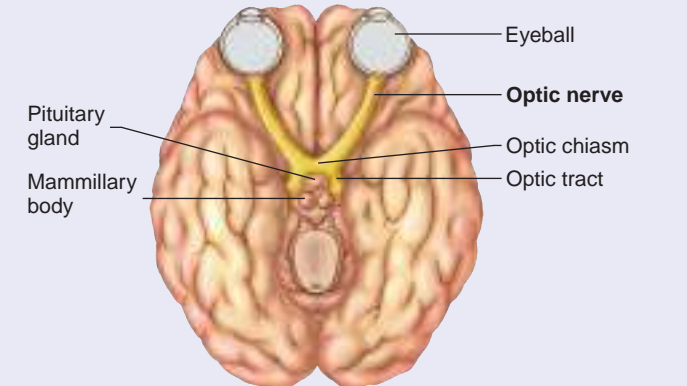

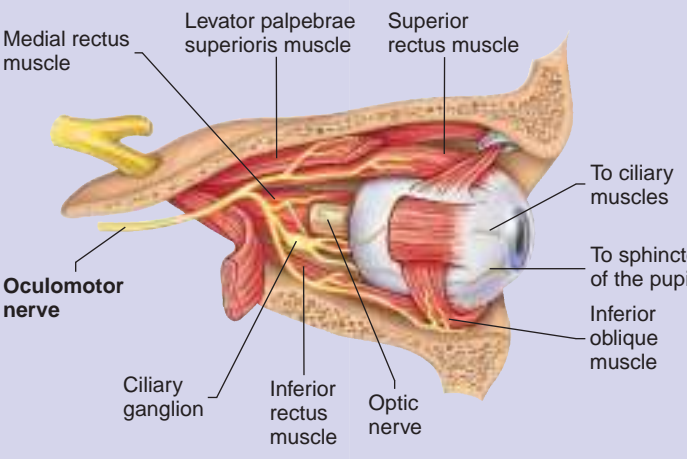

Dentists inject anesthetic to block sensory transmission by the alveolar nerves. The superior alveolar nerves are not usually anesthetized directly because they are difficult to approach with a needle. For this reason, the maxillary teeth are usually anesthetized locally by inserting the needle beneath the oral mucosa surrounding the teeth. The inferior alveolar nerve is probably anesthetized more often than any

other nerve in the body. To anesthetize this nerve, the dentist inserts the needle somewhat posterior to the patient's last molar and extends the needle near where the mandibular branch of the trigeminal nerve enters the mandibular foramen.

During an inferior alveolar block, several nondental nerves are usually anesthetized. The mental nerve, which supplies cutaneous inner-

vation to the anterior lip and chin, is a distal branch of the inferior alveolar nerve. When the inferior alveolar nerve is blocked, the mental nerve is blocked also, resulting in a numb lip and chin. Nerves lying near the point where the inferior alveolar nerve enters the mandible are often also anesthetized during inferior alveolar anesthesia. For example, the lingual nerve can be anesthetized to produce a numb tongue.

TABLE 13.5 Cranial Nerves and Their Functions

Cranial Nerve	Foramen or Fissure*	Function	Consequences of Lesions to Nerve
I: Olfactory 	Cribriform plate	Sensory: sense of smell	Inability to smell
II: Optic 	Optic foramen	Sensory: sense of vision	Blindness on the affected side
III: Oculomotor 	Superior orbital fissure	Motor[†]: motor to eye muscles (superior, medial, and inferior rectus; inferior oblique) and upper eyelid (levator palpebrae superioris) Proprioceptive from those muscles Parasympathetic: parasympathetic to the sphincter of the pupil (causing constriction) and the ciliary muscle of the lens (causing accommodation)	Pupil dilation; eye deviates inferiorly and laterally due to muscle paralysis, resulting in double vision; eyelid droops (ptosis); blurred vision due to loss of accommodation

*Route of entry or exit from the skull.

[†]Proprioception is a sensory function, not a motor function; however, motor nerves to muscles also contain some proprioceptive afferent fibers from those muscles. Because proprioception is the only sensory information carried by some cranial nerves, these nerves are still considered "motor."

TABLE 13.5 Cranial Nerves and Their Functions—Continued

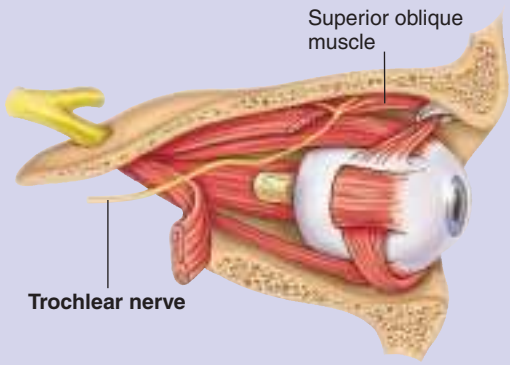

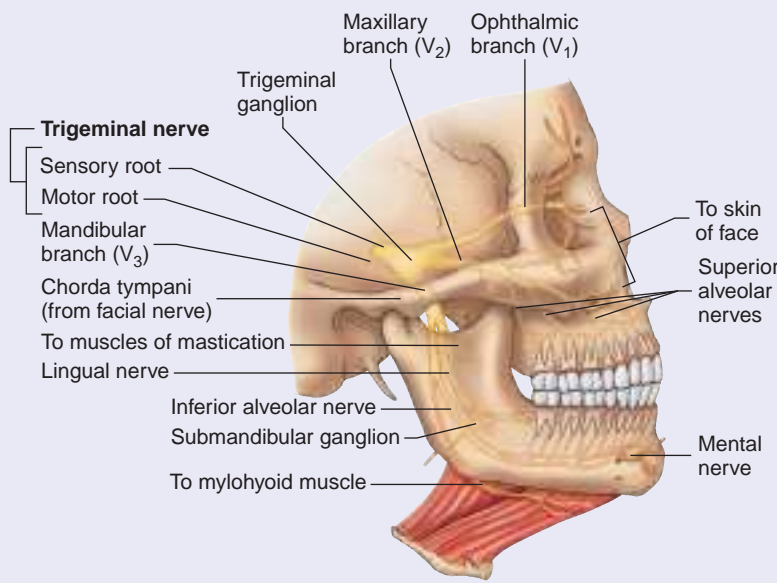

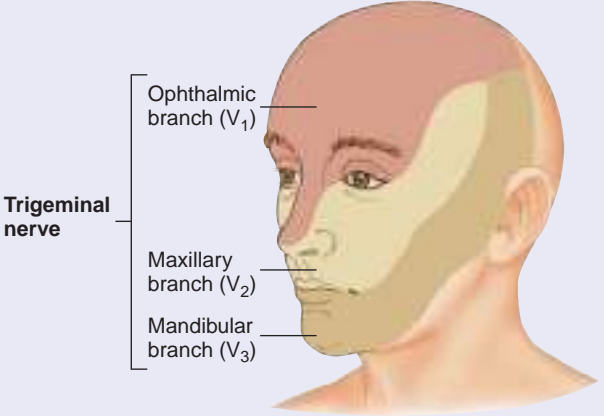

Cranial Nerve	Foramen or Fissure*	Function	Consequences of Lesions to Nerve
<p>IV. Trochlear</p> 	<p>Superior orbital fissure</p>	<p>Motor*: motor to one eye muscle (superior oblique) Proprioceptive from that muscle</p> 	<p>Difficulty moving the eye inferiorly and laterally which leads to double vision</p>

XII. Hypoglossal	Hypoglossal canal	<p>Motor: motor to intrinsic and extrinsic tongue muscles (styloglossus, hypoglossus, genioglossus) and throat muscles (thyrohyoid and geniohyoid)</p> <p>Proprioceptive from those muscles</p>	When protruded, the tongue deviates toward the side of the damaged nerve

The **glossopharyngeal** (glos'ō-fă-rin'jē-ăl) **nerve (IX)**, like the facial nerve, is somatic motor, sensory, and parasympathetic in function and has both sensory and parasympathetic ganglia. The glossopharyngeal nerve is somatic motor to one muscle of the pharynx and supplies parasympathetic innervation to the parotid salivary glands. The glossopharyngeal nerve is sensory for the sense of taste in the posterior one-third of the tongue. It also supplies tactile sensory innervation from the posterior tongue, middle ear, and pharynx, and it transmits sensory stimulation from receptors in the carotid arteries, which monitor blood pressure and blood carbon dioxide, oxygen, and pH levels (see chapter 21).

The **vagus** (vā'gŭs) **nerve (X)**, like the facial and glossopharyngeal nerves, is somatic motor, sensory, and parasympathetic in function and has both sensory and parasympathetic ganglia. Most muscles of the soft palate, pharynx, and larynx are innervated by the vagus nerve. Damage to the laryngeal branches of the vagus nerve can interfere with normal speech. The vagus nerve is sensory for taste from the root of the tongue (see chapter 15). It is sensory for the inferior pharynx and the larynx and transmits sensory input from receptors in the aortic arch, which monitor blood pressure and the levels of carbon dioxide, oxygen, and pH in the blood (see chapter 21). In addition, the vagus nerve conveys sensory information from the thoracic and abdominal organs. The parasympathetic part of the vagus nerve is very important in regulating the functions

of the thoracic and abdominal organs. It carries parasympathetic fibers to the heart and lungs in the thorax and to the digestive organs and kidneys in the abdomen.

The **accessory nerve (XI)** is a somatic motor nerve that has both cranial and spinal roots. The cranial root joins the vagus nerve (hence the name *accessory*) and participates in its function. However, the presence of the cranial root in the human brainstem is variable. The major component of the accessory nerve is the spinal root, which originates from the superior part of the cervical spinal cord, enters the cranial cavity through the foramen magnum, and then exits through the jugular foramen. The accessory nerve provides the major innervation to the sternocleidomastoid and trapezius muscles of the neck and shoulder.

The **hypoglossal nerve (XII)** is a somatic motor nerve that arises from the ventral surface of the medulla oblongata. It supplies the intrinsic tongue muscles, three of the four extrinsic tongue muscles, and the thyrohyoid and the geniohyoid muscles.

► Predict 5

Injury to the accessory nerve may result in sternocleidomastoid muscle dysfunction, a condition called torticollis (sometimes called wry neck), in which the head is drawn to one side. If the head is turned to the left, does this position indicate injury to the left or the right spinal component of the accessory nerve?

Diseases and Disorders

TABLE 13.6 CNS and Cranial Nerves

Condition	Description
CNS DISORDERS*	
Cerebral aneurysm	Excessive dilation or ballooning of an artery; hemorrhaging (leaking) of the aneurysm leads to a hematoma within the brain or in the extradural, subdural, or subarachnoid spaces around the brain
Stroke	Loss of blood flow to the brain; caused by bleeding in the brain or meninges or a clot or spasm blocking cerebral blood vessels, which results in a local area of cell death; symptoms include general intellectual deficiency, memory loss, short attention span, moodiness, disorientation, and irritability
Concussion	A blow to the head that produces momentary loss of consciousness; can lead to <i>postconcussion syndrome</i> , which can include headaches, fatigue, difficulties with mental tasks, depression, and personality changes
Cerebral compression	Increased intracranial pressure; can be caused by hematomas, hydrocephalus, tumors, edema from a severe head blow, or spinal cord injury
CRANIAL NERVE DISORDERS	
Trigeminal neuralgia	Sharp pain in the face involving the trigeminal nerve; cause is unknown; can be triggered by touch near the mouth area
Migraine	Severe headache with associated sensory symptoms; cause unknown but involves the trigeminal nerve; can be triggered by environmental factors; tends to be hereditary
Facial palsy	Unilateral paralysis of the facial muscles involving the facial nerve; side of the face droops; can result from a stroke, infections, acute nerve damage, or a brain tumor; most common type is called <i>Bell palsy</i> , in which cause is unknown, but it is believed to be due to viral infection of the facial nerve
Herpes simplex I	Viral infection characterized by lesions (<i>cold sores</i>) on the lips or nasal region; virus can remain dormant in trigeminal ganglion; reactivated often at times of stress or reduced immune resistance

* For more CNS disorders, see Diseases and Disorders tables in chapters 12 and 14.

Reflexes Involving Cranial Nerves

Reflexes integrated within the spinal cord were discussed in chapter 12. Many of the body's functions, especially those involved in maintaining homeostasis, involve reflexes that are integrated within the brain. Some of these reflexes, such as those involved in controlling heart rate (see chapter 20), blood pressure (see chapter 21), and respiration (see chapter 23), are integrated in the brainstem and many involve cranial nerve X (vagus nerve).

Many of the brainstem reflexes are associated with cranial nerve function. In general, these reflexes involve sensory input from the cranial nerves or spinal cord and the motor output of the cranial nerves.

Turning the eyes toward a flash of light, a sudden noise, or a touch on the skin is an example of a brainstem reflex. Moving the eyes to track a moving object is another complex brainstem reflex. Some of the sensory neurons from cranial nerve VIII form a reflex arc with neurons of cranial nerves V and VII, which send axons to muscles of the middle ear and dampen the effects of very loud, sustained noises on delicate inner ear structures (see chapter 15). Reflexes that occur during chewing allow the jaws to react to foods of various hardness and protect the teeth from breaking on very hard foods. Both the sensory and motor components of the reflex arc are carried by cranial nerve V. Reflexes involving input through cranial nerve V and output

through cranial nerve XII move the tongue to position food between the teeth for chewing and then move the tongue out of the way, so that it is not bitten.

ASSESS YOUR PROGRESS

25. What are the three major functions of the cranial nerves?
26. Which cranial nerves are sensory only? With what sense is each of these associated?
27. Name the cranial nerves that are somatic motor and proprioceptive only. What muscles or groups of muscles does each nerve supply? What is proprioception?
28. What cranial nerve provides the sensory cutaneous innervation of the face? How is this nerve important in dentistry? Name the muscles that would not function if this nerve were damaged.
29. Which four cranial nerves have a parasympathetic function? Describe the functions of each of these nerves.
30. Which cranial nerve leaves the head and neck region?
31. Give an example of reflex integration by cranial nerves.

Answer

Learn to Predict From page 433

In addition to Marvin's broken jaw, the question suggested that he experienced damage to a cranial nerve, specifically the one associated with controlling the muscles of the tongue. Chapter 11 explained that somatic motor neurons innervate skeletal muscle, so the cranial nerve associated with motor control of the tongue is the affected nerve. Tables 13.4 and 13.5 summarize the functional organization of the cranial nerves. By reviewing these tables, we find that the hypoglossal nerve (XII) innervates intrinsic and extrinsic tongue muscles; therefore, this cranial nerve was damaged

during Marvin's accident. More specifically, the damage was on the right side and caused paralysis of the tongue muscles on the right side. Thus, only the left side of the tongue can stick out. The hypoglossal nerve also innervates some throat muscles, such as the thyrohyoid and the geniohyoid muscles, which may also be affected.

Answers to the rest of this chapter's Predict questions are in appendix G.

13.1 Development of the CNS (p. 434)

The brain and spinal cord develop from the neural tube. The ventricles and central canal develop from the lumen of the neural tube.

13.2 Brainstem (p. 437)

Medulla Oblongata

1. The medulla oblongata is continuous with the spinal cord and contains ascending and descending tracts.
2. The pyramids are tracts controlling voluntary muscle movement.
3. The olives are nuclei that function in equilibrium, coordination, and modulation of sound from the inner ear.
4. Medullary nuclei regulate the heart, blood vessels, respiration, swallowing, vomiting, coughing, sneezing, and hiccuping. The nuclei of cranial nerves V, VII, and IX–XII are in the medulla oblongata.

Pons

1. The pons is superior to the medulla oblongata.
2. Ascending and descending tracts pass through the pons.
3. Pontine nuclei regulate sleep and respiration. The nuclei of cranial nerves V–VIII are in the pons.

Midbrain

1. The midbrain is superior to the pons.
2. The midbrain contains the nuclei for cranial nerves III, IV, and V.
3. The tectum consists of four colliculi. The two inferior colliculi are involved in hearing, and the two superior colliculi in visual reflexes.
4. The tegmentum contains ascending tracts and the red nuclei, which are involved in motor activity.
5. The cerebral peduncles are the major descending motor pathway.
6. The substantia nigra connects to other basal nuclei and is involved with muscle tone and movement.

Reticular Formation

The reticular formation consists of nuclei scattered throughout the brainstem. The reticular system functions in many brainstem activities,

Summary

including motor control, pain perception, rhythmic contractions, and the sleep-wake cycle.

13.3 Cerebellum (p. 439)

1. The cerebellar cortex contains more neurons than the cerebral cortex does. The Purkinje cells are the largest cells in the CNS.
2. The cerebellum has three parts, which control balance, gross motor coordination, and fine motor coordination.
3. The cerebellum corrects discrepancies between intended movements and actual movements.
4. The cerebellum can “learn” highly specific, complex motor activities.

13.4 Diencephalon (p. 440)

The diencephalon is located between the brainstem and the cerebrum.

Thalamus

1. The thalamus consists of two lobes connected by the interthalamic adhesion. The thalamus functions as an integration center.
2. Most sensory input synapses in the thalamus. Pain is registered in the thalamus.
3. The thalamus also has some motor functions.

Subthalamus

The subthalamus is inferior to the thalamus and is involved in motor function.

Epithalamus

The epithalamus is superior and posterior to the thalamus and contains the habenula, which influences emotions through the sense of smell. The pineal gland may play a role in the onset of puberty.

Hypothalamus

1. The hypothalamus, the most inferior portion of the diencephalon, contains several nuclei and tracts.

2. The mammillary bodies are reflex centers for olfaction.
3. The hypothalamus regulates many endocrine functions (e.g., metabolism, reproduction, response to stress, and urine production). The pituitary gland attaches to the hypothalamus.
4. The hypothalamus regulates body temperature, hunger, thirst, satiety, swallowing, and emotions.

13.5 Cerebrum (p. 442)

1. The cortex of the cerebrum is folded into ridges called gyri and grooves called sulci, or fissures.
2. The longitudinal fissure divides the cerebrum into left and right hemispheres. Each hemisphere has five lobes.
 - The frontal lobes are involved in smell, voluntary motor function, motivation, aggression, and mood.
 - The parietal lobes contain the major sensory areas receiving general sensory input, taste, and balance.
 - The occipital lobes contain the visual centers.
 - The temporal lobes receive olfactory and auditory input and are involved in memory, abstract thought, and judgment.
3. Tracts connect areas of the cortex within the same hemisphere (association fibers), between hemispheres (commissural fibers), and with other parts of the brain and the spinal cord (projection fibers).

Basal Nuclei

1. Basal nuclei include the corpus striatum, subthalamic nuclei, and substantia nigra.
2. The basal nuclei are important in controlling motor functions.

Limbic System

1. The limbic system includes parts of the cerebral cortex, basal nuclei, the thalamus, the hypothalamus, and the olfactory cortex.
2. The limbic system controls visceral functions through the autonomic nervous system and the endocrine system and is involved in emotions and memory.

13.6 Meninges, Ventricles, and Cerebrospinal Fluid (p. 445)

Meninges

1. The brain and spinal cord are covered by the dura, arachnoid, and pia mater.
2. The dura mater attaches to the skull and has two layers that can separate to form dural sinuses.
3. Beneath the arachnoid mater, the subarachnoid space contains CSF, which helps cushion the brain.
4. The pia mater attaches directly to the brain.

Ventricles

1. The lateral ventricles in the cerebrum are connected to the third ventricle in the diencephalon by the interventricular foramen.
2. The third ventricle is connected to the fourth ventricle in the pons by the cerebral aqueduct. The central canal of the spinal cord is connected to the fourth ventricle.

Cerebrospinal Fluid

1. CSF is produced from the blood in the choroid plexus of each ventricle. CSF moves from the lateral to the third and then to the fourth ventricle.

2. From the fourth ventricle, CSF enters the subarachnoid space through three apertures.
3. CSF leaves the subarachnoid space through arachnoid granulations and returns to the blood in the dural venous sinuses.

13.7 Blood Supply to the Brain (p. 451)

1. The brain receives blood from the internal carotid and vertebral arteries. The latter form the basilar artery. The basilar and internal carotid arteries contribute to the cerebral arterial circle. Branches from the circle and basilar artery supply the brain.
2. The blood-brain barrier is formed from the endothelial cells of the capillaries in the brain and the astrocytes in the brain tissue.

13.8 Cranial Nerves (p. 451)

Cranial nerves perform sensory, somatic motor, and parasympathetic functions.

Characteristics of the Cranial Nerves

1. The olfactory (I) and optic (II) nerves are involved in the senses of smell and vision, respectively.
2. The oculomotor nerve (III) innervates four of six extrinsic eye muscles and the upper eyelid. The oculomotor nerve also provides parasympathetic supply to the iris and lens of the eye.
3. The trochlear nerve (IV) controls one of the extrinsic eye muscles.
4. The trigeminal nerve (V) supplies the muscles of mastication, as well as a middle ear muscle, a palatine muscle, and two throat muscles. The trigeminal nerve has the greatest cutaneous sensory distribution of any cranial nerve. Two of the three trigeminal nerve branches innervate the teeth.
5. The abducens nerve (VI) controls one of the extrinsic eye muscles.
6. The facial nerve (VII) supplies the muscles of facial expression, an inner ear muscle, and two throat muscles. It is involved in the sense of taste. It is parasympathetic to two sets of salivary glands and to the lacrimal glands.
7. The vestibulocochlear nerve (VIII) is involved in the senses of hearing and balance.
8. The glossopharyngeal nerve (IX) is involved in taste and supplies tactile sensory innervation from the posterior tongue, middle ear, and pharynx. It is also sensory for receptors that monitor blood pressure and gas levels in the blood. The glossopharyngeal nerve is parasympathetic to the parotid salivary glands.
9. The vagus nerve (X) innervates the muscles of the pharynx, palate, and larynx. It is also involved in the sense of taste. The vagus nerve is sensory for the pharynx and larynx and for receptors that monitor blood pressure and gas levels in the blood. The vagus nerve is sensory for thoracic and abdominal organs. The vagus nerve provides parasympathetic innervation to the thoracic and abdominal organs.
10. The accessory nerve (XI) has only a spinal component. It supplies the sternocleidomastoid and trapezius muscles.
11. The hypoglossal nerve (XII) supplies the intrinsic tongue muscles, three of four extrinsic tongue muscles, and two throat muscles.

Reflexes Involving Cranial Nerves

Many reflexes involved in homeostasis involve the cranial nerves and occur in the brainstem.

REVIEW AND COMPREHENSION

- Which of these parts of the embryonic brain is correctly matched with the structure it becomes in the adult brain?
 - mesencephalon—midbrain
 - metencephalon—medulla oblongata
 - myelencephalon—cerebrum
 - telencephalon—pons and cerebellum
- To separate the brainstem from the rest of the brain, a cut would have to be made between the
 - medulla oblongata and pons.
 - pons and midbrain.
 - midbrain and diencephalon.
 - thalamus and cerebrum.
 - medulla oblongata and spinal cord.
- Important centers for heart rate, blood pressure, respiration, swallowing, coughing, and vomiting are located in the
 - cerebrum.
 - medulla oblongata.
 - midbrain.
 - pons.
 - cerebellum.
- In which part of the brain does decussation of descending tracts involved in the conscious control of skeletal muscles occur?
 - cerebrum
 - diencephalon
 - midbrain
 - pons
 - medulla oblongata
- The cerebral peduncles are a major descending motor pathway in the
 - cerebrum.
 - cerebellum.
 - pons.
 - midbrain.
 - medulla oblongata.
- The superior colliculi are involved in _____, whereas the inferior colliculi are involved in _____.
 - hearing, visual reflexes
 - visual reflexes, hearing
 - balance, motor pathways
 - motor pathways, balance
 - respiration, sleep
- The cerebellum communicates with other regions of the CNS through the
 - flocculonodular lobe.
 - cerebellar peduncles.
 - vermis.
 - lateral hemispheres.
 - folia.
- The major relay station for sensory input that projects to the cerebral cortex is the
 - hypothalamus.
 - thalamus.
 - pons.
 - cerebellum.
 - midbrain.
- The part of the diencephalon directly connected to the pituitary gland is the
 - hypothalamus.
 - epithalamus.
 - subthalamus.
 - thalamus.
- Which of the following is a function of the hypothalamus?
 - regulates autonomic nervous system functions
 - regulates the release of hormones from the posterior pituitary
 - regulates body temperature
 - regulates food intake (hunger) and water intake (thirst)
 - All of these are correct.
- The grooves on the surface of the cerebrum are called the
 - nuclei.
 - commissures.
 - tracts.
 - sulci.
 - gyri.
- Which of these areas is located in the postcentral gyrus of the cerebral cortex?
 - olfactory cortex
 - visual cortex
 - primary motor cortex
 - primary somatic sensory cortex
 - primary auditory cortex
- Which of these cerebral lobes is important in voluntary motor function, motivation, aggression, sense of smell, and mood?
 - frontal
 - insula
 - occipital
 - parietal
 - temporal
- Fibers that connect areas of the cerebral cortex within the same hemisphere are
 - projection fibers.
 - commissural fibers.
 - association fibers.
 - All of these are correct.
- The basal nuclei are located in the
 - inferior cerebrum.
 - diencephalon.
 - midbrain.
 - All of these are correct.
- The most superficial of the meninges is a thick, tough membrane called the
 - pia mater.
 - dura mater.
 - arachnoid mater.
 - epidural mater.
- The ventricles of the brain are interconnected. Which of these ventricles are *not* correctly matched with the structures that connect them?
 - lateral ventricle to the third ventricle—interventricular foramina
 - left lateral ventricle to right lateral ventricle—central canal
 - third ventricle to fourth ventricle—cerebral aqueduct
 - fourth ventricle to subarachnoid space—median and lateral apertures
- Cerebrospinal fluid is produced by the _____, circulates through the ventricles, and enters the subarachnoid space. The cerebrospinal fluid leaves the subarachnoid space through the _____.
 - choroid plexuses, arachnoid granulations
 - arachnoid granulations, choroid plexuses
 - dural venous sinuses, dura mater
 - dura mater, dural venous sinuses
- Water-soluble molecules of the blood plasma move across the blood-brain barrier by
 - diffusion.
 - endocytosis.
 - exocytosis.
 - symport.
 - filtration.
- The cranial nerve involved in chewing food is the
 - trochlear (IV).
 - trigeminal (V).
 - abducens (VI).
 - facial (VII).
 - vestibulocochlear (VIII).
- The cranial nerve responsible for focusing the eye (innervating the ciliary muscle of the eye) is the
 - optic (II).
 - oculomotor (III).
 - trochlear (IV).
 - abducens (VI).
 - facial (VII).
- The cranial nerve involved in moving the tongue is the
 - trigeminal (V).
 - facial (VII).
 - glossopharyngeal (IX).
 - accessory (XI).
 - hypoglossal (XII).
- The cranial nerve involved in feeling a toothache is the
 - trochlear (IV).
 - trigeminal (V).
 - abducens (VI).
 - facial (VII).
 - vestibulocochlear (VIII).

24. From this list of cranial nerves:

- | | |
|----------------------|------------------------------|
| (1) olfactory (I) | (4) abducens (VI) |
| (2) optic (II) | (5) vestibulocochlear (VIII) |
| (3) oculomotor (III) | |

Select the nerves that are sensory only.

- a. 1,2,3 b. 2,3,4 c. 1,2,5 d. 2,3,5 e. 3,4,5

25. From this list of cranial nerves:

- | | |
|---------------------------|-----------------------|
| (1) trigeminal (V) | (4) vagus (X) |
| (2) facial (VII) | (5) hypoglossal (XII) |
| (3) glossopharyngeal (IX) | |

Select the nerves involved in the sense of taste.

- a. 1,2,3 b. 1,4,5 c. 2,3,4 d. 2,3,5 e. 3,4,5

26. From this list of cranial nerves:

- | | |
|----------------------|------------------------------|
| (1) oculomotor (III) | (4) vestibulocochlear (VIII) |
| (2) trigeminal (V) | (5) glossopharyngeal (IX) |
| (3) facial (VII) | (6) vagus (X) |

Select the nerves that are part of the parasympathetic division of the ANS.

- a. 1,2,4,5 b. 1,3,5,6 c. 1,4,5,6 d. 2,3,4,5 e. 2,3,5,6

Answers in appendix E

CRITICAL THINKING

- What happens to the developing brain if the CSF is not properly drained, resulting in early hydrocephalus?
- A patient exhibits enlargement of the lateral and third ventricles, but no enlargement of the fourth ventricle. What do you conclude?
- During a lumbar puncture (spinal tap), blood is discovered in the patient's CSF. What does this finding suggest?
- Describe a clinical test to evaluate each of the 12 cranial nerves.
- A patient presented to her physician with a loss of muscle tone and coordination. She was unable to perform coordinated tasks, such as touching the tip of her finger to her nose. Which part of her brain did the physician conclude was damaged?
- A baseball player was accidentally struck on the bridge of his nose with a baseball, resulting in fractures of several facial bones. Soon after sustaining the injury, he noticed that he had lost his sense of smell. Explain how this probably happened.
- Following a car accident in which he hit the left side of his head on the car door, Stanley developed diplopia (double vision) and was unable to move his left eye laterally (abduct the left eye). Explain how this injury caused Stanley's symptoms.
- Over the past month, Andy has noticed that touching his upper lip, even during eating or drinking, produces intense pain in the area extending from the upper lip to just below his right eye. His ability to chew and swallow is not affected. Andy's dentist told him it was not a dental problem and he should see his physician. The physician explained that the condition might be temporary and that the cause is unknown. Explain what cranial nerve is responsible for these symptoms.
- Afton, a teacher for the past 25 years, spent Saturday and Sunday skiing in very cold weather. The following Friday, she got up to get ready for school and was shocked to find that the right side of her face was drooping. She went to the emergency room, where tests could find no evidence of a stroke or a tumor. A physician diagnosed the condition and told Afton that it might be temporary. After about a week, her condition improved. What disorder did the physician diagnose, and what probably brought it on?

Answers in appendix F

Learn to Predict

When told to put on blindfolds, the students in the school's new crime scene investigation lab became somewhat nervous—but it turned out to be a simple demonstration of how receptors in the skin detect hot and cold. Each blindfolded student was told to touch a hot object (55°C) with one hand and a cold object (5°C) with the other hand. After a few seconds, the instructor asked the students to identify which hand was touching each object. Were they able to answer correctly? After reading the chapter and recalling how spinal nerves and cranial nerves convey information to the brain, as described in chapters 12 and 13, you will be ready to answer the question. **Determine whether the students could tell which hand was touching which object; then, keeping in mind the complexity of the brain, identify the parts of the CNS involved in making this distinction.**

Integration of Nervous System Functions

There are thought to be more connections in the human brain than there are stars in the Milky Way. These connections allow you to read and understand this paragraph while disregarding the weight of the book in your hands, if you are holding it, or the weight of your forearms on the desk or on your lap. You are also probably not aware of the small noises around you or the clothes touching your body, until your attention is drawn to them. You certainly are not aware of changes in your blood pressure or your body fluid pH and blood glucose levels, yet your nervous system is actively processing all this sensory input and controlling the responses to that input.

In addition, the human brain is capable of other unique and complex functions—such as recording history, reasoning, and planning—to a degree unparalleled in the animal kingdom. Many of these functions can be studied only in humans. That is why much of human brain function remains elusive and is one of the most challenging frontiers of anatomy and physiology.

Photo: Image of the hippocampus stained to reveal the organization of glial cells (cyan), neurofilaments (green) and DNA (yellow). The hippocampus is part of the limbic system and plays important roles in the consolidation of information from short-term memory to long-term memory.

14.1 Sensation

LEARNING OUTCOMES

After reading this section, you should be able to

- A. List the types of somatic and visceral sensory receptors, tell where they are located, and describe how they function in sensation.**
- B. Describe the roles of receptor potentials and adaptation.**
- C. Differentiate between primary and secondary receptors, and between tonic and phasic receptors.**
- D. List the major ascending sensory tracts and state a function for each.**
- E. Describe the sensory and association areas of the cerebral cortex and discuss their interactions.**

Sensation is the process initiated by stimuli acting on sensory receptors. **Perception** is the conscious awareness of those sensations. The brain constantly receives sensations as action potentials from a wide variety of sensory receptors that receive stimuli from both inside and outside the body. Sensory receptors respond to stimuli by generating action potentials that are propagated along nerves to the spinal cord and brain. Perception results when the brain interprets the sensation-generated action potentials in the

cerebral cortex. Some other parts of the brain are involved in modulating sensations before they are perceived. For example, the thalamus and amygdala receive and integrate pain signals.

The **senses** are the means by which the brain receives information about the environment and the body. Historically, five senses were recognized: smell, taste, sight, hearing, and touch. Today, the senses are divided into two basic groups: general and special.

The **general senses** have receptors distributed over a large part of the body. They are divided into two groups: somatic senses and visceral senses (table 14.1; figure 14.1). The **somatic senses** provide sensory information about the body and the environment. Somatic senses include touch, pressure, proprioception, temperature, and pain. **Proprioception** (prō-prē-ō-sep'-shun) is the sense of your body's position and movement. An example of proprioception is the ability of a person to touch their nose when their eyes are closed. This is often used as a field sobriety test. The **visceral senses** provide information about various internal organs and consist primarily of pain and pressure.

The **special senses** are localized to specific organs that have specialized receptors (table 14.1). The special senses—smell, taste, sight, hearing, and balance—are considered in detail in chapter 15.

Not all of the sensory information detected by sensory receptors results in perception. Some action potentials reach areas of the brain where they are not consciously perceived. Two examples are proprioception and detection of change in homeostatic variables. For proprioception, although we can be consciously aware of body

TABLE 14.1

Classification of the Senses

Types of Sense	Receptor Type	Receptor Structure	Initiation of Response
GENERAL SENSES			
Somatic			
Touch	Mechanoreceptors	Meissner corpuscle Hair follicle receptor Merkel disk Pacinian corpuscle Ruffini end organ Free nerve endings	Compression of receptors
Stroking			
Texture			
Vibration			
Skin stretch			
Itch, tickle	Mechanoreceptors	Merkel disk Pacinian corpuscle Free nerve endings	Compression of receptors Compression of receptors Temperature around nerve endings
Pressure			
Proprioception			
Temperature	Thermoreceptors	Cold receptors Warm receptors	
Pain	Nociceptors	Free nerve endings	Irritation of nerve endings (e.g., mechanical, chemical, or thermal)
Visceral			
Pain	Nociceptors	Free nerve endings	Irritation of nerve endings
Pressure	Mechanoreceptors	Pacinian corpuscle	Compression of receptors
SPECIAL SENSES			
Smell	Chemoreceptors	Specialized	Binding of molecules to membrane receptors
Taste	Chemoreceptors	Specialized	Binding of molecules to membrane receptors
Sight	Photoreceptors	Specialized	Chemical change in receptors initiated by light
Hearing	Mechanoreceptors	Specialized	Bending of microvilli on receptor cells
Balance	Mechanoreceptors	Specialized	Bending of microvilli on receptor cells

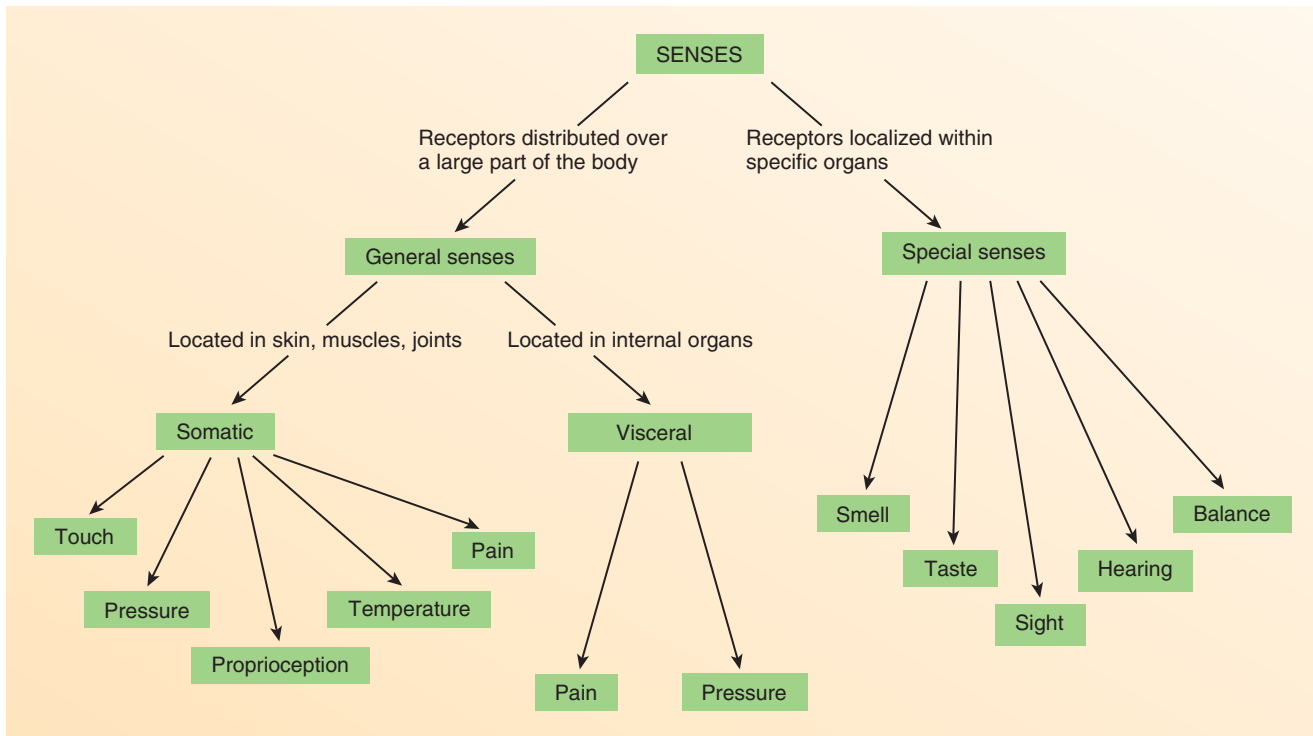

FIGURE 14.1 Classification of the Senses

position and movements, much of this sensory information is propagated to the cerebellum, where it is processed at an unconscious level. For homeostasis, for example homeostasis of the blood, sensory information from receptors that monitor blood pressure, blood oxygen, and pH levels are processed unconsciously in the medulla oblongata. Because blood pressure must be regulated constantly to maintain homeostasis, if we had to regulate blood pressure consciously, we would not be able to think of much else. Homeostasis, therefore, is controlled largely without our conscious involvement.

Even the cerebral cortex screens much of what it receives and does not perceive many of the action potentials that reach it. In addition, humans exhibit selective awareness. We are more aware of sensations on which we focus our attention than on other sensations. If we were aware of all the sensory information that arrived at the cerebral cortex, we would probably not be able to function.

Sensory Receptors

Types of Sensory Receptors

Sensory receptors are commonly classified by three criteria: (1) type of stimulus they detect (table 14.1), (2) location in the body, and (3) receptor structure (table 14.2). The various senses depend on sensory receptors specialized to respond to specific types of stimuli (table 14.1). **Mechanoreceptors** respond to mechanical force such as compression, bending, or stretching of cells. The senses of touch, pressure, proprioception, hearing, and balance all depend on a variety of mechanoreceptors. **Chemoreceptors** respond to chemicals. Smell and taste depend on chemoreceptors.

Thermoreceptors respond to changes in temperature at the site of the receptor and are necessary for the sense of temperature. **Photoreceptors** respond to light striking the receptor cells and are necessary for vision. **Nociceptors** (nō-si-sep'ters; L., *noceo*, hurt), or *pain receptors*, respond to extreme mechanical, chemical, and thermal stimuli. Most sensory receptors typically respond to one type of stimulus, but some nociceptors respond to more than one.

Sensory receptors are also classified into groups based on their location. **Cutaneous receptors** are associated with the skin; **visceroreceptors** are associated with the viscera or organs; and **proprioceptors** are associated with joints, tendons, and other connective tissue. Cutaneous receptors provide information about the external environment, visceroreceptors provide information about the internal environment, and proprioceptors provide information about body position, movement, and the extent of stretch or the force of muscular contractions.

Based on structure, sensory receptors involved in general sensation can be divided into eight major types (table 14.2). Each of these receptor types responds to specific types of stimuli. Structurally, the simplest and most common sensory receptors are the **free nerve endings** (figure 14.2), which are relatively unspecialized neuronal branches similar to dendrites. Free nerve endings are distributed throughout most parts of the body and are especially abundant in epithelial and connective tissues. These receptors are responsible for a number of sensations, including pain, temperature, itch, and movement.

The free nerve endings responsible for temperature detection respond to three types of sensations. One type, the **cold receptor**, increases its rate of action potential production as the skin is

FIGURE 14.2 Sensory Receptors in the Skin

cooled. The cold receptor is also activated by menthol, which gives mint its cool taste. The second type, the **warm receptor**, increases its rate of action potential production as skin temperature increases. Both cold and warm receptors respond most strongly to changes in temperature. Cold receptors are 10 to 15 times more

numerous than warm receptors in any given area of skin. The third type is a pain receptor that is stimulated by extreme cold or heat. At very cold temperatures (0°–12°C), only pain receptors are stimulated. As the temperature increases above 15°C, the pain sensation ends. Between 12°C and 35°C, cold fibers are

TABLE 14.2 Sensory Receptors		
Type of Receptor	Structure	Function
Free nerve ending	Branching, no capsule	Pain, itch, tickle, temperature, joint movement, and proprioception
Merkel disk	Consists of flattened expansions at the end of axons; each expansion is associated with a Merkel cell	Light touch and superficial pressure
Hair follicle receptor	Wrapped around hair follicles or extending along the hair axis; each axon supplies several hairs, and each hair receives branches from several neurons, resulting in considerable overlap	Light touch; responds to very slight bending of the hair
Pacinian corpuscle	Onion-shaped capsule composed of several cell layers with a single central nerve process	Deep cutaneous pressure, vibration, and proprioception
Meissner corpuscle	Several branches of a single axon associated with specialized Schwann cells and surrounded by a connective tissue capsule	Two-point discrimination
Ruffini end organ	Branching axon with numerous small, terminal knobs surrounded by a connective tissue capsule	Continuous touch or pressure; responds to depression or stretch of the skin
Muscle spindle	Three to 10 striated muscle fibers enclosed by a loose connective tissue capsule, striated only at the ends, with sensory nerve endings in the center	Proprioception associated with detection of muscle stretch; important for control of muscle tone
Golgi tendon organ	Surrounds a bundle of tendon fasciculi and is enclosed by a delicate connective tissue capsule; nerve terminations are branched, with small swellings applied to individual tendon fasciculi	Proprioception associated with the stretch of a tendon; important for control of muscle contraction

stimulated, and, between 25°C and 47°C, nerve fibers from warm receptors are stimulated. Therefore, “comfortable” temperatures, between 25°C and 35°C, stimulate both warm and cold receptors. Temperatures above 47°C stimulate pain receptors but do not stimulate warm receptors. One pain receptor that is activated by high temperature is also activated by capsaicin, the chemical that gives chili peppers their hot taste.

Merkel (mer/'kĕl) **disks**, or *tactile disks*, are more complex than free nerve endings (figure 14.2). A Merkel disk consists of axonal branches that end as flattened expansions, each associated with a specialized epithelial cell. These receptors are distributed throughout the basal layers of the epidermis just superficial to the basement membrane and are associated with dome-shaped mounds of thickened epidermis in hairy skin. Merkel disks are involved with the sensations of light touch and superficial pressure. These receptors can detect a skin displacement of less than 1 mm (1/25 inch).

Hair follicle receptors, or *hair end organs*, respond to very slight bending of the hair and are involved in light touch (figure 14.2). These receptors are extremely sensitive and require very little stimulation to elicit a response. The sensation, however, is not very well localized. The dendritic tree at the distal end of a sensory axon has several hair follicle receptors. The field of hairs innervated by these receptors overlaps with the fields of hair follicle receptors of adjacent axons. The considerable overlap in the endings of sensory neurons helps explain why light touch is not highly localized; however, because of converging signals within the CNS, it is very sensitive.

Pacianian (pa-sin/'ē-an, pa-chin/'ē-an) **corpuses**, or *lamelated corpuses*, are complex receptors that resemble an onion (figure 14.2). A single dendrite extends to the center of each Pacinian corpuscle. The corpuses are located within the subcutaneous tissue, where they are responsible for deep cutaneous

pressure and vibration. Pacinian corpuses associated with the joints help relay proprioceptive information about joint positions.

Meissner (mīs/'ner) **corpuses**, or *tactile corpuses*, are distributed throughout the dermal papillae (figure 14.2; see chapter 5) and are involved in two-point discrimination. **Two-point discrimination** (fine touch) is the ability to detect simultaneous stimulation of Meissner corpuses in two distinct receptor fields by touching at two points on the skin (figure 14.3). The distance between two points that a person can detect as separate points of stimulation differs for various regions of the body. This sensation is important in evaluating the texture of objects. Meissner corpuses are numerous and close together in the tongue and fingertips but are less numerous and more widely separated in other areas, such as the back.

Ruffini (rū-fē/'nē) **end organs** are located in the dermis of the skin (see figure 14.2), primarily in the fingers. They respond to pressure on the skin directly superficial to the receptor and to stretch of adjacent skin. These receptors are important in responding to continuous touch or pressure.

Muscle spindles (figure 14.4) consist of 3–10 specialized muscle fibers that are located in skeletal muscles; they provide information about the length of the muscle (see “Stretch Reflex” in section 12.2). Muscle spindles are important to the control and tone of postural muscles. Brain centers act through descending tracts to either increase or decrease action potentials in gamma motor neurons. Stimulation of the gamma motor system, caused by stretch of the muscle, activates the stretch reflex, which in turn increases the tone of the muscles involved.

Golgi tendon organs are proprioceptive receptors associated with the fibers of a tendon near the junction between the muscle and the tendon (figure 14.5). They are activated by an increase in tendon tension, caused either by contraction of the muscle or by passive stretch of the tendon.

FIGURE 14.3 Two-Point Discrimination

Two-point discrimination can be demonstrated by touching a person’s skin with the two points of a compass. When the two points are closer together than the receptor field, the individual perceives only one point. When the two points of the compass are opened wider, the person becomes aware of two points. In each of these images, the person is detecting two points, but a greater distance between the compass points is required on the back.

FIGURE 14.4 Muscle Spindle

Responses of Sensory Receptors

Once a sensory receptor has been stimulated, the receptor produces a graded potential called a **receptor potential**. Recall that a graded potential is a local change in the membrane potential that can vary from small to large (see chapter 11). If the receptor potential is large enough to reach threshold, an action potential is produced and is propagated toward the CNS. Sensory receptor cells that conduct action potentials in response to the receptor potential are called **primary receptors** (figure 14.6a). Most sensory neurons, including

FIGURE 14.5 Golgi Tendon Organ

all those in table 14.2, belong to this category. Other receptor cells, called **secondary receptors**, have no axons or have short, axonlike projections and generally produce receptor potentials (figure 14.6b). The receptor potentials cause the release of neurotransmitters from the receptor cell, which bind to receptor proteins on the membrane of a neuron. This causes a receptor potential in the neuron, which produces an action potential if threshold is reached. The receptor cells of the special senses of taste, hearing, and balance belong to this category.

PROCESS FIGURE 14.6 Comparison of Primary and Secondary Receptors

(a) A primary receptor has an axon that conducts action potentials in response to the receptor potential. (b) A secondary receptor has no axon, but the receptor potential results in the release of a neurotransmitter, which in turn stimulates a postsynaptic neuron.

Some sensations have the quality of **adaptation**, decreased sensitivity to a continued stimulus. After exposure to a certain stimulus strength for a time, the response of the receptors or the sensory pathways lessens from when the stimulus was first applied. The local graded depolarization that produces a receptor potential adapts, or returns, to its resting level, even though the stimulus is still applied. For example, when a person first gets dressed, tactile receptors and pathways relay information to the brain, creating an awareness that the clothes are touching the skin. After a time, the action potentials from the skin decrease, and the clothes are not perceived.

The rate of adaptation varies for different receptors, as occurs in proprioception. Proprioception provides information about the precise position and rate of movement of various body parts, the weight of an object being held in the hand, and the range of movement of a joint. This information is involved in activities such as walking, climbing stairs, shooting a basketball, driving a car, eating, and writing. Receptors for this system are located around joints and in muscles. Two types of proprioceptors provide positional information: tonic receptors and phasic receptors.

Tonic receptors generate action potentials as long as a stimulus is applied so that they adapt very slowly. For example, information from slowly adapting receptors allows us to know where our little finger is at all times without having to look for it.

Phasic receptors adapt rapidly so they are most sensitive to changes in stimuli. For example, information from phasic receptors allows us to know where our little finger is as it moves; thus, we can control its movement through space and predict where it will be in the next moment.

We are usually not conscious of tonic or phasic input because the higher brain centers ignore it most of the time. Through selective awareness, however, we can call up the information when we wish. For example, where is the thumb of your right hand at this moment? Were you aware of its position a few seconds ago?

ASSESS YOUR PROGRESS

1. In general, into what three groups can sensory receptors be classified? What does each provide information about?
2. List the eight major types of sensory receptors, indicate where they are located, and state the functions they perform.
3. What is the difference between primary and secondary receptors. What effect does a receptor potential have on them?
4. What is adaptation? Give an example. Describe tonic and phasic receptors.

Sensory Pathways

Sensory information from the periphery is transmitted via action potentials along sensory pathways, or tracts, to the brain. These pathways are called *ascending* spinal pathways (table 14.3). Each pathway is involved with specific modalities (the types of information transmitted). The neurons that make up each pathway are associated with specific types of sensory receptors. For example,

thermoreceptors in the skin generate action potentials that are propagated along the sensory pathway for pain and temperature, whereas Golgi tendon organs located in tendons generate action potentials that are propagated along the sensory pathway involved with proprioception.

The names of many ascending pathways in the CNS indicate their origin and termination. The first half of the name indicates its origin and the second half indicates its termination. Ascending pathways, therefore, usually begin with the prefix *spino-*, indicating that they originate in the spinal cord (figure 14.7). For example, a spinocerebellar (spī'nō-ser-e-bel'ar) tract originates in the spinal cord and terminates in the cerebellum. The names of other pathways indicate their location in the spinal cord. For example, the name dorsal-column/medial-lemniscal system is a combination of the pathway names in the spinal cord and brainstem.

Conscious and unconscious sensory input are transmitted by different ascending pathways. The two major pathways involved in the conscious perception of external stimuli are the spinothalamic tract of the anterolateral system and the dorsal-column/medial-lemniscal system (table 14.3). The pathways carrying sensory input that we are not consciously aware of include some of the tracts of the anterolateral system (the spinomesencephalic and spinoreticular tracts) and the spinocerebellar tract.

Anterolateral System

The **anterolateral system** is one of the two major systems that convey cutaneous sensory information to the brain (figure 14.7). The anterolateral system includes three tracts: spinothalamic, spinoreticular, and spinomesencephalic. The **spinothalamic tract** allows conscious perception of pain and temperature information, as well as light touch and pressure, tickle, and itch sensations (figure 14.8). The **spinoreticular tract** and the **spinomesencephalic tract** carry pain and touch sensations to other parts of the brain, where the information is not consciously perceived (table 14.3). There is, however, considerable overlap among these three tracts within the anterolateral system.

The spinothalamic tract transmits sensory signals from peripheral receptors to the cerebral cortex through three neurons in sequence—the primary, secondary, and tertiary neurons (figure 14.8). The **primary neurons** of the spinothalamic tract are the first neurons in the pathway. Primary neurons connect the sensory receptor with the spinal cord. The primary neuron cell bodies are in the dorsal root ganglia. The primary neurons relay sensory input from the periphery to the posterior horn of the spinal cord, where they synapse with interneurons. The interneurons, which are not specifically named in the three-neuron sequence, synapse with secondary neurons. **Secondary neurons** in the spinal cord relay information to the brain. Axons from secondary neurons cross to the *contralateral*, or opposite, side of the spinal cord through the anterior portion of the gray and white commissures and enter the spinothalamic tract. From there, the axons ascend to the thalamus. In the thalamus, axons from the secondary neurons synapse with cell bodies of tertiary neurons. **Tertiary neurons** in the thalamus relay information to neurons in the somatic sensory cortex.

TABLE 14.3 Ascending Spinal Pathways

Pathway	Modality (Information Transmitted)	Origin	Primary Cell Body	Secondary Cell Body	Crossover
Anterolateral System					
Spinothalamic tract	Pain, temperature, light touch, pressure, tickle, and itch	Cutaneous receptors	Dorsal root ganglion	Posterior horn of spinal cord	Level at which primary neuron enters spinal cord for pain and temperature or 8–10 segments from where primary neuron enters spinal cord for light touch
Spinoreticular tract	Pain	Cutaneous receptors	Dorsal root ganglion	Posterior horn of spinal cord	Reticular formation
Spinomesencephalic tract (including spinotectal)	Pain and touch	Cutaneous receptors	Dorsal root ganglion	Posterior horn of spinal cord	At point of origin
Dorsal-Column/Medial-Lemniscal System					
Fasciculus gracilis	Proprioception, two-point discrimination, pressure, and vibration from inferior half of body	Joints, tendons, and muscles	Dorsal root ganglion	Medulla oblongata	Medulla oblongata
Fasciculus cuneatus	Proprioception, two-point discrimination, pressure, and vibration from superior half of body	Joints, tendons, and muscles	Dorsal root ganglion	Medulla oblongata	Medulla oblongata
Spinocerebellar Tract					
Posterior	Proprioception	Joints and tendons	Dorsal root ganglion	Posterior horn of spinal cord	Uncrossed
Anterior	Proprioception	Joints and tendons	Dorsal root ganglion	Posterior horn of spinal cord	Some uncrossed; some cross at point of entry, recross at cerebellum

The spinoreticular and spinomesencephalic tracts ascend with the spinothalamic tract through the spinal cord but then divert to brainstem and midbrain nuclei. Some neurons in the spinoreticular tracts do not cross over but ascend on the *ipsilateral*, or same, side of the spinal cord on which they enter. A portion of the spinomesencephalic tract, called the **spinotectal** (spī-nō-tek'täl) **tract**, ends in the superior colliculi of the midbrain and transmits action potentials involved in reflexes that turn the head and eyes toward a point of cutaneous stimulation.

➤ Predict 2

Describe the clinical effect of a lesion on one side of the spinal cord that interrupts the spinothalamic tract of the anterolateral system.

Dorsal-Column/Medial-Lemniscal System

The **dorsal-column/medial-lemniscal** (lem-nis'käl) **system** consists of two pathways that carry the sensations of two-point discrimination, proprioception, pressure, and vibration (figure 14.9). This

system is named for the dorsal column of the spinal cord and the medial lemniscus, which is the continuation of the dorsal column in the brainstem. The term *lemniscus* means “ribbon” and refers to the thin, ribbonlike appearance of the pathway as it passes through the brainstem.

Primary neurons of the dorsal-column/medial-lemniscal system are located in the dorsal root ganglia. They are the largest cell bodies in the dorsal root ganglia, especially those for two-point discrimination. Many axons of the primary neurons of the dorsal-column/medial-lemniscal system enter the spinal cord, ascend its entire length without crossing to its opposite side, and synapse with secondary neurons located in the medulla oblongata. Others synapse in the thoracic portion of the spinal cord.

In the spinal cord, the dorsal-column/medial-lemniscal system is divided into two tracts (see figure 14.7) based on the source of the stimulus. The **fasciculus gracilis** (gras'i-lis; thin) conveys sensations from the lower part of the body, *below* the midthoracic level. The **fasciculus cuneatus** (kū'nē-ā'tūs; wedge-shaped) conveys sensations from the upper part of the body, *above* the

Tertiary Cell Body	Termination	Side of Body Where Fibers Terminate
Thalamus	Cerebral cortex	Contralateral
Reticular formation	Reticular formation, thalamus	Contralateral, ipsilateral
Superior colliculus	Mesencephalon (mid-brain), superior colliculus	Contralateral
Thalamus	Cerebral cortex, cerebellum	Contralateral
Thalamus	Cerebral cortex, cerebellum	Contralateral
Cerebellum	Cerebellum	Ipsilateral
Cerebellum	Cerebellum	Ipsilateral

midthorax. The fasciculus gracilis terminates by synapsing with secondary neurons in the **nucleus gracilis** or with neurons of the posterior spinocerebellar tracts. The fasciculus cuneatus primarily terminates by synapsing with secondary neurons in the **nucleus cuneatus**. Both the nucleus gracilis and the nucleus cuneatus are in the medulla oblongata. Secondary neurons exit the nucleus gracilis and the nucleus cuneatus, cross to the opposite side of the medulla through the decussations of the medial lemniscus, and ascend through the medial lemniscus to synapse with tertiary neurons in the thalamus. Tertiary neurons from the thalamus project to the primary somatic sensory cortex (see “Sensory Areas of the Cerebral Cortex,” later in this chapter).

► Predict 3

Bill and Mary were involved in an accident, and each experienced loss of proprioception, fine touch, and vibration on the left side of the body below the waist. Physicians determined by magnetic resonance imaging (MRI) that Bill had damage to his spinal cord and that Mary had damage to her brainstem. Explain which side of the spinal cord was damaged in Bill and which side of the brainstem was damaged in Mary.

FUNDAMENTAL Figure

FIGURE 14.7 Ascending Pathways at the Cervical Level of the Spinal Cord

Ascending pathways (green) are labeled on the left side of the figure only, although they exist on both sides.

Trigeminothalamic Tract

As the fibers of the spinothalamic tracts pass through the brainstem, they are joined by fibers of the **trigeminothalamic tract**. The trigeminothalamic tract is the facial equivalent of the spinothalamic and dorsal-column/medial-lemniscal system. It is made up primarily of afferent fibers from the trigeminal nerve, along with a few tactile afferent fibers from the ear and tongue carried by cranial nerves VII, IX, and sometimes X. This tract carries the same sensory information as the spinothalamic tracts and dorsal-column/medial-lemniscal system but from the face, nasal cavity, and oral cavity, including the teeth. As with the spinothalamic tracts and dorsal-column/medial-lemniscal system, primary neurons of the trigeminothalamic tract from one side of the face synapse with secondary neurons that cross to the opposite side of the brainstem. These secondary neurons synapse with tertiary neurons in the thalamus, which project to the somatic sensory cortex.

Spinocerebellar Tracts

The **spinocerebellar tracts** (see figure 14.7) carry proprioceptive information to the cerebellum, where information concerning actual movements can be monitored and compared with cerebral information representing intended movements. Two spinocerebellar tracts extend through the spinal cord: the posterior and anterior spinocerebellar tracts.

The **posterior spinocerebellar tract** (figure 14.10) carries information from the upper part of the body in the thoracic and upper lumbar regions. It contains uncrossed nerve fibers that enter

FIGURE 14.8 Spinothalamic Tract of the Anterolateral System

The spinothalamic tract of the anterolateral system transmits action potentials for pain and temperature. (1) Primary neurons enter the spinal cord and synapse with interneurons that synapse with secondary neurons. (2) The secondary neurons cross to the opposite side of the spinal cord, ascend to the thalamus, and synapse with tertiary neurons. (3) The tertiary neurons connect to the somatic sensory cortex. Lines on the inset indicate levels of section. The orange arrow indicates the direction of action potentials. **AP R**

the cerebellum through the inferior cerebellar peduncles. The **anterior spinocerebellar tract** carries information from the lower trunk and lower limbs. It contains both crossed and uncrossed nerve fibers that enter the cerebellum through the superior cerebellar peduncle. The crossed fibers recross in the

FIGURE 14.9 Dorsal-Column/Medial-Lemniscal System

The fasciculus gracilis and the fasciculus cuneatus (not illustrated) convey proprioception, pressure, vibration, and two-point discrimination. (1) Primary neurons enter the spinal cord, ascend ipsilaterally, and synapse with secondary neurons in the medulla oblongata. (2) The secondary neurons cross to the opposite side of the spinal cord, ascend to the thalamus, and synapse with tertiary neurons. (3) The tertiary neurons connect to the somatic sensory cortex. Lines on the inset indicate levels of section. The orange arrow indicates direction of action potentials.

cerebellum. Both spinocerebellar tracts transmit proprioceptive information to the cerebellum from the same side of the body as the cerebellar hemisphere to which they project. Why the anterior spinocerebellar tract crosses twice to accomplish this feat is unknown. Much of the proprioceptive information carried from the lower limbs by the fasciculus gracilis of the dorsal-column/medial-lemniscal system is transferred by synapses in the inferior thorax to the spinocerebellar system and enters the cerebellum as unconscious proprioceptive information. The spinocerebellar tracts convey very little information from the upper limbs to the

FIGURE 14.10 Posterior Spinocerebellar Tract

This tract transmits proprioceptive information from (1) primary neurons in the thorax, upper limbs, and upper lumbar region to (2) secondary neurons that project to the cerebellum. Lines on the inset indicate levels of section. The orange arrow indicates direction of action potentials.

cerebellum. Proprioception from the upper limbs is projected to the thalamus. This input enters the cerebellum through the inferior peduncle from the nucleus cuneatus of the dorsal-column/medial-lemniscal system. Therefore, the dorsal-column/medial-lemniscal system is involved not only in conscious awareness of proprioception but also in unconscious neuromuscular functions.

➤ Predict 4

Most of the neurons from the fasciculus gracilis synapse in the inferior thorax and enter the spinocerebellar system, whereas most of the neurons from the fasciculus cuneatus synapse in the nucleus cuneatus and then continue to the thalamus and cerebrum. Therefore, it can be deduced that most of the proprioception from the lower limbs is unconscious and most of the proprioception from the upper limbs is conscious. Explain why this difference in the two sets of limbs is of value.

Descending Pathways Modifying Sensation

Descending pathways “descend” from the brain to the spinal cord. The corticospinal tract (described in section 14.2) and other

descending tracts send collateral branches to the thalamus, reticular formation, trigeminal nuclei, and spinal cord. Neuromodulators, such as endorphins and enkephalin, released from axons originating in these CNS regions, decrease the frequency of action potentials in sensory tracts (see the discussion of presynaptic inhibition in chapter 11). Through this route, the cerebral cortex or other brain regions may reduce the conscious perception of sensations, including pain.

ASSESS YOUR PROGRESS

- What are the functions of the anterolateral and dorsal-column/medial-lemniscal systems? Describe where the neurons of these systems cross over and synapse.
- How is the trigeminothalamic tract different from the spinothalamic tract?
- What kind of information is carried by the spinocerebellar tracts? Where do the anterior and posterior spinocerebellar tracts originate? Do these tracts terminate on the same or opposite side of the body from where they originate?
- How do descending pathways modulate sensation?

Sensory Areas of the Cerebral Cortex

Sensory pathways project to specific regions of the cerebral cortex called **primary sensory areas** (figure 14.11). The terms *area* and *cortex* are often used interchangeably to refer to the same functional region of the cerebral cortex. These areas are where sensations are perceived. The primary sensory areas of the cerebral cortex must be intact in order for conscious perception, localization, and identification of a stimulus.

The **primary somatic sensory cortex**, or *general sensory area*, receives general sensory input, such as pain, pressure, and temperature, from the thalamus. The primary somatic sensory cortex occupies most of the postcentral gyrus (see chapter 13).

The primary somatic sensory cortex is organized spatially relative to the general plan of the body (figure 14.12). For example, sensory impulses conducting input from the feet project to the most superior portion of the primary somatic sensory cortex, and sensory impulses from the face project to the most inferior portion. The pattern of the primary somatic sensory cortex in each hemisphere is arranged in the form of an upside-down half **homunculus** (hō-mŭngk'ū-lŭs; little human) representing the opposite side of the body, with the feet located superiorly and the head inferiorly. The size of various regions of the primary somatic sensory cortex is related to the number of sensory receptors in that area of the body. For example, the density of sensory receptors is much greater in the face than in the legs; therefore, a greater area of the primary somatic sensory cortex contains sensory neurons associated with the face, and the homunculus has a disproportionately large face. In addition to allowing perception of somatic stimuli, the primary somatic sensory cortex also localizes the site of sensation on the surface of the body. This phenomenon, called **projection**, allows the brain to refer a stimulus to the appropriate location on the surface of the body. An example is when you feel the touch of a

Pain is a sensation characterized by a group of unpleasant and complex perceptual and emotional experiences that trigger autonomic, psychological, and somatic motor responses. Pain sensation has two components: (1) rapidly conducted action potentials carried by large-diameter, myelinated axons, resulting in sharp, well-localized, pricking or cutting pain, followed by (2) more slowly propagated action potentials, carried by smaller, less heavily myelinated axons, resulting in diffuse burning or aching pain. Research indicates that pain receptors have very uniform sensitivity, which does not change dramatically from one instant to another. The variations in pain sensation that we experience result from the mechanisms by which pain receptors are stimulated, differences in the integration of action potentials from the pain receptors, and complex interactions in the cerebral cortex, cingulate gyrus, and thalamus, where the emotional component of pain is registered. Neurons in the cerebral cortex respond to pain stimuli selectively based on prior experience and context. Stress, for example, can reduce pain perception.

Although the dorsal-column/medial-lemniscal system contains no pain fibers, tactile and mechanoreceptors are often activated by the same stimuli that affect pain receptors. Action potentials from tactile receptors provide information that allows the pain sensation to be localized. Superficial pain is highly localized, in part, because of the simultaneous stimulation of pain receptors and mechanoreceptors in the skin. Deep, or visceral, pain is not highly localized because of fewer mechanoreceptors in the deeper structures, and it is normally perceived as a diffuse pain.

Dorsal-column/medial-lemniscal system neurons are involved in what is called the **gate-control theory** of pain control. Primary neurons of the dorsal-column/medial-lemniscal system send out collateral branches that synapse with interneurons in the posterior horn of the spinal cord. These interneurons have an inhibitory effect on secondary neurons of the spinothalamic tract. Thus, pain action potentials traveling through the spinothalamic tract can be suppressed by action potentials that originate in neurons of the dorsal-column/medial-lemniscal system. The arrangement

may act as a “gate” for pain action potentials transmitted in the spinothalamic tract. Increased activity in the dorsal-column/medial-lemniscal system tends to close the gate, thereby reducing pain action potentials transmitted in the spinothalamic tract. Descending pathways from the cerebral cortex or other brain regions can also regulate this “gate.”

The gate-control theory may explain the physiological basis for the following methods that have been used to reduce the intensity of chronic pain: electrical stimulation of the dorsal-column/medial-lemniscal neurons, transcutaneous electrical stimulation (applying a weak electrical stimulus to the skin), acupuncture, massage, and exercise. The frequency of action potentials that are transmitted in the dorsal-column/medial-lemniscal system is increased when the skin is rubbed vigorously and when the limbs are moved. This may explain why vigorously rubbing a large area around the source of pricking pain tends to reduce the intensity of the pain. Exercise normally decreases the sensation of pain, and exercise programs are important in managing chronic pain not associated with illness. Acupuncture may lessen pain through the action of a gating mechanism that inhibits pain transmission upward in the spinal cord.

Analgesics are pain-relieving medications that act in much the same way as gate control. Some analgesics act in the periphery to reduce inflammation and the activation of peripheral nerves; others block the transmission of pain sensations in the spinal cord from primary neurons to neurons of the ascending pathways. Other analgesics function at the level of the cerebral cortex to modulate pain.

Referred Pain

Referred pain is a painful sensation in a region of the body that is not the source of the pain stimulus. Most commonly, patients sense referred pain in the skin or other superficial structures when internal organs are damaged or inflamed. This sensation usually occurs because both the area of skin to which the pain is referred and the visceral area that is damaged are innervated by neurons that project to the same area of the cerebral cortex. The brain cannot distinguish between the two sources of

painful stimuli, and the painful sensation is referred to the most superficial structures innervated by the converging neurons. This referral may occur because the number of receptors is much greater in superficial structures than in deep structures and the brain is more “accustomed” to dealing with superficial stimuli.

Referred pain is clinically useful in diagnosing the actual cause of a painful stimulus. Heart attack victims often feel cutaneous pain radiating from the left shoulder down the arm. Other examples of referred pain are shown in figure 14A.

Phantom Pain

Phantom pain occurs in people who have had appendages amputated or a structure, such as a tooth, removed. Many of these people perceive pain (which may be intense) or other sensations in the amputated structure as if it were still in place. If a neuron pathway that transmits action potentials is stimulated at any point along that pathway, action potentials are initiated and propagated toward the CNS. Integration results in the perception of pain that is projected to the site of the sensory receptors, even if those sensory receptors are no longer present. A similar phenomenon can be easily demonstrated by bumping the ulnar nerve where it crosses the elbow (the funny bone). Even though the neurons are stimulated at the elbow, we often feel a sensation of pain in the fourth and fifth digits.

A factor that may be important in phantom pain is the lack of touch, pressure, and proprioceptive impulses from the amputated limb. Those action potentials suppress the transmission of pain action potentials in the pain pathways, as explained by the gate-control theory of pain. When a limb is amputated, the inhibitory effect of sensory information is removed. As a consequence, the intensity of phantom pain may increase. Another factor in phantom pain may be that the cerebral cortex retains an image of the amputated body part.

Chronic Pain

Chronic pain is long-lasting. Some chronic pain has a known cause, such as tissue damage, as in the case of arthritis. Other chronic pain cannot be associated with tissue damage and has no known cause.

FIGURE 14A Areas of Referred Pain on the Body Surface

Pain from the indicated internal organs is referred to the surface areas shown.

Pain is important in warning us of potentially injurious conditions because pain receptors are stimulated when tissues are injured. However, chronic pain, such as migraine headaches, localized facial pain, or back pain, can be very debilitating, and the pain loses its value of providing information about the condition of the body. People suffering from chronic pain often feel helpless and hopeless, and they may become dependent on drugs. The pain can interfere with vocational pursuits; therefore, many chronic pain sufferers are unemployed or even housebound and socially isolated. They may be easily frustrated or angered and exhibit symptoms of major depression, all qualities associated with **chronic pain syndrome**. Over

2 million people in the United States at any given time experience chronic pain sufficient to impair activity.

Chronic pain may originate with acute pain associated with an injury or may develop for no apparent reason. How sensory signals are processed in the thalamus and cerebrum may determine whether the input is evaluated as mere discomfort, minor pain, or severe pain and how much distress is associated with the sensation. The brain actively regulates the amount of pain information that gets through to the level of perception, thereby suppressing much of the input. If this dampening system becomes less functional, pain perception may increase. Other nervous system factors, such as

the loss of some sensory modalities from an area or habituation of pain transmission, which may remain even after the stimulus is removed, may intensify otherwise normal pain sensations. Treatment often requires a multidisciplinary approach, including surgery or psychotherapy. Some sufferers respond well to drug therapy, but certain drugs, such as opiates, have a diminishing effect the longer they are used and may become addictive.

Sensitization in Chronic Pain

Tissue damage within an area of injury, such as the skin, can cause increased sensitivity in the nerve endings in the area of damage, a condition called **peripheral sensitization**. One class of pain receptors is not activated by traditional noxious stimuli but is recruited only when tissues become inflamed. These receptors, once activated, add to the total barrage of sensory signals to the brain and intensify the sensation of pain.

The CNS may also respond to tissue damage by decreasing its pain threshold, thereby increasing its sensitivity to pain. This condition, called **central sensitization**, apparently results from a specific subset of receptors that is only recruited during repetitive neuron firing, as occurs when a person experiences intense pain sensations. These receptors maintain a chronic, hyperexcitable state in the CNS that can result in chronic pain.

This information concerning peripheral and central sensitization and the knowledge that sensitization involves neuronal and chemical receptors not normally involved in sensation may lead to the discovery of new drugs for treating chronic pain. Rather than searching for new analgesics, which may decrease a broad range of sensations, researchers now have an opportunity to develop a new class of drugs that may block sensitization without diminishing other sensations, including normal pain.

A man has constipation that is causing distension and painful cramping in his colon. What kind of pain does he experience (local or diffuse), and where does he perceive it? Explain.

FIGURE 14.11 Functional Regions of the Lateral Side of the Left Cerebral Cortex **APR**

mosquito landing on your arm and you know exactly where to slap.

There are other primary sensory areas of the cerebral cortex (see figure 14.11). The **taste area**, where taste sensations are consciously perceived in the cortex, is located in the insula, deep to the inferior end of the postcentral gyrus. The **olfactory cortex** (not shown in figure 14.11) is on the inferior surface of the temporal lobe and is where both conscious and unconscious responses to odor are perceived and processed (see chapter 15). The **primary auditory cortex**, where auditory stimuli are processed by the brain, is located in the superior part of the temporal lobe. The **visual cortex**, where portions of visual images are processed, is located in the occipital lobe. In the visual cortex, color, shape, and movement are processed separately rather than as a complete “color motion picture.” These sensory areas are discussed more fully in chapter 15.

Sensory Processing

Cortical areas immediately adjacent to the primary sensory areas are called **association areas** (see figure 14.11). The **somatic sensory association area** is posterior to the primary somatic sensory cortex, and the **visual association area** is anterior to the visual cortex (see figure 14.11). These areas function in the process of recognition. The association areas receive and integrate information from the primary somatic sensory area and other brain regions. This allows evaluation and recognition of the sensory input. For example, when sensory action potentials originating in the retina of the eye reach the visual cortex, the image is

perceived. Action potentials then pass from the visual cortex to the visual association area, where the visual information is compared with past visual experience (“Have I seen this before?”). On the basis of this comparison, the visual association area “decides” whether the visual input is recognized and passes judgment concerning the significance of the input. For example, when surveying a crowd, we generally pay less attention to a person we have never seen before than to someone we know.

The visual association area, like other association areas of the cortex, has reciprocal connections with other parts of the cortex that influence decisions. For example, the visual association area has input from the frontal lobe, where emotional value is placed on the visual input. Because of these numerous connections, visual information is judged several times as it passes beyond the visual association area. This may be one of the reasons that two individuals’ perceptions of the same painting can be vastly different.

14.2 Control of Skeletal Muscles

LEARNING OUTCOMES

After reading this section, you should be able to

- Describe the primary motor area of the cerebral cortex and discuss how it interacts with other parts of the frontal lobe.**
- Distinguish between upper and lower motor neurons, and between direct and indirect tracts.**
- Explain how the basal nuclei and the cerebellum regulate motor function.**

The motor system of the brain and spinal cord is responsible for maintaining the body's posture and balance; for moving the trunk, head, limbs, and eyes; and for communicating through facial expressions and speech. Reflexes mediated through the spinal cord (see chapter 12) and the brainstem (see chapter 13) are responsible for some body movements. These are called **involuntary movements** because they occur without conscious thought. **Voluntary movements**, on the other hand, are consciously activated to achieve a specific goal, such as walking or typing. Although consciously activated, most voluntary movements occur automatically once learned. Thus, a toddler who is just learning to walk must concentrate on every step. However, once the toddler starts walking, he or she does not have to think about the moment-to-moment control of every muscle because neural circuits in the reticular formation and spinal cord automatically control the limbs. After learning a complex task, such as texting or typing, people can perform it relatively automatically.

Voluntary movements depend on upper and lower motor neurons. **Upper motor neurons** connect the cerebral cortex to lower motor neurons directly or through interneurons. The cell bodies of upper motor neurons are in the cerebral cortex. **Lower motor neurons** connect upper motor neurons to skeletal muscles. They have axons that leave the central nervous system and extend through peripheral nerves to innervate skeletal muscles. The cell bodies of lower motor neurons are located in the anterior horns of the spinal cord gray matter and in the cranial nerve nuclei of the brainstem.

Voluntary movements require the following steps:

1. The cerebral cortex communicates with the basal nuclei and cerebellum to plan, coordinate, and execute movements.
2. Initiation begins in the premotor areas of the cerebral cortex upon stimulation of upper motor neurons.
3. The axons of the upper motor neurons form the descending tracts. They stimulate lower motor neurons, which stimulate skeletal muscles to contract.

Motor Areas of the Cerebral Cortex

Body movements are controlled by several motor areas of the brain. Motor pathways from the **primary motor cortex**, or *primary motor area* (see figure 14.11), control many voluntary movements, especially the fine motor movements of the hands. The primary motor cortex occupies the precentral gyrus (see chapter 13). Upper motor neurons are located in three areas of the cortex. About 30% are located in the primary motor cortex. Another 30% are located in the premotor area, and the rest are in the primary somatic sensory cortex.

The cortical functions of the primary motor cortex are spatially arranged according to the general body plan—similar to the spatial arrangement of the primary somatic sensory cortex (figure 14.13). The neuron cell bodies controlling motor functions of the feet are in the most superior and medial portions of the precentral gyrus, whereas those for the face are in the inferior region. As with the primary somatic sensory cortex, the size of various regions in the primary motor cortex is related to the number of motor units in that area of the body. Muscle groups with many motor units are represented by relatively large areas of the

FIGURE 14.13 Spatial Organization of the Primary Motor Cortex

Cerebral cortex seen in frontal section on the left side of the brain. The figure of the body (homunculus) depicts the nerve distributions; the size of each body region shown indicates relative innervation. The cortex occurs on both sides of the brain but appears on only one side in this illustration. The inset shows the motor region of the left hemisphere (purple).

primary motor cortex. For example, muscles performing precise movements, such as those controlling the hands and face, have many motor units, each of which has a small number of muscle fibers. Multiple-motor-unit summation (see chapter 9) can precisely control the force of contraction of these muscles, because only a few muscle fibers at a time are recruited. Muscle groups with few motor units are represented by relatively small areas of the primary motor cortex, even if the muscles innervated are quite large. For example, the muscles controlling movements of the thigh and leg have proportionately fewer motor units than the muscles of the hand, but they have many more and much larger

muscle fibers per motor unit. Thigh and leg muscles are less precisely controlled because the activation of a motor unit stimulates the contraction of many large muscle fibers.

The **premotor area** of the cerebral cortex is located anterior to the primary motor cortex (see figure 14.11). It is the staging area where motor functions are organized before they are initiated in the primary motor cortex. For example, if a person decides to take a step, the neurons of the premotor area are stimulated first. The determination is made in the premotor area as to which muscles must contract, in what order, and to what degree. Action potentials are then passed to the upper motor neurons in the primary motor cortex, which actually initiate the planned movements.

The **prefrontal area** controls the motivation and foresight to plan and initiate movements. It is the next most anterior portion of the brain. This association area is well developed only in primates and especially in humans. Along with motivation, the prefrontal area is involved in the regulation of emotional behavior and mood. The large size of this area of the brain in humans may account for our emotional complexity and our relatively well-developed capacity to think ahead and feel motivated.

Amyotrophic Lateral Sclerosis

Amyotrophic (ă-mī-ō-trō'fik) lateral sclerosis (ALS), also called Lou Gehrig disease, usually affects people between the ages of 40 and 70. About 5–10% of ALS cases are inherited. The condition begins with weakness and clumsiness and progresses within 2–5 years to loss of muscle control as both upper and lower motor neurons are selectively destroyed. ALS patients progressively lose their ability to stand, walk, use their hands, swallow, chew, and eventually to breathe. In contrast to the loss of motor functions, cognitive abilities are relatively unaffected. Most people die from respiratory failure within 3–5 years, but there can be very different rates of progression. For example, the physicist Stephen Hawking has survived for more than 50 years, but that is very unusual. The causes of noninherited ALS remain unknown. About 20% of the inherited forms result from a mutation in DNA coding for the enzyme **superoxide dismutase (SOD)**. SOD is involved in eliminating the free radical superoxide from the body.

Free radicals are molecules that readily accept electrons, which makes them highly reactive. They can strip electrons from proteins, lipids, or nucleic acids, thereby destroying their functions and resulting in cell dysfunction or death. Free-radical damage has been implicated in ALS, arteriosclerosis, arthritis, cancer, and aging. Superoxide, one of the most important and toxic free radicals, forms as oxygen reacts with other free radicals. Although oxygen is critical for aerobic respiration, it is also dangerous to tissues. SOD catalyzes the conversion of superoxide to hydrogen peroxide, which is then converted by catalase to oxygen and water. Apparently, if SOD is defective, superoxide is not degraded and can destroy cells. Motor neurons appear to be particularly sensitive to superoxide attack.

ASSESS YOUR PROGRESS

12. Compare upper motor neurons with lower motor neurons.
13. Where are the primary motor, premotor, and prefrontal areas of the cerebral cortex located? Explain the sequential nature of their functions.
14. Why are some areas of the body represented as larger than other areas on the spatial map of the primary motor cortex?

Motor Pathways

Motor pathways, or tracts, are *descending* pathways from regions of the cerebrum or cerebellum to the brainstem or spinal cord. The pathways carry action potentials along axons that originate in the upper motor neurons. The names of descending pathways are based on their origin and termination. Much like the names of ascending pathways, the prefix indicates a pathway's origin, and the suffix indicates its destination. For example, the corticospinal tract is a motor pathway that originates in the cerebral cortex and terminates in the spinal cord (figure 14.14).

The descending motor fibers are divided into two groups: direct pathways and indirect pathways (table 14.4; figure 14.15). The **direct pathways**, also called the *pyramidal* (pi-ram'i-dal) *system*, are involved in maintaining muscle tone and controlling the speed and precision of skilled movements. These are primarily fine movements involved in dexterity. Most of the **indirect pathways**, sometimes called the *extrapyramidal system*, are involved in less precise control of motor functions, especially those associated with overall body coordination and cerebellar function, such as posture. Many of the indirect pathways are phylogenetically older and control more "primitive" movements of the trunk and proximal portions of the limbs. The direct pathways, which exist only in mammals, may be thought of as overlying the indirect pathways and are more involved in finely controlled movements of the face and distal portions of the limbs. Some indirect pathways, such as those from the basal nuclei and cerebellum, help in fine control of the direct pathways.

Direct Pathways

Direct pathways (figure 14.16) are so named because upper motor neurons in the cerebral cortex, whose axons form these pathways, synapse directly with lower motor neurons in the brainstem or spinal cord. They are also called the pyramidal system because the fibers of these pathways form the medullary **pyramids**. The direct pathways include groups of nerve fibers arrayed into two tracts: corticospinal and corticobulbar. The **corticospinal tract** is involved in direct cortical control of movements below the head (figure 14.16). The **corticobulbar tract** is involved in direct cortical control of movements in the head and neck.

The corticospinal tract consists of axons of upper motor neurons located in the primary motor and premotor areas of the frontal lobes and the somatic sensory parts of the parietal lobes. The axons descend through the **internal capsules** and the cerebral peduncles of the midbrain to the pyramids of the medulla oblongata. At the inferior end of the medulla, most (75–85%) of the corticospinal fibers cross to the opposite side of the CNS through the **pyramidal decussation**. Recall that decussation refers to a

crossing of fibers. This is visible on the anterior surface of the inferior medulla. The crossed fibers descend in the **lateral corticospinal tract** of the spinal cord (figure 14.16). The remaining fibers (15–25%) descend uncrossed in the **anterior corticospinal tract** and decussate near the level where they synapse with lower motor neurons. The anterior corticospinal tracts supply the neck and upper limbs, and the lateral corticospinal tracts supply all levels of the body (table 14.4).

Most of the corticospinal fibers synapse with interneurons in the lateral portions of the spinal cord central gray matter. The interneurons, in turn, synapse with the lower motor neurons of the anterior horn that innervate primarily distal limb muscles.

Damage to the corticospinal tracts results in reduced muscle tone, clumsiness, and weakness but not in complete paralysis, even if the damage is bilateral. Experiments have demonstrated that bilateral sectioning of the medullary pyramids results in (1) loss of contact-related activities, such as tactile placing of the foot and grasping, (2) defective fine movements, and (3) hypotonia (reduced tone). These and other experimental data support the conclusion that the corticospinal system is superimposed over the older, indirect pathways and that it has many parallel functions. The main function of the direct pathways is to add speed and agility to conscious movements, especially of the hands, and to provide a high degree of fine motor control, as in movements of individual fingers. Spinal cord lesions that affect both the direct and the indirect pathways result in complete paralysis.

The corticobulbar tracts are analogous to the corticospinal tracts. The corticobulbar tracts extend to the brainstem (*bulbar*, brainstem) and innervate the head, whereas the corticospinal tracts extend to the spinal cord and innervate the rest of the body. Cells that contribute to the corticobulbar tracts are in regions of the cortex similar to those of the corticospinal tracts. Corticobulbar tracts follow the same basic route as the corticospinal system down to the level of the brainstem. At that point, most corticobulbar fibers terminate in the **cranial nerve nuclei**, where they synapse with interneurons and lower motor neurons. These nuclei give rise to the nerves that control tongue movements, mastication, facial expression, some eye movements, and palatine, pharyngeal, and laryngeal movements.

Indirect Pathways

The indirect pathways (figure 14.17) are so named because axons from motor neurons of the cerebrum and cerebellum do not directly synapse with lower motor neurons. Instead, they first synapse in an intermediate nucleus in the brainstem. The indirect pathways begin with the neurons in those brainstem nuclei. They do not pass through the pyramids or through the corticobulbar tracts and, therefore, are sometimes called extrapyramidal. The major tracts are the rubrospinal, vestibulospinal, reticulospinal, and tectospinal tracts. Many interconnections and feedback loops are present in this system.

Neurons of the **rubrospinal tract** begin in the red nucleus (rubro means red), which is located at the boundary between the diencephalon and the midbrain. The tract decussates in the midbrain and descends in the lateral column of the spinal cord. The red nucleus receives input from both the motor cortex and the cerebellum. Lesions in the red nucleus result in *intention tremors* (action tremors) similar to those seen in cerebellar lesions

TABLE 14.4 Descending Spinal Pathways

Pathway	Functions Controlled	Examples of Movements Controlled	Origin	Crossover
Direct				
Corticospinal tract	Conscious, skilled movements			
Lateral	Movements below the head, especially of the hands	Typing and push-ups	Cerebral cortex	Inferior end of the medulla oblongata
Anterior	Movements of the neck and trunk	Moving with a hula hoop	Cerebral cortex	Level of the lower motor neuron
Corticobulbar tract	Movements of the head and face	Facial expression and chewing	Cerebral cortex	Varies for the different cranial nerves
Indirect				
Rubrospinal	Unconscious movements			
	Movement coordination	Positioning of digits and the palm of the hand when reaching out to grasp	Red nucleus	Midbrain
Vestibulospinal	Maintenance of upright posture and balance	Extension of the upper limbs when falling	Vestibular nucleus	Uncrossed
Reticulospinal	Posture adjustment and walking	Maintenance of posture when standing on one foot	Reticular formation	Some uncrossed; some cross at termination
Tectospinal	Movements of the head and neck in response to visual and auditory reflexes	Movement of the head and neck away from a sudden flash of light	Superior colliculus	Midbrain

FUNDAMENTAL Figure

FIGURE 14.14 Descending Pathways at the Cervical Level of the Spinal Cord

Descending pathways (purple) are labeled on the left side of the figure only, although they exist on both sides. **APR**

(see Diseases and Disorders, table 14.5, later in this chapter). The function of the red nucleus, therefore, is closely related to cerebellar function. The rubrospinal tract is the one indirect tract that is very closely related to the direct, corticospinal tract. It terminates in the lateral portion of the spinal cord central gray matter with the corticospinal tract. It plays a major role in regulating fine motor control of muscles in the distal part of the upper limbs. Damage to the rubrospinal tract impairs forearm and hand movements but does not greatly affect general body movements.

The **vestibulospinal tracts** (see figure 14.14) originate in the vestibular nuclei of the medulla oblongata and descend in the anterior column of the spinal cord. They then synapse with interneurons and lower motor neurons in the ventromedial portion of the spinal cord central gray matter. Their fibers preferentially influence neurons innervating extensor muscles in the trunk and the proximal portion of the lower limbs and are involved primarily in the maintenance of upright posture. The vestibular nuclei receive major input from the vestibular nerve, which is involved in maintaining balance (see chapter 15), and the cerebellum.

The **reticulospinal tract** (see figure 14.14) originates in the reticular formation of the pons and medulla oblongata and descends in the anterior portion of the lateral column of the spinal cord. It then synapses with interneurons and lower motor neurons in the ventromedial portion of the spinal cord central gray matter. The reticulospinal tract maintains posture by controlling the trunk and proximal upper and lower limb muscles during certain movements. For example, when a person who is standing lifts one foot off the ground, the weight of the body shifts to the other limb. During this type of movement, the reticulospinal tract apparently

Termination	Side of Body Where Fibers Terminate
Anterior horn of the spinal cord	Contralateral
Anterior horn of the spinal cord	Contralateral
Cranial nerve nuclei in the brainstem (lower motor neuron)	Contralateral
Anterior horn of the spinal cord	Contralateral
Anterior horn of the spinal cord	Ipsilateral
Anterior horn of the spinal cord	Ipsilateral or contralateral
Cranial nerve nucleus in the medulla oblongata and anterior horn of the upper levels of the spinal cord (lower motor neurons that turn the head and neck)	Contralateral

enhances the functions of the alpha motor neurons in the crossed extensor reflex, so that balance is maintained.

The **tectospinal tract** originates in the superior colliculus, which has been called the *tectum*, or roof, of the mesencephalon. This tract controls reflex movement of the head to bright lights, noises, and rapid movements.

Another major portion of the indirect pathways involves the basal nuclei (see figure 14.15). The basal nuclei have a number of connections within the brain, and they interact with indirect pathways, such as the rubrospinal tract, by which they modulate motor functions.

ASSESS YOUR PROGRESS

15. What are the structural and functional differences between direct and indirect pathways?
16. What two tracts form the direct pathways? What area of the body is supplied by each tract?
17. Describe the location of the neurons in each tract, as well as where they synapse.
18. Name the structures and tracts that form the indirect pathways. What functions do they control?

Modifying and Refining Motor Activities

Basal Nuclei

The **basal nuclei** (see figure 13.10) are important in planning, organizing, and coordinating motor movements and posture. Complex neural circuits connect the basal nuclei with each other, with the

thalamus, and with the cerebral cortex. These connections form several feedback loops, some of them stimulatory and others inhibitory.

The basal nuclei stimulatory circuits facilitate muscle activity, especially at the beginning of a voluntary movement, such as rising from a sitting position or beginning to walk. The inhibitory circuits facilitate the actions of the stimulatory circuits by inhibiting muscle activity in antagonist muscles. Inhibitory circuits also decrease muscle tone when the body, limbs, and head are at rest (eliminating random and “unwanted” movements of the trunk and limbs). Disorders of the basal nuclei result in increased muscle tone and exaggerated, uncontrolled movements when at rest. Some people have difficulty rising from a sitting position and initiating walking. A specific feature of some basal nuclei disorders is a *resting tremor*, slight shaking of the hands when the muscle is relaxed and not performing a task. Parkinson disease and cerebral palsy are basal nuclei disorders.

Cerebellum

The **cerebellum** (ser-e-bel'ūm; see figure 13.6) consists of three functional parts: the vestibulocerebellum, the spinocerebellum, and the cerebrotocerebellum.

Clinical IMPACT

Parkinson Disease

Parkinson disease is characterized by muscular rigidity; loss of facial expression; tremor; a slow, shuffling gait; and general lack of movement. The disease usually occurs after age 55. A resting tremor, called “pill-rolling,” is characteristic of Parkinson disease; it consists of circular movement of the opposed thumb and index fingertips. The increased muscular rigidity in Parkinson disease results from defective inhibition of some of the basal nuclei by the substantia nigra, one of the basal nuclei in the midbrain. Parkinson disease is caused by the death of dopamine-containing neurons in the substantia nigra. However, the cause of the neuronal death is not known. Dopamine is an inhibitory neurotransmitter that is required to modulate motor activity.

Parkinson disease can be treated with levodopa (lē-vō-dō'pā; L-dopa), a precursor to dopamine, or more effectively with Sinemet®, a combination of L-dopa and carbidopa (kar-bi-dō'pā). Carbidopa is a decarboxylase inhibitor that prevents L-dopa from breaking down before it can reach the brain. Because of the long-term side effects associated with levodopa, including dyskinesias, other dopamine agonists, such as ropinirole and pramipexole, are being examined. Researchers have discovered a protein, called **glial cell line-derived neurotrophic factor (GDNF)**, that selectively promotes the survival of dopamine-secreting neurons. Alternatively, chronic stimulation of the globus pallidus (part of the lentiform nucleus) with an electrical pulse generator has shown some success. Treatment of the disorder by transplanting fetal tissues or stem cells from adult tissues that are capable of producing dopamine is also under investigation.

FIGURE 14.15 Descending Pathways

The direct pathways (corticobulbar and corticospinal) are indicated by the dark purple arrow. The indirect pathways and their interconnections are indicated by the light purple arrows.

The **vestibulocerebellum**, or flocculonodular lobe, receives direct input from the vestibular structures, especially the semicircular canals (see chapter 15), and sends axons to the vestibular nuclei of the brainstem. It helps maintain muscle tone in postural

FIGURE 14.16 Direct Pathways

Lateral and anterior corticospinal tracts are responsible for movement below the head. Upper motor neuron axons descend to the medulla oblongata. Most axons decussate in the medulla oblongata and descend in the lateral corticospinal tracts in the spinal cord. Some axons continue as the anterior corticospinal tracts and decussate in the spinal cord. Upper motor neurons synapse with interneurons that synapse with lower motor neurons. Lines on the inset indicate levels of section. The orange arrow indicates direction of action potentials.

FIGURE 14.17 Indirect Pathways

Examples of indirect pathways are rubrospinal and reticulospinal tracts. Neurons from the cerebrum project to neurons in brainstem nuclei. The axons of these neurons form the reticulospinal and rubrospinal tracts. Lines on the inset indicate levels of section. The orange arrow indicates direction of action potentials.

muscles. It also helps control balance, especially during movements, and coordinate eye movement.

The **spinocerebellum** consists of the **vermis** and the medial portion of the **lateral hemisphere**. The spinocerebellum helps accomplish fine motor coordination of simple movements by means of its comparator function. A **comparator** is a sensing device that compares the data from two sources—in this case, the motor cortex and peripheral structures (figure 14.18). In this way, the comparator function coordinates simple movements, such as touching your nose. Action potentials from the motor cortex descend into the spinal cord to initiate voluntary movements. At the same time, action potentials are carried from the motor cortex to the cerebellum to give the cerebellar neurons information representing the intended movement. In addition, action potentials from proprioceptive neurons ascend through the spinocerebellar tracts and simultaneously arrive at the cerebellum. Proprioceptive neurons innervate the joints and tendons of the structure being moved, such as the elbow or knee, and provide information about the position of the body or body parts. These action potentials give the cerebellar neurons information from the periphery about the actual movements. The cerebellum compares the action potentials from the motor cortex with those from the moving structures. That is, it compares the intended movement with the actual movement. If a difference is detected, the cerebellum sends action potentials through the thalamus to the motor cortex and to the spinal cord to correct the discrepancy. The result is smooth, coordinated movements.

The **cerebrocerebellum** consists of the lateral two-thirds of the lateral hemispheres. It communicates with the motor, premotor, and prefrontal portions of the cerebral cortex in planning and practicing rapid, complex motor actions that require coordination and training. These connections from the cerebrum to the cerebellum constitute a large portion of the axons in the cerebral peduncles. Because of the cerebrocerebellum, with training, a person can perform highly skilled and rapid movements more quickly than would be possible with only the comparator function of the cerebellum. In these cases, the cerebellum participates with the cerebrum in learning highly specialized movements, such as playing the piano or swinging a baseball bat. The cerebrocerebellum is also involved in cognitive functions, such as rhythm, conceptualization of time intervals, some word associations, and solutions to pegboard puzzles—tasks once thought to occur only in the cerebrum.

Cerebellar dysfunction results in (1) decreased muscle tone, (2) balance impairment, (3) a tendency to overshoot when reaching for or touching an object, and (4) an intention tremor, which is shaking in the hands that occurs only while attempting to perform a task. Although the cerebellum and basal nuclei both control motor functions, they have opposite effects, and they exhibit opposite symptoms when injured. Cerebellar dysfunction results in decreased muscle tone and an intention tremor, whereas basal nuclei dysfunction often results in increased muscle tone and a resting tremor.

14.3 Brainstem Functions

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the sensory input from the brainstem.**
- B. Explain the role of the reticular activating system (RAS).**
- C. Discuss the motor output and reflexes of the brainstem.**

The major ascending and descending pathways project through the brainstem. In addition, the brainstem contains the nuclei of most cranial nerves (see table 13.4 and figure 13.4c) and the nuclei of the reticular formation. The nuclei of cranial nerves III–X and XII are in the brainstem. Only collateral branches of cranial nerve II (optic nerve) project to brainstem nuclei. Cranial nerves I (olfactory nerve) and XI (spinal accessory nerve) do not have projections to or nuclei in the brainstem.

Sensory Input Projecting Through the Brainstem

The brainstem receives sensory input from collateral branches of ascending spinal cord pathways and from the axons of most cranial nerves. This includes sensory input from cranial nerves: II (vision), V (tactile sensation from the face, nasal cavity, and oral cavity), VII (taste), VIII (hearing and balance), IX (taste and tactile sensation in the throat), and X (taste, tactile sensation in the larynx, and visceral sensation in the thorax and abdomen). Among these all except cranial nerve II have sensory nuclei in the brainstem. Many of these nuclei are involved in the special senses (see chapter 15).

As noted earlier, fibers of the spinothalamic tracts passing through the brainstem are joined by fibers of the trigeminothalamic tract. This tract carries tactile sensations, such as pain and temperature, two-point discrimination, and light touch, from the face, the nasal cavity, and the oral cavity, including the teeth.

RAS Functions of the Brainstem

The **reticular formation** is a group of nuclei scattered throughout the brainstem that is involved in regulating cyclical motor functions.

An important part of the reticular formation is the **reticular activating system (RAS)**. The RAS regulates the sleep-wake cycle. Collateral branches of trigeminothalamic tract neurons

FIGURE 14.19 Reticular Activating System

The reticular activating system can be stimulated by inputs from the cerebral cortex (mental activities) and from the limbic system (emotional activities), as well as by a variety of sensory inputs from other stimuli, such as visual (sudden flashes of light), auditory (a ringing alarm clock), olfactory (the smell of coffee), and somatosensory (touching the face) stimuli. **APR**

project to the RAS, where they stimulate wakefulness and consciousness. Also projecting to the RAS are collateral branches of cranial nerves II (optic), V (trigeminal), and VIII (vestibulocochlear); ascending tactile sensory pathways; and descending neurons from the cerebrum. Visual and acoustic stimuli, as well as mental activities, stimulate the RAS to help maintain alertness and attention. A stimulus such as a sudden flash of bright light, a ringing alarm clock, the smell of coffee, or a feather touching the face can arouse consciousness (figure 14.19). The removal of auditory, visual, and other stimuli may lead to drowsiness or sleep. For example, consider what happens to students during a monotonous lecture in a dark lecture hall. The RAS controls the brain's level of arousal or consciousness. Damage to RAS cells of the reticular formation can result in a lack of consciousness or coma.

Certain drugs can either depress or stimulate the RAS. General anesthetics and many tranquilizers depress it. On the other hand, ammonia (smelling salts) and other irritants stimulate trigeminal nerve endings in the nose. As a result, action potentials travel to the reticular formation and the cerebral cortex to arouse an unconscious patient.

► Predict 6

Luke tried to go to sleep, but a dripping bathroom faucet kept him awake. Explain.

Motor Output and Reflexes Projecting Through the Brainstem

The brainstem is an important conduit and integration site for descending motor pathways and reflexes. Both direct and indirect motor pathways pass through the brainstem. As discussed earlier, the direct descending pathways originate in the cerebral cortex and pass directly through the brainstem (corticospinal tracts) or synapse in cranial nerve motor nuclei to initiate movements within the head, such as eye movements (corticobulbar tract). The indirect pathways synapse with brainstem nuclei, which in turn send descending fibers into the spinal cord. Descending fibers from the reticular formation constitute one of the body's most important motor pathways. Fibers from the reticular formation are critical in controlling many functions, such as respiratory movements and cardiac rhythms. The brainstem contains the motor nuclei of cranial nerves III–VII, IX, X, and XII. Functionally, the motor output projecting through the brainstem can be classified into two categories: somatic motor and parasympathetic.

Somatic Motor Output and Reflexes

Cranial nerves III (oculomotor), IV (trochlear), and VI (abducens) are involved in voluntary and reflex eye movements. These nerves are controlled by the **superior colliculi**, which are midbrain structures that coordinate eye movements. Voluntary visual tracking of moving objects involves action potentials from the cerebrum to the superior colliculi. Visual tracking with both eyes to the right involves the lateral rectus muscle and abducens nerve of the right eye and the medial rectus muscle and oculomotor nerve of the left eye. Coordination of these two nerves and muscles requires nuclei of the reticular formation. The eye muscles, along with the muscles of the neck (mainly the trapezius and sternocleidomastoid,

innervated by cranial nerve IX), can also be involved in reflexes that are initiated in the superior colliculi in response to visual and auditory stimuli. Collateral branches from the optic tract (II) synapse in the superior colliculi. Axons from the superior colliculi project to cranial nerve nuclei III, IV, and VI and to the upper cervical part of the spinal cord (motor neurons of XI), where they stimulate the motor neurons involved in turning the eyes and head toward a visual stimulus. Similarly, the superior colliculi also receive input from auditory pathways, which can initiate a reflex that turns the eyes and head toward a sudden noise. Axons in the spinomesencephalic pathway of the spinal cord (see table 14.3) also project to the superior colliculi. Input from this pathway initiates a reflex that turns the eyes and head toward a tactile stimulus on the body.

Motor fibers from cranial nerve V (trigeminal) innervate the muscles of mastication and control chewing; however, once the chewing cycle is initiated, the reticular formation regulates the cycle. Even though the initiation of chewing can be under conscious control, the presence of food in the mouth initiates a reflex between the sensory nuclei and the motor nucleus of cranial nerve V, thereby starting the chewing cycle. Other reflexes in the trigeminal nerve system detect how hard or soft an item is in the mouth and adjust the bite accordingly. Reflexes between the trigeminal sensory nuclei and the motor nucleus of cranial nerve XII (hypoglossal) control the tongue to help place the food between the teeth for chewing, while keeping the tongue out of harm's way.

Cranial nerve VII (facial), which innervates the muscles of facial expression, is controlled by the cerebrum and is very important in communication.

Cranial nerves IX (glossopharyngeal) and X (vagus) send somatic motor fibers to muscles of the pharynx and larynx associated with swallowing and speech. Swallowing, once initiated under conscious control, continues as a reflex. The pharyngeal muscles of swallowing are largely innervated by the vagus nerve and, to a smaller extent, by the glossopharyngeal nerve.

Unlike swallowing, which is largely a reflex, speech is highly controlled by the cerebrum. The vagus nerve innervates the muscles of the larynx responsible for voice production and controls the pharyngeal and most palatine muscles responsible for moving the soft palate during speech. The complex movements of the tongue during speech are controlled by the hypoglossal nerve (XII), which innervates nearly all the muscles of the tongue.

Parasympathetic Output and Reflexes

The constriction of the pupil involves parasympathetic stimulation through the oculomotor (III) nerve. The visual reflexes resulting in pupil constriction are coordinated through nuclei in the reticular formation. These reflexes are also coordinated by a nuclear region in the diencephalon called the pretectal area (so named because it is in front of the tectum, the roof of the midbrain).

Sensory input from the trigeminal (V) nerve can initiate several reflexes. Tactile sensory input from the nasal cavity via the trigeminal nerve can trigger a sneeze reflex. Tactile sensory input from the oral cavity via the trigeminal nerve informs the cerebrum that food or some other object is in the mouth. The presence of an object in the mouth—even a nonfood item, such

as a marble—stimulates a reflex between the trigeminal sensory nuclei and the motor nuclei of the facial (VII) and glossopharyngeal (IX) nerves, which innervate the salivary glands to stimulate salivation.

Sensory input from the glossopharyngeal nerve (IX) conveys tactile information from the back of the tongue, the soft palate, and the throat (pharynx) to the brainstem. Mechanical stimulation of these areas can initiate a gag reflex, whereas other stimulation of the throat can initiate a cough reflex. Sensory input from the vagus nerve (X) conveys tactile information from the larynx (voicebox) and the thoracic and abdominal viscera. Tactile input from the larynx can also initiate a cough reflex. In addition, the vagus nerve (X) is involved in many complex reflexes associated with vital functions, such as heart rate, respiration, and digestion. Many of these involve the reticular formation and are discussed in later chapters.

Vital Functions Controlled in the Brainstem

Many vital functions, such as heart rate, blood pressure, and respiration, are regulated by nuclei in the brainstem. When a person is involved in a serious accident or is extremely ill, these vital functions may be affected. Therefore, many emergency medical procedures are designed to evaluate brainstem function.

Predict 7

Some types of epilepsy are treated by placing an electronic device inside the neck to stimulate the vagus nerve. Minor injury to the vagus nerve during implantation of the device can lead to hoarseness. Why is this so? Can you predict two other consequences of minor injury to the vagus nerve?

ASSESS YOUR PROGRESS

24. Which cranial nerves provide sensory input to brainstem nuclei?
25. What is the reticular formation? What are the roles of the reticular activating system?
26. Discuss the somatic motor output and reflexes from the brainstem.
27. Describe the parasympathetic reflexes that involve the brainstem.
28. What are some vital functions that are regulated by the brainstem?

14.4 Higher Brain Functions

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Compare and contrast the two cortical areas required for speech.

- B. Describe the pathway that connects the cerebral hemispheres.**
- C. Describe the types of brain wave patterns and how they relate to sleep.**
- D. Compare and contrast the features of working, short-term, and both types of long-term memory.**
- E. Describe the functions of the limbic system, including the impact of olfactory stimuli.**

The human brain is capable of many functions besides awareness of sensory input and control of skeletal muscles. Speech, mathematical and artistic abilities, sleep, memory, emotions, and judgment are functions of the brain.

Speech

In most people, the speech area is in the left cerebral cortex. Two major cortical areas are involved in speech: the **Wernicke area** (sensory speech area), a portion of the parietal lobe, and the **Broca area** (motor speech area) in the inferior part of the frontal lobe (see figure 14.11). The Wernicke area is necessary for understanding and formulating coherent speech. The Broca area initiates the complex series of movements necessary for speech. The Wernicke and Broca areas are connected by a bundle of neurons known as the **arcuate fasciculus** (figure 14.20a).

For someone to speak a word that he or she sees, as when reading aloud, the following sequence of events shown in figure 14.20b must take place: (1) Action potentials from the eyes reach the primary visual cortex, where the word is seen. The word is then recognized in the visual association area and (2) understood in parts of the Wernicke area. (3) Action potentials representing the word are conducted through association fibers that connect the Wernicke and Broca areas. In the Broca area, the word is formulated as it will be spoken. (4) Action potentials are then propagated to the premotor area, where the movements are programmed, and finally to the primary motor cortex, where the proper movements are triggered.

The sequence of events required to repeat a word that has been heard is similar. (1) The information passes from the ears to the primary auditory cortex and then to the auditory association area, where the word is recognized, and (2) continues to the Wernicke area, where the word is understood. From the Wernicke area, it follows the same route as for speaking words that are seen, going to (3) the Broca area, then (4) to the premotor area and primary motor cortex.

Predict 8

Vern, age 75, is recovering from a stroke that caused some right-side paralysis. He understands verbal commands and instructions, but his speech is hesitant and distorted. In addition, Vern's facial expressions, especially on the right side, are limited, and he has some difficulty chewing and swallowing. Explain these manifestations.

Communication Between the Right and Left Hemispheres

The cortex of the right cerebral hemisphere controls muscular activity in and receives sensory input from the left half of the body. The left cerebral hemisphere controls muscles in and receives sensory

input from the right half of the body. Sensory information received by the cortex of one hemisphere is shared with the other through connections between the two hemispheres called **commissures** (kom'i-shürz; joining together). The largest of these commissures is the **corpus callosum** (kōr'pūs kă-lō'süm), which is a broad band of tracts at the base of the longitudinal fissure (see figure 13.1).

Language and perhaps other functions, such as artistic activities, are not shared equally between the left and right cerebral hemispheres. The left hemisphere is more involved in analytical skills, such as mathematics and speech. The right hemisphere is involved in activities such as spatial perception, the recognition of faces, and musical ability.

Brain Waves and Sleep

Different levels of consciousness can be revealed by different patterns of electrical activity in the brain. Electrodes placed on a person's scalp and attached to a recording device can record the brain's electrical activity, producing an **electroencephalogram** (ē-lek'trō-en-sef'ă-lō-gram; **EEG**; figure 14.21). These electrodes are not sensitive enough to detect individual action potentials, but they can detect the simultaneous action potentials in large numbers of neurons. As a result, the EEG displays wavelike patterns of electrical activity known as **brain waves**. Brain waves are produced continuously, but their intensity and frequency differ from time to time based on the state of brain activity. Most of the time, EEG patterns from a given individual are irregular, with no particular pattern, because, although the normal brain is active, most of its electrical activity is not synchronous. At other times, however, specific patterns can be detected.

Clinical IMPACT

Aphasia

Damage to the language areas of the cerebral cortex may result in **aphasia** (ă-fă'zē-ă), absent or defective speech or language comprehension. The most common cause is a stroke. It is estimated that 25–40% of stroke survivors exhibit aphasia.

There are several types of aphasia, depending on the site of the lesion. **Receptive aphasia** (Wernicke aphasia) is caused by a lesion in the Wernicke area. This condition is characterized by defective auditory and visual comprehension of language, defective naming of objects, and repetition of spoken sentences. Both **jargon aphasia**, in which a person may speak fluently but unintelligibly, and **conduction aphasia**, characterized by poor repetition but relatively good comprehension, can result from a lesion in the tracts between the Wernicke and Broca areas. **Anomic** (ă-nō'mik) **aphasia**, caused by the isolation of the Wernicke area from the parietal or temporal association areas, is characterized by fluent but circular speech resulting from poor word-finding ability. **Expressive aphasia** (Broca aphasia), caused by a lesion in the Broca area, is characterized by hesitant and distorted speech.

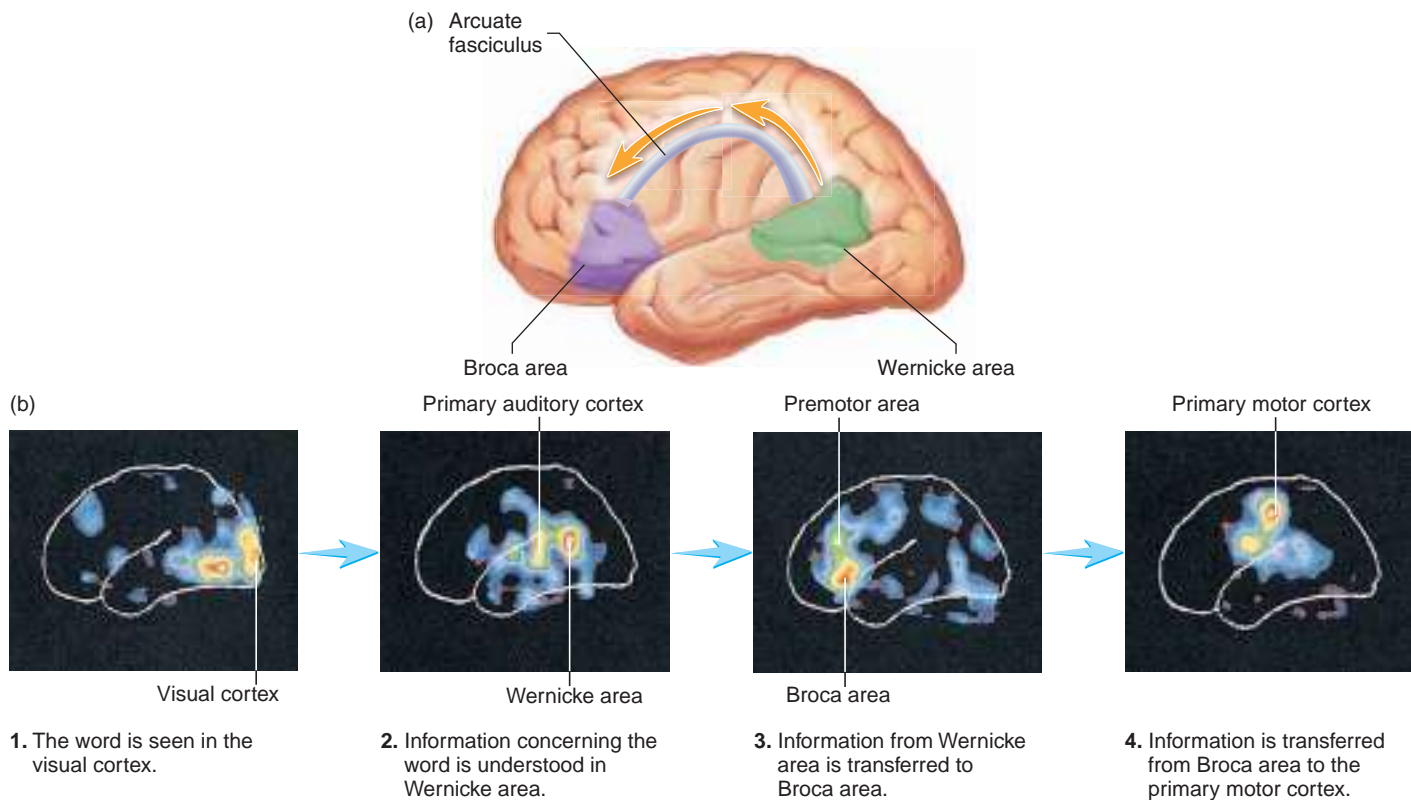

FIGURE 14.20 Demonstration of Cortical Activities During Speech

(a) The arcuate fasciculus connects the two key areas involved in speech, the Broca area and the Wernicke area. The *orange arrows* indicate direction of action potentials. (b) Steps 1–4 show the pathway followed when reading words aloud. Positron emission tomography (PET) scans show the areas of the brain that are most active during various phases of speech. The highest level of brain activity is indicated in *red*, with successively lower levels represented by *yellow*, *green*, and *blue*.

The different levels of consciousness in an awake and a sleeping person are marked by different types of brain wave patterns. These regular patterns are classified as alpha, beta, theta, or delta waves (figure 14.21). **Alpha waves** are observed in a normal person who is awake but in a quiet, resting state with the eyes closed. **Beta waves** have a higher frequency than alpha waves and occur during intense mental activity. **Theta waves** usually occur in children, but they can also occur in adults who are experiencing frustration or who have certain brain disorders. **Delta waves** occur in infants, in patients with severe brain disorders, and in people who are in deep sleep.

Brain wave patterns vary during the four stages of sleep (figure 14.21*c,d*). During the beginning of sleep, a rapid transition takes place from a beta rhythm to an alpha rhythm. As sleep deepens, progressively more delta waves occur. A sleeping person arouses several times during a period of sleep. Dreaming occurs during periods when eye movement can be observed in a sleeping person; this state is called **rapid eye movement (REM) sleep**.

Distinct types of EEG patterns can be detected in patients with specific brain disorders, such as epileptic seizures. Similar to EEG patterns, neurologists can also measure **evoked potentials**, which are electrical responses caused by light, sound, or somatosensory stimuli. EEGs and evoked potentials are useful tools to diagnose neurological disorders and determine the appropriate treatment.

ASSESS YOUR PROGRESS

29. Trace the sequence of events that must occur for a person to repeat a word that he or she hears.
30. Name the largest pathway that connects the right and left cerebral hemispheres.
31. What functions are localized in each cerebral hemisphere?
32. What does an EEG measure?
33. What conditions produce alpha, beta, theta, and delta waves, respectively?
34. Explain how brain waves change during sleep. What is REM sleep?

Memory

Memory can be viewed as the capacity to store knowledge for later retrieval. The storage of memory can be divided into three stages: working, short-term, and long-term (figure 14.22). Long-term memories can also be subdivided based on the type of the memory: those dealing with facts (*declarative*) and those dealing with skills (*procedural*). Both types involve networks of neurons that work together to form a memory.

Clinical IMPACT

Hemisphere Dominance

For most functions and in most people, dominance of one cerebral hemisphere over the other is probably not very important, because the two hemispheres are in constant communication through the corpus callosum, literally allowing the right hand to know what the left hand is doing. However, in some cases, as a last resort to treat epileptic seizures, people have had their corpus callosum severed, and this has led to some interesting functional defects. For example, if a patient with a severed corpus callosum is asked to reach behind a screen to touch one of several items with one hand without being able to see it and then is asked to point out the same object with the other hand, the person cannot do it. Tactile information from the left hand enters the right somatic sensory cortex, but that information is not transferred to the left hemisphere, which controls the right hand. As a result, the left hemisphere cannot direct the right hand to the correct object.

Additional evidence that each brain hemisphere is responsible for specific functions is the fact that a person who has had a stroke in the right parietal lobe may lose the ability to recognize faces while retaining essentially all other brain functions. A more severe lesion in the left parietal lobe can take away a person's ability to recognize the right side of his or her body or even to identify simple objects, a defect called **amorphosynthesis** (ă-mŏr'fō-sin'thĕ-sis). Some people with a similar lesion in the right cerebral hemisphere tend to ignore the left half of the world, including the left half of their own bodies. These people may completely ignore a person who is to their left but react normally when the person moves to their right. They may also fail to dress the left half of their bodies or to eat the food on the left half of their plates.

Working Memory

The brain briefly stores information required for the immediate performance of a task. This task-associated memory is called **working memory**. It is transient, lasting only a few seconds to minutes, but highly detailed. It occurs mostly in the frontal cortex. The number of information bits (about seven) that can be stored at any one time is the primary limiting factor for working memory. However, the amount varies from person to person. More bits can be stored when they are grouped into segments separated by spaces—as is done with phone numbers. When new information is presented, or when the person is distracted, information previously stored in working memory is eliminated; therefore, if a person is given a second telephone number or if the person's attention is drawn to something else, the first number is usually forgotten.

Short-Term Memory

Short-term memory lasts longer than working memory and can be stored from minutes to days. Short-term memories are stored by

Case STUDY

Multiple Sclerosis

Betty, a 32-year-old woman, woke up one morning with weakness in her lower limbs. By that afternoon, she had become completely exhausted, with a familiar ache in her left eye and tingling sensations in her fingers. At the end of the day, she could barely stand up, and her left eye was blurry and increasingly painful. Betty's family physician made an appointment for her with a neurologist. The neurologist suspected **multiple sclerosis (MS)**, an autoimmune disease that results in the demyelination of CNS neurons, which become sclerotic, or hard. He ordered an MRI scan and a **visual evoked potential (VEP) test**, which is a recording of action potentials in the optic nerve “evoked” in response to visual stimuli. During the VEP test, electrodes were placed on Betty's scalp, and she was asked to respond to visual stimuli, first with her normal eye covered by an eye patch and then with her normal eye uncovered.

The MRI scan showed lesions in the optic nerve and white matter of the brain, and the VEP test showed optic nerve dysfunction. These results confirmed a diagnosis of multiple sclerosis accompanied by **optic neuritis**, or inflammation of the optic nerve. Betty's neurologist explained that, in multiple sclerosis, damage has occurred to sensory neurons that conduct sensory information to the brain, as well as to motor neurons that conduct motor stimulation from the brain to the muscles. Betty asked if she could be cured. The neurologist replied that she would experience periods of remission, which might be interrupted by symptomatic periods. He also warned that, with each successive episode, neurons might become progressively more damaged.

► Predict 9

- What effect does demyelination have on action potential propagation along axons? How does this explain blurred vision?
- How would you explain the weakness and tingling that Betty experienced?

a mechanism involving increased synaptic transmission. Short-term memory is susceptible to brain trauma, such as physical injury or decreased oxygen, and to certain drugs that affect neural function, such as general anesthetics. The formation of short-term memory involves the enhancement of synaptic activity by **long-term potentiation**, which facilitates, or *potentiates*, the future transmission of action potentials (figure 14.23). In long-term potentiation, there is either an increase in the number of vesicles containing the neurotransmitter glutamate released on the presynaptic side or an increase in the number and activity of glutamate receptors on the postsynaptic side. In both cases, glutamate-mediated synaptic transmission is increased in the postsynaptic neuron. Long-term potentiation involves the activation of protein kinases by calcium. Calcium enters the postsynaptic terminal via glutamate receptors and binds to the protein **calmodulin**. The calcium/calmodulin complex activates **calmodulin-dependent protein kinase II**, which both phosphorylates glutamate receptors to

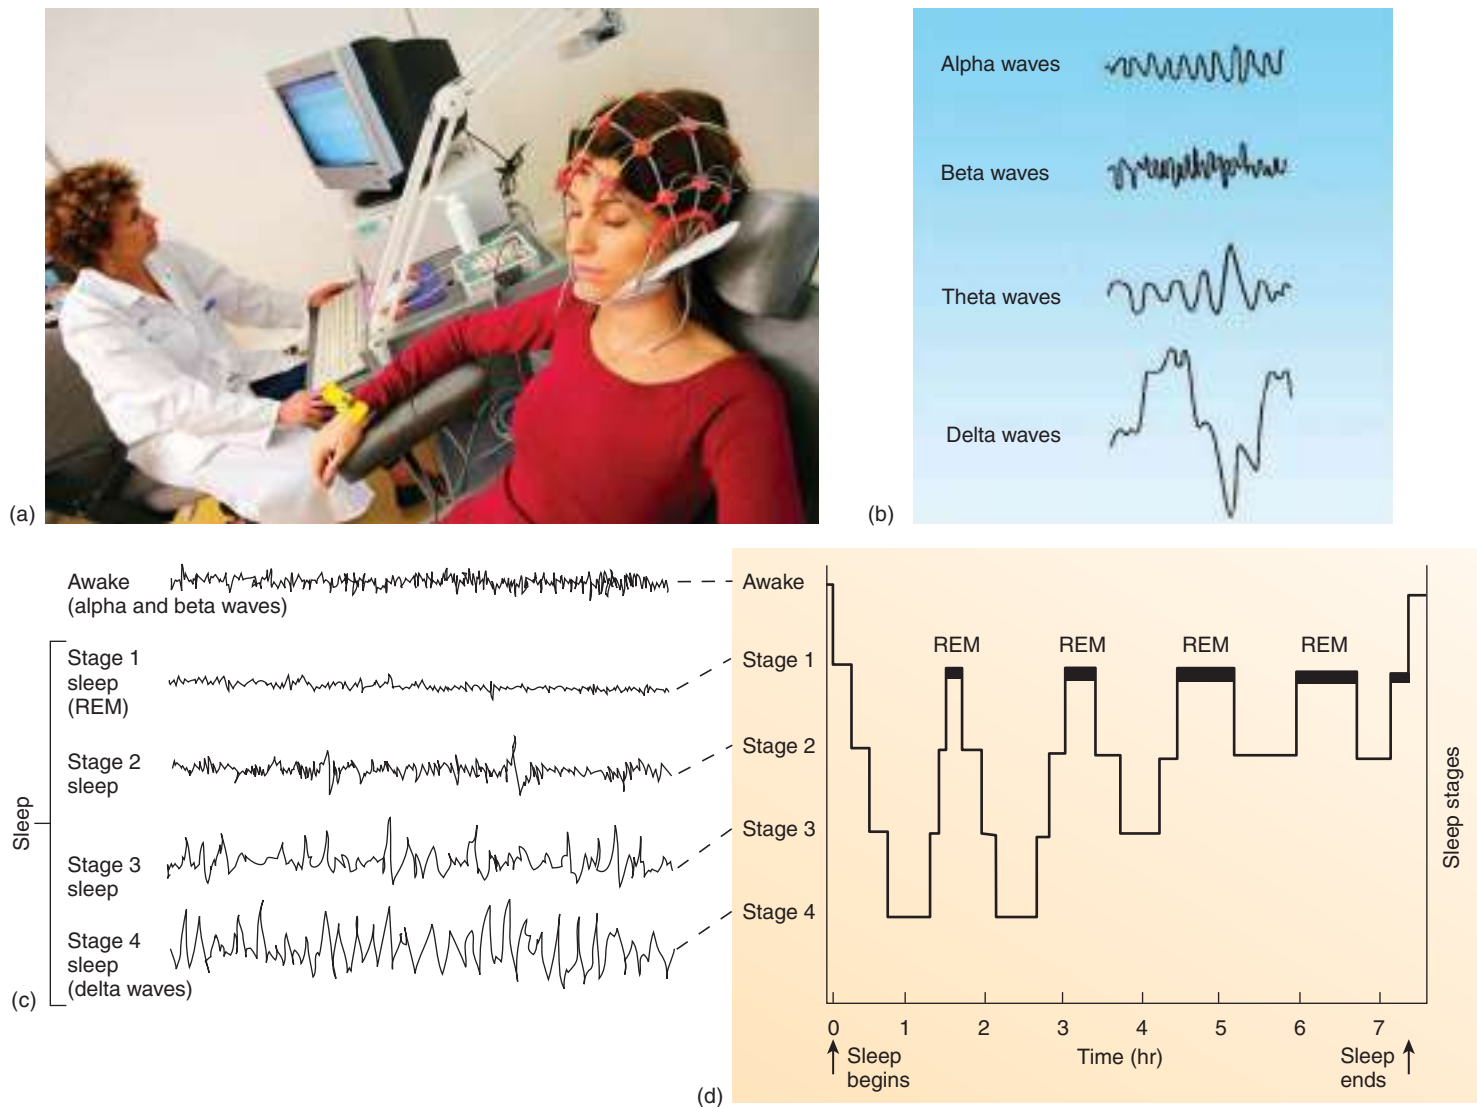

FIGURE 14.21 Electroencephalograms (EEGs) Showing Brain Waves

(a) A patient with electrodes attached to her head. (b) Four EEG tracings: alpha waves, often seen in a relaxed individual with eyes closed; beta waves, typical of an alert individual; theta waves, seen in the first stage of sleep; and delta waves, characteristic of deep sleep. (c) EEG tracings when a person is awake and during four stages of sleep. (d) A typical night's sleep pattern in a young adult. The time spent in REM sleep is labeled and shown by dark bars.

increase their activity and sends signals to move additional glutamate receptors from internal vesicles to the postsynaptic membrane. Thus, long-term potentiation increases transmission at selected synapses to allow short-term memory. This is best understood from studies of the hippocampus, described later in this section.

Long-Term Memory

Long-term memory requires the prior formation of short-term memory. It is a more stable storage state that lasts from days to years or a lifetime. Long-term memories are stabilized by the formation of additional synaptic connections following new protein synthesis. Unlike short-term memories, long-term memories are more resistant to disruption by brain trauma.

The process of transferring short-term memory to long-term memory is called **consolidation**. Consolidation is a gradual process involving the formation of new and stronger synaptic connections that can occur over a period of years and probably involves multiple steps. Repeating the information and associating it with existing memories or a strong emotion increases the consolidation of short-term to long-term memory.

The process of consolidation involves the synthesis of new proteins that increase the number and size of synaptic contacts, along with the increased synaptic transmission of long-term potentiation. Genes that encode proteins involved in synapse formation are turned on by cAMP and calcium signaling pathways. A **cAMP-responsive transcription factor** called CREB is particularly important for activating gene transcription. The newly synthesized proteins include cytoskeletal proteins that create small protrusions from

FIGURE 14.22 Memory Processing

dendrites called **dendritic spines**. New synapses are then formed on the dendritic spines. Thus, long-term memory is longer-lasting due to an increased number of strengthened synapses.

Declarative and Procedural Memories

Another way to classify memory is in terms of the type of information stored: declarative or procedural. Both types of memory appear to use similar neural mechanisms at the cellular level, but in response to different types of information and in different parts of the brain.

Declarative memory, also called *explicit memory*, involves the retention of facts you can easily state or *declare*. For example, names, dates, and places involve declarative memory. The formation of declarative short-term memory involves the parts of the temporal

lobe called the **hippocampus** (hip-pō-kam'pūs; shaped like a seahorse) and the **amygdala** (ă-mig'dă-lă; almond-shaped; see figure 13.11). The hippocampus is required for the factual content, such as a person's name, whereas the amygdala contributes emotional overtones to the memory, such as feelings of like or dislike associated with that person. Emotion and mood apparently serve as gates in the brain, influencing what is stored in declarative memory. The amygdala is also a key to the development of fear, along with the prefrontal cortex and the hypothalamus. Much of what is stored as declarative memory is not consolidated or is gradually lost through time, although memories with emotional overtones persist longer.

Procedural memory, also called *implicit* or *reflexive memory*, involves the development of skills or *procedures*. For example, riding a bicycle and playing the piano involve procedural memory. Procedural memory is stored primarily in the cerebellum (see figure 13.6) and the **premotor area** of the cortex (see figure 14.11). Procedural memory is also involved in conditioned reflexes. A famous example is Pavlov's experiments—each time he fed a group of dogs, a bell was rung; soon the dogs salivated when the bell rang, even if no food was present. Only a small amount of procedural memory is lost through time.

Storage and Retrieval of Memories

Memory appears to be distributed in large networks in the brain rather than confined to a particular storage area. A network of neurons and their pattern of activity, called a **memory engram**, or

PROCESS FIGURE 14.23 Cellular Mechanisms of Long-Term Potentiation

Both presynaptic and postsynaptic mechanisms are shown, although usually only one occurs at a single synapse.

Clinical IMPACT

Fear

Some aspects of fearful responses appear to be “hardwired” in the brain and do not require learning. For example, infant rodents are terrified when exposed to a cat, even though they have never seen a cat before. Loud sounds seem to be particularly effective in eliciting fear responses. A direct collateral branch runs from the auditory pathway to the amygdala, which does not involve the cerebral cortex. Fear can be evoked by a loud sound acting directly on the amygdala. Overcoming fear, however, requires the involvement of the cerebral cortex; therefore, the stimulation of fear appears to involve one process, its suppression another. Flaws in either process can result in fear-related disorders, such as anxiety, depression, panic, phobias, and posttraumatic stress disorder.

memory trace, is probably involved in the long-term retention of information, a thought, or an idea. In other words, memories are not a single set of neurons but, rather, a collection of the activity between groups of interconnected neurons. For example, there is no “Grandma” neuron, whereby Grandma is completely forgotten if that neuron is damaged. In this model, the pattern of strengthened synapses distributed throughout the memory engram constitutes the memory, and the process of strengthening these synapses is the consolidation of the memory.

The memory engram is thought to be generated from memories of multiple features—for instance, color, smell, shape, taste, and emotion—that are each represented in the regions of the brain responsible for those features. This is similar to the original sensory processing of an experience by specific brain regions. Likewise, parts of declarative memory appear to be stored separately in various parts of the cerebrum, especially in the temporal and parietal lobes, much like storing items in separate

Clinical IMPACT

Sleep and Memory

Is “pulling an all-nighter” a good idea when preparing for an exam, or is it better to quit studying early and get some sleep? Does sleep actually help in memory processing? So far, research results disagree. A number of studies indicate that REM sleep plays a critical role in learning. Other research, however, indicates that REM sleep is critical to the consolidation of procedural memory but not declarative memory. There is no clear evidence that REM sleep helps consolidate declarative memory, the type of memory used in an examination. Some data suggest that deep, slow-wave sleep (SWS), which occurs early in the night, may be important in consolidating declarative memory.

“pigeonholes.” Memories of people appear to be stored separately from memories of places. People’s faces may be stored in yet other “pigeonholes.” Family members appear to be stored together. Damage to one part of the brain, such as a stroke, can remove certain memories without affecting others.

The retrieval of a complete memory requires accessing parts of the memory from different “pigeonholes.” A complex memory requires accessing and reassembling segments of memory each time the memory is recalled. For example, the memory of an experience may be stored in at least four different “pigeonholes”—where you were, whom you were with, what happened, and how you felt—each stored in a separate place. The complexity of this process may be responsible for the changes in what we remember over time. On occasion, parts of unrelated memories may be pulled out and put together incorrectly to create a “false memory.”

Limbic System

The limbic system includes the olfactory cortex, deep cortical regions, and various nuclei (see figure 13.11). It influences emotions, visceral responses to emotions, motivation, mood, long-term declarative memory, and sensations of pain and pleasure. This system is associated with basic survival instincts: reproduction and the acquisition of food and water.

A major source of sensory input into the limbic system is the olfactory nerves. The smell or thought of food stimulates the sense of hunger in the hypothalamus, which motivates us to seek food. Many animals can also smell water, even over great distances.

Clinical IMPACT

Headaches

Headaches have a variety of causes and are generally poorly understood. **Tension headaches** are caused by muscle tension. They consist of a dull, steady pain in the forehead, temples, and neck or throughout the head. Tension headaches are associated with stress, fatigue, and poor posture.

Migraine headaches (*migraine*, half a skull) usually occur on only one side of the head and appear to involve a combination of neurological dysfunction and abnormal dilation and constriction of blood vessels. For some people, a migraine can start with an aura, which is a sensation that often involves distorted vision, shooting lines, and blind spots. Migraines consist of severe throbbing, pulsating pain, along with sensitivity to sensory input, especially light and sound. They are also accompanied by nausea or vomiting. About 12% of the population suffers from migraines, with about 70% having a family history of the disorder. Women are affected three times more often than men. Common triggers include stress, certain foods and alcohol, altered sleep patterns, strong sensory stimuli (lights, sounds, smells), weather changes, and, for women, the menstrual cycle. Fortunately, the severity and frequency of attacks usually decrease with age.

MICROBES In Your Body

Brain Function: Is It Affected by Our Gut Microbiota?

Most of us would agree that our mental state can affect our health. For example, many students often find themselves “coming down with something” just about the time midterm or final exams are happening. This can be explained by the fact that stress hormones depress our immune system. But is the opposite connection true? Would most people agree that our brain’s function, and perhaps even its development, can be influenced by the health of another organ in our body?

In today’s medical world, we’re on the cusp of a paradigm shift. Surprising new evidence suggests that certain central nervous system diseases are linked to our gut microbiota population. Moreover, evidence suggests that there is bidirectional signaling between the gut and the brain, via a gut-brain axis. This might mean that simply adjusting the gut microbe population can help treat disorders such as depression and anxiety.

There is a growing body of data from both human and mouse studies that supports the notion of a gut-brain axis. In humans, disorders of the gut, such as irritable bowel syndrome (IBS) and inflammatory bowel disease (IBD), occur in conjunction with high levels of anxiety. Treatment of IBS/IBD patients with probiotics, supplemental bacteria that foster further gut bacterial growth, has been useful

in minimizing the symptoms of these disorders. Similarly, patients suffering from chronic liver disease experience a complication called hepatic encephalopathy, which decreases cognition. When untreated, these patients have elevated serum levels of gut microbe-specific short-chain fatty acids. These short-chain fatty acids induce autism-like behavior; however, upon antibiotic treatment and reduced levels of these short-chain fatty acids, patients regain normal cognition. Further, autism patients also experience benefits from antibiotic treatment, albeit temporarily.

In mice studies, the connection between behavior and gut microbiota is becoming well established. For example, numerous studies with naturally bacteria-free mice, called germ-free mice, have demonstrated a relationship between stress and anxiety-related behaviors and gut microbiota populations. Germ-free mice have higher stress and anxiety levels, which are decreased upon colonization with normal gut microbiota. In fact, calm mice become anxious when they receive transplants of gut microbiota from already anxious mice. The reverse is also true. In addition, scientists have examined indicators of brain function, such as levels of the molecule brain-derived neurotrophic factor (BDNF), an important regulator of multiple cognitive and emotional behaviors. BDNF

is crucial for supporting neuronal survival and increasing the growth of new neurons and synapses. Germ-free mice produce less BDNF than do mice with normal gut microbiota. In particular, limbic system structures, including the hippocampus, hypothalamus, and amygdala, produce lower levels of BDNF in germ-free mice. Upon colonization of germ-free mice with gut microbiota, BDNF levels return to normal.

There is much more work to be done to completely unravel the mystery of the gut-brain axis. However, there is clearly a developing link between cognition and emotional behaviors and gut microbiota.

➤ Predict 10

You learned that IBS/IBD patients, among others, tend to have higher levels of anxiety when their condition goes untreated. You also learned that gut bacteria produce short-chain fatty acids, which can enter the blood plasma in levels sufficient enough to be measured by a clinical test. It is thought that these short-chain fatty acids are responsible for inducing the anxiety experienced by IBS/IBD patients. Propose a mechanism by which the short-chain fatty acids might communicate with the areas in the brain that regulate anxiety.

Reproduction in some animals, such as dogs and cats, involves olfactory detection of **pheromones** (fer’ō-mōnz), molecules released into the air by one animal that attract another animal of the same species, usually of the opposite sex. Pheromones released by human females can influence the menstrual cycles of other women.

The **cingulate gyrus** of the limbic system appears to function as a “satisfaction center” for the brain and is associated with the feeling of satisfaction after a meal or after sexual intercourse. The cingulate gyrus can be directly affected by chemicals such as alcohol and other drugs that cause physical dependence. The brain becomes dependent on these substances for a quick sense of satisfaction. Obsessions and compulsions, such as compulsive gambling, kleptomania, and even overeating, exhibit neurological patterns in the cingulate gyrus that are similar to those seen in addiction.

The relationship of the hippocampus to the limbic system and to memory is important to survival. For example, it is very important to remember where to obtain food. Once a person has eaten, the satiety center in the hypothalamus is stimulated, the hunger center is inhibited, and the person feels full, or satiated. The hypothalamus

interacts with the cingulate gyrus and other parts of the limbic system to produce a sense of satisfaction associated with satiation.

Lesions in the limbic system can result in unusual behaviors, such as a voracious appetite, increased sexual activity that is often inappropriate, and docility, including the loss of normal fear and anger responses. Because the hippocampus is part of the temporal lobe, damage to that portion can also lead to loss of memory formation.

ASSESS YOUR PROGRESS

35. Name and briefly describe what occurs in the three stages of memory.
36. Describe the processes that result in the formation of short-term and long-term memory.
37. Distinguish between declarative and procedural memory.
38. Explain how a memory is stored and then retrieved.
39. What are the functions of the limbic system? Which of the special senses provides major input to the limbic system?

14.5 Effects of Aging on the Nervous System

LEARNING OUTCOME

After reading this section, you should be able to

A. Describe the effects of aging on the nervous system.

As a person ages, sensory function gradually declines because of decreases in the number of sensory neurons, the function of the remaining neurons, and the amount of CNS processing. In the skin, free nerve endings and hair follicle receptors remain largely unchanged with age. However, Meissner corpuscles and Pacinian corpuscles decrease in number, and the capsules of those that remain become thicker, structurally distorted, and thereby reduced in function. As a result of these changes in Meissner corpuscles and Pacinian corpuscles, elderly people are less conscious of anything touching or pressing on their skin, have a decreased sense of two-point discrimination, and experience more difficulty identifying objects by touch. These functional changes leave elderly people more prone to skin injuries and give them a greater sense of isolation.

A loss of Pacinian corpuscles also results in a decreased sense of position of the limbs and the joints, which can affect balance and coordination. The functions of Golgi tendon organs and muscle spindles also decline with increasing age. As a result, information about the position, tension, and length of tendons and muscles decreases, further reducing the senses of movement,

posture, and position, as well as the control and coordination of movement.

Other sensory neurons with reduced function include those that monitor blood pressure, thirst, objects in the throat, the amount of urine in the urinary bladder, and the amount of feces in the rectum. As a result, elderly people are more prone to high blood pressure, dehydration, swallowing and choking problems, urinary incontinence, and constipation or bowel incontinence.

A general decline in the number of motor neurons also occurs. By age 60, as many as 50% of the lower motor neurons in the lumbar region of the spinal cord may have been lost. Muscle fibers innervated by the lost motor neurons are also lost, resulting in a general decline in muscle mass. The remaining motor units can compensate for some of the lost function. However, this often makes older people work harder to perform activities that were previously not so difficult. Loss of motor units also leads to more rapid fatigue, because the remaining units must perform compensatory work. However, regular physical exercise can forestall and reduce these declines.

Reflexes slow as people age, because both the generation and the conduction of action potentials and synaptic functions slow. The number of neurotransmitters and receptors declines. Age-related changes in the CNS also slow reflexes. The more complicated the reflex, the more it is affected by age. As reflexes slow, older people are less able to react automatically, quickly, and accurately to changes in internal and external conditions.

The size and weight of the brain decrease as a person ages. At least some of these changes result from the loss of neurons within the cerebrum. The remaining neurons can apparently compensate

Clinical GENETICS

Alzheimer Disease

Alzheimer disease is a severe type of dementia that affects an estimated 10% of all people older than 65 and nearly half of those older than 85. Occasionally, it begins before the age of 60. Alzheimer disease involves a general decrease in brain size, resulting from loss of neurons in the cerebral cortex. The gyri become narrower, and sulci widen. The frontal lobes and specific regions of the temporal lobes are affected most severely. Alzheimer symptoms include general intellectual deficiency, memory loss, short attention span, moodiness, disorientation, and irritability.

Alzheimer disease is characterized by the appearance of **amyloid** (am'i-loyd) **plaques** and **neurofibrillary tangles**. Amyloid plaques are localized axonal enlargements of degenerating nerve fibers, containing large amounts of β -amyloid protein; neurofibrillary tangles

are filaments inside the cell bodies of dead or dying neurons.

There are two types of Alzheimer disease: early-onset and late-onset. Both have a genetic component. The early-onset form is relatively rare, occurring in less than 5% of cases. It can occur between ages 30 and 60. Most of the early-onset cases are caused by mutations in one of three genes. All three of these genes cause an increase in aggregates of β -amyloid protein. The early-onset form is inherited in an autosomal dominant manner, which means that if a child inherits a mutant gene, then they will almost certainly get Alzheimer disease.

The more common late-onset form occurs after age 60. The causes of late-onset Alzheimer disease are not as well understood as the early-onset form. The disease is apparently caused by a combination of genetic and environmental factors. While a single gene has

not been identified, there are genetic factors that increase the risk of late-onset Alzheimer disease. One genetic risk factor is inheritance of a specific allele or form of the **apolipoprotein E** (ap'ō-lip-ō-prō'tēn; **APOE**) gene called **APOE ϵ 4**. The APOE protein binds to β -amyloid protein and is known to transport cholesterol in the blood. About 40% of people with late-onset Alzheimer disease have the **APOE ϵ 4** allele. However, the **APOE ϵ 4** allele is only a risk factor, which means that not everyone with that allele will develop Alzheimer disease.

Currently, large genetic screens have identified several additional genes that increase the risk of Alzheimer disease. These discoveries may provide the needed clues to prevent this devastating disease.

for much of this loss. In addition to loss of neurons, structural changes occur in the remaining neurons. Neuron plasma membranes become more rigid, the endoplasmic reticulum becomes more irregular in structure, neurofibrillary tangles develop in the cells, and amyloid plaques form in synapses. All these changes decrease the ability of neurons to function. Age-related changes in brain function include decreases in voluntary movement, conscious sensations, reflexes, memory, and sleep. Short-term memory decreases in most older people. This change varies greatly among individuals, but in general such changes are slow until about age 60 and then become more rapid, especially after age 70. However, the total amount of memory loss is normally not great for most people. Older people have the most difficulty assimilating information that is unfamiliar and presented verbally and rapidly. Some of these problems may occur as older people are required to deal with new information in the face of existing, contradictory memories. Long-term memory appears to be unaffected or even improved in older people.

As with short-term memory, thinking, which includes problem solving, planning, and intelligence, generally declines slowly

until age 60 but more rapidly thereafter. However, these changes are slight and quite variable. Many older people show no change, and about 10% show an increase in thinking ability. Many of these changes are affected by a person's background, education, health, motivation, and experience. It appears that continued mental activity can decrease the loss of mental skills with aging.

Older people tend to require more time to fall asleep and experience more periods of waking during the night, which are also of greater duration. Factors that can affect sleep include pain, indigestion, rhythmic leg movements, sleep apnea, decreased urinary bladder capacity, and circulatory problems. There is, on average, an increase in stage 1 sleep, which is the least restful, and less time spent in stage 4 and REM sleep, which are the most restful.

ASSESS YOUR PROGRESS

40. How does aging affect sensory function?
41. How does loss of motor neurons affect muscle mass?
42. Does aging always produce memory loss?

Diseases and Disorders

TABLE 14.5

Integrated CNS Disorders*

Condition	Description
CNS MOVEMENT DISORDERS	
Dyskinesias	General term for movement disorders; often involve basal nuclei
Parkinson disease	Caused by a lesion in basal nuclei; characterized by muscular rigidity, resting tremor, general lack of movement, and a slow, shuffling gait
Huntington disease	Dominant hereditary disorder; causes progressive degeneration of basal nuclei; characterized by involuntary movements
Cerebral palsy	General term for defects in motor functions or coordination due to brain damage caused by abnormal development or injury during pregnancy, birth, or first years of life; symptoms include increased muscle tone, resting tremors, difficulty speaking and swallowing, and slow, writhing, aimless movements
Cerebellar lesions	Often result in movements that are ataxic (jerky) and dysmetric (poor estimation of movement distance and force, such as overshooting when reaching for an object); can cause an intention tremor (i.e., the more one tries to control a movement, the greater the tremor becomes), in contrast to the resting tremor of Parkinson disease, which is reduced during purposeful movement
OTHER CNS DISORDERS	
Alzheimer disease	Dementia; usually affects older people; involves loss of neurons in the cerebral cortex; symptoms include general intellectual deficiency, memory loss, short attention span, moodiness, disorientation, and irritability
Tay-Sachs disease	Hereditary lipid-storage disorder of infants; primarily affects the CNS; symptoms include paralysis, blindness, and death
Epilepsy	Seizures involving a sudden, massive neuronal discharge, which may result in involuntary muscle contractions (convulsions)
Headaches	May be due to inflammation, dental irritations, eye disorders, tension in head and neck muscles, or unknown causes
Dyslexia	Reading deficiency; reading level is below that expected based on overall intelligence; symptoms vary but include confusion between similar letters, such as <i>b</i> and <i>d</i> ; cause is not known
Stroke	Caused by bleeding in the brain or a clot or spasm blocking cerebral blood vessels, resulting in a local area of cell death; symptoms include loss of speech, numbness, and paralysis

* For more CNS disorders, see "Diseases and Disorders" tables in chapters 12 and 13.

Systems PATHOLOGY

Stroke

Background Information

Scott had suffered a “stroke,” also referred to as a **cerebrovascular accident (CVA)**. The term **stroke** describes a heterogeneous group of conditions involving the death of brain tissue due to disruption of its vascular supply. Scott was at high risk of developing a stroke. He was approaching middle age, was overweight, did not exercise enough, smoked, was under stress, and had a poor diet.

There are two types of stroke: **Hemorrhagic stroke** results from bleeding of arteries supplying brain tissue, and **ischemic (is-kē'mik) stroke** results when arteries supplying brain tissue are blocked (figure 14B). Most strokes (87%) are ischemic. The blockage in ischemic stroke can result from a thrombus, which is a clot that develops in place within an artery, or an embolism, which is a plug composed of a detached thrombus or other foreign body, such as a fat globule or gas bubble, that becomes lodged in an artery, blocking it. Correct diagnosis of the type of stroke, usually by brain imaging, is crucial for determining the appropriate treatment. For hemorrhagic strokes, surgery may be needed to stop the bleeding. For ischemic strokes, the patient is often treated with drugs to break apart the blood clot and minimize further clotting, which would only worsen a hemorrhagic stroke.

The combination of motor loss (as exhibited by weakness in the limbs) and sensory loss (evidenced by loss of pain and temperature sensation in the left lower limb and loss of all sensation in the right side of the face), along with the ataxia, dizziness, nystagmus, and hoarseness, suggests that the stroke affected the brainstem and cerebellum. Blockage of the vertebral artery, a major artery supplying the brain, can result in an area of dead tissue called a lateral medullary infarction. Damage to the descending motor tracts in that area, above the medullary crossover point, causes muscle weakness. Damage to ascending tracts can result in loss of pain and temperature sensation or other sensory modalities, depending on the affected tract. Damage to cranial nerve nuclei causes the loss of pain and temperature sensation in the face, dizziness, blurred vision, nystagmus, vomiting, and hoarseness. These signs and symptoms are not observed unless the lesion is in the brainstem, where these nuclei are located. Some damage to the cerebellum, also supplied by branches of the vertebral artery, can account for the ataxia.

Anterior

(a)

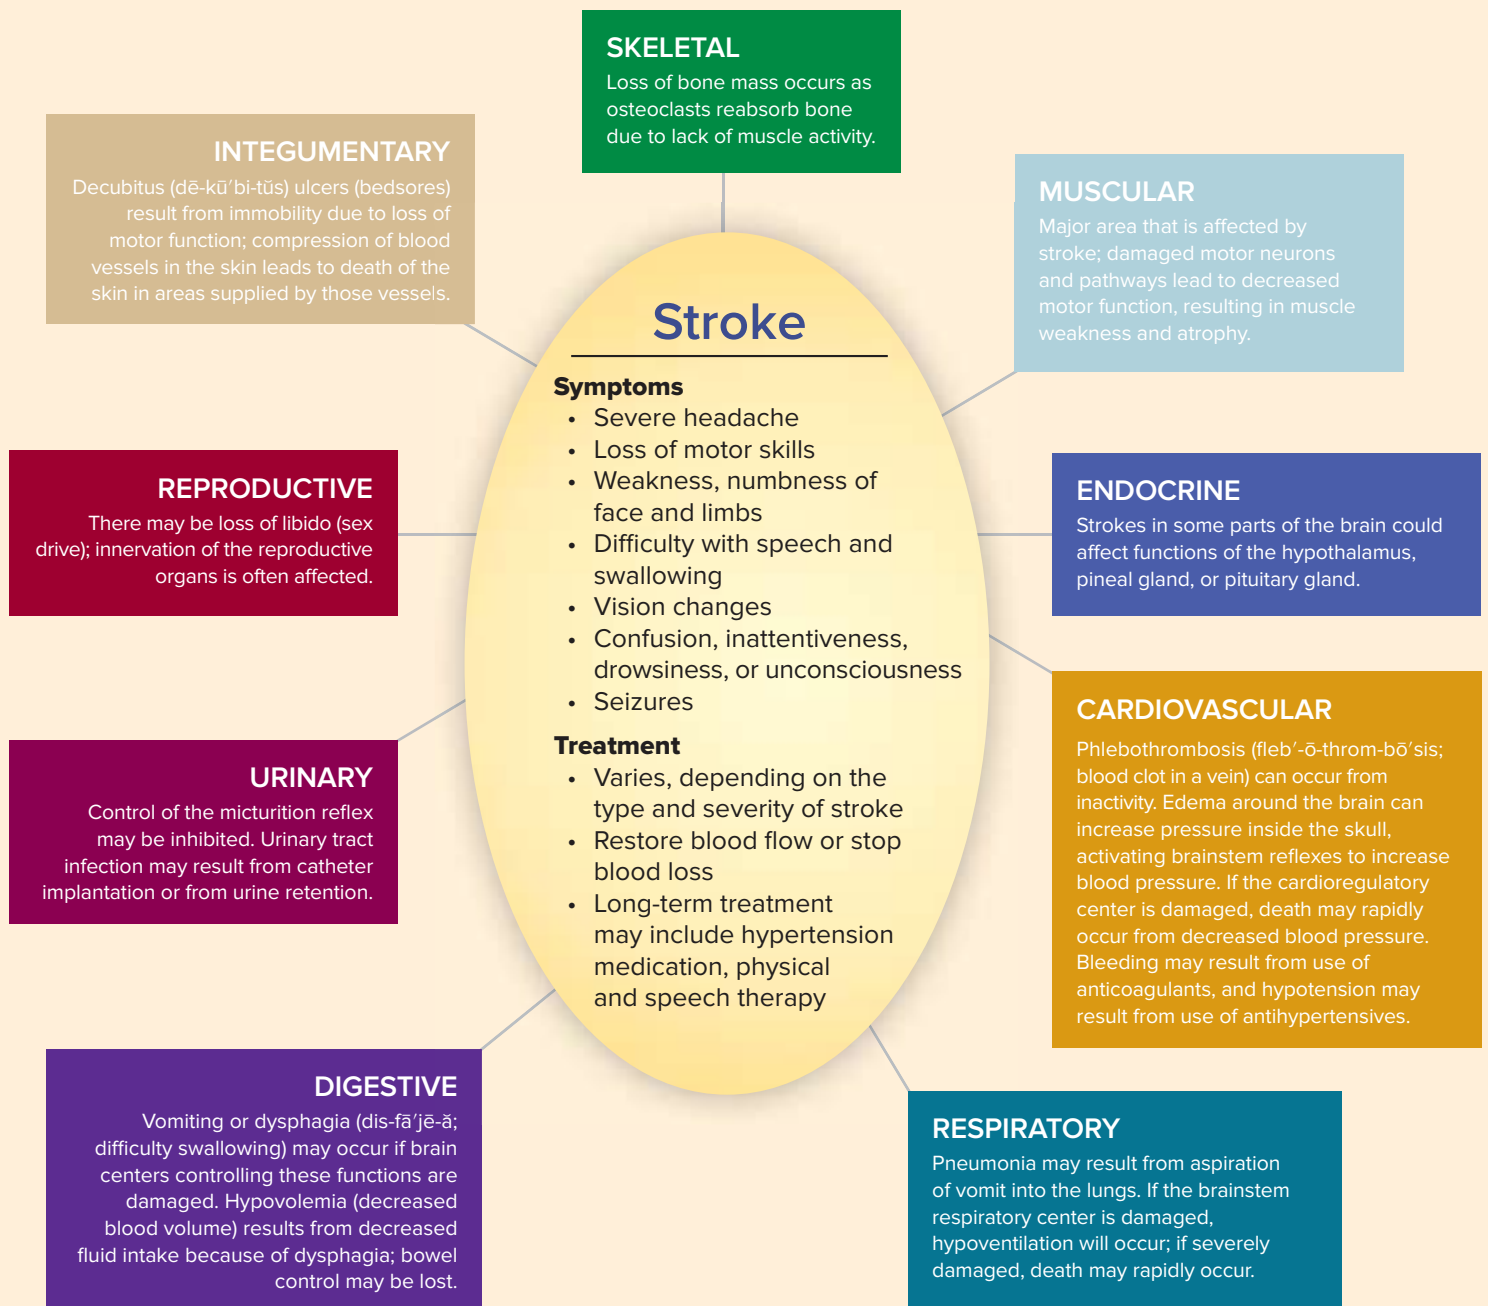

(b)

Posterior

Figure 14B Images of Stroke

(a) Computed tomography (CT) scan showing a left thalamic hemorrhage in the brain of a patient with a hemorrhagic stroke. The accumulated blood is seen as a *bright red* area in the image. (b) Colorized MRI showing disrupted blood flow to the left side (the viewer's right) of the brain (*yellow*). This disruption can cause a stroke.

General responses to neurological damage include drowsiness, disorientation, inattentiveness, loss of consciousness, and even seizures. Depression, due to either neurological damage or discouragement, is also common. Slight dilation of the pupils, short and shallow respiration, and increased pulse rate and blood pressure are all signs of Scott's anxiety about his current condition and his immediate future. Because he lost consciousness, Scott would not remember the last few minutes of what he was watching on television when he had his stroke. People in these circumstances are often worried about how they are going to deal with work tomorrow. They often

have no idea that the motor and sensory losses may be permanent or that a long stretch of therapy and rehabilitation lies ahead.

► Predict 11

Given that Scott exhibited weakness in his right limbs and loss of pain and temperature sensation in his right lower limb and left side of his face, which side of the brainstem was most severely affected by the stroke? Explain your answer.

Answer

Learn to Predict From page 465

The students touched a hot (55°C) object with one hand and a cold (5°C) object with the other hand. We learned in this chapter that thermoreceptors allow us to distinguish between hot and cold stimuli. In section 14.1 we read that cold receptors respond to temperatures between 12°C and 35°C, whereas warm receptors respond to temperatures between 25°C and 47°C. However, temperatures both below 12°C and above 47°C stimulate pain receptors. Therefore, the students would most likely not be able to distinguish between the cold and hot objects. They would just feel pain.

The second part of the question asked us to identify the part of the CNS involved in making this distinction. In chapter 12 we learned that sensory neurons carry information from receptors in

the skin to the spinal cord, which is then conveyed to the brain. This chapter explained more specifically that the sensation of pain and temperature are carried through the spinothalamic system to the thalamus, then to the primary sensory cortex. Chapter 13 taught us that the primary sensory cortex is located in the post-central gyrus of the cerebrum. Stimulation of neurons in specific areas of the primary sensory cortex allows a person to perceive a particular sensation and locate the site of stimulation. The ability to recognize the stimulus also involves association areas of the cerebrum near the primary sensory cortex.

Answers to the rest of this chapter's Predict questions are in appendix G.

Summary

14.1 Sensation (p. 466)

1. Sensation requires a stimulus, a sensory receptor, and conduction of an action potential to the CNS.
2. Perception is the conscious awareness of stimuli received by sensory receptors.
3. The senses include general senses (somatic and visceral) and special senses.
4. The somatic senses include touch, pressure, temperature, proprioception, and pain.
5. The visceral senses are primarily pain and pressure.
6. The special senses are smell, taste, sight, hearing, and balance.

Sensory Receptors

1. Receptors include mechanoreceptors, chemoreceptors, thermoreceptors, photoreceptors, and nociceptors.
2. Free nerve endings detect light touch, pain, itch, tickle, and temperature.
3. Merkel disks respond to light touch and superficial pressure.
4. Hair follicle receptors wrap around the hair follicle and are involved in the sensation of light touch when the hair is bent.
5. Pacinian corpuscles, located in the subcutaneous tissue, detect pressure. In joints, they serve a proprioceptive function.
6. Meissner corpuscles, located in the dermis, are responsible for two-point discriminative touch.
7. Ruffini end organs are involved in continuous touch or pressure.
8. Muscle spindles, located in skeletal muscle, are proprioceptors.
9. Golgi tendon organs, embedded in tendons, respond to changes in tension.
10. A stimulus produces a receptor potential in a sensory receptor. Primary receptors have axons that transmit action potentials toward the CNS. Secondary receptors have no axons but release neurotransmitters.
11. Adaptation is decreased sensitivity to a continued stimulus. Tonic receptors adapt slowly; phasic receptors adapt rapidly.

Sensory Pathways

1. Ascending pathways carry conscious and unconscious sensations. The two major ascending systems are the anterolateral and the dorsal-column/medial-lemniscal systems.
2. In the anterolateral system,
 - The spinothalamic tract carries pain, temperature, light touch, pressure, tickle, and itch sensations.
 - The spinothalamic tracts are formed by primary neurons that enter the spinal cord and synapse with secondary neurons. The secondary neurons conducting pain and temperature sensations cross the spinal cord and ascend to the thalamus, where they synapse with tertiary neurons that project to the somatic sensory cortex. Axons conducting other sensations, such as light touch or itch, may ascend several spinal cord levels before crossing.
 - The ascending neurons of the spinoreticular tract ascend both contralaterally and ipsilaterally, project to the reticular formation, and influence the level of consciousness.
 - The ascending neurons of the spinomesencephalic tract carry action potentials from cutaneous pain receptors. The spinomesencephalic tract also contributes to eye reflexes.
3. The dorsal-column/medial-lemniscal system carries the sensations of two-point discrimination, proprioception, pressure, and vibration. Primary neurons enter the spinal cord and ascend to the medulla, where they synapse with secondary neurons. Secondary neurons cross over and project to the thalamus. Tertiary neurons extend from there to the somatic sensory cortex.
4. The trigeminothalamic tract carries sensory information from the face, nose, and mouth.
5. In the spinocerebellar system and other tracts,
 - The spinocerebellar tracts carry unconscious proprioception to the cerebellum from the same side of the body.

- Neurons of the dorsal-column/medial-lemniscal system synapse with the neurons that carry proprioceptive information to the cerebellum.
6. Descending pathways can reduce conscious perception of sensations.

Sensory Areas of the Cerebral Cortex

1. Sensory pathways project to primary sensory areas in the cerebral cortex.
2. Sensory areas are organized spatially in the primary somatic sensory cortex in the postcentral gyrus.

Sensory Processing

Association areas of the cerebral cortex process sensory input from the primary sensory areas.

14.2 Control of Skeletal Muscles (p. 479)

1. Upper motor neurons are located in the cerebral cortex, cerebellum, and brainstem. Lower motor neurons are found in the cranial nuclei or the anterior horn of the spinal cord gray matter.
2. Upper motor neurons in the cerebral cortex and other brain areas project to lower motor neurons in the brainstem and spinal cord.

Motor Areas of the Cerebral Cortex

1. The primary motor cortex, premotor area, and prefrontal area are staging areas for motor function.
2. The motor cortex is organized spatially in the precentral gyrus.

Motor Pathways

1. The direct pathways maintain muscle tone and control fine, skilled movements in the face and distal limbs. The indirect pathways control conscious and unconscious muscle movements in the trunk and proximal limbs.
2. The corticospinal tracts control muscle movements below the head.
 - About 75–85% of the upper motor neurons of the corticospinal tracts cross over in the medulla to form the lateral corticospinal tracts in the spinal cord.
 - The remaining upper motor neurons pass through the medulla oblongata to form the anterior corticospinal tracts, which cross over in the spinal cord.
 - The upper motor neurons of both tracts synapse with interneurons, which then synapse with lower motor neurons in the spinal cord.
3. The corticobulbar tracts innervate the head muscles. Upper motor neurons synapse with interneurons in the reticular formation, which in turn synapse with lower motor neurons in the cranial nerve nuclei.
4. The indirect pathways include the rubrospinal, vestibulospinal, and reticulospinal tracts, as well as fibers from the basal nuclei.
5. The indirect pathways are involved in conscious and unconscious trunk and proximal limb muscle movements, posture, and balance.

Modifying and Refining Motor Activities

1. Basal nuclei are important in planning, organizing, and coordinating motor movements and posture.
2. The cerebellum has three parts.
 - The vestibulocerebellum controls balance and eye movement.
 - The spinocerebellum has a comparator function that corrects discrepancies between intended movements and actual movements.
 - The cerebrocerebellum can “learn” highly specific complex motor activities.

14.3 Brainstem Functions (p. 486)

The brainstem contains nuclei for cranial nerves III–X and XII and nuclei of the reticular formation.

Sensory Input Projecting Through the Brainstem

The brainstem receives sensory input from ascending spinal cord pathways and from the axons of cranial nerves.

RAS Functions of the Brainstem

Collateral branches of cranial nerves II, V, and VIII project to the reticular activating system (RAS) of the brainstem, where they stimulate wakefulness and consciousness.

Motor Output and Reflexes Projecting Through the Brainstem

1. Descending spinal pathways either pass directly through the brainstem or synapse with brainstem nuclei.
2. The brainstem controls several somatic motor and parasympathetic reflexes.

Vital Functions Controlled in the Brainstem

The brainstem controls many vital functions, including heart rate, blood pressure, and respiration.

14.4 Higher Brain Functions (p. 488)

Speech

1. The speech area is in the left cerebral cortex in most people.
2. The Wernicke area comprehends and formulates speech.
3. The Broca area receives input from the Wernicke area and sends impulses to the premotor and motor areas, which cause the muscle movements required for speech.

Communication Between the Right and Left Hemispheres

1. Each cerebral hemisphere controls and receives input from the opposite side of the body.
2. The right and left hemispheres are connected by commissures. The largest commissure is the corpus callosum, which allows the sharing of information between hemispheres.
3. In most people, the left hemisphere is dominant, controlling speech and analytical skills. The right hemisphere controls spatial and musical abilities.

Brain Waves and Sleep

1. Electroencephalograms (EEGs) record the electrical activity of the brain as alpha, beta, theta, and delta waves.
2. Some brain disorders can be detected with EEGs.
3. Sleep patterns are characterized by specific EEGs.

Memory

1. Three stages of memory exist: working, short-term, and long-term.
2. Short-term memory requires long-term potentiation.
3. Long-term memory is converted from short-term by consolidation.
4. The two types of memory are declarative and procedural.

Limbic System

1. The limbic system includes the olfactory cortex, deep cortical regions, and nuclei.
2. The limbic system is involved with emotions, motivation, mood, visceral functions, and memory. Olfactory stimulation is a major influence.

14.5 Effects of Aging on the Nervous System (p. 496)

1. A general decline in sensory and motor functions occurs as a person ages.
2. Short-term memory decreases in most older people.
3. Thinking ability does not decrease in most older people.

REVIEW AND COMPREHENSION

1. Nociceptors respond to
 - a. changes in temperature at the site of the receptor.
 - b. compression, bending, or stretching of cells.
 - c. painful mechanical, chemical, or thermal stimuli.
 - d. light striking a receptor cell.
2. Which of these types of sensory receptors respond to pain, itch, tickle, and temperature?
 - a. Merkel disks
 - b. Meissner corpuscles
 - c. Ruffini end organs
 - d. free nerve endings
 - e. Pacinian corpuscles
3. Which of these types of sensory receptors are involved with proprioception?
 - a. free nerve endings
 - b. Golgi tendon organs
 - c. muscle spindles
 - d. Pacinian corpuscles
 - e. All of these are correct.
4. The sensory receptors in the dermis and hypodermis responsible for sensing continuous touch or pressure are
 - a. Merkel disks.
 - b. Meissner corpuscles.
 - c. Ruffini end organs.
 - d. free nerve endings.
 - e. Pacinian corpuscles.
5. Decreased sensitivity to a continued stimulus is called
 - a. adaptation.
 - b. projection.
 - c. translation.
 - d. conduction.
 - e. phantom pain.
6. Secondary neurons in the spinothalamic tracts synapse with tertiary neurons in the
 - a. medulla oblongata.
 - b. gray matter of the spinal cord.
 - c. cerebellum.
 - d. thalamus.
 - e. midbrain.
7. If the spinothalamic tract on the right side of the spinal cord is severed,
 - a. pain sensations below the damaged area on the right side are eliminated.
 - b. pain sensations below the damaged area on the left side are eliminated.
 - c. temperature sensations are unaffected.
 - d. neither pain sensations nor temperature sensations are affected.
8. Fibers of the dorsal-column/medial-lemniscal system
 - a. carry the sensations of two-point discrimination, proprioception, pressure, and vibration.
 - b. cross to the opposite side in the medulla oblongata.
 - c. are divided into the fasciculus gracilis and the fasciculus cuneatus in the spinal cord.
 - d. include secondary neurons that exit the medulla and synapse in the thalamus.
 - e. All of these are correct.
9. Tertiary neurons in both the spinothalamic tract and the dorsal-column/medial-lemniscal system
 - a. project to the somatic sensory cortex.
 - b. cross to the opposite side in the medulla oblongata.
 - c. are found in the spinal cord.
 - d. connect to quaternary neurons in the thalamus.
 - e. are part of a descending pathway.
10. Unlike the anterolateral and dorsal-column/medial-lemniscal systems, the spinocerebellar tracts
 - a. are descending tracts.
 - b. transmit information from the same side of the body as the side of the CNS to which they project.
 - c. have four neurons in each pathway.
 - d. carry only pain sensations.
 - e. have primary neurons that synapse in the thalamus.
11. General sensory inputs (pain, pressure, temperature) to the cerebrum end in the
 - a. precentral gyrus.
 - b. postcentral gyrus.
 - c. central sulcus.
 - d. corpus callosum.
 - e. arachnoid mater.
12. Neurons from which area of the body occupy the greatest area of the somatic sensory cortex?
 - a. foot
 - b. leg
 - c. torso
 - d. arm
 - e. face
13. A cutaneous nerve to the hand is severed at the elbow. The distal end of the nerve at the elbow is then stimulated. The person reports
 - a. no sensation because the receptors are gone.
 - b. a sensation only in the region of the elbow.
 - c. a sensation “projected” to the hand.
 - d. a vague sensation on the side of the body containing the cut nerve.
14. Which of these areas of the cerebral cortex is involved in providing the motivation and foresight to plan and initiate movements?
 - a. primary motor cortex
 - b. primary somatic sensory cortex
 - c. prefrontal area
 - d. premotor area
 - e. basal nuclei
15. Which of these pathways is *not* an ascending (sensory) pathway?
 - a. spinothalamic tract
 - b. corticospinal tract
 - c. dorsal-column/medial-lemniscal system
 - d. trigeminothalamic tract
 - e. spinocerebellar tract
16. The _____ tracts innervate the head muscles.
 - a. corticospinal
 - b. rubrospinal
 - c. vestibulospinal
 - d. corticobulbar
 - e. dorsal-column/medial-lemniscal

17. Most fibers of the corticospinal tract
- decussate in the medulla oblongata.
 - synapse in the pons.
 - descend in the rubrospinal tract.
 - begin in the cerebellum.
18. A person with a spinal cord injury is suffering from paresis (partial paralysis) in the right lower limb. Which of these pathways is probably involved?
- left lateral corticospinal tract
 - right lateral corticospinal tract
 - left dorsal-column/medial-lemniscal system
 - right dorsal-column/medial-lemniscal system
19. Which of these pathways is *not* an indirect (extrapyramidal) pathway?
- reticulospinal tract
 - rubrospinal tract
 - corticobulbar tract
 - vestibulospinal tract
20. The indirect (extrapyramidal) system is concerned with
- posture.
 - proximal limb movements.
 - trunk movements.
 - All of these are correct.
21. The major effect of the basal nuclei is
- to act as a comparator for motor coordination.
 - to decrease muscle tone and inhibit unwanted muscular activity.
 - to affect emotions and emotional responses to odors.
 - to modulate pain sensations.
22. Which part of the cerebellum is correctly matched with its function?
- vestibulocerebellum—planning and learning rapid, complex movements
 - spinocerebellum—comparator function
 - cerebrocerebellum—balance
 - None of these are correct.
23. Given the following events:
- Action potentials from the cerebellum go to the motor cortex and spinal cord.
 - Action potentials from the motor cortex go to lower motor neurons and the cerebellum.
 - Action potentials from proprioceptors go to the cerebellum.
- Arrange the events in the order they occur in the cerebellar comparator function.
- 1,2,3
 - 1,3,2
 - 2,1,3
 - 2,3,1
 - 3,2,1
24. The brainstem
- consists of ascending and descending pathways.
 - contains cranial nerve nuclei III–X and XII.
 - has nuclei and connections that form the reticular activating system.
 - has many important reflexes, some of which are necessary for survival.
 - has all of these features.
25. Given these areas of the cerebral cortex:
- Broca area
 - primary motor cortex
 - premotor area
 - Wernicke area
- If a person hears and understands a word and then says the word out loud, in what order are the areas used?
- 1,4,2,3
 - 1,4,3,2
 - 3,1,4,2
 - 4,1,2,3
 - 4,1,3,2
26. The main connection between the right and left hemispheres of the cerebrum is the
- intermediate mass.
 - corpus callosum.
 - vermis.
 - unmyelinated nuclei.
 - thalamus.
27. Which of these activities is associated with the left cerebral hemisphere in most people?
- sensory input from the left side of the body
 - mathematics and speech
 - spatial perception
 - recognition of faces
 - musical ability
28. The limbic system is involved in the control of
- sleep and wakefulness.
 - posture.
 - higher intellectual processes.
 - emotion, mood, and sensations of pain or pleasure.
 - hearing.
29. Long-term memory involves
- a change in the cytoskeleton of neurons.
 - an increased number of dendritic spines.
 - cAMP signaling pathways that increase gene transcription.
 - specific protein synthesis.
 - All of these are correct.
30. Concerning long-term memory,
- declarative (explicit) memory involves the development of skills, such as riding a bicycle.
 - procedural (implicit, or reflexive) memory involves the retention of facts, such as names, dates, or places.
 - much of declarative (explicit) memory is lost through time.
 - declarative (explicit) memory is stored primarily in the cerebellum and premotor area of the cerebrum.
 - All of these are correct.

Answers in appendix E

CRITICAL THINKING

- Describe all the sensations and perceptions involved when a woman picks up an apple and bites into it. Explain which of these sensations are special and which are general. What types of receptors are involved?
- Some student nurses are at a party. Because they love anatomy and physiology so much, they are discussing adaptation of the special senses. They make the following observations:
 - When entering a room, people easily notice an odor, such as brewing coffee. A few minutes later, the odor might be barely detectable, if at all, no matter how hard they try to smell it.
 - When entering a room, people can detect the sound of a ticking clock. Later the sound is not noticed until people make a conscious effort to hear it. Then the ticking is easy to hear.
 Explain the basis for each of these observations.
- A patient suffered a loss of two-point discrimination and proprioception on the right side of the body. Voluntary movement of muscles was not affected, and pain and temperature sensations were normal. Is it possible to conclude that the right side of the spinal cord was damaged?

4. A patient has a lesion in the central core of the spinal cord. Physicians suspect that the fibers that decussate and are associated with the lateral spinothalamic tracts are affected in the area of the lesion. What observations are consistent with that diagnosis?
5. A person who was injured in a car accident exhibits the following symptoms: extreme paresis on the right side, including the arm and leg; reduction of pain sensation on the left side; and normal tactile sensation on both sides. Which tracts are damaged? Where in the spinal cord did the patient suffer tract damage?
6. A patient with a cerebral lesion exhibits loss of fine motor control of the left hand, arm, forearm, and shoulder. All other motor and sensory functions appear to be intact. Describe the location of the lesion as precisely as possible.
7. A patient suffers brain damage in an automobile accident. Physicians suspect that the cerebellum is the part of the brain affected. On the basis of what you know about cerebellar function, how can they confirm that the cerebellum is involved?
8. Woody Knothead was accidentally struck in the head with a baseball bat. He fell to the ground, unconscious. Later, when he regained consciousness, he could not remember any of the events that happened 10 minutes before the accident. Explain. What complications might develop at a later time?
9. Perry is a 93-year-old man who uses his computer to communicate with family and friends and to write poems and essays. One day last week, his daughter noticed that Perry was unable to use the computer keyboard normally with his right hand, and this ability deteriorated further over the next few hours. Perry was also experiencing muscle weakness on the right side, and soon he could not support himself with his right lower limb without using a cane; later in the day, he could hardly move his right lower limb at all. Concerned about a stroke, Perry's daughter took him to the emergency room, where radiographs and an MRI revealed a subdural hematoma. Explain how a subdural hematoma could be responsible for Perry's condition.

Answers in appendix F

15

The Special Senses

Historically, physiologists thought humans had just five senses: smell, taste, sight, hearing, and touch. Today they recognize many more. The original sense of “touch” has been categorized into multiple types of *general senses*, including pressure, touch, pain, and others. The general senses are described in chapter 14. Smell, taste, sight, hearing, and balance are now classified as *special senses*. This chapter describes the five special senses and the organs associated with each.

Learn to Predict

Freddy, a 67-year-old father and grandfather, was sitting on his couch with his hand over his left ear. His whole family was visiting and the noise level was pretty high in the living room. “What’s wrong?” asked his wife. “I never realized how loud our family is,” he laughed. For most of his life, Freddy suffered from complete hearing loss in his left ear. Recently, he underwent a surgery that replaced two auditory ossicles in his left ear and now his hearing has been restored. Freddy is hearing his family in a whole new way. **After reading about the process of hearing in this chapter, explain the reason for Freddy’s hearing loss, how this affected his ability to locate the direction of noises, and how his hearing was restored.**

Photo: Photograph of an isolated cochlea from the inner ear.

15.1 Olfaction

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe olfactory neurons and explain how airborne molecules can stimulate action potentials in olfactory nerves.**
- B. Locate the areas of the brain where olfaction is processed.**
- C. Explain the processes involved in olfactory adaptation.**

Olfaction (ol-fak'shŭn), the sense of smell, occurs in response to odors that stimulate sensory receptors in the extreme superior region of the nasal cavity, called the **olfactory region** (figure 15.1a). The olfactory region is lined with a specialized epithelium called the **olfactory epithelium**. (The rest of the nasal cavity is involved in respiration, and its major anatomical features are described in chapter 23.)

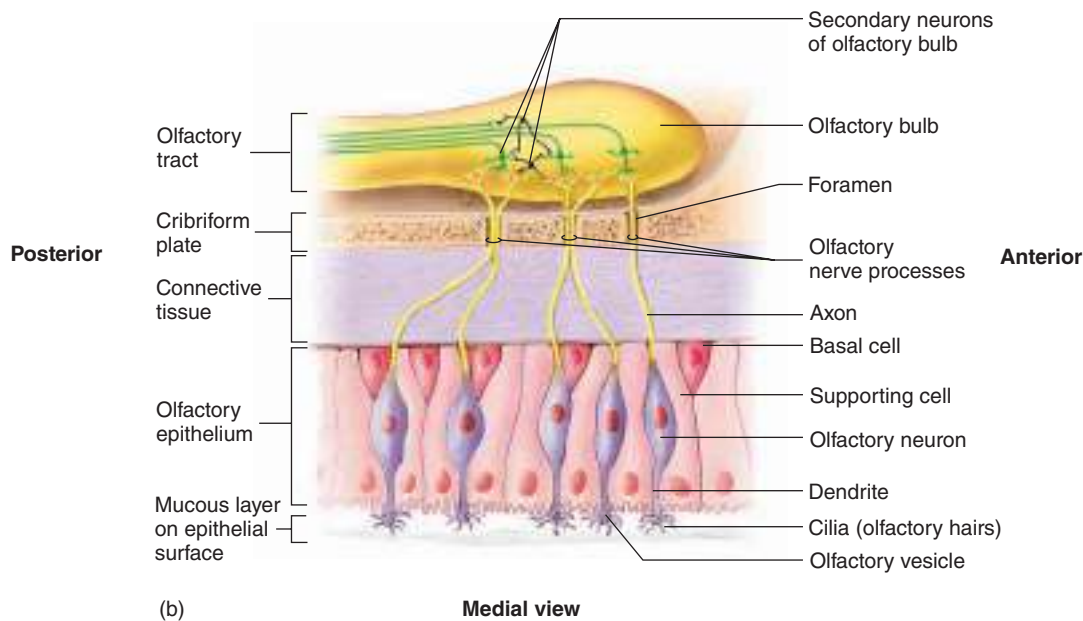

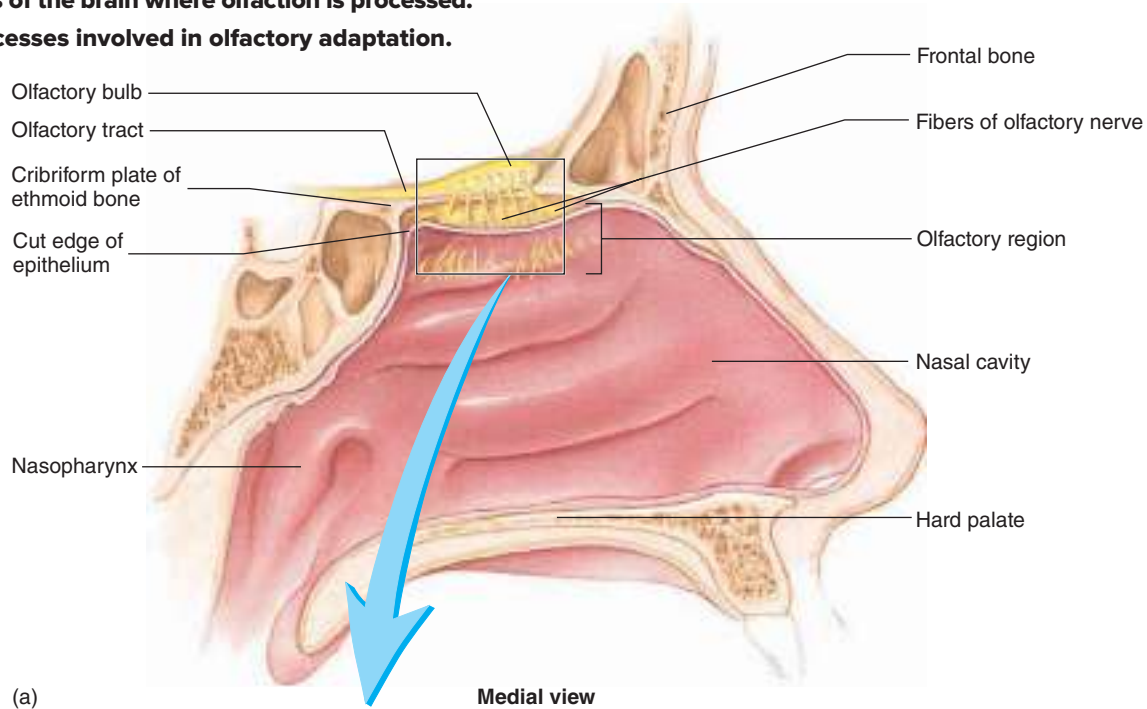

FIGURE 15.1 Olfactory Region, Epithelium, and Bulb

(a) The lateral wall of the nasal cavity (cut in sagittal section), showing the olfactory region and olfactory bulb. (b) Close-up of the olfactory epithelium, showing the olfactory nerve processes passing through the cribriform plate and the fine structure of the olfactory bulb. **APR**

Olfactory Epithelium and Bulb

The olfactory epithelium contains approximately 10 million **olfactory neurons** (figure 15.1*b*). Olfactory nerves, formed by the axons of these olfactory neurons, project through numerous small foramina in the bony cribriform plate (see chapter 7) to the **olfactory bulbs**. The **axons** of the olfactory neurons synapse with secondary neurons of the olfactory bulbs. From the bulbs, **olfactory tracts** project to the cerebral cortex.

The dendrites of olfactory neurons extend to the epithelial surface of the nasal cavity, and their ends are modified into bulbous enlargements called **olfactory vesicles** (figure 15.1*b*). These vesicles possess cilia called **olfactory hairs**, which lie in a thin mucous film on the epithelial surface.

Airborne molecules enter the nasal cavity and are dissolved in the fluid covering the olfactory epithelium. Some of these molecules, referred to as **odorants** (ō'dŏr-ants), bind to odorant receptor molecules (chemoreceptors) of the olfactory hair membranes (figure 15.2). A G protein, associated with each odorant receptor molecule, is activated by the binding of the odorant. The

α subunit of the activated G protein binds to and activates adenylylase cyclase, which in turn catalyzes the formation of cyclic AMP (cAMP) from ATP. cAMP in these cells causes Na^+ and Ca^{2+} channels to open. The influx of ions into the olfactory hairs results in depolarization and the production of action potentials in the olfactory neurons.

Odorant receptor molecules are composed of seven transmembrane polypeptide subunits produced by a large family of genes. Combinations of subunits from approximately 1000 different odorant receptor molecules can be produced. These receptor molecules can react to odorants of different sizes, shapes, and functional groups. These capabilities, together with multiple intracellular pathways involving G proteins, adenylylase cyclase, and ion channels, allow for a wide variety of detectable smells—about 4000 for the average person. Some researchers have grouped this wide range of smells into seven primary classes: (1) camphoraceous (e.g., mothballs), (2) musky, (3) floral, (4) pepperminty, (5) ethereal (e.g., fresh pears), (6) pungent, and (7) putrid. However, other studies point to the possibility of as many as 50 primary odors.

PROCESS FIGURE 15.2 Action of Odorant Binding to Membrane Receptor of Olfactory Hair

In most people, the threshold for detecting odors is extremely low, so very few odorant molecules are required to trigger a response. Apparently, there is rather low specificity in the olfactory epithelium, so that a given receptor may react to more than one type of odorant. However, if odorant receptor molecules become saturated with odorants, they no longer respond to odorant molecules. This adaptation makes a person less sensitive to an odorant after being exposed to it for a short time. For example, when you first enter a movie theater, the distinctive odor of popcorn is very noticeable, but it becomes almost unnoticeable after you have been in the theater for a short time.

The primary olfactory neurons have the most exposed nerve endings of any neurons, and they are constantly being replaced. The entire olfactory epithelium, including the olfactory neurons, degenerates and is lost from the surface about every 2 months. Lost olfactory cells are replaced by a proliferation of **basal cells** in the olfactory epithelium. Recall from chapter 4 that most neurons are permanent cells that have a very limited ability to replicate. So this replacement of olfactory neurons is unique among neurons.

Neuronal Pathways for Olfaction

Axons from the olfactory neurons form the olfactory nerves (cranial nerve I), which enter the olfactory bulbs (see figure 15.1*b*). Within the olfactory bulbs, the olfactory neurons synapse with secondary neurons, which relay olfactory information to the brain through the olfactory tracts. Olfactory bulb neurons also receive input from nerve cell processes entering the olfactory bulb from the brain, enhancing adaptation that occurs along this first part of the olfactory pathway.

Recent studies have found that the processing of olfactory stimuli is quite complex, involving multiple areas of the cerebrum. This dispersed organization differs from other sensory projections, which generally lead to specific regions of the brain. The consequence of the complex organization is that olfactory stimuli cause not only perception of specific odors but also emotional and autonomic responses. The majority of neurons in the olfactory tracts project to **central olfactory cortex areas** in the temporal and frontal lobes of the cerebrum (figure 15.3), where olfactory stimuli are processed to allow us to perceive odors. These central areas include the **piriform cortex** located at the junction between the temporal and frontal lobes, the **amygdala** of the temporal lobe, and the **orbitofrontal cortex**. In addition, olfactory tract neurons project to secondary olfactory areas, which appear to be involved with emotional and autonomic responses to olfactory stimuli. **Secondary olfactory areas** include the hypothalamus, hippocampus, and structures of the limbic system.

ASSESS YOUR PROGRESS

1. Where are olfactory neurons located? Explain their structure.
2. Describe the initiation of an action potential in an olfactory neuron. Name all of the structures and cells that the action potential encounters on its way to the olfactory cortex.
3. What is unique about olfactory neurons with respect to replacement?
4. Where are the central olfactory cortex areas located?

- 1 Processes of the olfactory nerves, formed by the axons of the olfactory neurons, project through the foramina in the cribriform plate to the olfactory bulb.
- 2 Axons of neurons in the olfactory bulb project through the olfactory tract to the olfactory areas of the cerebrum.
- 3 The central olfactory cortex areas, located in the temporal and frontal lobes, are involved in the complex processing of olfactory stimuli perception.

PROCESS FIGURE 15.3 Olfactory Cortex and Neuronal Pathways

15.2 Taste

LEARNING OUTCOMES

After reading this section, you should be able to

- List the types of papillae and outline the structure and function of a taste bud.
- List the five major tastants. Relate the relationship of taste to smell.
- Describe the formation of an action potential in a taste cell for each type of tastant.
- Trace the pathway of the action potential to the taste area of the cerebral cortex.

The sensory structures that detect **taste**, or *gustatory*, stimuli are the **taste buds**. You may think that those bumps on your tongue are your taste buds. That is a common misconception, but those bumps are actually **papillae** (pă-pil'ē). Most taste buds are located along the edges of those papillae. However, taste buds are also located on other areas of the tongue, the palate, and even the lips and throat, especially in children. The four major types of papillae are named according to their shape (figure 15.4): **filiform** (fil'i-form; filament-shaped), **vallate** (val'āt; surrounded by a wall), **foliate** (fō'lē-āt; leaf-shaped), and **fungiform** (fün'ji-fōrm; mushroom-shaped). Taste buds (figure 15.4c–e) are associated with vallate, foliate, and fungiform papillae. Filiform papillae are the most numerous papillae on the surface of the tongue but have no taste

FIGURE 15.4 Papillae

(a) Surface of the tongue. (b) Filiform papilla. (c) Vallate papilla. (d) Foliate papilla. (e) Fungiform papilla. (f) Scanning electron micrograph of the surface of the tongue. **APR**

buds. Rather, filiform papillae provide a rough surface on the tongue, allowing it to manipulate food more easily.

Vallate papillae are the largest but least numerous of the papillae. Eight to 12 of these papillae form a V-shaped row along the border between the anterior and posterior parts of the tongue (figure 15.4a). Foliate papillae are distributed in folds on the sides of the tongue and contain the most sensitive of the taste buds. They are most numerous in young children and decrease with age. In adults, they are located mostly posteriorly. Fungiform papillae are scattered irregularly over the entire superior surface of the tongue, appearing as small, red dots interspersed among the far more numerous filiform papillae.

Histology of Taste Buds

Taste buds are oval structures embedded in the epithelium of the tongue and mouth (figure 15.5). Each of the 10,000 taste buds found in the oral cavity consists of three major types of specialized epithelial cells. The sensory cells of each taste bud consist of about 50 **taste cells**, or *gustatory cells*. The remaining two cell types, which are nonsensory cells, are **basal cells** and **supporting cells**. Each taste cell has several microvilli, called **taste hairs**, or *gustatory hairs*, extending from its apex into a tiny opening in the epithelium called the **taste pore**, or *gustatory pore*. Like olfactory cells, the taste cells are replaced continuously, each having a normal life span of about 10 days.

Function of Taste

Substances called **tastants** (tās'tants), dissolved in saliva, enter the taste pores and, by various mechanisms, cause the taste cells to depolarize. These cells do not have classic axons but have short connections with secondary sensory neurons (see chapter 14).

Those connections have some characteristics of chemical synapses. Neurotransmitters (apparently, including ATP) are released from the taste cells and stimulate action potentials in the axons of sensory neurons associated with them.

Five major classes of tastants are recognized: salt, sour, sweet, bitter, and umami. The taste of **salt** results when Na^+ diffuses through Na^+ channels (figure 15.6a) of the taste hairs or other cell surfaces of taste cells, resulting in depolarization of the cells. The **sour** taste results when hydrogen ions (H^+) of acids cause depolarization of taste cells by one of three mechanisms (figure 15.6b): (1) They can enter the cell directly through H^+ channels, (2) they can bind to ligand-gated K^+ channels and block the exit of K^+ from the cell, or (3) they can open ligand-gated channels for other positive ions and allow them to diffuse into the cell. **Sweet** and **bitter** tastants bind to receptor molecules (figure 15.6c,d) on the taste hairs of taste cells and cause depolarization through a G protein mechanism. A taste called **umami** (ū-ma'mē; Japanese term loosely translated as savory) results when amino acids, such as glutamate, bind to receptors (figure 15.6e) on taste hairs of taste cells and cause depolarization through a G protein mechanism.

Other factors can influence the sense of taste. The texture of food in the oral cavity also affects the perception of taste. Hot or cold food may interfere with the taste buds' ability to function in tasting food. If a cold fluid is held in the mouth, the body warms the fluid and the taste becomes enhanced. On the other hand, adaptation is very rapid for taste. This adaptation apparently occurs both at the level of the taste bud and within the CNS. Adaptation may begin within 1 or 2 seconds after a taste sensation is perceived, and complete adaptation may occur within 5 minutes.

Although all taste buds are able to detect all five of the basic tastes, each taste cell is usually most sensitive to one. As with olfaction, however, the specificity of the receptor molecules is not perfect. For example, artificial sweeteners have different chemical structures than the sugars they are designed to replace, and some are many times more powerful than natural sugars in stimulating taste sensations. Presumably, our ability to perceive many different tastes is achieved through combinations of the five basic taste sensations.

Our perception of taste is strongly influenced by olfactory sensations. To demonstrate this phenomenon, pinch your nose while trying to taste something. With olfaction blocked, it is difficult to distinguish between the tastes of a piece of apple and a piece of potato. This is one reason that a person with a cold has a reduced sensation of taste.

Thresholds vary for the five primary tastes. Sensitivity for bitter substances is the highest; sensitivities for sweet and salty tastes are the lowest. Sugars, some other carbohydrates, and certain proteins produce sweet tastes; many proteins and amino acids produce umami tastes; acids produce sour tastes; metal ions tend to produce salty tastes; and alkaloids (bases) produce bitter tastes. Many alkaloids

FIGURE 15.5 Taste Buds

(a) Foliate papilla. (b) A taste bud. (c) A taste cell.

(a) **Salt:** Sodium ions diffuse through Na^+ channels, resulting in depolarization.

(b) **Sour (acid):** Hydrogen ions (H^+) from acids can cause depolarization by one of three mechanisms: (1) They can enter the cell directly through H^+ channels, (2) they can bind to gated K^+ channels, closing the gate and preventing K^+ from leaving the cell, or (3) they can open ligand-gated channels for other positive ions.

(c) **Sweet:** Sugars, such as glucose, or artificial sweeteners bind to receptors and cause the cell to depolarize by means of a G protein mechanism. The α subunit of the G protein activates adenylylate cyclase, which produces cAMP. cAMP activates a kinase that phosphorylates K^+ channels. The K^+ channels close, resulting in depolarization.

(d) **Bitter:** Bitter tastants, such as quinine, bind to receptors and cause depolarization of the cell through a G protein mechanism. The α subunit of the G protein activates phospholipase C, which converts phosphoinositol (PIP_2) to inositol triphosphate (IP_3). IP_3 causes Ca^{2+} release from intracellular stores and depolarization of the cell.

(e) **Glutamate (umami):** Amino acids, such as glutamate, bind to receptors and cause depolarization through a G protein mechanism. The α subunit of the G protein activates adenylylate cyclase, which catalyzes the conversion of ATP to cAMP. cAMP opens Ca^{2+} channels. The influx of Ca^{2+} causes depolarization of the cell.

FIGURE 15.6 Actions of the Major Tastants

are poisonous; thus, the high sensitivity for bitter tastes may be protective. On the other hand, humans tend to crave sweet, salty, and umami tastes, perhaps in response to the body's need for sugars, carbohydrates, proteins, and minerals.

Neuronal Pathways for Taste

Taste sensations are carried by three cranial nerves: the facial nerve (VII), glossopharyngeal nerve (IX), and vagus nerve (X). The **chorda tympani** (kōr'dā tim'pā-ne; so named because it crosses over the surface of the tympanic membrane of the middle ear), a branch of the facial nerve (VII), transmits taste sensations from the anterior two-thirds of the tongue, except from the vallate papillae. The glossopharyngeal nerve (IX) carries taste sensations from the posterior one-third of the tongue, the vallate papillae, and the superior pharynx. In addition to these two major nerves, the vagus nerve (X) carries a few fibers for taste sensation from the epiglottis.

These nerves extend from the taste buds to the tractus solitarius of the medulla oblongata (figure 15.7). Fibers from this nucleus decussate and extend to the thalamus. Neurons from the thalamus project to the taste area of the cerebrum, which is located

in the insula, deep within the lateral fissure between the temporal and parietal lobes.

Predict 2

Ernie has difficulty swallowing, loss of taste sensation in the posterior one-third of the right half of his tongue, and decreased salivation, especially on the right side. Describe the sensory portion of the affected neuropathway in Ernie.

ASSESS YOUR PROGRESS

5. Name and describe the four kinds of papillae on the tongue. Which ones are associated with taste buds?
6. Describe the structure of a taste bud.
7. What are the five primary tastes? Describe how each type of tastant causes depolarization of a taste cell.
8. Starting with the taste hair, name the structures and cells that an action potential would encounter on the way to the taste area of the cerebral cortex.
9. How is the sense of taste related to the sense of smell?

- 1 Axons of sensory neurons, which synapse with taste receptors, pass through cranial nerves VII, IX, and X and through the ganglion of each nerve (enlarged portion of each nerve).
- 2 The axons enter the brainstem and synapse in the nucleus of the tractus solitarius.
- 3 Axons from the nucleus of the tractus solitarius synapse in the thalamus.
- 4 Axons from the thalamus terminate in the taste area of the insula.

PROCESS FIGURE 15.7 Pathways for the Sense of Taste

The facial nerve (anterior two-thirds of the tongue), glossopharyngeal nerve (posterior one-third of the tongue), and vagus nerve (root of the tongue) all carry taste sensations. The trigeminal nerve carries tactile sensations from the anterior two-thirds of the tongue. The chorda tympani from the facial nerve (carrying taste input) joins the trigeminal nerve.

15.3 Visual System

LEARNING OUTCOMES

After reading this section, you should be able to

- List the accessory structures of the eye and explain their functions.
- Describe the chambers of the eye and the fluids they contain.
- Name the tunics of the eye, list the parts of each tunic, and describe the function of each part.
- Explain the differences between rods and cones.
- Describe the structure of the retina and explain how light stimulates action potentials in the optic nerves.
- Relate how images are focused on the retina.
- Describe the pathway an action potential will travel from the rods and cones to the visual cortex.
- Relate the arrangement of the visual field to binocular vision and depth perception.

The visual system includes the eyes, the accessory structures, and the optic nerves (II), tracts, and pathways. The **eye** includes the eyeball (the globe of the eye) and the lens. The eyes respond to light and initiate afferent action potentials, which are transmitted from the eyes to the brain by the optic nerves and tracts. We obtain much of our information about the world through the visual system. For example, education is largely based on visual input and depends on our ability to read words and numbers. Visual input includes information about light and dark, movement, and color. Visual stimuli can come from far greater distances than can stimuli for any other sense. The eye can detect light originating from stars billions of miles away.

Accessory Structures

Accessory structures protect, lubricate, move, and in other ways aid the function of the eye. These structures include the eyebrows, eyelids, eyelashes, conjunctiva, lacrimal apparatus, and extrinsic eye muscles (figure 15.8).

Eyebrows

The **eyebrows** are a collection of hairs superior to the orbits. A major function of the eyebrows is to prevent perspiration from

FIGURE 15.8 Accessory Structures of the Left Eye

running down the forehead and into the eyes and irritating them. Eyebrows also help shade the eyes from direct sunlight.

Eyelids

The **eyelids**, or *palpebrae* (pal-pē'brē), with their associated lashes, protect the eyes from foreign objects. The space between the two eyelids is called the **palpebral fissure**, and the angles where the eyelids join at the medial and lateral margins of the eye are called **canthi** (kan'thī; corners of the eye; figure 15.8). The medial canthus contains a small, reddish-pink mound called the **caruncle** (kar'ŭng-kl; mound of tissue), which houses some modified sebaceous and sweat glands.

The eyelids consist of five layers of tissue (figure 15.9). From the outer to the inner surface, they are (1) a thin layer of skin on the external surface; (2) a thin layer of areolar connective tissue; (3) a layer of skeletal muscle consisting of the orbicularis oculi and levator palpebrae superioris muscles; (4) a crescent-shaped layer of dense connective tissue called the **tarsal** (tar'sāl) **plate**, which helps maintain the shape of the eyelid; and (5) the palpebral conjunctiva (described in the next section), which lines the inner surface of the eyelid and the anterior surface of the eyeball.

If an object suddenly approaches the eye, the eyelids protect the eye by rapidly closing and then opening (blink reflex). Blinking, which normally occurs about 25 times per minute, also helps keep the eye lubricated by spreading tears over the surface. Movements of the eyelids are a function of skeletal muscles. The orbicularis oculi muscle closes the lids, and the levator palpebrae superioris elevates the upper lid (see figures 10.7 and 15.9). The eyelids also help regulate the amount of light entering the eye.

Eyelashes (see figures 15.8 and 15.9) are attached as a double or triple row of hairs to the free edges of the eyelids. **Ciliary glands** are modified sweat glands that open into the follicles of the eyelashes to keep them lubricated. A **sty** forms when one of these glands becomes inflamed. **Meibomian** (mī-bō'mē-an) **glands**, or *tarsal glands*, are sebaceous glands near the inner margins of the eyelids; they produce **sebum** (sē'bŭm), which lubricates the lids and restrains tears from flowing over the margin of the eyelids. A **chalazion** (ka-lā'zē-on), or *meibomian cyst*, is an infection or a blockage of a meibomian gland.

Conjunctiva

The **conjunctiva** (kon-jŭnk-tī'vā) is a thin, transparent mucous membrane associated with the eyelids and the exposed areas of the eye. The **palpebral conjunctiva** covers the inner surface of the eyelids, and the **bulbar conjunctiva** covers the anterior white surface of the eye (figure 15.9). The points at which the palpebral and bulbar conjunctivae meet are the superior and inferior **conjunctival fornices** (sing. fornix). The secretions of the conjunctiva help lubricate the surface of the eye. **Conjunctivitis** is an inflammation of the conjunctiva caused by an infection or other irritation. One type of conjunctivitis caused by a bacterium is **acute contagious conjunctivitis**, also called *pinkeye*.

Lacrimal Apparatus

The **lacrimal** (lak'ri-māl) **apparatus** (figure 15.10) consists of a lacrimal gland situated in the superolateral corner of the orbit

Sagittal section

FIGURE 15.9 Sagittal Section Through the Eye, Showing Its Accessory Structures **APR**

- 1 Tears are produced in the lacrimal gland and exit the gland through several lacrimal ducts.
- 2 The tears pass over the surface of the eye.
- 3 Tears enter the lacrimal canaliculi.
- 4 Tears are carried through the lacrimal sac to the nasolacrimal duct.
- 5 Tears enter the nasal cavity from the nasolacrimal duct.

PROCESS FIGURE 15.10 Lacrimal Apparatus

and a nasolacrimal duct beginning in the inferomedial corner of the orbit. The **lacrimal gland** is innervated by parasympathetic fibers from the facial nerve (VII). The gland produces tears, which leave the gland through several **lacrimal ducts** and pass over the anterior surface of the eyeball. The gland produces tears constantly at the rate of about 1 mL/day to moisten the surface of the eye, lubricate the eyelids, and wash away foreign objects. Tears are mostly water but also contain some salts, mucus, and lysozyme, an enzyme that kills certain bacteria. Most of the fluid produced by the lacrimal glands evaporates from the surface of the eye, but excess tears are collected in the medial corner of the eye by the **lacrimal canaliculi**. The opening of each lacrimal canaliculus is called a **punctum** (pŭngk'tŭm; pl. puncta). The upper and lower eyelids each have a punctum located near the medial canthus on a small lump called a **lacrimal papilla**. The lacrimal canaliculi open into a **lacrimal sac**, which drains into the **nasolacrimal duct** (figure 15.10). The nasolacrimal duct opens into the inferior meatus of the nasal cavity beneath the inferior nasal concha (see chapter 23).

Predict 3

Explain why it is often possible to “taste” medications, such as eyedrops, that have been placed into the eyes. Why does a person’s nose “run” when he or she cries?

Extrinsic Eye Muscles

Six **extrinsic muscles** of the eye (figures 15.11 and 15.12; see chapter 10) cause the eyeball to move within the orbit. Four of these muscles run more or less straight anteroposteriorly: the superior, inferior, medial, and lateral **rectus muscles**. Two other muscles, the superior and inferior **oblique muscles**, are positioned at an angle to the globe of the eye.

The specific actions of the eye muscles are listed in table 10.8. The movements of the eye can be described graphically by a figure resembling the letter *H*. The clinical test for normal eye movement is therefore called the **H test**. A person’s inability to move the eye toward one part of the *H* may indicate dysfunction of either an extrinsic eye muscle or the cranial nerve to the muscle.

The superior oblique muscle is innervated by the trochlear nerve (IV). The nerve is so named because the superior oblique muscle goes around a little pulley, or trochlea, in the superomedial corner of the orbit. The lateral rectus muscle is innervated by the abducens nerve (VI), so named because the lateral rectus muscle abducts the eye. The other four extrinsic eye muscles are innervated by the oculomotor nerve (III).

ASSESS YOUR PROGRESS

- Describe the structures and state the functions of the eyebrows, eyelids, and eyelashes.
- How do the conjunctiva, lacrimal apparatus, and extrinsic eye muscles aid in the function of the eye?

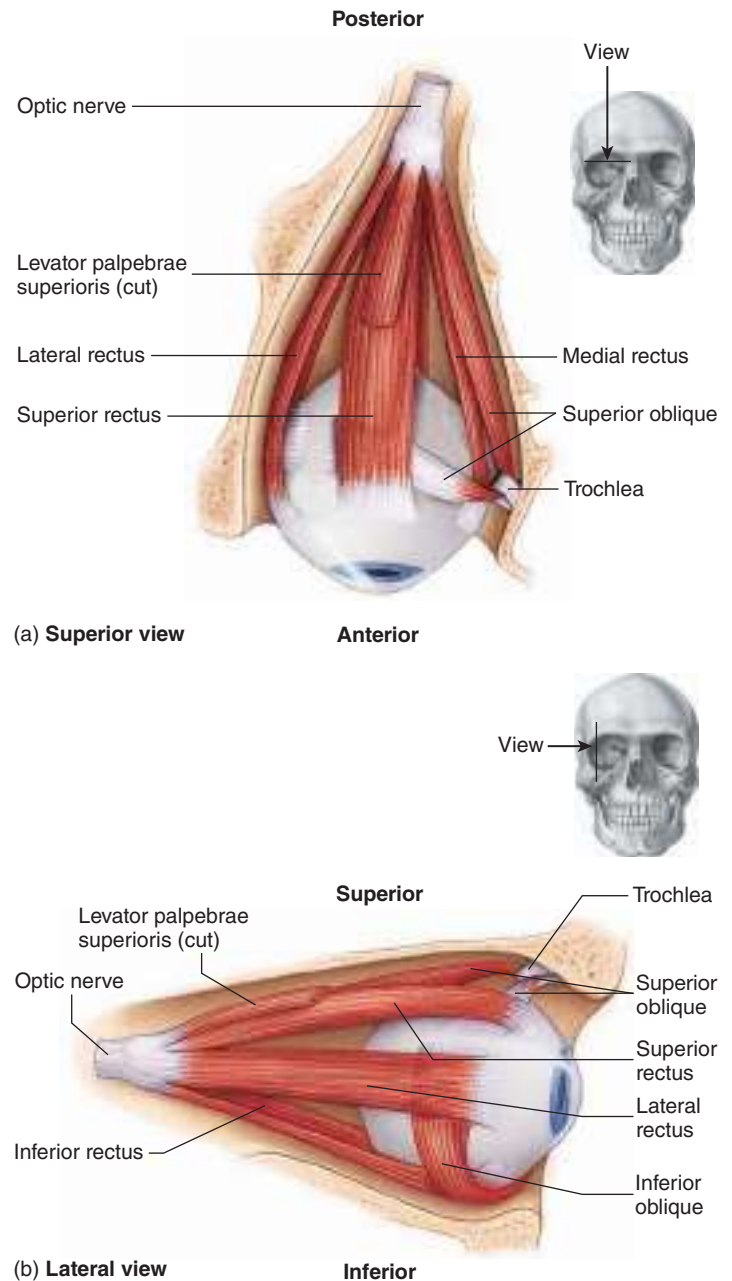

FIGURE 15.11 Extrinsic Muscles of the Eye

Anatomy of the Eye

The wall of the eyeball is composed of three layers, or **tunics** (figure 15.13). The outer layer is the **fibrous tunic** and it consists of the sclera and cornea. The middle layer is the **vascular tunic** and it consists of the choroid, ciliary body, and iris. The inner layer is the **nervous tunic** and it consists of the retina.

Fibrous Tunic

As stated previously, the fibrous tunic consists of the sclera and the cornea. The **sclera** (sklēr'ă) is the white, outer layer of the posterior five-sixths of the eyeball. It is a firm, opaque tissue layer that consists of dense collagenous connective tissue with elastic fibers. The sclera

FIGURE 15.12 Photograph of the Eye and Its Associated Structures

helps maintain the shape of the eyeball, protects its internal structures, and provides an attachment point for the muscles that move it. Usually, a small portion of the sclera can be seen as the “white of the eye” when the eye and its surrounding structures are intact (see figure 15.8). The bulbar conjunctiva is loosely attached to the sclera.

The sclera is continuous anteriorly with the cornea. The **cornea** (kōr'nē-ă) is an avascular, transparent structure that permits light to enter the eye. As light passes through the cornea, the light bends, or refracts. Refraction of light is an important part of focusing, so the cornea is also a part of the eye's focusing system. The cornea consists of a connective tissue matrix containing collagen, elastic fibers, and proteoglycans, with a layer of stratified squamous epithelium covering the outer surface and a layer of simple squamous epithelium on the inner surface. The outer epithelium is continuous with the bulbar conjunctiva over the sclera. Large collagen fibers are white, whereas smaller collagen fibers and proteoglycans are transparent. The cornea is transparent, rather than white, like the sclera, in part because fewer large collagen fibers and more proteoglycans are present in the cornea than in the sclera. The transparency of the cornea also results from its

FUNDAMENTAL Figure

FIGURE 15.13 Layers of the Eyeball, Sagittal Section

low water content. In the presence of water, proteoglycans trap water and expand, which scatters light. In the absence of water, the proteoglycans decrease in size and do not interfere with the passage of light through the matrix.

The central part of the cornea receives oxygen from the outside air. Contact lenses worn for long periods must therefore be permeable, so that air can reach the cornea. The most common eye injuries are cuts or tears of the cornea caused by a stick, a stone, or some other foreign object hitting the cornea. Extensive injury to the cornea may cause connective tissue deposition, thereby making the cornea opaque. The cornea was one of the first organs to be transplanted. Several characteristics make it relatively easy to transplant: It is easily accessible and relatively easily removed; it is avascular, so it does not require extensive circulation, as other tissues do; and it is less immunologically active and therefore less likely to be rejected than other tissues are.

Vascular Tunic

The middle tunic of the eyeball is called the vascular tunic because it contains most of the blood vessels of the eyeball (figure 15.13). The arteries of the vascular tunic are derived from a number of arteries called **short ciliary arteries**, which pierce the sclera in a circle around the optic nerve. These arteries are branches of the **ophthalmic** (of-thal'mik) **artery**, which is a branch of the internal carotid artery. The vascular tunic contains a large number of melanin-containing pigment cells and appears black in color. The portion of the vascular tunic associated with the sclera of the eye is the **choroid** (ko'royd). The term *choroid* means “membrane” and suggests that this layer is relatively thin (0.1–0.2 mm thick). Anteriorly, the vascular tunic consists of the ciliary body and the iris.

The **ciliary** (sil'ē-ar-ē) **body** is continuous with the choroid, and the **iris** is attached at its lateral margins to the ciliary body (figure 15.14a,b). The ciliary body consists of an outer **ciliary ring** and an inner group of **ciliary processes**, which are attached to the lens by **suspensory ligaments**. The ciliary body contains smooth muscles called the **ciliary muscles**, which are arranged with the outer muscle fibers oriented radially and the central fibers oriented circularly. The ciliary muscles function as a sphincter, and contraction of these muscles can change the shape of the lens. (This function is described in more detail later in this section.) The ciliary processes are a complex of capillaries and cuboidal epithelium that produces aqueous humor.

The iris is the “colored part” of the eye, and its color differs from person to person. A large amount of melanin in the iris causes it to appear brown or even black. Less melanin results in light brown, green, or gray irises. Even less melanin causes the eyes to appear blue. If there is no pigment in the iris, as occurs in albinism, the iris appears pink because blood vessels in the eye reflect light back to the iris. The genetics of eye color are quite complex. Many genes affect eye color, which explains the complexity of eye colors and inheritance patterns. Interestingly, although many newborn babies have blue eyes, their eye color changes over the first year of life. As melanin production increases during the first year, it accumulates in the iris, resulting in the more permanent eye color.

The iris is a contractile structure, consisting mainly of smooth muscle, surrounding an opening called the **pupil**. Light enters the

eye through the pupil. The iris regulates the amount of light entering the eye by controlling the size of the pupil. The smooth muscle of the iris is organized into two groups: a circular group called the **sphincter pupillae** (pū-pil'ē) and a radial group called the **dilator pupillae** (figure 15.14c,d). When the sphincter pupillae contract, the iris decreases, or constricts, the size of the pupil. The sphincter pupillae are innervated by parasympathetic fibers from the oculomotor nerve (III). When the dilator pupillae contract, the pupil is dilated. The dilator pupillae are innervated by sympathetic fibers. The ciliary muscles, sphincter pupillae, and dilator pupillae are sometimes referred to as the *intrinsic eye muscles*.

Retina

The **retina** is the nervous tunic of the eyeball (see figure 15.13). It consists of the outer **pigmented layer**, which is composed of pigmented simple cuboidal epithelium, and the inner **neural layer**, which responds to light. The neural layer contains numerous photoreceptor cells: 120 million **rods** and 6 or 7 million **cones**, as well as numerous relay neurons. The retina covers the inner surface of the eyeball posterior to the ciliary body. A more detailed description of the histology and function of the retina is presented later in this section.

When the posterior region of the retina is examined with an **ophthalmoscope** (of-thal'mō-skōp), several important features can be observed (figure 15.15a). The **macula** (mak'ū-lă) is a small, yellow spot, approximately 4 mm in diameter, near the center of the posterior retina. In the center of the macula is a small pit, the **fovea** (fō'vē-ă) **centralis**. The fovea centralis is the region of the retina where light is most focused when the eye is looking directly at an object. The fovea centralis contains only cone cells, and the cells are more tightly packed there than anywhere else in the retina. Because of the high number of photoreceptors in this area, the fovea centralis is the portion of the retina with the greatest visual acuity (the ability to see fine images). This is why

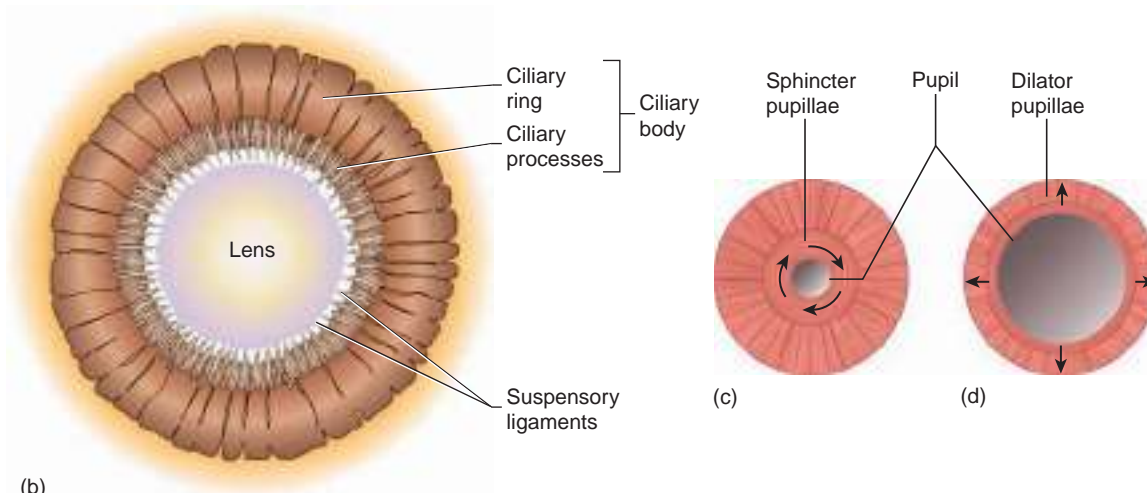

Clinical IMPACT

Ophthalmoscopic Examination of the Retina

Eye doctors use ophthalmoscopes to examine the retina during a routine eye exam. Often the pupils are dilated to increase the “window” in which to see the eye’s interior. Examination of the retina can reveal some general body disorders. **Hypertension**, or high blood pressure, results in “nicking” (compression) of the retinal veins where the abnormally pressurized arteries cross them. **Increased cerebrospinal fluid (CSF) pressure** associated with hydrocephalus may cause the optic disc to swell, a condition referred to as **papilledema** (pă-pil-e-dē'mă). Furthermore, **cataracts** (opacity of the lens; see the Diseases and Disorders table 15.2, “Vision,” later in this chapter) are usually discovered or confirmed by ophthalmoscopic examination.

objects are best seen when viewed directly in front of the eye. The **optic disc** is a white spot just medial to the macula through which the central retinal artery enters and the central retinal vein exits the eyeball. Branches from these vessels spread over the surface of the retina. This is also the spot where nerve processes from the neural layer of the retina meet, pass through the two outer tunics, and exit the eye as the optic nerve. The optic disc contains no photoreceptor cells and does not respond to light. Because of its lack of photoreceptors, the optic disc is called the **blind spot** of the eye (figure 15.15b).

Chambers of the Eye

The interior of the eye is divided into three chambers: the **anterior chamber**, the **posterior chamber**, and the **vitreal chamber** (*vit'rē-ŭs*) **chamber** (*postremal chamber*; see figure 15.13). The anterior chamber is the area between the cornea and the iris. The smaller posterior chamber lies between the iris and the lens (see figure 15.14a). The anterior and posterior chambers are filled with **aqueous humor**, which helps maintain intraocular pressure. The pressure within the eyeball keeps it inflated and is

FIGURE 15.15 Ophthalmoscopic View of the Left Retina

(a) The posterior wall of the retina as seen when looking through the pupil. The optic disc is the white area where the blood vessels and optic nerve associate with the retina. The macula with the fovea centralis (the part of the retina with the greatest visual acuity) is the darker spot at the center. (b) Demonstration of the blind spot. Close your right eye. largely responsible for maintaining the eyeball's shape. The aqueous humor also refracts light and provides nutrition for the structures of the anterior chamber, such as the avascular cornea. Aqueous humor is produced by the ciliary processes as a blood filtrate and is returned to the circulation through a venous ring at the base of the cornea called the **scleral venous sinus** (canal of Schlemm; see figure 15.14a). The production and removal of aqueous humor result in the "circulation" of aqueous humor and maintenance of a constant intraocular pressure. If circulation of the aqueous humor is inhibited, a defect called **glaucoma** (glaw-kō'mă), characterized by an abnormal increase in intraocular pressure, can result.

The vitreous chamber of the eye is much larger than the anterior and posterior chambers. It is almost completely surrounded by the retina and is filled with a transparent, jellylike substance called **vitreous humor**. Vitreous humor is not produced as rapidly as the aqueous humor is, and its turnover is extremely slow. Like the aqueous humor, the vitreous humor helps maintain intraocular pressure and therefore the shape of the eyeball, and it holds the lens and retina in place. It also functions in the refraction of light in the eye.

Lens

The **lens** is an unusual biological structure. It is transparent and biconvex, with the greatest convexity on its posterior side. The lens's anterior surface consists of a layer of cuboidal epithelial cells, and its posterior region contains very long, columnar epithelial cells called **lens fibers**. Cells from the anterior epithelium proliferate and give rise to the lens fibers at the equator of the lens. The lens fibers lose their nuclei and other cellular organelles and accumulate a set of proteins called **crystallines**. This crystalline lens is covered by a highly elastic, transparent **capsule**.

The lens is suspended between the posterior chamber and the vitreous chamber by the suspensory ligaments of the lens, which are connected from the ciliary body to the lens capsule.

ASSESS YOUR PROGRESS

12. Name the three tunics of the eye, describe the parts of the tunics, and explain their functions.
13. How does the pupil constrict? How does it dilate?
14. What is the blind spot? What are the fovea centralis and macula?
15. Name the three chambers of the eye and the substances that fill each chamber.
16. What is the function of the ciliary process and the scleral venous sinus?
17. Describe the structure of the lens, and explain how it is held in place.

Functions of the Eye

As light passes through the pupil of the iris, it is focused on the retina by the cornea, lens, and humors. The light striking the retina is converted into action potentials, which are relayed to the brain.

The electromagnetic spectrum comprises the entire range of wavelengths, or frequencies, of electromagnetic radiation, from very short gamma waves at one end of the spectrum to the longest radio waves at the other end (figure 15.16). **Visible light** is the portion of the electromagnetic spectrum that can be detected by the human eye and includes wavelengths between 380 and 750 nm. This range is sometimes called the **visible spectrum**. Within the visible spectrum, each color has a different wavelength.

An important characteristic of light rays is that they can bend. As light passes from air to a denser substance, such as glass or water, its speed slows. If the surface of that substance is at an angle other than 90 degrees to the direction the light rays are traveling, the rays bend, because the speed of light varies as it encounters the new medium. This bending of light is called **refraction**.

If the surface of a lens is concave, with the lens thinnest in the center, the light rays diverge as a result of refraction. If the surface is convex, with the lens thickest in the center, the light rays tend to converge. As light rays converge, they finally reach a point at which they cross. This point is called the **focal point (FP)**, and causing light to converge is called **focusing**. No image forms exactly at the focal point, but an inverted, focused image can form on a surface some distance past the focal point. How far past the focal point the focused image forms depends on a number of factors. A biconvex lens causes light to focus closer to the lens than

FIGURE 15.16 Electromagnetic Spectrum

The visible light spectrum is enlarged to show the wavelengths of the various colors.

does a lens with a single convex surface. Furthermore, the more nearly spherical the lens, the closer to the lens the light is focused; the more flattened the biconcave lens, the more distant is the point where the light is focused.

If light rays strike an object that is not transparent, they bounce off the surface. This phenomenon is called **reflection**. If the surface is very smooth, such as the surface of a mirror, the light rays bounce off in a specific direction. If the surface is rough, the light rays are reflected in several directions and produce a more diffuse reflection.

The focusing system of the eye projects a clear image on the retina. Light rays converge as they pass from the air through the convex cornea. Additional convergence occurs as light encounters the aqueous humor, lens, and vitreous humor. The greatest contrast in media density is between the air and the cornea; therefore, the greatest amount of convergence occurs at that point. However, the shape of the cornea and its distance from the retina are fixed, so that the cornea cannot make any adjustment in the location of the focal point. Fine adjustment in focal point location is accomplished by changing the shape of the lens. In general, focusing can be accomplished in two ways: (1) by keeping the shape of the lens constant and moving it nearer or farther from the point at which the image will be focused, as occurs in a camera, microscope, or telescope, or (2) by keeping the distance constant and changing the shape of the lens, which is the technique used in the eye.

As light rays enter the eye and are focused, the image formed just past the focal point is inverted. Action potentials that represent the inverted image are passed to the visual cortex of the cerebrum, where the brain interprets them as being right side up.

Because the visual image is inverted when it reaches the retina, the image of the world focused on the retina is upside down. However, the brain processes information from the retina so that the world is perceived the way “it really is.” If, as an experiment,

a person wears glasses that invert the image entering the eye, he or she sees the world upside down for a few days, after which the brain adjusts to the new input to set the world right side up again. If the glasses are then removed, another adjustment period is required before the brain makes the world “right” again.

When the ciliary muscles are relaxed, the suspensory ligaments of the ciliary body maintain elastic pressure on the lens, thereby keeping it relatively flat and allowing for distant vision (figure 15.17a). The condition in which the lens is flattened so that nearly parallel rays from a distant object are focused on the retina is referred to as **emmetropia** (em-ě-trō’pě-ă) and is the normal resting condition of the lens. The point at which the lens does not have to thicken for focusing to occur is called the **far point of vision** and is normally 20 feet or more from the eye.

When an object is brought closer than 20 feet to the eye, three events bring the image into focus on the retina: accommodation by the lens, constriction of the pupil, and convergence of the eyes.

1. **Accommodation.** The lens is a flexible structure that can change shape depending on the amount of tension in the suspensory ligaments of the ciliary body. The shape of the lens changes, depending on whether the eye is focusing on an object that is near or farther away. The process of changing the shape of the lens is referred to as **accommodation**. When the eye focuses on a nearby object, the ciliary muscles contract as a result of parasympathetic stimulation from the oculomotor nerve (III). This sphincterlike contraction pulls the choroid more anteriorly, toward the lens, reducing the tension on the suspensory ligaments. The decrease in tension allows the lens to assume a more spherical form because of its own elastic nature (figure 15.17b). The more spherical lens then has a more convex surface, causing greater refraction of light.

As light strikes a solid object, the rays are reflected in every direction from the object’s surface. However, only a small portion of the light rays reflected from a solid object pass through the pupil and enter the eye. An object far away from the eye appears small compared with a nearby object, because only nearly parallel light rays enter the eye from a distant object (figure 15.17a). When viewing an object closer to the eye, converging rays and parallel rays leaving the object can enter the eye (figure 15.17b), and the object appears larger.

When rays from a distant object reach the lens, they do not have to be refracted to any great extent to be focused on the retina, and the lens can remain fairly flat. When an object is closer to the eye, the more obliquely directed rays must be refracted to a greater extent to be focused on the retina. Accommodation occurs as the lens becomes more spherical, allowing for the refraction of light needed to focus the light rays on the retina (see figure 15.17b).

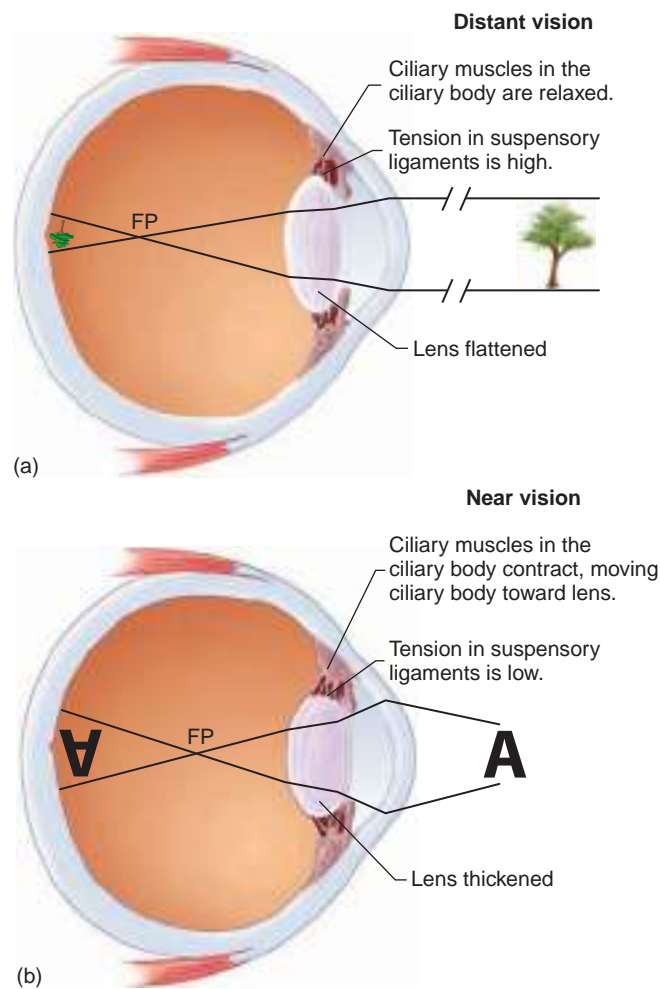

FIGURE 15.17 Focus and Accommodation

The focal point (FP) is where light rays cross. (a) Distant vision. Mainly parallel rays from the viewed object reach the eye. The lens is flattened, and the image is focused on the retina. (b) Accommodation for near vision. Oblique rays must be refracted more to allow for focus. The lens is more rounded, and the image is focused on the retina.

If you move this book closer and closer to your eyes, eventually you will not be able to see the words clearly. As an object is brought closer and closer to the eye, accommodation becomes more and more difficult, because the lens cannot become any more convex. At some point, the eye can no longer focus the object, and it is seen as a blur. The point at which this blurring occurs is called the **near point of vision**. It is usually 2–3 inches from the eye for a child, 4–6 inches for a young adult, 20 inches for a 45-year-old adult, and 60 inches for an 80-year-old adult. The increase in the near point of vision that develops with age is called **presbyopia**. It occurs because the lens becomes less flexible with increasing age, and it is the reason some older people say they could read with no problem if only they had longer arms.

2. **Pupil constriction.** Similarly to the previous description, as you move this book closer and closer to your eye, the words will remain in focus until you reach the near point of vision. That means that there is a range of distances from which

you can still see objects clearly. **Depth of focus** is the greatest distance through which an object (for example, a book that you are reading) can be moved and still remain in focus on the retina. The main factor affecting depth of focus is the size of the pupil. If the pupil diameter is small, the depth of focus is greater than if the pupil diameter is large. Therefore, with a smaller pupil opening, an object may be moved slightly nearer or farther from the eye without disturbing its focus. This is particularly important when viewing an object at close range, because the interest in detail is much greater, and thus the acceptable margin for error is smaller. When the pupil is constricted, the light entering the eye tends to pass more nearly through the center of the lens and is more accurately focused than light passing through the edges of the lens. Recall that the pupil diameter also regulates the amount of light entering the eye. The dimmer the light, the greater the pupil diameter must be. Therefore, as the pupil constricts during close vision, more light is required on the object being observed to see it clearly.

3. **Convergence.** Because the light rays entering the eyes from a distant object are nearly parallel, both pupils can pick up the light rays when the eyes are directed more or less straight ahead. As an object moves closer, however, the eyes must be rotated medially, so that the object is kept focused on corresponding areas of each retina. Otherwise, the object appears blurry. This medial rotation of the eyes, called **convergence**, is accomplished by a reflex that stimulates the medial rectus muscle of each eye. To observe convergence, have someone stand facing you. Ask the person to reach out one hand and extend an index finger as far in front of his or her face as possible. Then have the person keep the gaze fixed on the finger while slowly bringing the finger in toward his or her nose until finally touching it. Notice the movement of the person's pupils. What happens?

Predict 4

During a recent Alaskan cruise, Max and his grandfather were staring at a glacier some distance from their tour boat. Suddenly, Max's mother interrupted them to show them a piece of ice one of the deck hands had scooped from the water in the bay. Max was able to focus on the piece of ice and see its clear blue features, but his grandfather had to reach for his glasses. What changes occurred in their eyes between the time they were staring at the glacier and the time they were looking at the piece of ice? Explain why Max's grandfather reached for his glasses.

Structure and Function of the Retina

Leonardo da Vinci, speaking of the eye, said, “Who would believe that so small a space could contain the images of all the universe?” The retina of each eyeball, which gives us the potential to see the whole world, is about the size and thickness of a postage stamp.

As stated earlier in this section, the retina consists of a neural layer and a pigmented layer (figure 15.18). The neural layer, in turn, has several sublayers: three neuron layers (composed of photoreceptor cells, bipolar cells, and ganglionic cells, respectively) and two plexiform (networklike) layers, where the neurons of adjacent layers synapse with each other. The outer plexiform layer is between the photoreceptor and bipolar cell layers. The inner plexiform layer is between the bipolar and ganglionic cell layers (figure 15.18a).

The pigmented layer, or pigmented epithelium, of the retina consists of a single layer of cells filled with the pigment melanin. Together with the pigment in the choroid, the pigmented layer isolates individual photoreceptors and reduces light scattering by providing a black matrix that absorbs light and enhances visual acuity. However, this pigmentation is not strictly necessary for vision. People with albinism (lack of pigment) can see, although their visual acuity is reduced because of some light scattering.

The portion of the neural layer nearest the pigmented layer consists of photoreceptor cells called rods and cones (figure 15.18b). The rods and cones are sensitive to stimulation from visible light. The light-sensitive portion of each photoreceptor cell is adjacent to the pigmented layer.

Rods

Rods are bipolar photoreceptor cells that are involved in noncolor vision; they are responsible for vision under conditions of reduced light (table 15.1). The modified, dendritic, light-sensitive part of a rod

Clinical IMPACT

Eye Pigment

The eyeball is a closed chamber that allows light to enter only through the pupil. The light is absorbed by the pigmented inner lining of the eyeball; thus, looking into it is like looking into a dark room. The pupil appears black because of the pigment in the choroid and the pigmented portion of the retina. However, if a bright light is directed into the pupil, the reflected light is red because of the blood vessels on the surface of the retina. This is why the pupils of a person looking directly at a flash camera often appear red in a photograph.

People with albinism lack the pigment melanin, and the pupil always appears red because the eyeball’s inner lining lacks melanin to absorb light and prevent it from being reflected from the back of the eyeball. The diffusely lighted blood vessels in the interior of the eyeball contribute to the red color of the pupil.

TABLE 15.1 Rods and Cones

Photoreceptive End	Photoreceptive Molecule	Function	Location
Rod			
Cylindrical	Rhodopsin	Noncolor vision; vision under conditions of low light	Over most of retina; none in fovea centralis
Cone			
Conical	Iodopsin	Color vision; visual acuity	Numerous in fovea centralis and macula; sparse over rest of retina

cell is cylindrical, with no taper from base to apex (figure 15.19a). This rod-shaped photoreceptive part contains about 700 double-layered membranous discs. The discs contain **rhodopsin** (rō-dop'sin), a purple pigment that consists of the protein **opsin** covalently bound to a yellow photosensitive pigment called **retinal** (derived from vitamin A). Retinal alternates between two conformations (shapes): 11-*cis*- and all-*trans*-, depending on exposure to light. Opsin is a protein much like a channel protein, consisting of seven transmembrane helical regions. An extracellular plug closes the external opening of the opsin "channel." G proteins and cyclic GMP (cGMP) phosphodiesterase enzymes are also associated with the disc membranes. Sodium ion channels are located in the outer membrane of the rod cell outer segment (figure 15.19d).

Figure 15.20 depicts the changes that rhodopsin undergoes in response to light. In the resting (dark) state, 11-*cis*-retinal is tightly bound to the internal surface of opsin. The extracellular plug helps keep retinal from being lost from the cell out of the opsin "channel." Cyclic GMP is attached to the Na⁺ channel, keeping it open. As rod cells absorb light, retinal changes shape from 11-*cis*-retinal to all-*trans*-retinal. This change causes opsin to also change shape (dark to light state). The changes in opsin activate a G protein called **transducin** (trans-doo'sin), which activates a cyclic GMP phosphodiesterase. The cGMP phosphodiesterase catalyzes the conversion of cGMP to GMP. This reaction causes cGMP to diffuse away from Na⁺ channels, resulting in closure of the Na⁺ channels and hyperpolarization of the cell (figure 15.21).

FIGURE 15.19 Sensory Receptor Cells of the Retina

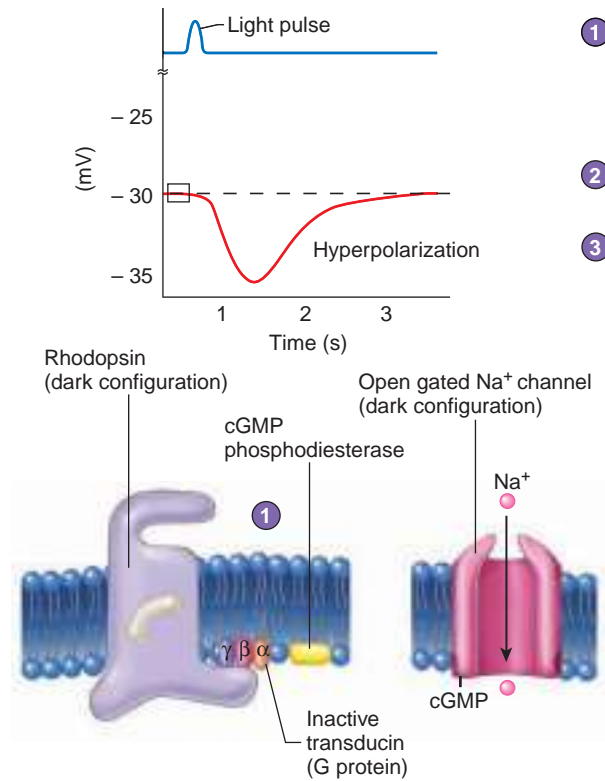

(a) Rod cell. (b) Cone cell. (c) Enlargement of the discs in the outer segment of a rod cell. (d) Enlargement of one of the discs, showing the relation of rhodopsin and a cGMP gated Na⁺ channel in the membrane.

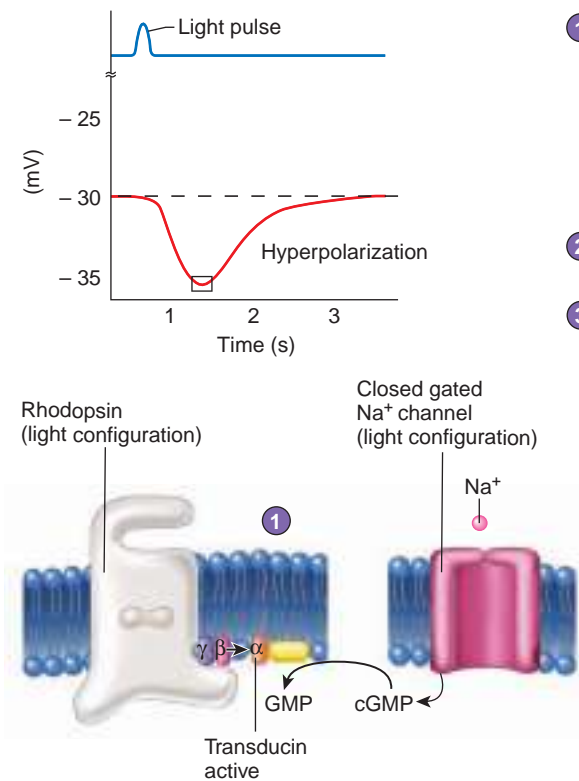

- 1 Retinal (in an inactive configuration called 11-*cis*-) is attached inside opsin to make rhodopsin. Cyclic GMP attached to a Na⁺ channel keeps it open.
- 2 Light causes retinal to change shape from 11-*cis*-retinal to all-*trans*-retinal. This change causes opsin also to change shape (from its dark to light configuration). This activated rhodopsin activates a G protein (called transducin), which activates a cGMP phosphodiesterase.
- 3 The cGMP phosphodiesterase catalyzes the conversion of cGMP to GMP, which decreases cGMP concentration and causes the cGMP to diffuse away from the Na⁺ channels, closing these channels.
- 4 All-*trans*-retinal detaches from opsin. Transducin is reassociated, and cGMP phosphodiesterase is inactivated.
- 5 Cyclic GMP concentration increases, and cGMP attaches to Na⁺ channels, causing them to open.
- 6 All-*trans*-retinal is converted to 11-*cis*-retinal, a process that requires energy.
- 7 11-*cis*-retinal attaches to opsin, which returns to its original (*dark*) configuration.

PROCESS FIGURE 15.20 Rhodopsin Cycle

FUNDAMENTAL Figure

- 1 Rod cell is unstimulated in dark conditions. Rhodopsin and the G protein, transducin, are both inactive, and gated Na⁺ channels with attached cGMP are open, allowing Na⁺ to enter the cell.
- 2 Glutamate is constantly released from the unstimulated rod cell.
- 3 Glutamate inhibits bipolar cells from releasing neurotransmitters that stimulate ganglionic cells.

- 1 Exposure to light stimulates the rod cell. Rhodopsin and the attached transducin are also activated. Transducin activates cGMP phosphodiesterase, which catalyzes the conversion of cGMP to GMP, closing Na⁺ channels. The rod cell is hyperpolarized when Na⁺ no longer enters the cell.
- 2 Glutamate release from rod cell decreases.
- 3 Bipolar cells release neurotransmitters that stimulate ganglionic cells to generate action potentials.

PROCESS FIGURE 15.21 Rod Cell Hyperpolarization

(a) In the dark, the rod cell is unstimulated. (b) In light, the rod cell becomes hyperpolarized.

This hyperpolarization in the photoreceptor cells is somewhat remarkable because most neurons respond to stimuli by depolarizing. When photoreceptor cells are not exposed to light and are in a resting, nonactivated state, gated Na^+ channels in their membranes are open, and Na^+ flows into the cell. This influx of Na^+ , referred to as the dark current, causes the photoreceptor cells to release the neurotransmitter glutamate from their presynaptic terminals (figure 15.21). Glutamate binds to receptors on the postsynaptic membranes of the bipolar cells of the retina, causing them to hyperpolarize. Thus, glutamate causes an inhibitory postsynaptic potential (IPSP) in the bipolar cells. The influx of Na^+ is offset by the efflux of K^+ through nongated K^+ channels. Equilibrium of Na^+ and K^+ in the cell is maintained by a sodium-potassium pump.

To summarize, when photoreceptor cells are exposed to light, the Na^+ channels close, less Na^+ enters the cell, and the amount of glutamate released from the presynaptic terminals decreases. As a result, the hyperpolarization in the bipolar cells decreases, and they depolarize sufficiently to release neurotransmitters, which stimulate ganglionic cells to generate action potentials. The number of Na^+ channels that close and the degree to which they close are proportional to the amount of light exposure.

At the final stage of this light-initiated reaction, retinal is completely released from the opsin. This free retinal may then be converted back to vitamin A, from which it was originally derived. The total vitamin A/retinal pool is in equilibrium, so that under normal conditions the amount of free retinal is relatively constant. To create more rhodopsin, the altered retinal must be converted back to its original shape, a reaction that requires energy. Once the retinal resumes its original shape, its recombination with opsin is spontaneous, and the newly formed rhodopsin can again respond to light.

The adjustment of the eyes to changes in light, as occurs when going from a darkened building into the sunlight or vice versa, is called **light and dark adaptation**. This adjustment is accomplished by changes in the amount of available rhodopsin. In bright light, excess rhodopsin is broken down, so that not as much is available to initiate action potentials, and the eyes become adapted to bright light. Conversely, in a dark room more rhodopsin is produced, making the retina more light-sensitive.

Light and dark adaptation also involves pupil reflexes. In dim light, the pupil enlarges to allow more light into the eye; in bright light, the pupil constricts to allow less light into the eye. In addition, during light conditions, rod function decreases and cone function increases, whereas the opposite happens during dark conditions. This occurs because rod cells are more sensitive to light than cone cells and because the rhodopsin in rods is depleted more rapidly than the visual pigment in cones.

Cones

Cones are bipolar photoreceptor cells with a conical, light-sensitive part that tapers slightly from base to apex (see figure 15.19*b*). The outer segments of the cone cells, like those of the rods, consist of double-layered discs. The discs are slightly more numerous and more closely stacked in the cones than in the rods.

Color vision and visual acuity are the functions of cone cells (table 15.1). Color is a function of the wavelength of light, and

each color results from a certain wavelength within the visible spectrum. Even though rods are very sensitive to light, they cannot detect color, and sensory input that ultimately reaches the brain from these cells is interpreted by the brain as shades of gray. Cones require relatively bright light to function. As a result, as the light decreases, so does the color of objects that can be seen until, under conditions of very low illumination, the objects appear gray. This occurs because, as the light decreases, fewer cone cells respond to the dim light.

Cone cells contain a visual pigment, **iodopsin** (τ - δ -dop'sin), which consists of retinal combined with a photopigment opsin protein. Three major types of color-sensitive opsin exist—blue, red, and green; each closely resembles the opsin proteins of rod cells but with somewhat different amino acid sequences. These color photopigments function in much the same manner as rhodopsin; however, whereas rhodopsin responds to the entire spectrum of visible light, each iodopsin is sensitive to a much narrower spectrum.

As can be seen in figure 15.22, considerable overlap occurs in the wavelength of light to which the blue, green, and red pigments are sensitive; however, each pigment absorbs light of a certain range of wavelengths. As light of a given wavelength, representing a certain color, strikes the retina, all cone cells containing photopigments capable of responding to that wavelength generate action potentials. Because of the overlap among the three types of cones, especially between the green and red pigments, different proportions of cone cells respond to each

FIGURE 15.22 Wavelengths to Which Blue, Green, and Red Pigments Are Sensitive

The red pigment exists in two chemical forms. One, found in 60% of the population, has the amino acid serine at position 180; the other, found in 40% of the population, has an alanine at position 180. Each red pigment has a slightly different wavelength sensitivity.

Diseases and Disorders

TABLE 15.2 Vision

Condition	Description
Infections	
Conjunctivitis (kon-jūnk-ti-vi'tis)	Inflammation of conjunctiva, usually from bacterial infection; one form, pinkeye, occurs primarily in children
Trachoma (tră-kō'mă)	Type of conjunctivitis caused by <i>Chlamydia</i> ; leading cause of infectious blindness in the world; transmitted by contact or flies
Neonatal gonorrheal ophthalmia	<i>Neisseria gonorrhoeae</i> infection in eyes of newborn infant whose mother has gonorrhea; can cause blindness if the infant is not treated with silver nitrate, tetracycline, or erythromycin drops soon after birth
Stye (stī)	Infection of eyelash hair follicle
Defects of Focus, Alignment, or Color Vision	
Myopia (mī-ō'pē-ă)	Nearsightedness—ability to see close but not distant objects; caused when refractive power of cornea and lens is too great relative to length of eye
Hyperopia (hī-per-ō'pē-ă)	Farsightedness—ability to see distant but not close objects; caused when cornea is too flat or lens has too little refractive power relative to length of eye
Presbyopia (prez-bē-ō'pē-ă)	Decrease in near vision, a normal part of aging
Astigmatism (ă-stig'mă-tizm)	Cornea or lens is not uniformly curved, so image is not sharply focused
Strabismus (stra-biz'mūs)	One or both eyes are misdirected; can result from weak eye muscles
Diplopia (di-plō'pē-ă)	Double vision
Color blindness	Complete or partial absence of perception of one or more colors (see figure 15B); most forms are more frequent in males
Blindness	
Cataract (kat'ă-rakt)	Clouding of lens as a result of advancing age, infection, or trauma; most common cause of blindness in the world
Macular degeneration	Loss of sharp central vision, peripheral vision maintained; leading cause of legal blindness in older Americans; most causes not known
Glaucoma (glaw-kō'mă)	Excessive pressure buildup in aqueous humor; may destroy retina or optic nerve, resulting in blindness
Diabetic retinopathy	Involves optic nerve degeneration, cataracts, retinal detachment; often caused by blood vessel degeneration and hemorrhage
Retinal detachment	Separation of sensory retina from pigmented retina; relatively common problem; may result in vision loss

wavelength, thus allowing color perception over a wide range. Color is interpreted in the visual cortex of the occipital lobe as combinations of sensory input originating from cone cells. For example, when orange light strikes the retina, 99% of the red-sensitive cones respond, 42% of the green-sensitive cones respond, and no blue cones respond. When yellow light strikes the retina, the response shifts, so that a greater number of green-sensitive cones respond. The variety of combinations created allows humans to distinguish among several million gradations of light and shades of color.

Not everyone sees the same red. Two forms of the red photopigment are common in humans. Approximately 60% of people have the amino acid serine in position 180 of the red opsin protein, whereas 40% have alanine in that position. That subtle difference in the protein results in slightly different absorption characteristics (figure 15.22). Even though we were each taught to recognize red when we see a certain color, apparently we do not all see that color in quite the same way.

Distribution of Rods and Cones in the Retina

Rods and cones are not evenly distributed across the retina. Cones are more numerous in areas of the retina associated with visual acuity. The macula and especially the fovea centralis function when visual acuity is required, such as for focusing on the words of this page. The fovea centralis has about 35,000 cones and no rods. The rest of the macula has more cones than rods. However, the 120 million rods are 10–20 times more plentiful than cones over most of the remaining retina. Rods are more highly concentrated away from the macula and are more important in low-light conditions.

► Predict 5

Explain why at night a person may notice a movement “out of the corner of the eye” but, when the person tries to focus on the area of movement, nothing seems to be there.

Clinical IMPACT

Visual Acuity

Visual acuity is the eye's ability to focus an image on the retina so that a clear image is perceived. Many factors affect visual acuity, including the shape of the eyeball and the flexibility of the lens. When a person's visual acuity is tested, a chart with rows of letters of decreasing size is placed 20 feet from the eye, and the person is asked to read the row of the smallest letters he or she can see clearly. The rows of letters are standardized for normal vision at 20 feet. If the person can clearly see the row of letters identified as 20 feet, his or her vision is considered 20/20, meaning the person can see at 20 feet what a person with normal vision can see at 20 feet. On the other hand, if the person can clearly see the row of letters identified as 40 feet, his or her vision is 20/40, meaning the person can see at 20 feet what a person with normal vision can see at 40 feet. In this case, a defect in visual acuity is diagnosed, and corrective lenses are usually prescribed. Some common visual acuity defects are myopia, hyperopia, presbyopia, and astigmatism.

Myopia

People who have **myopia** (mī-ō'pē-ă), or nearsightedness, can see close objects clearly, but distant objects appear blurry. Myopia is a defect of the eye in which the focusing system, the cornea and lens, is optically too powerful, or the eyeball is too long (axial myopia). As a result, the focal point is too near the lens, and the image is focused in front of the retina (figure 15Aa).

Myopia is corrected by a concave lens that counters the refractive power of the eye. Concave lenses cause the light rays coming to the eye to diverge and are therefore called "minus" lenses (figure 15Ab).

Another technique for correcting mild myopia is **radial keratotomy** (ker'ă-tot'ō-mē), which consists of making a series of four to eight radiating cuts in the cornea. The cuts are intended to weaken the dome of the cornea slightly, so that it becomes more flattened and eliminates the myopia. One problem with the technique is that it is difficult to predict how much flattening will occur. In one study of 400 patients 5 years after the surgery, 55% had normal vision, 28% were still somewhat myopic, and 17% had become hyperopic. Another problem is that some patients are bothered by glare following radial keratotomy, because the slits apparently do not heal evenly.

FIGURE 15A Visual Disorders and Their Correction

More recently, an alternative procedure, **lasix**, or *laser corneal sculpturing*, has become more common for correcting myopia. Lasix is a laser surgery procedure in which a thin portion of the cornea is etched away to make the cornea less convex. The advantage of this procedure is that the results can be predicted more accurately than can those of radial keratotomy.

Hyperopia

People who have **hyperopia** (hī-per-ō'pē-ă), or farsightedness, can see distant objects clearly, but close objects appear blurry. In hyperopia, the cornea and lens system is optically too weak or the eyeball is too short. The image is focused behind the retina (figure 15Ac).

Hyperopia can be corrected by convex lenses that cause light rays to converge as they approach the eye (figure 15Ad). Such lenses are called "plus" lenses.

Presbyopia

Presbyopia (prez-bē-ō'pē-ă) is the normal, presently unavoidable degeneration of the accommodation power of the eye associated with aging. It occurs because the lens becomes

sclerotic and less flexible. The eye is presbyopic when the near point of vision has increased beyond 9 inches. The average age for the onset of presbyopia is the mid-40s. Avid readers and people who engage in fine, close work may develop the symptoms earlier.

Presbyopia can be corrected by wearing "reading glasses" for close work and removing them to see at a distance. Because constantly removing and replacing glasses is annoying and because reading glasses hamper vision of only a few feet away, many people wear **bifocals**, which have different lenses in the top and the bottom, or **progressive lenses**, which have a graded lens.

Astigmatism

Astigmatism (ă-stig'mă-tizm) is a type of refractive error that affects the quality of focus. If the cornea or lens is not uniformly curved, the light rays do not focus at a single point, but fall as a blurred circle. Regular astigmatism can be corrected by glasses formed with the opposite curvature gradation. In irregular astigmatism, the abnormal form of the cornea fits no specific pattern and is very difficult to correct with glasses.

Clinical GENETICS

Color Blindness

Color blindness results from the dysfunction of one or more of the three photopigments (red, green, blue) involved in color vision. If one pigment is dysfunctional and the other two are functional, the condition is called **dichromatism**. An example of dichromatism is red-green color blindness (figure 15B).

Red-green color blindness is common in males, but not females. About 7% of males have some degree of color blindness, which is over eight times more common than in females. The basis for this male prevalence is that the genes for the red and green photopigments are arranged in tandem on the X chromosome (see chapter 29). Since males have only one X chromosome, they are more likely to be affected by an X-linked mutation than females, who have a higher probability of having a good gene on one of their two X chromosomes.

The vast majority, over 95%, of color blindness involves red-green color vision, not blue vision. The reason can be traced to the tandem arrangement of the red and green photopigment genes. Not only are the two genes next to each other, but they are also nearly identical; differences in only 3 of the 360 amino acids determine the red versus green wavelength absorption characteristics. Because the red and green genes are

so similar and adjacent to each other, it is relatively easy for mistakes to occur during development as DNA is replicated and exchanged between chromosomes (see chapter 29). Hence, an X chromosome may lack one or both genes, or it may have a hybrid gene containing exons

from both red and green genes, which may or may not alter their degree of functionality. The blue photopigment gene is rarely associated with color blindness, since it is not adjacent to another photopigment gene. It is also not X-linked, so it is equally rare in males and females.

FIGURE 15B Color Blindness Charts

(a) A person with normal color vision can see the number 74, whereas a person with red-green color blindness sees the number 21. (b) A person with normal color vision can see the number 5, whereas a person with red-green color blindness sees the number 2.

Reproduced from Ishihara's Tests for Colour Blindness published by Kanehara & Co., Ltd., Tokyo, Japan, but tests for color blindness cannot be conducted with this material. For accurate testing, the original plates should be used.

Inner Layers of the Retina

The middle and inner cell layers of the neural layer of the retina consist of two major neuron types: bipolar cells and ganglion cells (see figure 15.18a). The rod and cone photoreceptor cells synapse with **bipolar cells**, which in turn synapse with **ganglion cells**. Except in the area of the fovea centralis, axons from the ganglion cells pass over the inner surface of the retina, converge at the **optic disc**, and exit the eye as the **optic nerve (II)**. The fovea centralis is devoid of ganglion cell processes, resulting in a small depression in this area—thus the name *fovea*, meaning “small pit.” Due to the absence of ganglion cell processes as well as the concentration of cone cells mentioned previously, visual acuity is further enhanced in the fovea centralis because light rays do not have to pass through as many tissue layers before reaching the photoreceptor cells.

Rod and cone cells differ in the way they interact with bipolar and ganglion cells. One bipolar cell receives input from numerous rods, and one ganglion cell receives input from several bipolar cells, so that spatial summation occurs and the signal is enhanced. This system allows awareness of stimuli from very dim light sources but decreases visual acuity in these cells.

Cones, on the other hand, exhibit little or no convergence on bipolar cells, so that one cone cell may synapse with only one bipolar cell. This system reduces light sensitivity but enhances visual acuity.

The area from which a ganglion cell receives input, called the **receptive field**, is roughly circular, with a smaller portion in the center, called the receptive field center, and a larger surrounding area. The receptive fields in the fovea centralis are very small, compared with the receptive fields of more peripheral parts of the retina. The small size of these receptive fields is consistent with the visual acuity of the fovea centralis.

Two types of receptive fields exist: on-center ganglion cells and off-center ganglion cells. On-center ganglion cells generate more action potentials when light is directed onto the receptive field center. Off-center ganglion cells generate more action potentials when light is turned off in the receptive field center or when light shines on the surrounding area. These receptive fields respond primarily to contrasts in light (edges) rather than to the absolute intensity of light.

Within the inner layers of the retina, interneurons modify the signals from the photoreceptor cells before the signal ever

leaves the retina (see figure 15.18). **Horizontal cells** form the outer plexiform layer and synapse with photoreceptor cells and bipolar cells. **Amacrine** (am'ă-krin) **cells** form the inner plexiform layer and synapse with bipolar and ganglion cells. **Interplexiform cells** form the bipolar layer and synapse with amacrine, bipolar, and horizontal cells to form a feedback loop. The interneurons are either excitatory or inhibitory on the cells with which they synapse. These interneurons enhance borders and contours, thereby increasing the intensity at boundaries, such as the edge of a dark object against a light background.

ASSESS YOUR PROGRESS

22. What function do the pigmented layer of the retina and the pigment of the choroid perform?
23. Describe the changes that occur in a rod cell after light strikes rhodopsin. How does rhodopsin re-form? Why is the response of a rod cell to a stimulus unusual?
24. How does dark and light adaptation occur?
25. What are the three types of cone cells? How do they produce the color we see?
26. Describe the arrangement of rods and cones in the fovea centralis, the macula, and the peripheral parts of the retina.
27. Starting with a rod or cone cell, name the cells or structures that an action potential encounters while traveling to the optic nerve.

Neuronal Pathways for Vision

Figure 15.23 shows the neuronal pathways that transmit action potentials generated by light from the time light enters the eye until it reaches the area of the cerebrum where vision is perceived. The optic nerve leaves the eye and exits the orbit through the optic foramen to enter the cranial cavity. Just inside the cranial cavity and just anterior to the pituitary gland, the optic nerves are connected to each other at the **optic chiasm** (kī'azm) (figure 15.23a, step 3). Ganglion cell axons from the nasal retina (the medial portion of the retina) cross through the optic chiasm and project to the opposite side of the brain. Ganglion cell axons from the temporal retina (the lateral portion of the retina) pass through the optic nerves and project to the brain on the same side of the body without crossing (figure 15.23a, step 4).

Beyond the optic chiasm, the route of the ganglionic axons is called the **optic tract** (figure 15.23a,b,d). Most of the optic tract axons terminate in the **lateral geniculate nucleus** of the thalamus. However, some axons do not terminate in the thalamus but separate from the optic tract to terminate in the **superior colliculi**, the center for visual reflexes (figure 15.23a, step 6; see chapter 13). Neurons of the lateral geniculate nucleus of the thalamus form the fibers of the **optic radiations**, which project to the **visual cortex** in the **occipital lobe** (figure 15.23a, step 7). Neurons of the visual cortex integrate the messages coming from the retina into a single message, translate that message into a mental image, and then transfer the image to other parts of the brain, where it is evaluated and either acted on or ignored.

The projections of ganglion cells from the retina of each eye can be related to the **visual field** for each eye (figure 15.23c). You can observe the visual field by closing one eye. Everything that you can see with the one open eye is the visual field of that eye. The visual field of each eye can be divided into temporal (lateral) and nasal (medial) parts. The temporal part of the visual field projects onto the nasal retina, whereas the nasal part projects to the temporal retina. The projections and nerve pathways are arranged such that images entering the eye from the right part of each visual field project to the left side of the brain. Conversely, the left part of each visual field projects to the right side of the brain (figure 15.23b).

Predict 6

In figure 15C, the lines at A and B depict two lesions on the visual pathways. The effect of a lesion at A in the optic radiations on the visual fields is depicted (with the right and left fields separated) in the ovals at the bottom of the figure. The black areas indicate what parts of the visual fields are defective. Describe the effect that the lesion at B has on the visual fields (see figure 15.23 for help).

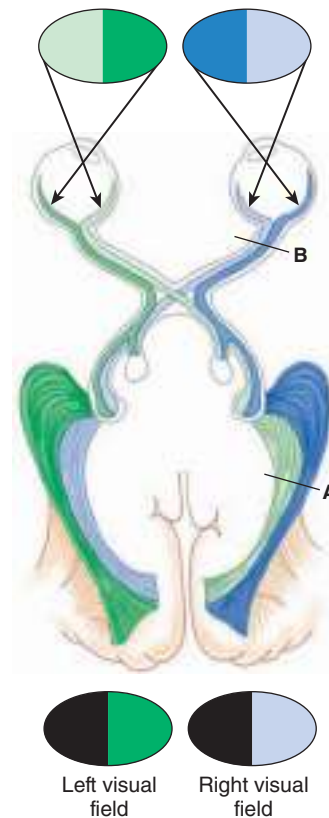

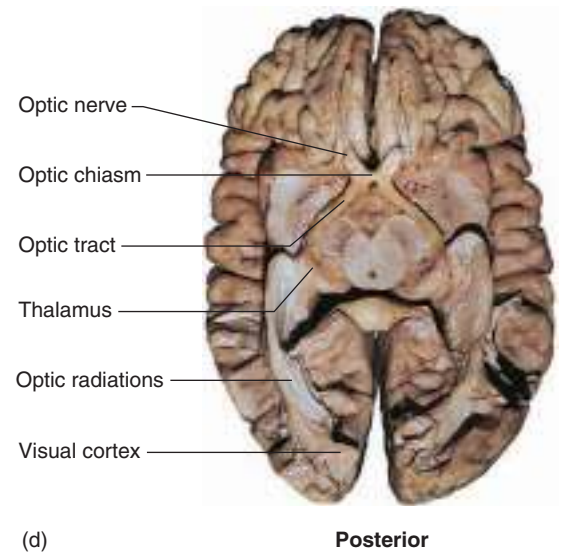

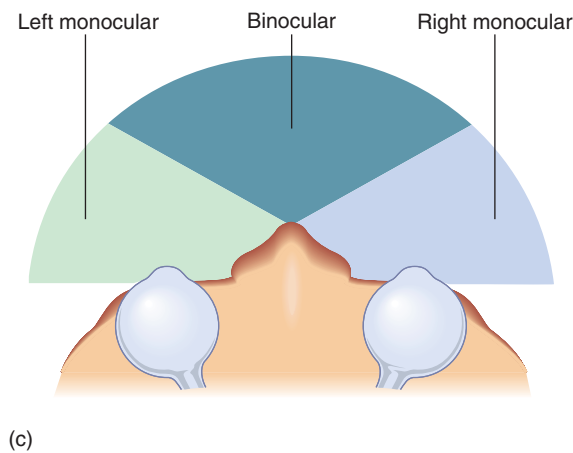

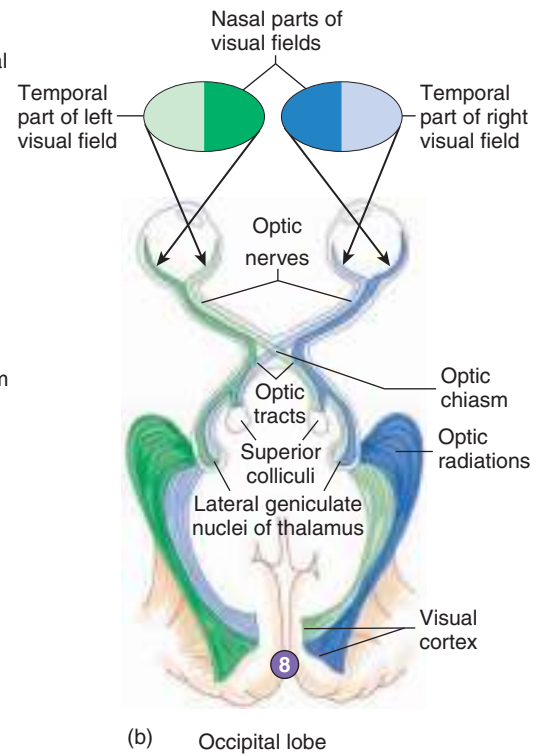

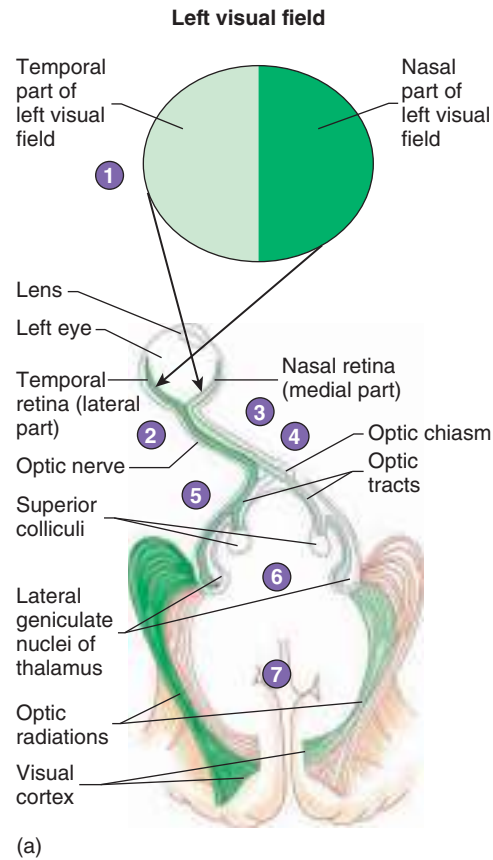

FIGURE 15C Effects of Lesions on Visual Pathways

Because the optic chiasm lies just anterior to the pituitary gland, a pituitary tumor can put pressure on the optic chiasm and cause visual defects. Because the nerve fibers crossing in the optic chiasm are carrying information from the temporal halves of the visual fields, a person with optic chiasm damage

- 1 Each visual field is divided into a temporal and a nasal half.
- 2 After passing through the lens, light from each half of a visual field projects to the opposite side of the retina.
- 3 An optic nerve consists of axons extending from the retina to the optic chiasm.
- 4 In the optic chiasm, axons from the nasal part of the retina cross and project to the opposite side of the brain. Axons from the temporal part of the retina do not cross.
- 5 An optic tract consists of axons that have passed through the optic chiasm (with or without crossing) to the thalamus.
- 6 The axons synapse in the lateral geniculate nuclei of the thalamus. Collateral branches of the axons in the optic tracts synapse in the superior colliculi.
- 7 An optic radiation consists of axons from thalamic neurons that project to the visual cortex.
- 8 The right part of each visual field (*dark green and light blue*) projects to the left side of the brain, and the left part of each visual field (*light green and dark blue*) projects to the right side of the brain.

PROCESS FIGURE 15.23 Visual Pathways

(a) Pathways for the left eye (superior view). (b) Pathways for both eyes (superior view). (c) Overlap of the fields of vision (superior view). (d) Inferior view of the brain, showing the visual nerves, tracts, and pathways. **APR**

cannot see objects in the temporal halves of the visual fields. This condition, called **tunnel vision**, is often an early sign of a pituitary tumor.

The visual fields of the eyes partially overlap (figure 15.23c). The region of overlap—the area seen with both eyes at the same time—is the area of **binocular vision**. Because humans see the

same object with both eyes, the image of the object reaches the retina of one eye at a slightly different angle from that of the other. With experience, the brain can interpret these differences in angle, so that distance can be judged quite accurately. Thus, binocular vision gives us **depth perception**, which is the ability to distinguish between near and far objects and to judge their distance.

ASSESS YOUR PROGRESS

28. What is a visual field?
29. Starting with the optic nerve, trace the action potential going from the right temporal visual field to the visual cortex.
30. Explain how binocular vision allows for depth perception.

15.4 Hearing and Balance

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the structures of the external ear and middle ear and state the function of each.**
- B. Explain the tunnels and chambers of the inner ear and the fluids they contain.**
- C. Describe the anatomy of the cochlea and, in particular, the cochlear duct.**

- D. Discuss the characteristics of sound.**
- E. Explain the process by which an action potential is generated by the hair cells of the spiral organ.**
- F. Trace a sound wave through the external, middle, and inner ears to the spiral organ.**
- G. Describe the pathway of an action potential from the hair cells of the spiral organ to the auditory cortex.**
- H. Explain how the structures of the vestibule and semicircular canals function in static and dynamic equilibrium.**
- I. Describe the pathway of an action potential from the balance organs to the various parts of the central nervous system and eyes.**

The organs of hearing and balance are divided into three parts: the external, middle, and inner ears (figure 15.24). The external and middle ears are involved in hearing only, whereas the inner ear functions in both hearing and balance.

FUNDAMENTAL Figure

FIGURE 15.24 External, Middle, and Inner Ears **AP R**

The **external ear** includes the **auricle** (aw'ri-kl; ear) and the **external auditory canal**. The external ear terminates medially at the **tympanic** (tim-pan'ik) **membrane**, or *eardrum*. The **middle ear** is an air-filled space within the petrous portion of the temporal bone that contains the **auditory ossicles**. The **inner ear** houses the sensory organs for both hearing and balance. It consists of interconnecting, fluid-filled tunnels and chambers within the petrous portion of the temporal bone.

Auditory Structures and Their Functions

External Ear

The auricle, or *pinna* (pin'ă), is the fleshy part of the external ear on the outside of the head; it consists primarily of elastic cartilage covered with skin (figure 15.25). Its shape helps collect sound waves and direct them toward the external auditory canal. The external auditory canal is lined with hairs and **ceruminous** (sĕ-roo'mi-nŭs) **glands**. Recall from chapter 5 that ceruminous glands are skin glands that produce **cerumen**, a modified sebum commonly called earwax. The hairs and cerumen help prevent foreign objects from reaching the delicate tympanic membrane. However, overproduction of cerumen may block the canal.

The tympanic membrane is a thin, semitransparent membrane that separates the external ear from the middle ear. It consists of three layers: a simple cuboidal epithelium on the inner surface and a thin stratified squamous epithelium on the outer surface, with a layer of connective tissue between. Sound waves reaching the tympanic membrane through the external auditory canal cause it to vibrate.

Rupture of the tympanic membrane can be caused by a foreign object thrust into the ear, an infection of the middle ear, or sufficient differential pressure between the middle ear and the outside air, as occurs when changing altitude in an airplane or diving into deep water. Rupture of the tympanic membrane may result in hearing impairment.

Middle Ear

Medial to the tympanic membrane is the air-filled cavity of the middle ear (see figure 15.24). Two covered openings, the round and oval windows, on the medial side of the middle ear separate it from the inner ear. Two additional openings provide air passages

FIGURE 15.25 Structures of the Auricle of the Right Ear

Clinical IMPACT

Function of the Chorda Tympani

A structure you might be somewhat surprised to find in the middle ear is the **chorda tympani**, a branch of the facial nerve carrying taste impulses from the anterior two-thirds of the tongue. It crosses over the inner surface of the tympanic membrane (see figure 15.24). The chorda tympani has nothing to do with hearing but is just passing through. However, this nerve can be damaged during ear surgery or by a middle ear infection, resulting in loss of taste sensation from the anterior two-thirds of the tongue on the side innervated by that nerve.

from the middle ear. One passage opens into the **mastoid air cells** in the mastoid process of the temporal bone. The other passageway, the **auditory tube**, or *pharyngotympanic tube* (also called the eustachian [ū-stā'shŭn] tube), opens into the pharynx and equalizes air pressure between the outside air and the middle ear cavity. Unequal pressure between the middle ear and the outside environment can distort the tympanic membrane, dampen its vibrations, and make hearing difficult. Distortion of the tympanic membrane, which occurs under these conditions, also stimulates pain fibers associated with it. Because of this distortion, when a person changes altitude, sounds seem muffled and the eardrum may become painful. Swallowing, yawning, chewing, and holding the nose and mouth shut while gently forcing air out of the lungs can relieve distortion of the tympanic membrane. These actions open the auditory tube, which allows air to pass through the auditory tube and equalizes air pressure on each side of the eardrum.

The middle ear contains three auditory ossicles (see figure 15.24)—the **malleus** (mal'ĕ-ŭs; hammer), the **incus** (ing'kŭs; anvil), and the **stapes** (stā'pĕz; stirrup). The auditory ossicles transmit vibrations from the tympanic membrane to the **oval window**. Like a flexible, bony bridge, the auditory ossicles form a physical connection between the tympanic membrane and the inner ear. The handle of the malleus is attached to the inner surface of the tympanic membrane. Vibration of the tympanic membrane causes the malleus to vibrate as well. The head of the malleus is attached by a very small synovial joint to the incus, which in turn is attached by a small synovial joint to the stapes. The foot plate of the stapes fits into the oval window and is held in place by a flexible **annular ligament**. Thus, movement of the tympanic membrane is conveyed through the malleus, incus, and stapes to the oval window.

Two small skeletal muscles originate from bone around the middle ear and insert onto auditory ossicles (figure 15.26). The **tensor tympani** (ten'sōr tim'păn-ĕ) muscle is attached to the malleus and is innervated by the trigeminal nerve (V). The **stapedius** (stā-pĕ'dĕ-ŭs) muscle is attached to the stapes and is innervated by the facial nerve (VII).

FIGURE 15.26 Auditory Ossicles and Muscles of the Middle Ear

Medial view of the middle ear (as though viewed from the inner ear), showing the three auditory ossicles with their ligaments and the two muscles of the middle ear: the tensor tympani and the stapedius.

Inner Ear

The tunnels and chambers inside the temporal bone are called the **bony labyrinth** (lab'i-rinth; maze; figure 15.27). Because the bony labyrinth consists of tunnels within the bone, it cannot easily be removed and examined separately. The bony labyrinth is lined with endosteum; when the inner ear is shown separately (figure 15.28a), the endosteum is what is depicted. Inside the bony labyrinth is a similarly shaped but smaller set of membranous tunnels and chambers called the **membranous labyrinth**. The inner surface of the endosteum and the outer surface of the membranous labyrinth are covered with a very thin layer of cells called the **perilymphatic cells** (figure 15.28b). The membranous labyrinth is filled with a clear fluid called **endolymph**, and the space between the membranous labyrinth and bony labyrinth is filled with a fluid called **perilymph**. Perilymph has a low concentration of K^+ and a high concentration of Na^+ , similar to cerebrospinal fluid. Endolymph has a different composition than perilymph in that endolymph has a high concentration of K^+ and a low concentration of Na^+ .

FIGURE 15.27 Inner Ear: Bony and Membranous Labyrinths

(a) The structures of the inner ear are embedded in the temporal bone. (b) The membranous labyrinth seen within the outline of the bony labyrinth. (c) A cross section through a semicircular canal and (d) a cross section through the cochlea show the relationship between the bony and membranous labyrinths.

FIGURE 15.28 Cochlea

(a) Inner ear structures. The outer surface (*gray*) is the endosteum lining the inner surface of the bony labyrinth. (b) Cross section of the cochlea. The outer layer is the endosteum lining the inner surface of the bony labyrinth. The membranous labyrinth (*pink*) is very small in the cochlea and consists of the vestibular and basilar membranes. The space between the membranous and bony labyrinths consists of two parallel tunnels: the scala vestibuli and the scala tympani. (c) Enlarged section of the cochlear duct (membranous labyrinth). (d) Individual sensory hair cell, greatly enlarged. **APR**

The bony labyrinth is divided into three regions: vestibule, semicircular canals, and cochlea. The **vestibule** (ves'ti-bool) and **semicircular canals** are primarily involved in balance, and the **cochlea** (kok'lē-ă) functions in hearing. The arrangement of the membranous labyrinth within the bony labyrinth of the cochlea results in three distinct regions of the cochlea: the scala vestibuli, the scala tympani, and the cochlear duct (figure 15.28b).

The **scala vestibuli** (skā'lă ves-tib'ū-lē; figure 15.28b) extends from the oval window to the **helicotrema** (hel'ikō-trē'mă) at the

apex of the cochlea. The **scala tympani** (tim'pănē) extends from the helicotrema, back from the apex, parallel to the scala vestibuli, to the membrane of the **round window**. The scala vestibuli and the scala tympani are the perilymph-filled spaces between the walls of the bony and membranous labyrinths.

The **cochlear duct**, or *scala media*, is formed by the membranous labyrinth of the cochlea. The cochlear duct is filled with endolymph. As you can see in figure 15.28b, the scala vestibule is situated above the cochlear duct and the scala tympani is

situated below the cochlear duct. The wall of the membranous labyrinth that borders the scala vestibuli is called the **vestibular membrane** (*Reissner membrane*); the wall of the membranous labyrinth bordering the scala tympani is the **basilar membrane** (figure 15.28*b,c*).

The vestibular membrane consists of a double layer of squamous epithelium and is the simplest region of the membranous labyrinth. The vestibular membrane is so thin that it has little or no mechanical effect on the transmission of sound waves through the inner ear; therefore, the perilymph and endolymph on the two sides of the vestibular membrane can be thought of mechanically as one fluid, even though they are chemically different. The basilar membrane is somewhat more complex and is of much greater physiological interest in relation to the mechanics of hearing. It has an acellular portion, consisting of collagen fibers, ground substance, and sparsely dispersed elastic fibers, and a cellular portion, composed of a thin layer of vascular connective tissue overlaid with simple squamous epithelium.

The basilar membrane is attached at one side to the bony **spiral lamina**, which projects from the sides of the **modiolus** (mō-dī'ō-lus), the bony core of the cochlea, like the threads of a screw. At the other side, the basilar membrane is attached to the lateral wall of the bony labyrinth by the **spiral ligament**, a local thickening of the endosteum. The distance between the spiral lamina and the spiral ligament (i.e., the width of the basilar membrane) increases from 0.04 mm near the oval window to 0.5 mm near the helicotrema. The collagen fibers of the basilar membrane are oriented across the membrane between the spiral lamina and the spiral ligament, somewhat like the strings of a piano. The collagen fibers near the oval window are both shorter and thicker than those near the helicotrema. The diameter of the collagen fibers in the membrane decreases as the basilar membrane widens. As a result, the basilar membrane near the oval window is short and stiff, and it responds to high-frequency vibrations, whereas the part near the helicotrema is wide and limber and responds to low-frequency vibrations.

Within the cochlear duct is the **spiral organ**, or *organ of Corti*, where the sensory cells for hearing are found (figure 15.28*b,c*). The spiral organ contains supporting epithelial cells and specialized sensory cells called **hair cells** (figure 15.28*d*). These hair cells have hairlike projections at their apical ends. In children, these projections consist of one cilium (kinocilium) and about 80 very long microvilli, often referred to as **stereocilia**, but in adults the cilium is absent from most hair cells. The hair cells are arranged in the spiral organ in four long rows extending the length of the cochlear duct. Each row contains 3500–4000 hair cells. The inner row consists of **inner hair cells**, which are the hair cells primarily responsible for hearing. The outer three rows contain **outer hair cells**, which are involved in regulating the tension of the basilar membrane. The outer hair cells are separated from the inner hair cells by a gap in the basilar membrane (figure 15.28*c*). The stereocilia of one inner hair cell form a conical group called a **hair bundle** (figure 15.29*a*). The length of each stereocilium within a hair bundle increases gradually from one side of the hair cell to the other. The stereocilia of an outer hair cell are arranged in a curved line (figure 15.29*b*). The tips of the longest stereocilia of the outer hair cells are embedded within an acellular,

FIGURE 15.29 Scanning Electron Micrograph of Cochlear Hair Cell Stereocilia

(a) Hair bundle of one inner hair cell. (b) Stereocilia of outer hair cells.

gelatinous shelf called the **tectorial membrane**, which is attached to the spiral lamina.

A **tip link** connects the tip of each stereocilium in a hair bundle to the side of the next longer stereocilium (figure 15.30). Each tip link is a *gating spring*, a pair of microtubule strands that attaches to the gate of a gated K^+ channel. The gated K^+ channels of hair cells open mechanically. As the stereocilia bend, the tip link pulls the K^+ gate open (figure 15.31). The response time for such a mechanism is very brief and much faster than for a gating mechanism involving the synthesis of intracellular chemical signals, such as cAMP.

Hair cells have no axons, but the basilar regions of each hair cell are covered by synaptic terminals of sensory neurons. The cell bodies of afferent neurons are located within the cochlear modiolus and are grouped into a **cochlear ganglion**, or *spiral ganglion* (see figure 15.28*b*). Afferent fibers of these neurons join to form the **cochlear nerve**. This nerve then joins the vestibular nerve to become the **vestibulocochlear nerve (VIII)**, which traverses the internal auditory canal and enters the cranial cavity.

ASSESS YOUR PROGRESS

31. Name the three regions of the ear, and list each region's parts.
32. Describe the relationship among the tympanic membrane, the auditory ossicles, and the oval window.
33. What are the functions of the external auditory canal and the auditory tube?
34. Explain how the membranous labyrinth of the cochlea is divided into three compartments. What is found in each compartment?
35. Describe the structure of the spiral organ.
36. Explain the differences between inner and outer hair cells.
37. Relate how tip links function.
38. How is the cochlear nerve formed?

Auditory Function

Vibration of matter, such as air, water, or a solid material, creates sound. No sound occurs in a vacuum. When a person speaks, the vocal cords vibrate, causing the air passing out of the lungs to

FIGURE 15.30 Tip Links on Inner Hair Cell Stereocilia

(a) Diagram of two stereocilia connected by one tip link. (b) Transmission electron micrograph of three stereocilia and two tip links. (c) Scanning electron micrograph of the tops of stereocilia, showing tip links.

1 In the unstimulated cell, the tip link is relaxed and the K⁺ channel gate is closed.

2 As the stereocilia are bent toward the taller stereocilium, the tip link stretches.

3 The force created by stretching the tip link opens the gate of the K⁺ channel, and K⁺ enters the cell.

PROCESS FIGURE 15.31 Action of the Tip Link to Open a K⁺ Channel When Two Stereocilia Bend

vibrate. The vibrations consist of bands of compressed air followed by bands of less compressed air (figure 15.32a). These vibrations are propagated through the air as sound waves, somewhat as ripples are propagated over the surface of water. Two major features of sound—volume and pitch—are directly related to the characteristics of sound waves. **Volume**, or loudness, is a function of sound wave *amplitude*, or height, measured in decibels (db; figure 15.32b). The greater the amplitude, the louder the sound. **Pitch** is a function of the sound wave *frequency* (i.e., the number of waves or cycles per second) measured in hertz (Hz; figure 15.32c). The higher the frequency, the higher the pitch. The normal range of human hearing is 20–20,000 Hz and 0 or more db. Sounds louder than 125 db are painful to the ear. Normal human speech ranges in volume between 250 and 8000 Hz. This is the range that is used when testing for hearing impairment, because it is the most important for communication.

Timbre (tam'br, tim'br) is the resonance quality or overtones of a sound. A “pure” sound wave would be represented by a smooth, sigmoid curve, but such a wave is extremely rare in nature. The sounds made by musical instruments and the human

voice are not smooth, sigmoid curves but rough, jagged curves formed by numerous, superimposed curves of various amplitudes and frequencies. The roughness of the curve accounts for the timbre. Timbre is the difference in quality between, for example, an oboe and a French horn playing a note at the same pitch and volume. The steps involved in the mechanical part of hearing are illustrated in figure 15.33.

External Ear

The auricle collects sound waves, which are then conducted through the external auditory canal toward the tympanic membrane. Sound waves travel relatively slowly in air (332 m/s), and a significant time interval may elapse between the time a sound wave reaches one ear and the time it reaches the other. The brain can interpret this interval to determine the direction from which a sound is coming.

Middle Ear

Sound waves strike the tympanic membrane and cause it to vibrate. This vibration in turn causes the three auditory ossicles of the middle ear to vibrate; by this mechanical linkage, vibration is

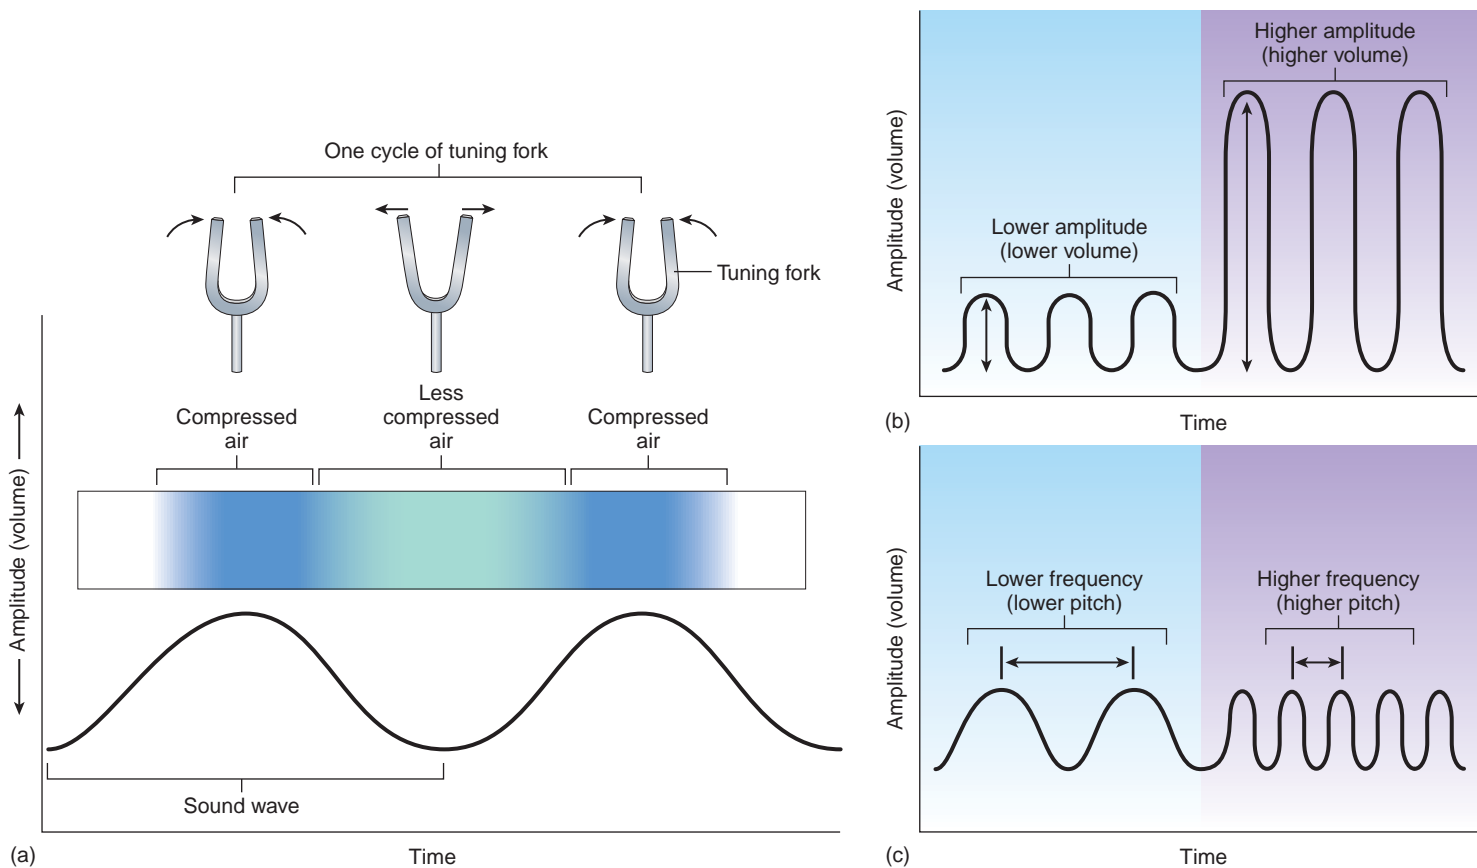

FIGURE 15.32 Sound Waves

(a) When an object, such as a tuning fork, vibrates, its movements alternate between compressing the air and decompressing the air, or making the air less compressed, thus producing sound. The human vocal cords function in the same way. Each sound wave consists of a region of compressed air between two regions of less compressed air (blue bars). The sigmoid (S-shaped) waves correspond to the regions of more compressed air (peaks) and less compressed air (troughs). The green shaded area represents the width of one cycle (distance between peaks). (b) Low- and high-volume sound waves. Compare the relative lengths of the arrows indicating the wave height (amplitude). (c) Lower- and higher-pitch sound. Compare the relative number of peaks (frequency) within a given time interval (between arrows).

FUNDAMENTAL Figure

- 1 Sound waves strike the tympanic membrane and cause it to vibrate.
- 2 Vibration of the tympanic membrane causes the malleus, the incus, and the stapes to vibrate.
- 3 The foot plate of the stapes vibrates in the oval window.
- 4 Vibration of the foot plate causes the perilymph in the scala vestibuli to vibrate.
- 5 Vibration of the perilymph causes the vestibular membrane to vibrate, which causes vibrations in the endolymph.
- 6 Vibration of the endolymph causes displacement of the basilar membrane. Short waves (high pitch) cause displacement of the basilar membrane near the oval window, and longer waves (low pitch) cause displacement of the basilar membrane some distance from the oval window. Movement of the basilar membrane is detected in the hair cells of the spiral organ, which are attached to the basilar membrane. Vibrations of the perilymph in the scala vestibuli and of the basilar membrane are transferred to the perilymph of the scala tympani.
- 7 Vibrations in the perilymph of the scala tympani are transferred to the round window, where they are dampened.

PROCESS FIGURE 15.33 Effect of Sound Waves on Cochlear Structures AP R

transferred to the oval window. More force is required to cause vibration in a liquid, such as the perilymph of the inner ear, than in air; thus, the vibrations reaching the perilymph must be amplified as they cross the middle ear. The foot plate of the stapes and its annular ligament, which occupy the oval window, are much smaller than the tympanic membrane. The area of the tympanic membrane is roughly 20 times that of the oval window. Because of this size difference, the mechanical force of vibration is amplified about 20-fold as it passes from the tympanic membrane through the ossicles and to the oval window.

The tensor tympani and stapedius muscles, attached to auditory ossicles, reflexively dampen excessively loud sounds (see figure 15.26). This so-called **sound attenuation reflex** protects the delicate ear structures from damage by loud noises. The sound attenuation reflex responds most effectively to low-frequency sounds and can reduce by a factor of 100 the energy reaching the oval window. The facial nerve and stapedius are primarily involved in the sound attenuation reflex. The trigeminal nerve and tensor tympani are only stimulated by extremely loud noise. The reflex is too slow to prevent damage from a sudden noise, such as a

gunshot, and it cannot function effectively for longer than about 10 minutes in response to prolonged noise.

Inner Ear

As the stapes vibrates, it produces waves in the perilymph of the scala vestibuli (figure 15.33). Vibrations of the perilymph are transmitted through the thin vestibular membrane and cause simultaneous vibrations of the endolymph. The mechanical effect is as though the perilymph and endolymph were a single fluid. Vibration of the endolymph causes distortion of the basilar membrane. Waves in the perilymph of the scala vestibuli are transmitted also through the helicotrema and into the scala tympani. However, because the helicotrema is very small, this transmitted vibration is probably of little consequence. Distortions of the basilar membrane, together with weaker waves coming through the helicotrema, cause waves in the scala tympani perilymph and ultimately result in vibration of the membrane of the round window. Vibration of the round window membrane is important to hearing because it acts as a mechanical release for waves from within the cochlea. If the round window were solid, it would reflect the waves,

much as the walls of a pool reflect water waves. These reflected waves would interfere with and dampen later waves, thus making it difficult to distinguish among different sounds. The round window also allows the relief of pressure in the perilymph, because fluid is not compressible, thereby preventing compression damage to the spiral organ.

The distortion of the basilar membrane is most important to hearing. As this membrane distorts, the hair cells resting on the basilar membrane move relative to the tectorial membrane, which remains stationary. The inner hair cell microvilli bend as they move against the tectorial membrane.

The apical portion of each hair cell is surrounded by endolymph, and the basal portion of the cell is surrounded by perilymph. Endolymph has a high K^+ concentration, similar to the intracellular K^+ concentration of hair cells. Perilymph has a low concentration of K^+ , similar to that of other extracellular fluid. The intracellular charge of hair cells compared with perilymph is -60 mV. The charge of the endolymph is $+80$ mV compared with the perilymph. This charge difference is called the **endocochlear potential**. Consequently, the intracellular charge of hair cells compared with endolymph is -140 mV, which is a large charge difference. Therefore, when K^+ channels open, K^+ flows into the hair cells because it is attracted to the negative charge inside the hair cell, even though the intracellular concentration of K^+ is about the same as in the endolymph. The movement of K^+ into the cells causes depolarization of the hair cells. This is a rare instance in which an increase in K^+ permeability of the plasma membrane of a cell results in depolarization.

In the unstimulated hair cell, approximately 15% of the gated K^+ channels are open, and the resting membrane potential of the cell is approximately -60 mV. If the hair bundle is bent toward the shortest stereocilium (negative stimulus), the tip link attached to the K^+ channel gates slackens, allowing the open K^+ channels to close, and the cell hyperpolarizes. If the hair bundle is bent toward the longest stereocilium (positive stimulus), the tip link pulls additional K^+ channel gates open, and K^+ rushes into the cell. The influx of K^+ into the hair cell causes a slight depolarization of the cell. This depolarization causes voltage-gated Ca^{2+} channels to open. Calcium ions rush into the cell, causing a further depolarization. The cell depolarizes by a total of about 10 mV. Depolarization of hair cells results in the increased release of neurotransmitters, which increases the action potential frequency in the afferent neurons. Hyperpolarization decreases neurotransmitter release and decreases action potential frequency in afferent neurons. Depolarization also opens voltage-gated K^+ channels in the basal portion of the hair cell. Potassium ions tend to leave the cell, causing the cell to repolarize.

The neurotransmitter released by the inner hair cells is apparently glutamate, but other neurotransmitters may also be involved. The release of neurotransmitters from the inner hair cells induces action potentials in the cochlear neurons that synapse on the hair cells. The cell bodies of those neurons are located in the cochlear ganglion.

The part of the basilar membrane that distorts as a result of endolymph vibration depends on the pitch of the sound that

created the vibration and, as a result, on the vibration frequency within the endolymph. The location of the optimal amount of basilar membrane vibration produced by a given pitch is determined by two factors: the width of the basilar membrane and the length and diameter of the collagen fibers stretching across the membrane at each level along the cochlear duct (figure 15.34). Higher-pitched tones cause optimal vibration near the base, and lower-pitched tones cause optimal vibration near the apex of the basilar membrane. As the basilar membrane vibrates, hair cells along a large part of the basilar membrane are stimulated. In areas of minimum vibration, the amount of stimulation may not reach threshold. In other areas, a low frequency of afferent action potentials may be transmitted, whereas in the optimally vibrating regions of the basilar membrane a high frequency of action potentials is initiated.

There are approximately twice as many nerve cells in the cochlear ganglion as there are hair cells. Over 90% of the afferent axons synapse with inner hair cells—about 10–30 axons per hair cell. Only a few, small-diameter afferent axons synapse with the three rows of outer hair cells. However, the outer cells receive input from efferent axons. Action potentials from those efferent axons stimulate the contraction of actin filaments within the hair cells, causing them to shorten. This adjustment in the height of the outer hair cells, attached to both the basilar membrane and the tectorial membrane, fine-tunes the tension of the basilar membrane and the distance between the basilar membrane and the tectorial membrane. Additional sensitivity can be adjusted within the inner hair cells. The mechanically gated K^+ channels

Clinical IMPACT

Loud Noises and Hearing Loss

Prolonged or frequent exposure to excessively loud noises can cause degeneration of the spiral organ at the base of the cochlea, resulting in high-frequency deafness. For example, loud music (amplified to 120 db) can impair hearing, although the actual amount of damage can vary from person to person. The defects may not be detectable on routine diagnosis, but they include decreased sensitivity to sound in specific narrow frequency ranges and decreased ability to discriminate between two pitches. Researchers have also investigated the effects of prolonged use of earbuds or earphones on hearing. Many feel that this type of exposure to sound, particularly loud music, could result in hearing loss.

Loud music, however, is not as harmful as the sudden sound of a nearby gunshot at 140 db. This sound is too sudden for the attenuation reflex to protect the inner ear structures, and the intensity is great enough to cause auditory damage. In fact, gunshot noise is the most common recreational cause of serious hearing loss.

FIGURE 15.34 Effect of Sound Waves on Points Along the Basilar Membrane

Points of maximum vibration along the basilar membrane result from stimulation by sounds of various frequencies (in hertz).

are attached to actin filaments inside the cell. Those filaments can move the K^+ channels along the plasma membrane, tightening or loosening the tip links. By this means, hair cells are tuned to very specific frequencies. Likewise, the response of an inner hair cell to stimulation is graded and can increase up to a point of saturation (when all the K^+ channels are open maximally). Inner hair cells are also very sensitive. A 100 nm (1-degree) deflection of the stereocilia results in a response that is 90% of maximum.

Afferent action potentials conducted by cochlear nerve fibers from all along the spiral organ terminate in the **superior olivary nucleus** in the medulla oblongata (figure 15.35; see chapter 13). These action potentials are compared with one another, and the strongest action potential, corresponding to the area of maximum basilar membrane vibration, is taken as standard. Efferent action potentials then are sent from the superior olivary nucleus back to the spiral organ to all regions where the maximum vibration did not occur. These action potentials inhibit the hair cells from initiating additional action potentials in the sensory neurons. Thus, only action potentials from regions of maximum vibration are sent to the cortex, where they become consciously perceived.

By this process, tones are localized along the cochlea. As a result of this localization, neurons along a given portion of the cochlea send action potentials to the cerebral cortex only in response to specific pitches, allowing for the recognition of a wide variety of sounds. Like the keys of a piano, the hair cells of the spiral organ are “tuned” to specific pitches. Action potentials near the base of the basilar membrane stimulate neurons in a certain part of the auditory cortex, which interpret the stimulus as a high-pitched sound, whereas action potentials from the apex stimulate a different part of the cortex, which interprets the stimulus as a low-pitched sound.

➤ Predict 7

Suggest some possible sites and mechanisms within the auditory structures to explain why certain people have “perfect pitch” and other people are “tone deaf.”

Sound volume, or loudness, is a function of sound wave amplitude. As high-amplitude sound waves reach the ear, the perilymph, endolymph, and basilar membrane vibrate more intensely, and the hair cells are stimulated more intensely. As a result of the increased stimulation, more hair cells send action potentials at a higher frequency to the cerebral cortex, where this information is perceived as a greater sound volume.

➤ Predict 8

Explain why it is much easier to perceive subtle musical tones when music is played somewhat softly, as opposed to very loudly.

Neuronal Pathways for Hearing

The vestibulocochlear (VIII) nerve transmits the senses of both hearing and balance. The vestibulocochlear nerve functions as two separate nerves carrying information from two separate but closely related structures. (*Vestibular* refers to the vestibule of the inner ear, which is involved in balance, and *cochlear* refers to the cochlea, the portion of the inner ear involved in hearing.)

The auditory pathways within the CNS are very complex, with both crossed and uncrossed tracts (figure 15.35). Therefore, unilateral CNS damage usually has little effect on hearing. The neurons from the cochlear ganglion synapse with CNS neurons

- 1 Sensory axons from the cochlear ganglion terminate in the cochlear nucleus in the brainstem.
- 2 Axons from the neurons in the cochlear nucleus project to the superior olivary nucleus or to the inferior colliculus.
- 3 Axons from the inferior colliculus project to the medial geniculate nucleus of the thalamus.
- 4 Thalamic neurons project to the auditory cortex.
- 5 Neurons in the superior olivary nucleus send axons to the inferior colliculus, back to the inner ear, or to motor nuclei in the brainstem that send efferent fibers to the middle ear muscles.

PROCESS FIGURE 15.35 Central Nervous System Pathways for Hearing

in the dorsal or ventral **cochlear nucleus** in the superior medulla oblongata near the inferior cerebellar peduncle. These neurons in turn either synapse in or pass through the superior olivary nucleus. Neurons terminating in this nucleus may synapse with efferent neurons returning to the cochlea to modulate pitch perception. Nerve fibers from the superior olivary nucleus also project to the trigeminal nerve (V) nucleus, which controls the tensor tympani, and the facial nerve (VII) nucleus, which controls the stapedius muscle. This reflex pathway dampens loud sounds by initiating contractions of these muscles (the sound attenuation reflex). Neurons synapsing in the superior olivary nucleus may also join other ascending neurons to the cerebral cortex.

Ascending neurons from the superior olivary nucleus travel in the **lateral lemniscus**. All ascending fibers synapse in the **inferior colliculi**, and neurons from there project to the **medial geniculate nucleus** of the **thalamus**, where they synapse with neurons that project to the cortex. These neurons terminate in the **auditory cortex** in the dorsal portion of the temporal lobe within the lateral fissure and, to a lesser extent, on the superolateral surface of the temporal lobe (see chapter 13). Neurons from the

inferior colliculus also project to the **superior colliculus**, where reflexes that turn the head and eyes in response to loud sounds are initiated.

41. What is the importance of the sound attenuation reflex?
42. Where do higher-pitched tones cause vibration of the basilar membrane? Lower-pitched tones?
43. Describe the neuronal pathways for hearing, from the cochlear nerve to the cerebral cortex.

Balance

The organs of balance are divided structurally and functionally into two parts. The first part, the **static labyrinth**, consists of the **utricle** (oo'tri-kl) and the **sacule** (sak'ul) of the vestibule and is primarily

FIGURE 15.36 Structure of the Utricular and Saccular Maculae

(a) Vestibule showing the location of the utricular and saccular maculae. (b) Enlargement of the utricle, showing hair cells and otoliths within it. (c) Enlarged hair cell, showing the kinocilium and stereocilia. (d) Colorized scanning electron micrograph of otoliths.

involved in evaluating the position of the head relative to gravity, although the system also responds to linear acceleration or deceleration, as when a person is in a car that is increasing or decreasing speed. The second part, the **dynamic labyrinth**, is associated with the semicircular canals and is involved in evaluating movements of the head.

Most of the utricular and saccular walls consist of simple cuboidal epithelium. However, the utricle and saccule each contain a specialized patch of epithelium about 2–3 mm in diameter called the **utricular macula** and the **saccular macula** (mak'ū-lă; figure 15.36*a,b*). The utricular macula is oriented parallel to the base of the skull, and the saccular macula is perpendicular to the base of the skull.

The utricular and saccular maculae resemble the spiral organ and consist of columnar supporting cells and hair cells. The “hairs” of these cells consist of numerous microvilli, called **stereocilia**, and one cilium, called a **kinocilium** (kī-nō-sil'ē-ŭm). The hairs are embedded in the otolithic membrane, a gelatinous mass weighted by the presence of **otoliths** (ō'tō-liths), tiny, crystallike structures composed of protein and calcium carbonate (figure 15.36*b,d*). The gelatinous mass moves in response to gravity, bending the hair cells and initiating action potentials in the associated neurons. The stereocilia function much as the stereocilia of cochlear hair cells do, with tip links connected to gated K^+ channels. Deflection of the hairs toward the kinocilium results in depolarization of the hair cell, whereas deflection of the hairs away from the kinocilium results in hyperpolarization of the hair cell. If the head is tipped, otoliths move in response to gravity and stimulate certain hair cells (figure 15.37).

The hair cells have no axons but synapse directly with neurons of the vestibulocochlear nerve (VIII). The hair cells release several neurotransmitters, one of which is glutamate. Research indicates that other neurotransmitters may also be involved.

The hair cells are constantly being stimulated at a low level by the otolith-weighted covering of the maculae; however, as this covering moves in response to gravity, the intensity of hair cell stimulation changes. This pattern of stimulation—and the subsequent pattern of action potentials from the numerous hair cells of the maculae—can be translated by the brain into specific information about head position or acceleration. Much of this information is not perceived consciously but is dealt with subconsciously. The body responds by making subtle tone adjustments in the muscles of the back and neck, which are intended to restore the head to its proper neutral, balanced position.

The dynamic labyrinth consists of three **semicircular canals** at nearly right angles to one another, one lying nearly in the transverse plane, one in the coronal plane, and one in the sagittal plane (figure 15.38*a*; see chapter 1). This arrangement of the semicircular canals in these three body planes, much like the x , y , and z axes of a three-dimensional structure, enables a person to detect movement in all directions. The base of each semicircular canal is expanded into an **ampulla**. Within each ampulla, the epithelium is specialized to form a **crista ampullaris** (kris'tă am-pū-lar'ŭs), which is structurally and functionally very similar to the sensory epithelium of the maculae. Each crista consists of a ridge or crest of epithelium with a curved, gelatinous mass, the **cupula** (koo'poo-lă), suspended over the crest. The hairlike processes of the crista hair cells (which are stereocilia similar to those of the

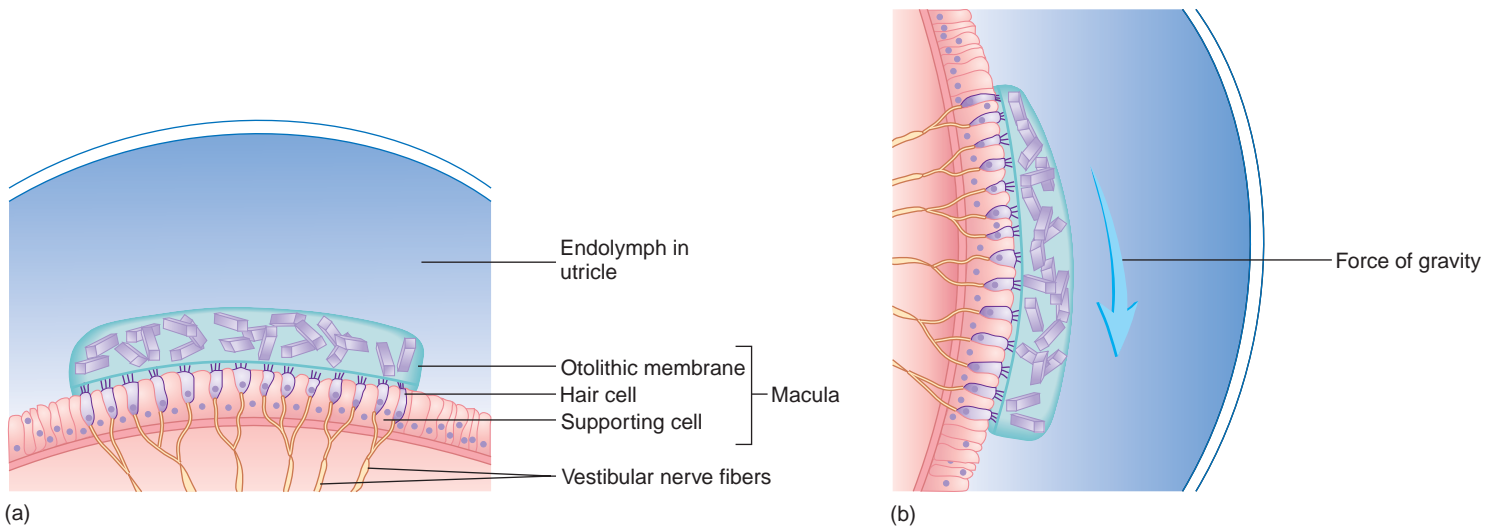

FIGURE 15.37 Function of the Vestibule in Maintaining Balance

(a) In an upright position, the otolithic membrane does not move. (b) As the position of the head changes, as when a person bends over, gravity causes the otolithic membrane to move.

hair cells in the maculae and the spiral organ) are embedded in the cupula (figure 15.38*b–d*). The cupula contains no otoliths and therefore does not respond to gravitational pull. Instead, the cupula is a float that is displaced by fluid movements within the semicircular canals. Endolymph movement within each semicircular canal moves the cupula, bends the hairs, and initiates action potentials (figure 15.39*b*).

As the head begins to move, the endolymph does not move at the same rate as the semicircular canals. This difference displaces the cupula in a direction opposite the direction the head is moving, resulting in relative movement between the cupula and the endolymph (figure 15.39). As movement continues, the fluid of the semicircular canals begins to move and catches up with the cupula, and stimulation stops. As the head stops moving, the endolymph continues to move because of its momentum, displacing the cupula in the same direction as the head was moving. Because

displacement of the cupula is most intense when the rate of head movement changes, this system detects changes in the rate of movement rather than movement alone. As with the static labyrinth, the information the brain obtains from the dynamic labyrinth is largely subconscious.

Neuronal Pathways for Balance

Neurons synapsing on the hair cells of the maculae and cristae ampullares converge into the **vestibular ganglion**, where their cell bodies are located (figure 15.40). Sensory fibers from these neurons join sensory fibers from the cochlear ganglion to form the vestibulocochlear nerve (VIII) and terminate in the **vestibular nucleus** within the medulla oblongata. Axons run from this nucleus to numerous areas of the CNS, such as the spinal cord, the cerebellum, the cerebral cortex, and the nuclei controlling extrinsic eye muscles.

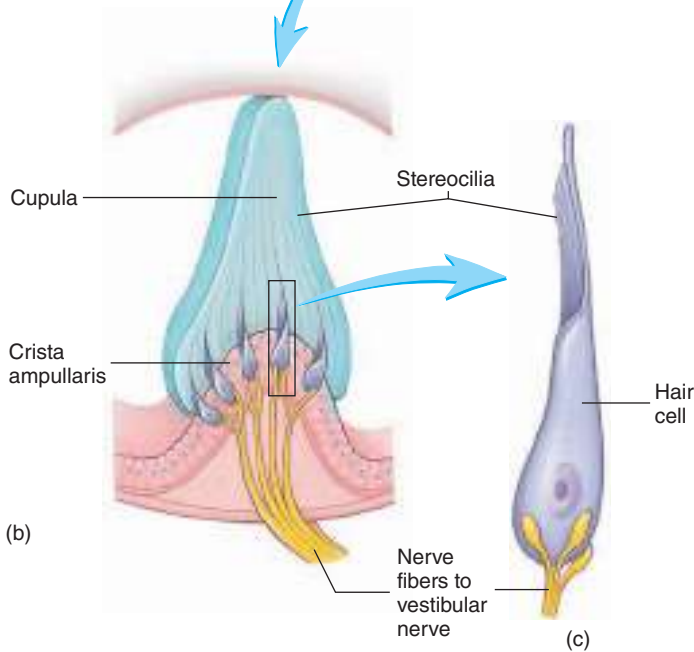

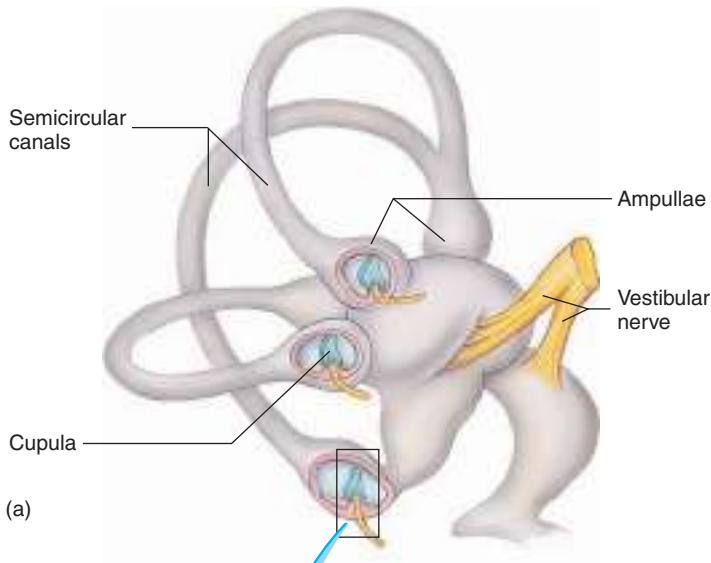

FIGURE 15.38 Semicircular Canals

(a) Semicircular canals, showing the location of the crista ampullaris in the ampullae. (b) Enlargement of the crista ampullaris, showing the cupula and hair cells. (c) Enlargement of a hair cell. (d) SEM of a crista ampullaris with hair cells. **AP R**

FIGURE 15.39 Function of the Semicircular Canals

The crista ampullaris responds to fluid movements within the semicircular canals. (a) When a person is still, the cupula is stationary, as when a person is standing (see figure 15.38b). (b) As a person moves (for example, when the person bends to touch her toes), the semicircular canals begin to move with the body (blue arrow), but the endolymph tends to remain stationary relative to the movement (red arrow pointing in opposite direction of body and semicircular canal movement), and the cupula is displaced by the endolymph in a direction opposite the direction of movement.

Balance is a complex process not simply confined to one type of input. In addition to vestibular sensory input, the vestibular nucleus receives input from proprioceptive neurons throughout the body, as well as from the visual system. In sobriety tests, people are asked to close their eyes while their balance is evaluated, because alcohol affects the proprioceptive and vestibular components of balance (cerebellar function) to a greater extent than it does the visual portion.

Reflex pathways exist between the dynamic part of the vestibular system and the nuclei controlling the extrinsic eye muscles

- 1 Sensory axons from the vestibular ganglion pass through the vestibular nerve to the vestibular nucleus, which also receives input from several other sources, such as proprioception from the legs.
- 2 Vestibular neurons send axons to the cerebellum, which influences postural muscles.
- 3 Vestibular neurons also send axons to motor nuclei (oculomotor, trochlear, and abducens), which control extrinsic eye muscles.
- 4 Vestibular neurons also send axons to the posterior ventral nucleus of the thalamus.
- 5 Thalamic neurons project to the vestibular area of the cortex.

PROCESS FIGURE 15.40 Central Nervous System Pathways for Balance

(oculomotor, trochlear, and abducens). A reflex pathway allows a person to maintain visual fixation on an object while the head is in motion. To demonstrate this function, try spinning a person around about 10 times in 20 seconds, then stopping him or her and observing eye movements. The reaction is most pronounced if the individual's head is tilted forward about 30 degrees while spinning, thus bringing the lateral semicircular canals into the horizontal plane. A slight oscillatory movement of the eyes occurs. The eyes track in the direction of motion and return with a rapid recovery movement before repeating the tracking motion. This oscillation of the eyes is called **nystagmus** (nis-tag'mŭs). If then asked to walk in a straight line, the person deviates in the direction of rotation; if asked to point to an object, his or her finger deviates in the direction of rotation.

47. Describe the crista ampullaris and its mode of operation.
48. Describe the neuronal pathways for balance.

15.5 Effects of Aging on the Special Senses

LEARNING OUTCOME

After reading this section, you should be able to

- A. Describe changes that occur with the special senses because of aging.

People experience only a slight loss in the ability to detect odors as they age. However, their ability to identify specific odors correctly decreases, especially in men over age 70.

In general, the sense of taste decreases as people age because the number of sensory receptors decreases and the brain's ability to interpret taste sensations declines. Responses to taste also change in some elderly people who are fighting cancer. One side effect of radiation treatment and chemotherapy is gastrointestinal discomfort,

Case STUDY

Motion Sickness

Earl booked his first trip on a charter fishing boat. Crossing the bar was invigorating, and Earl was surprised that all those warnings about seasickness did not seem to apply to him. At last, the boat arrived at the fishing site, the engine was cut, and the sea anchor was set. As the boat drifted, it began to roll and pitch. For the first time, Earl noticed the unpleasant mixture of smelly bait and diesel fumes. Earl felt a little light-headed and a bit drowsy; then he began to feel nauseated, and his face became pale. “I’m seasick,” he realized. Trying to fish seemed to worsen his condition. Eventually, his nausea intensified and he leaned over the boat rail and vomited into the ocean. “Improves the fishing,” the ship owner shouted to him cheerily. After that, Earl felt distinctly better, and his condition continued to improve. He found that looking at the horizon rather than at the water helped.

He enjoyed the rest of the trip and even caught a couple of fish.

Seasickness is a form of **motion sickness**, which consists of nausea, weakness, and other dysfunctions resulting from stimulation of the semicircular canals during motion, as may occur while riding in a boat, an automobile, an airplane, a swing, or an amusement park ride. Motion sickness can progress to vomiting and incapacitation. It occurs because the brain simultaneously perceives differing sensory input from the semicircular canals, eyes, and proprioceptors in the lower limbs. Motion sickness can be decreased by closing the eyes or looking at a distant object, such as the horizon.

Various drugs are used to treat motion sickness. Antiemetics, such as anticholinergic or antihistamine medications, can counter the nausea and vomiting. Scopolamine is an anticholinergic drug that blocks acetylcholine-mediated

transmission in the parasympathetic nervous system. Scopolamine can be administered transdermally in the form of a patch placed on the skin behind the ear (Transdermal-Scop). A patch lasts about 3 days. It depresses parasympathetic activity within areas of the CNS, such as the hypothalamus, in response to vestibular stimulation. Unfortunately, scopolamine also depresses other CNS functions, which may cause side effects such as restlessness, agitation, psychosis, mania, and Parkinson-like tremors. Cyclizine (Marezine), dimenhydrinate (Dramamine), and diphenhydramine (Benadryl) are antihistamines that affect the neural pathways from the vestibule.

Predict 9

Explain why closing your eyes can help decrease motion sickness. Why might looking at the horizon help?

which causes patients to lose their appetite because of conditioned taste aversions.

The lenses of the eyes lose flexibility as a person ages, because the connective tissue of the lenses becomes more rigid. Consequently, the lenses’ ability to change shape is at first reduced and eventually completely lost. Recall that this condition, called presbyopia, is the most common age-related change in the eyes. In addition, the number of cones decreases, especially in the fovea centralis. These changes cause a gradual decline in visual acuity and color perception. The most common visual problem in older people

requiring medical treatment, such as surgery, is the development of cataracts. Macular degeneration, which affects visual acuity in the center of the visual field, is the leading cause of vision loss in people over the age of 60. Other age-related defects affecting vision include glaucoma and diabetic retinopathy.

As people age, the number of hair cells in the cochlea decreases, leading to age-related hearing loss, called **presbycusis** (prez’bē-ă-koo’sis). This decline does not occur equally in both ears, however. As a result, because direction is determined by comparing sounds coming into each ear, elderly people may experience a

Diseases and Disorders

TABLE 15.3 Hearing and Balance

Condition	Description
Conductive hearing loss	Mechanical deficiency in transmission of sound waves from external ear to spiral organ
Sensorineural hearing loss	Deficiencies of spiral organ or nerve pathways
Otosclerosis	Type of conductive hearing loss resulting from spongy bone growing over oval window and immobilizing stapes; can be surgically corrected
Tinnitus (ti-nī’tus)	Phantom sound sensations, such as ringing in ears; a common problem
Otitis media	Low-grade fever, lethargy, irritability, and pulling at ear; in extreme cases, can damage or rupture tympanic membrane; common in young children
Inner ear infection	Can decrease detection of sound and maintenance of balance; may be caused by chronic middle ear infections
Motion sickness	Nausea and weakness caused when information to brain from semicircular canals conflicts with information from eyes and position sensors in back and lower limbs
Meniere disease	Vertigo, hearing loss, tinnitus, and a feeling of fullness in the affected ear; most common disease involving dizziness from inner ear; cause unknown but may involve a fluid abnormality in ears

Clinical IMPACT

Hearing Impairment and Functional Replacement of the Ear

The term **hearing-impaired** refers to any type or degree of hearing loss. Two types of hearing impairment have been identified: conductive and sensorineural. In **conductive hearing loss**, the spiral organ and neuronal pathways for hearing function normally, but there is a mechanical deficiency in the transmission of sound waves from the external ear to the spiral organ. Conductive hearing loss often can be treated—for example, by removing earwax blocking the external auditory canal or by replacing or repairing the auditory ossicles. If the degree of conductive hearing loss does not justify surgical treatment, or if treatment does not resolve the hearing loss, a hearing aid may be worn to help transmit the amplified (louder) sound waves through the conductive blockage and provide normal stimulation to the spiral organ.

Sensorineural hearing loss involves the spiral organ or neuronal pathways. Sound waves are transmitted normally to the spiral organ,

but the nervous system's ability to respond to the sound waves is impaired. People with sensorineural hearing loss commonly use hearing aids, which produce amplified sound waves that stimulate the spiral organ more than normal, helping overcome the perception of reduced sound volume. Sound clarity also improves with sound amplification but may never be perceived as normal.

The term **deaf** refers to sensorineural hearing loss so profound that the sense of hearing is nonfunctional, with or without amplification, for ordinary purposes of life. Stimulation of the spiral organ or hearing nerve pathways can help deaf people hear.

Research is being conducted on ways to replace the hearing pathways with electrical circuits. One approach involves directly stimulating the cochlear nerve using electrical impulses. Types of sensorineural deafness in which the hair cells of the spiral organ are impaired can now be partially corrected by

implanting a prosthesis consisting of a microphone for picking up the initial sound waves, a microelectronic processor for converting the sound into electrical signals, a transmission system for relaying the signals to the inner ear, and a long, slender electrode threaded into the cochlea. This electrode delivers electrical signals directly to the endings of the cochlear nerve (figure 15D). High-frequency sounds are picked up by the microphone and transmitted through specific circuits to terminate near the oval window, whereas low-frequency sounds are transmitted farther up the cochlea to cochlear nerve endings near the helicotrema.

For patients with vestibulocochlear nerve damage, research is under way to develop a technique for implanting electrodes directly into the cochlear nucleus of the brainstem. These implanted electrodes would be of various lengths, so that they could stimulate parts of the cochlear nucleus, at various depths from the surface, that respond to sounds of different frequencies.

- 1 A receiver, a transmitter, and an antenna are implanted under the skin near the auricle.
- 2 A small lead from the transmitter is fed through the external auditory canal, tympanic membrane, and middle ear into the cochlea.
- 3 In the cochlea, the cochlear nerve can be directly stimulated by electrical impulses from the receiver.

FIGURE 15D Cochlear Implant

decreased ability to localize the origin of certain sounds. In some people, this leads to a general sense of disorientation. In addition, CNS defects in the auditory pathways can result in difficulty understanding sounds with echoes or background noise. Such a deficit makes it difficult for elderly people to understand rapid or broken speech.

With age, the number of hair cells in the saccule, utricle, and ampullae decreases. The number of otoliths also declines. As a

result, elderly people experience decreased sensitivity to gravity, acceleration, and rotation, leading to dizziness (instability) and vertigo (a feeling of spinning). Many elderly people feel they cannot maintain posture and are prone to fall.

ASSESS YOUR PROGRESS

49. Explain the changes in smell, taste, vision, hearing, and balance that occur with aging.

Answer

Learn to Predict ◀ From page 505

We learn that Freddy's surgery replaced two of the three auditory ossicles. Recall that the auditory ossicles distribute sound waves from the tympanic membrane to the oval window of the inner ear, where the sound waves can then stimulate hair cells of the cochlear duct. If Freddy's auditory ossicles were not functional, we can predict that his loss of hearing was conductive hearing loss due to the absence of functional auditory ossicles. To address the question of sound location, recall that the brain can determine the direction from which a sound is coming because of the time interval between

when the sound reaches one ear and the time it reaches the other. Since Freddy had complete hearing loss in one ear, his ability to determine the direction from which a sound came was probably diminished. Finally, by replacing the damaged auditory ossicles, Freddy's hearing was restored, because sound waves can now be conducted from Freddy's tympanic membrane to his oval window.

Answers to the rest of this chapter's Predict questions are in appendix G.

15.1 Olfaction (p. 506)

Olfaction is the sense of smell.

Olfactory Epithelium and Bulb

1. Olfactory neurons in the olfactory epithelium are bipolar neurons. Their distal ends are enlarged as olfactory vesicles, which have long cilia.
2. The cilia have receptors that respond to dissolved substances. There are approximately 1000 different odorant receptors.
3. The receptors activate a G protein complex, which opens ion channels.
4. At least 7 (but perhaps as many as 50) primary odors exist. The olfactory neurons have a very low threshold and adapt rapidly.

Neuronal Pathways for Olfaction

1. Axons from the olfactory neurons extend as olfactory nerves to the olfactory bulb, where they synapse with secondary neurons of the olfactory bulb. Axons from these cells form the olfactory tracts. The olfactory bulb neurons can modulate output to the olfactory tracts.
2. The olfactory tracts terminate in the olfactory cortex of the temporal lobe, which is involved in the conscious perception of smell. Other areas of the brain, including parts of the limbic system and hypothalamus, are involved with visceral and emotional responses to smell.

15.2 Taste (p. 509)

Taste buds are usually associated with vallate, foliate, and fungiform papillae. Filiform papillae do not have taste buds.

Histology of Taste Buds

1. Taste buds consist of basal cells, supporting cells, and taste cells.
2. The taste cells have taste hairs that extend into taste pores.

Function of Taste

1. Receptors on the taste hairs detect dissolved substances.
2. Five basic types of taste exist: salty, sour, sweet, bitter, and umami.

Summary

Neuronal Pathways for Taste

1. The facial nerve carries taste sensations from the anterior two-thirds of the tongue, the glossopharyngeal nerve from the posterior one-third of the tongue, and the vagus nerve from the epiglottis.
2. The neural pathways for taste extend from the medulla oblongata to the thalamus and to the cerebral cortex.

15.3 Visual System (p. 513)

Accessory Structures

1. The eyebrows prevent perspiration from entering the eyes and help shade the eyes.
2. The eyelids consist of five tissue layers. They protect the eyes from foreign objects and help lubricate the eyes by spreading tears over their surface.
3. The conjunctiva covers the inner eyelid and the anterior part of the eye.
4. Lacrimal glands produce tears, which flow across the surface of the eye. Excess tears enter the lacrimal canaliculi and reach the nasal cavity through the nasolacrimal canal. Tears lubricate and protect the eye.
5. The extrinsic eye muscles move the eyeball.

Anatomy of the Eye

1. The fibrous tunic is the outer layer of the eyeball. It consists of the sclera and the cornea.
 - The sclera is the posterior four-fifths of the eyeball. It is white connective tissue that maintains the shape of the eyeball and provides a site for muscle attachment.
 - The cornea is the anterior one-fifth of the eye. It is transparent and refracts light that enters the eye.
2. The vascular tunic is the middle layer of the eyeball.
 - The iris is smooth muscle regulated by the autonomic nervous system. It controls the amount of light entering the pupil.
 - The ciliary muscles control the shape of the lens. They are smooth muscles regulated by the autonomic nervous system. The ciliary process produces aqueous humor.

- The retina is the nervous tunic of the eyeball and contains neurons sensitive to light.
 - The fovea centralis is the area of greatest visual acuity.
 - The optic disc is the location through which nerves exit and blood vessels enter the eye. It has no photosensory cells and is therefore the blind spot of the eye.
- The eyeball has three chambers: anterior, posterior, and vitreous.
 - The anterior and posterior chambers are filled with aqueous humor, which circulates and leaves by way of the scleral venous sinus.
 - The vitreous chamber is filled with vitreous humor.
- The lens is held in place by the suspensory ligaments, which are attached to the ciliary muscles.

Functions of the Eye

- Light is the portion of the electromagnetic spectrum that humans can see.
- When light travels from one medium to another, it can bend, or refract. Light striking a concave surface refracts outward (divergence). Light striking a convex surface refracts inward (convergence).
- Converging light rays meet at the focal point and are said to be focused.
- The cornea, aqueous humor, lens, and vitreous humor all refract light. The cornea is responsible for most of the convergence, whereas the lens can adjust the focal point by changing shape.
 - Relaxation of the ciliary muscles causes the lens to flatten into its normal resting condition, called emmetropia.
 - Contraction of the ciliary muscles causes the lens to become more spherical. This change in lens shape enables the eye to focus on objects that are nearby, a process called accommodation.
- The far point of vision is the distance at which the eye no longer has to change shape to focus on an object. The near point of vision is the closest an object can come to the eye and still be focused.
- The pupil becomes smaller during accommodation, increasing the depth of focus.

Structure and Function of the Retina

- The pigmented layer of the retina provides a black backdrop for increasing visual acuity.
- Rods are responsible for vision in low illumination (night vision).
 - A pigment called rhodopsin is split by light into retinal and opsin, producing hyperpolarization in the rod.
 - Light adaptation is caused by the reduction of rhodopsin; dark adaptation is caused by the production of rhodopsin.
- Cones are responsible for color vision and visual acuity.
 - Cones are of three types, each with a different type of iodopsin photopigment. The photopigments are most sensitive to blue, red, and green wavelengths.
 - Perception of many colors results from mixing the ratio of the different types of cones that are active at a given moment.
- Most visual images are focused on the fovea centralis, which has a very high concentration of cones. Moving away from the fovea centralis, fewer cones are present; the periphery of the retina contains mostly rods.
- The rods and the cones synapse with bipolar cells, which in turn synapse with ganglion cells, which form the optic nerves.
- Bipolar and ganglion cells in the retina can modify information sent to the brain.
- Ganglion cells have receptive fields with on-centers or off-centers. This arrangement enhances contrast.

Neuronal Pathways for Vision

- Ganglion cell axons extend to the lateral geniculate ganglion of the thalamus, where they synapse. From there, neurons form the optic radiations that project to the visual cortex.
- Neurons from the nasal visual field (temporal retina) of one eye and the temporal visual field (nasal retina) of the opposite eye project to the same cerebral hemisphere. Axons from the nasal retina cross in the optic chiasm, and axons from the temporal retina remain uncrossed.
- Depth perception is the ability to judge relative distances of an object from the eyes and is a property of binocular vision. Binocular vision results because a slightly different image is seen by each eye.

15.4 Hearing and Balance (p. 532)

The external and middle ears are involved in hearing only, whereas the inner ear functions in both hearing and balance.

Auditory Structures and Their Functions

- The external ear consists of the auricle and the external auditory canal.
- The middle ear connects the external and inner ears.
 - The tympanic membrane is stretched across the external auditory canal.
 - The malleus, incus, and stapes connect the tympanic membrane to the oval window of the inner ear.
 - The auditory tube connects the middle ear to the pharynx and equalizes pressure.
 - The middle ear is connected to the mastoid air cells.
- The bony labyrinth of the inner ear is a canal system within the temporal bone that contains perilymph and the membranous labyrinth.
 - Endolymph is inside the membranous labyrinth.
 - The bony labyrinth has three parts: the semicircular canals, the vestibule (containing the utricle and the saccule), and the cochlea.
- The cochlea is a spiral-shaped canal within the temporal bone.
 - The cochlea is divided into three compartments by the vestibular and basilar membranes. The scala vestibuli and scala tympani contain perilymph. The cochlear duct contains endolymph and the spiral organ.
 - The spiral organ consists of inner and outer hair cells that attach to the tectorial membrane.

Auditory Function

- Sound waves are funneled by the auricle down the external auditory canal, causing the tympanic membrane to vibrate.
- The tympanic membrane vibrations are passed along the auditory ossicles to the oval window of the inner ear.
- Movement of the stapes in the oval window causes the perilymph, vestibular membrane, and endolymph to vibrate, producing movement of the basilar membrane.
- Movement of the basilar membrane causes bending of the stereocilia of inner hair cells in the spiral organ.
- Bending of the stereocilia pulls on tip links, which open K^+ channels.
- Potassium ions entering the hair cell depolarize the cell, which opens Ca^{2+} channels. Calcium ions entering the cell cause further depolarization.
- Depolarization causes the release of glutamate, generating action potentials in the vestibulocochlear nerve.
- Some vestibulocochlear nerve axons synapse in the superior olivary nucleus. Efferent neurons from this nucleus project back to the cochlea, where they regulate the perception of pitch.

- The round window protects the inner ear from pressure buildup and dissipates sound waves.

Neuronal Pathways for Hearing

- Axons from the vestibulocochlear nerve synapse in the medulla oblongata. Neurons from the medulla oblongata project axons to the inferior colliculi, where they synapse. Neurons from this point project to the thalamus and synapse. Thalamic neurons extend to the auditory cortex.
- Efferent neurons project to the cranial nerve nuclei responsible for controlling the muscles that dampen sound in the middle ear.

Balance

- The static labyrinth is involved in evaluating the position of the head relative to gravity and detecting linear acceleration and deceleration.
 - The utricle and saccule in the inner ear contain maculae. The maculae consist of hair cells with the hairs embedded in a membrane that contains otoliths.
 - The otolithic membrane moves in response to gravity.

- Dynamic balance evaluates movements of the head.
 - Three semicircular canals at right angles to one another are present in the inner ear. The ampulla of each semicircular canal contains the crista ampullaris, which has hair cells with hairs embedded in a gelatinous mass, the cupula.
 - When the head moves, endolymph within the semicircular canal moves the cupula.

Neuronal Pathways for Balance

- Axons from the maculae and the cristae ampullares extend to the vestibular nucleus of the medulla oblongata. Fibers from the medulla run to the spinal cord, cerebellum, cortex, and nuclei that control the extrinsic eye muscles.
- Balance also depends on proprioception and visual input.

15.5 Effects of Aging on the Special Senses (p. 546)

Elderly people experience a functional decline in all the special senses: olfaction, taste, vision, hearing, and balance. These declines can result in loss of appetite, visual impairment, disorientation, and risk of falling.

REVIEW AND COMPREHENSION

- Which of these statements is *not* true with respect to olfaction?
 - Olfactory sensation is relayed directly to the cerebral cortex without passing through the thalamus.
 - Olfactory neurons are replaced about every 2 months.
 - The olfactory cortex is involved in the conscious perception of smell.
 - The secondary olfactory areas are responsible for visceral and emotional reactions to odors.
 - The olfactory cortex is in the occipital lobe of the cerebrum.
- Taste cells
 - are found only on the tongue.
 - extend through tiny openings called taste buds.
 - have no axons but release neurotransmitters when stimulated.
 - have axons that extend directly to the taste area of the cerebral cortex.
- Which of these is *not* one of the basic tastes?
 - spicy
 - salt
 - bitter
 - umami
 - sour
- Which of these types of papillae have no taste buds associated with them?
 - vallate
 - filiform
 - foliate
 - fungiform
- The fibrous tunic of the eye includes the
 - conjunctiva.
 - sclera.
 - choroid.
 - iris.
 - retina.
- The ciliary body
 - contains smooth muscles that attach to the lens by suspensory ligaments.
 - produces the vitreous humor.
 - is part of the iris of the eye.
 - is part of the sclera.
 - All of these are correct.
- The lens normally focuses light onto the
 - optic disc.
 - iris.
 - macula.
 - cornea.
 - ciliary body.
- Given these structures:
 - lens
 - aqueous humor
 - vitreous humor
 - cornea

Which of the following arrangements lists the structures in the order that light entering the eye encounters them?

- 1,2,3,4
 - 1,4,2,3
 - 4,1,2,3
 - 4,2,1,3
 - 4,3,2,1
- Contraction of the smooth muscle in the ciliary body causes the
 - lens to flatten.
 - pupil to constrict.
 - lens to become more spherical.
 - pupil to dilate.
 - Given these events:
 - Bipolar cells depolarize.
 - Glutamate release from presynaptic terminals of photoreceptor cells decreases.
 - Light strikes photoreceptor cells.
 - Photoreceptor cells are depolarized.
 - Photoreceptor cells are hyperpolarized.

Choose the arrangement that lists the correct order of events, starting with the photoreceptor cells in the resting, nonactivated state.

- 1,2,3,4,5
 - 2,4,3,5,1
 - 3,4,2,5,1
 - 4,3,5,2,1
 - 5,3,4,1,2
- Given these neurons in the retina:
 - bipolar cells
 - ganglionic cells
 - photoreceptor cells
 Choose the arrangement that lists the correct order of the cells encountered by light as it enters the eye and travels toward the pigmented layer of the retina.
 - 1,2,3
 - 1,3,2
 - 2,1,3
 - 2,3,1
 - 3,1,2

- Which of these photoreceptor cells is *not* correctly matched with its function?
 - rods—vision in low light
 - cones—color vision
 - rods—visual acuity
- Concerning dark adaptation,
 - the amount of rhodopsin increases.
 - the pupils constrict.
 - it occurs more rapidly than light adaptation.
 - All of these are correct.

14. In the retina are cones that are most sensitive to a particular color. Given this list of colors:
(1) red (2) yellow (3) green (4) blue
Indicate which colors correspond to specific types of cones.
a. 2,3 b. 3,4 c. 1,2,3 d. 1,3,4 e. 1,2,3,4
15. Given these areas of the retina:
(1) macula (3) optic disc
(2) fovea centralis (4) periphery of the retina
Choose the arrangement that lists the areas according to the density of cones, starting with the area that has the highest density of cones.
a. 1,2,3,4 b. 1,3,2,4 c. 2,1,4,3 d. 2,4,1,3 e. 3,4,1,2
16. Axons in the optic nerve from the right eye
a. all go to the right occipital lobe.
b. all go to the left occipital lobe.
c. all go to the thalamus.
d. go mostly to the thalamus, but some go to the superior colliculus.
e. go partly to the right occipital lobe and partly to the left occipital lobe.
17. A person with an abnormally powerful focusing system is _____ and uses a _____ to correct his or her vision.
a. nearsighted, concave lens c. farsighted, concave lens
b. nearsighted, convex lens d. farsighted, convex lens
18. Which of these structures is found within or is a part of the external ear?
a. oval window c. ossicles e. cochlear duct
b. auditory tube d. external auditory canal
19. Given these ear bones:
(1) incus (2) malleus (3) stapes
Choose the arrangement that lists the ear bones in order from the tympanic membrane to the inner ear.
a. 1,2,3 b. 1,3,2 c. 2,1,3 d. 2,3,1 e. 3,2,1
20. Given these structures:
(1) perilymph (3) vestibular membrane
(2) endolymph (4) basilar membrane
Which of the following arrangements lists the structures in the order sound waves coming from the outside encounter them in producing sound?
a. 1,3,2,4 b. 1,4,2,3 c. 2,3,1,4 d. 2,4,1,3 e. 3,4,2,1
21. The spiral organ is within the
a. cochlear duct. c. scala tympani. e. semicircular canals.
b. scala vestibuli. d. vestibule.
22. An increase in the loudness of sound occurs as a result of an increase in the _____ of the sound wave.
a. frequency c. resonance
b. amplitude d. Both a and b are correct.
23. Interpretation of different sounds is possible because of the ability of the _____ to vibrate at different frequencies and stimulate the _____.
a. vestibular membrane, vestibular nerve
b. vestibular membrane, spiral organ
c. basilar membrane, vestibular nerve
d. basilar membrane, spiral organ
24. Which structure is a specialized receptor within the utricle?
a. macula c. spiral organ
b. crista ampullaris d. cupula
25. Damage to the semicircular canals affects the ability to detect
a. sound.
b. the position of the head relative to the ground.
c. the movement of the head in all directions.
d. All of these are correct.

Answers in appendix E

CRITICAL THINKING

- An elderly man with normal vision develops cataracts. He is surgically treated by removing the lenses of his eyes. What kind of glasses should he wear to compensate for the removal of his lenses?
- Perhaps you have heard that eating carrots is good for the eyes. What is the basis for this claim?
- A man stares at a black clock on a white wall for several minutes. Then he shifts his view and looks at only the blank white wall. Although he is no longer looking at the clock, he sees a light clock against a dark background. Explain what is happening.
- Describe the results of a lesion of the optic chiasm.
- Explain how several hours of reading can cause eyestrain, or eye fatigue. Describe what structures are involved.
- Persistent exposure to loud noise can cause loss of hearing, especially for high-frequency sounds. What part of the ear is probably damaged? Be as specific as possible.
- Professional divers are subject to increased pressure as they descend to the bottom of the ocean. Sometimes this pressure can lead to damage to the ear and loss of hearing. Describe the normal mechanisms that adjust for changes in pressure, suggest some conditions that might interfere with pressure adjustment, and explain how the increased pressure might cause loss of hearing.
- If a vibrating tuning fork is placed against the mastoid process of the temporal bone, the vibrations are perceived as sound, even if the external auditory canal is plugged. Explain how this happens.

Answers in appendix F

16

Learn to Predict

On the first pretty day of spring, Officer Smith was sitting in her patrol car, observing traffic near the town's busy park, when a sports car suddenly sped past. Realizing that families with young children may be crossing the same street on their way to the park, Officer Smith quickly pursued the speeding car. **By recalling information about the integration of nervous system functions from previous chapters and reading chapter 16, describe in general the neural pathways involved in Officer Smith's quick reactions—the movement of her skeletal muscles, her increased heart rate, and the decreased movements and secretions in her digestive system.**

Autonomic Nervous System

During a picnic on a sunny spring day, it is easy to concentrate on the delicious food and the pleasant surroundings. Maintaining homeostasis requires no conscious thought. The autonomic nervous system (ANS) helps keep body temperature at a constant level by controlling the activity of sweat glands and the amount of blood flowing through the skin. The ANS also helps regulate the complex activities necessary for digesting food. Absorbed nutrients travel to the tissues through the bloodstream because the ANS controls the heart rate, which helps maintain the necessary blood pressure. Without the ANS, all of the activities necessary to maintain homeostasis would be overwhelming.

This chapter examines the autonomic nervous system. A functional knowledge of the ANS enables you to predict general responses to a variety of stimuli, explain responses to changes in environmental conditions, comprehend symptoms that result from abnormal autonomic functions, and understand how drugs affect the ANS.

Photo: Colorized scanning electronmicrograph (SEM) of cells of the adrenal medulla.

16.1 Overview of the Autonomic Nervous System

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Explain the basic function of the autonomic nervous system (ANS).
- B. List the divisions of the autonomic nervous system and describe the conditions under which each is more influential.

The autonomic nervous system (ANS) maintains homeostasis of the body by regulating many activities, including heart rate, breathing rate, body temperature, digestive processes, and urinary functions. Imagine the many changes that your body experiences during the day, from waking and preparing for the day to exercising and completing other daily tasks. All of these changes in activity involve differences in energy demands by your tissues. When you are very active, your contracting skeletal muscles require more energy reserves. When you are resting, the energy demands of your skeletal muscles decrease, but the energy demands of other tissues, such as the smooth muscle of your digestive tract, increase. It is the function of the ANS to alter the activity of smooth muscle, cardiac muscle, and glands to match the needs of the different tissues of the body during varying levels of activity.

Recall from chapter 11 that the motor division of the nervous system controls the effectors (muscles and glands) of the body. The motor division consists of two parts: the somatic motor system and the ANS. The somatic motor system regulates the activities of skeletal muscle (see chapter 14) and the ANS regulates the activity of all the other effectors (smooth muscle, cardiac muscle, and glands). The ANS is further subdivided into the sympathetic division, the parasympathetic division, and the enteric nervous system. The enteric nervous system consists of nervous tissue of the digestive tract. The sympathetic and parasympathetic divisions regulate the activity of effectors throughout the body, but each division influences the tissues under different conditions. The sympathetic division, often referred to as the fight-or-flight division, has more influence on effectors under conditions of increased physical activity or stress, whereas the parasympathetic division has more influence under conditions of rest and is often referred to as the rest-and-digest division.

ASSESS YOUR PROGRESS

1. Describe the function of the ANS.
2. List the divisions of the ANS. Under what conditions would each division be more influential?

16.2 Contrasting the Somatic and Autonomic Nervous Systems

LEARNING OUTCOMES

After reading this section, you should be able to

- A. Describe the structural and functional differences between the somatic nervous system and the ANS.

- B. Describe the relationship between preganglionic and postganglionic neurons. Contrast somatic and autonomic motor neurons with sensory neurons.

The peripheral nervous system (PNS) is composed of sensory and motor neurons. As described in chapter 11, **sensory neurons** carry action potentials from the many sensory receptors of the body to the central nervous system (CNS), and **motor neurons** carry action potentials from the CNS to the effectors of the body (muscles and glands). Motor neurons that innervate skeletal muscle are called somatic motor neurons, and they are part of the somatic nervous system. Motor neurons that innervate smooth muscle, cardiac muscle, and glands are called autonomic motor neurons, and they are part of the autonomic nervous system (ANS). In this section, we compare the somatic motor system and the ANS. The rest of the chapter focuses on the structure and function of the autonomic nervous system.

A **nerve** is a bundle of axons, or nerve fibers, that connects the CNS to sensory receptors, muscles, and glands. A nerve may contain the axons of autonomic, somatic, and sensory neurons but the proportions of the specific types of axons vary from nerve to nerve. For example, nerves innervating smooth muscle, cardiac muscle, and glands, such as the vagus nerves, consist primarily of axons of sensory neurons and autonomic motor neurons. Nerves innervating skeletal muscles, such as the sciatic nerves, consist primarily of axons of sensory neurons and somatic motor neurons. Some cranial nerves, such as the olfactory, optic, and vestibulocochlear nerves, are composed entirely of sensory neuron axons.
