Filtration	Air drawn through a filter unit; particles trapped; 0.2 μm pore size	Viable particles; viable microorganisms (on nonnutrient surfaces, limited to spores and microorganisms that resist drying); concentration over time. Example use: air sampling for *Aspergillus* spp., fungal spores, and dust	Paper, cellulose, glass wool, gelatin foam, and membrane filters	1–50	Yes	Filter must be agitated first in rinse fluid to remove and disperse trapped microorganisms; rinse fluid is assayed; used more for sampling dust and chemicals	Sartorius AirPort MD8 air sampler with gelatin membrane filter (Sartorius Corporation)

Centrifugation	Aerosols subjected to centrifugal force; particles impacted onto a solid surface	Viable particles; viable microorganisms (on nonnutrient surfaces, limited to spores and microorganisms that resist drying); concentration over time. Example use: air sampling for *Aspergillus* spp., and fungal spores	Coated glass or plastic slides, and agar surfaces	40–50	Yes	Calibration is difficult and is done only by the factory; relative comparison of airborne contamination is its general use	Biotest RCS Plus
Electrostatic precipitation	Air drawn over an electrostatically charged surface; particles become charged	Viable particles; viable microorganisms (on nonnutrient surfaces, limited to spores and microorganisms that resist drying); concentration over time	Solid collecting surfaces (glass, agar)	85	Yes	High-volume sampling rate, but equipment is complex and must be handled carefully; not practical for use in healthcare settings	—
Thermal precipitation	Air drawn over a thermal gradient; particles repelled from hot surfaces; settle on colder surfaces	Size measurements	Glass coverslip, and electron microscope grid	0.003–0.4	Yes	Determine particle size by direct observation; not frequently used because of complex adjustments and low sampling rates	—

[a]Most samplers require a flow meter or anemometer and a vacuum source as auxiliary equipment.

(Data from references *27*, *28*, *35*, and *36*.)

BOX 72-2

Selecting an Air-Sampling Device

The following factors must be considered when choosing an air-sampling instrument:

- Viability and type of the microorganism to be sampled
- Compatibility with the selected method of analysis
- Sensitivity of particles to sampling
- Assumed concentrations and particle size
- Whether airborne clumps must be broken (i.e., total viable microorganism count vs. particle count)
- Volume of air to be sampled and length of time sampler is to be continuously operated
- Background contamination
- Ambient conditions
- Sampler collection efficiency
- Effort and skill required to operate sampler
- Availability and cost of sampler, plus backup samplers in case of equipment malfunction
- Availability of auxiliary equipment and utilities (e.g., vacuum pumps, electricity, and water)

(Data from Wolf HW, Skaliy P, Hall LB, et al. Sampling microbiological aerosols. Public Health Service publication No. 686. Washington, DC: Government Printing Office, 1964.)

and/or sampling method chosen should, however, have an adequate sampling rate to collect a sufficient number of particles in a reasonable time period so that a representative sample of air is obtained for biological analysis. Newer analytical techniques for assaying air samples include polymerase chain reaction (PCR) methods and enzyme-linked immunosorbent assays.

Water Sampling

A detailed discussion of the principles and practices of water sampling has been published (42). Water sampling in healthcare settings is used to detect waterborne pathogens of clinical significance or to determine the quality of finished water in a facility's distribution system. Routine testing of the water in a healthcare facility is usually not indicated, but sampling in support of outbreak investigations can help determine appropriate infection-control measures. Water-quality assessment in dialysis settings is another instance where routine microbiologic sampling of water is important and where standards have been established (see hemodialysis, Chapter 63).

Healthcare facilities that conduct water sampling should have their samples assayed in a laboratory that uses established methods and QA protocols. Water specimens are not "static specimens" at ambient temperature; potential changes in both numbers and types of microbial populations can occur during transport. Consequently, water samples should be sent to the testing laboratory cold (i.e., at ~39.2°F [4°C]) and testing should be done as soon as practical after collection (preferably within 24 hours).

Because most water sampling in healthcare facilities involves the testing of finished water from the facility's distribution system, a reducing agent (i.e., sodium thiosulfate [$Na_2S_2O_3$]) needs to be added to neutralize residual chlorine or other halogen in the collected sample. If the water contains elevated levels of heavy metals, then a chelating agent should be added to the specimen. The minimum volume of water to be collected should be sufficient to complete any and all assays indicated; 100 mL is considered a suitable minimum volume. Sterile collection equipment should always be used.

Sampling of water from the distribution sytem from a tap requires flushing of the water line before sample collection. If the tap is a mixing faucet, attachments (e.g., screens and aerators) must be removed, and hot and then cold water must be run through the tap before collecting the sample (42). If the cleanliness of the tap is questionable, disinfection with 500 to 600 parts per million (ppm) sodium hypochlorite (1:100 v/v dilution of chlorine bleach) and flushing the tap should precede sample collection. If biofilm associated organisms are sought, samples are collected from inside the faucet head, screens and aerators with a non-cotton swab prior to flushing of the tap.

Microorganisms in finished or treated water often are physically damaged ("stressed") to the point that growth is limited when assayed under standard conditions. Such situations lead to false-negative readings and misleading assessments of water quality. Appropriate neutralization of halogens and chelation of heavy metals are crucial to the recovery of these microorganisms. The choice of recovery media and incubation conditions will also affect the assay. Incubation temperatures should be closer to the ambient temperature of the water rather than at 98.6°F (37°C), optimum growth temperature of the specific microorganism sought, and recovery media should be formulated to provide appropriate concentrations of nutrients to support microorganisms exhibiting less than rigorous growth (42). High-nutrient content media (e.g., blood agar and tryptic soy agar [TSA]) may actually inhibit the growth of these damaged microorganisms. Reduced nutrient media (e.g., diluted peptone and R2A) are preferable for recovery of these microorganisms (42).

Use of aerobic, heterotrophic plate counts allows both a qualitative and quantitative measurement for water quality. If bacterial counts in water are expected to be high in number (e.g., during waterborne outbreak investigations), assaying small quantities using pour plates or spread plates is appropriate (42). Membrane filtration is used when low-count specimens are expected and larger sampling volumes are required (>100 mL). The sample is filtered through the 0.45 µm or 0.22 µm membrane, and the filter is applied directly face-up onto the surface of the agar plate and incubated.

Unlike the testing of potable water supplies for coliforms (which uses standardized test and specimen collection parameters and conditions), water sampling to support epidemiologic investigations of disease outbreaks may be subjected to modifications dictated by the circumstances present in the facility. Assay methods for waterborne pathogens may also not be standardized. Therefore, control or comparison samples should be included in the experimental design. Any departure from a standard method should be fully documented and should be considered when interpreting results and developing strategies. Assay methods specific for clinically significant waterborne pathogens (e.g., *Legionella* spp., *Aeromonas* spp., *Pseudomonas* spp., and *Acinetobacter* spp.) are more complicated and costly

compared with both methods used to detect coliforms and other standard indicators of water quality.

Microbiologic Sampling of Environmental Surfaces

Routine environmental-surface sampling (e.g., surveillance cultures) in healthcare settings is neither cost-effective nor warranted (*37*,43). When indicated, surface sampling should be conducted with multidisciplinary approval in adherence to carefully considered plans of action and policy (Box 72-3). Microbiologic sampling of nonporous and porous surfaces is used currently for research, as part of an epidemiologic investigation, or as part of a comprehensive approach for specific QA purposes. As a research tool, surface sampling has been used to determine (a) potential environmental reservoirs of pathogens *(44–47)*; (b) survival of microorganisms on surfaces *(47,48)*; and (c) the sources of the environmental contamination *(49)*. Some or all of these approaches can also be used during outbreak investigations *(47)*.

Microbiologic sampling of surfaces involves selecting a representative sample of the surface to be studied and collecting microbial contaminants from the surface with appropriate sampling devices and laboratory-approved sampling media. Choosing the appropriate sampling devices depends on the sampling phase during an investigation, the area and type of surface being sampled, and the limitations of the sampling method. The objectives for a sampling event must be defined to provide useable, defendable, applicable, and scientifically meaningful data for use in the decision-making process of an investigation. Insight and consultation with the laboratory is important to the development of a successful sampling strategy. The interpretation of results should be based on the understanding of the recovery efficiencies of the materials and the limitations of the processing method. Methods used for routine sampling of environmental surfaces include swabs, wipes/sponges, agar contact plates, surface rinse, and vacuums (2). Additionally, there are microbial properties and environmental influences that may affect the sampling, detection, or the results of the analysis (Box 72-4) (2).

BOX 72-3

Undertaking Environmental-Surface Sampling

The following factors should be considered before engaging in environmental-surface sampling:

- Background information from the literature and present activities (i.e., preliminary results from an epidemiologic investigation)
- Location of surfaces to be sampled
- Method of sample collection and the appropriate equipment for this task
- Number of replicate samples needed and which control or comparison samples are required
- Parameters of the sample assay method and whether the sampling will be qualitative, quantitative, or both
- An estimate of the maximum allowable microbial numbers or types on the surface(s) sampled (refer to the Spaulding classification for devices and surfaces)
- Some anticipation of a corrective action plan

(Data from Bond WW, Sehulster LM. Microbiological culturing of environmental and medical-device surfaces. In: Isenberg HD, Miller JM, Bell M, eds. *Clinical microbiology procedures handbook*. Washington, DC: American Society for Microbiology Press, 2004:Section 13.)

BOX 72-4

Variables Affecting Sampling, Detection, and Analysis

- Ability of the agent to survive or produce active toxins on surfaces for extended periods of time in various environmental conditions
  - Spores of *Bacillus anthracis* and *Clostridium* spp. can persist for years on surfaces such as paper or nonporous surfaces *(50)*.
  - Some vegetative bacteria (e.g., *Staphylococcus aureus*) can survive for weeks or months depending upon the presence of organic material, available moisture, or a suitable carrier.
  - If detection is dependent on culture, consider the conditions since deposition
    - If viability of the microorganism is unlikely, then sampling for detection by alternate means (i.e., polymerase chain reaction [PCR]) should be considered or used in conjunction with culture.
- Interference from particulates, other microorganisms, growth inhibitors, or assay inhibitors
  - Particulates such as dust, heavy metals, or fibers may inhibit growth, interfere with PCR, or make recognition of characteristic colony morphology difficult in culture *(51)*.
  - Large numbers of background bacteria present can compete with the target microorganism in culture, or interfere with PCR by providing an excess of nontarget deoxyribonucleic acid (DNA) *(52)*.
  - Clay and organic substances (e.g., humic acid in soil) can inhibit growth in culture and interfere with PCR assays *(51)*.
- Adherence properties of microorganisms
  - Vegetative bacteria are more likely to be affected than bacterial spores by the chemical and/or physical properties of the surface.
  - Adherence can be influenced by temperature, humidity, presence of other organics on the surface or deposition media.
- Laboratory assay used for detection
  - Materials and wetting compounds may not be compatible with assay reagents.
  - Growth media, diluents, or neutralizers may be inhibitory to the microorganism being detected.

Surface Sampling Considerations Essential components of a successful sampling strategy during any microbiological investigation include (a) properly trained personnel; (b) a sound sampling strategy; (c) a qualified laboratory; (d) laboratory-approved sample media and supplies; (e) appropriate safety policies; (f) thorough recordkeeping and documentation; and (g) QA and quality-control (QC) procedures (53). The condition and documentation of the sample received by the laboratory for analysis are of primary importance. If samples are improperly

collected and mishandled or are not representative of the area/location, the laboratory results will be meaningless. Decisions about an area in question are based on a relatively small numbers of representative samples; therefore, established sampling procedures must be applied uniformly and consistently (54).

Two basic elements must be present in any plan to sample: the use of sterile equipment and the use of the aseptic technique. In order to ensure the reliability of the results, it is critical to ensure that the media, solutions, and the sample containers are sterile and remain sterile. Use of prepackaged sterile supplies and equipment prior to their end-of-use date are the easiest way to ensure that sampling is done with sterile materials. Aseptic technique ensures that no additional contamination is introduced into the sample during the collection process and that a representative sample has been collected (54). In order to utilize the aseptic technique during sampling, the concept of the "clean person/contaminated person" is suggested for sampling in hospitals, but must be used by responsible persons when evaluating a biological agent event. In practical terms, this becomes a two-person sampling team, with one individual only handling the sampling media (the sampler) and the other individual handling all other supplies (support person) (54). The support person will employ aseptic techniques to open packages and make sampling devices and equipment available to the sampler. The sampler is the only person to touch the sample media. The sampler will collect the sample and place the device into an open sample container that is held by the support person. Once the sample is placed into the sample container and two plastic sealable bags, the sample will be decontaminated and placed into a third bag or container. All individuals for either role should be trained in aseptic techniques prior to undertaking microbiologic sampling (2). Additionally, persons involved with microbiologic sampling should use personal protective equipment appropriate to the task (e.g., gloves, lab coat, respirator) (53).

Depending on the overall objective indicating the need for microbiologic sampling, the approach to sampling may encompass three phases—the screening phase, the characterization phase, and the clearance or postremediation phase (2). It may not be necessary to include all three of these phases in the sampling plan. The screening phase provides an opportunity to get a general sense and extent of potential contamination through the use of qualitative sampling and analysis. Outbreak investigations that utilize screening phase activities most likely are attempting to evaluate contamination involving large and/or diverse areas of the healthcare facility. The characterization phase activities involve a more focused, quantitative approach to sampling. This is typically used in outbreak investigations to ascertain specific information about pathogens (i.e., potential for infection, viability of the microorganism, possible source and extent of contamination, and routes of spread) (2). Sampling for quantitative results requires attention to the surface area sampled, since results will be reported as the concentration of the agent in a given area sampled (Box 72-5). There must be uniformity of sample collection materials or devices, as well as personnel techniques. Laboratory processing for quantitative results involves more time and effort, as well as more supplies and reagents; communication with the laboratory early in the planning stages is, therefore, crucial. The clearance or postremediation phase sampling activities are typically used to determine if an area is safe for occupancy, usually following a decontamination or disinfecting treatment (2). Either qualitative or quantitative microbiologic sampling can be used depending on the type of information needed and the anticipated action plan based on the results. When undertaking environmental sampling to evaluate the effectiveness of a large space decontamination process, biological indicators (e.g., spore strips) should always be included in the sampling design (2). Environmental sampling of surfaces does not stand alone on its own merit. Rather, there must be evidence that the decontamination process was successful (i.e., inactivation of biological indicators placed throughout the treated space). Spore strips of *Geobacillus stearothermophilus* or *Bacillus atrophaeus* are suitable for this purpose. Postremediation phase sampling in healthcare facilities is currently used with contemporary room treatments such as vaporized hydrogen peroxide.

BOX 72-5

Sampling Area and Sampling Devices

- Moist swab: 100 cm^2, approximately 4 $in.^2$
- Moist wipe: 8 ft^2 for 9 in. × 9 in. wipe
  Up to several square meters with a 15 × 25 cm rayon wipe
  1 ft^2 with a 3 in. × 3 in. noncotton gauze pad
- Moist sponge: ≤1 m^2 with a 1.5 in. × 3 in. sponge
- HEPA[a] sock: No known documented guidelines
- Contact plate: Area of plate only
- Historic guidelines for sampling areas are based on knowledge from the food industry and experience from sampling in a clinical setting. These guidelines are subject to change.

[a]HEPA, high efficiency particulate air.
(Data from References 2, 24, 53, 55, and 56.)

Use of Neutralizers The presence of residual disinfectants should be considered when sampling after a germicidal treatment. This is most important when using such disinfectants such as sodium hypochlorite, quaternary ammonium compounds, hydrogen peroxide, and phenolics. In such cases, inclusion of specific neutralizers in the recovery media or sampling media is important to prevent carrying the residual disinfectant into the assay or culture media (Table 72-2). Such carry over may result in toxic effects and reduced numbers or erroneous assay results. When incorporating neutralizers into a sampling device or analytical method, the potential toxic effect of the neutralizer should be evaluated for each microorganism. The sampling team should consult with laboratory personnel when making decisions on the appropriate neutralizers to be incorporated in the sampling device. The choice of neutralizer will be based on the type of disinfectant used for decontamination and knowledge of the neutralizer's toxicity to the agent to be sampled (2,24,57).

Media and Diluents Meaningful results depend on the selection of appropriate sampling and assay techniques (24). The media, reagents, and equipment required for

Examples of Eluents and Diluents for Environmental-Surface Sampling[a]

Solutions	*Concentration in Water*
Ringer	1/4 strength
Peptone water	0.1–1.0%
Buffered peptone water	0.067 M phosphate, 0.43% NaCl, 0.1% peptone
Phosphate-buffered saline phosphate, 0.9% NaCl	0.02 M
Sodium chloride (NaCl)	0.25–0.9%
Calgon Ringer[b]	1/4 strength
Thiosulfate Ringer[c]	1/4 strength
Water	—
Tryptic soy broth (TSB)	—
Brain–heart infusion broth (BHI) supplemented with 0.5% beef extract	—

[a]A surfactant (e.g., polysorbate [i.e., Tween 80®]) may be added to eluents and diluents. A concentration ranging from 0.01% to 0.1% is generally used, depending on the specific application. Foaming may occur during use.
[b]This solution is used for dissolution of calcium alginate swabs.
[c]This solution is used for neutralization of residual chlorine.
(Data from Bond WW, Sehulster LM. Microbiological culturing of environmental and medical-device surfaces. In: Isenberg HD, Miller JM, Bell M, eds. *Clinical microbiology procedures handbook*. Washington, DC: American Society for Microbiology Press, 2004:Section 13 and International Organization for Standardization (ISO). *Sterilization of medical devices—microbiological methods, Part 1*. ISO Standard 11737-1. Geneva, Switzerland: International Organization for Standardization, 1995.)

surface sampling are available from any well-equipped microbiology laboratory and laboratory supplier. For quantitative assessment of surface microorganisms, dilutions of eluents from sampling devices are cultured on nonselective, nutrient-rich agar media (e.g., TSA and brain–heart infusion broth [BHI] with or without 5% sheep or rabbit blood supplement). Further sample workup may require the use of selective media for the isolation and enumeration of specific groups of microorganisms. Examples of selective media are MacConkey agar (MAC [selects for gram-negative bacteria]), Cetrimide agar (selects for *Pseudomonas aeruginosa*), or Sabouraud dextrose and malt extract agars and broths (select for fungi). Qualitative determinations of specific microorganisms from surfaces require the use of selective or nonselective media.

Effective sampling of surfaces requires moisture, either already present on the surface to be sampled or via moistened swabs, sponges, wipes, agar surfaces, or membrane filters (24,*58–60*). Dilution fluids and rinse fluids include various buffers or general purpose broth media (Table 72-3). If disinfectant residuals are expected on surfaces being sampled, specific neutralizer chemicals should be used in both the growth media and the dilution or rinse fluids (61). Alternatively, instead of adding neutralizing chemicals to existing culture media (or if the chemical nature of the disinfectant residuals is unknown), the use of either (a) commercially available media including a variety of specific and nonspecific neutralizers or (b) double-strength broth media will facilitate optimal recovery of microorganisms. The inclusion of appropriate control specimens should be included to rule out both residual antimicrobial activity from surface disinfectants and potential toxicity caused by the presence of neutralizer chemicals carried over into the assay system (24).

Microbiologic Methods for Surface Sampling Several methods can be used for collecting environmental-surface samples (Table 72-4) (2). Sample/rinse methods are frequently chosen because of their versatility. However, these sampling methods are the most prone to errors caused by manipulation of the swab, gauze pad, or sponge (62). Additionally, no microbiocidal or microbiostatic agents should be present in any of these items when used for sampling (62). Each of the rinse methods requires effective elution of microorganisms from the item used to sample the surface. Thorough mixing of the rinse fluids after elution (e.g., via manual or mechanical mixing using a vortex mixer, shaking with or without glass beads, and ultrasonic bath) will help to remove and suspend material from the sampling device and break up clumps of microorganisms for a more accurate count (62). In some instances, the item used to sample the surface (e.g., gauze pad and sponge) may be immersed in the rinse fluids in a sterile bag and subjected to stomaching (62). This technique, however, is suitable only for soft or absorbent items that will not puncture the bag during the elution process.

If sampling is conducted as part of an epidemiologic investigation of a disease outbreak, identification of isolates to species level is mandatory, and characterization beyond the species level is preferred (24). When interpreting the results of the sampling, the expected degree of microbial contamination associated with the various categories of surfaces in the Spaulding classification must be considered. Environmental surfaces should be visibly clean; recognized pathogens in numbers sufficient to result

in secondary transfer to other animate or inanimate surfaces should be absent from the surface being sampled (24). Although the interpretation of a sample with positive microbial growth is self-evident, an environmental-surface sample (especially one obtained from a housekeeping surface) that shows no growth does not represent a "sterile" surface. Sensitivities of the sampling and assay methods (i.e., level of detection) must be taken into account when no-growth samples are encountered. Properly collected control samples will help rule out extraneous contamination of the surface sample.

The methods to collect surface samples have been organized based on whether they will be collected from porous and nonporous surfaces. Each sampling method has its recommended use and advantages (Table 72-4) (2). Porous surfaces are typically uneven and include carpets, draperies, concrete, asphalt, upholstery, ceiling tiles, and stucco. Nonporous surfaces are even surfaces that include ceramics, vinyl, stainless steel, metals, painted and coated wood surfaces, and plastics. There are different methods of sampling for either type of surface, porous or nonporous.

Nonporous Surface Sampling Nonporous sampling methods include wiping the surface to remove any biological substance present. Methods to sample nonporous surfaces include wipe samples with premoistened gauze pads or sponges, swab sampling with a noncotton swab, the collection of a surface sample with an agar contact plate or replicate organism detection and counting plate (RODAC).

Wipe Sampling This sampling technique is best for screening large nonporous surfaces (Box 72-6) (2). Wipes work

BOX 72-6

Wipe-Sampling Procedures

Wipe-Sampling Procedure

Below is one possible procedure for doing a wipe sample on a nonporous surface. Please note that this protocol is not endorsed by any agency and a validated procedure has not been established.

Equipment and Apparatus

- Sterile sample containers
- Wrapped sterile noncotton gauze pad (2 in. × 2 in.) or 3M Sponge-Stick with Neutralizing Buffer (cellulose sponge premoistened with 10 mL Neutralizing Buffer [1.5 in. × 3 in. cellulose sponge folded over a handle, biocide-free, packaged in a sealable transport bag]: 3M, St. Paul MN: catalogue no. SSL 10NB or equivalent)
- 5 ml of appropriate sterile water, or other sterile laboratory-determined wetting solution in premeasured bottles or with measured sterile dropper
- Disposable, sterile sampling template with 1 ft^2 opening (optional)
- Sterile nonpowdered sampling gloves
- Sealable plastic bags
- Sample forms and permanent marker

Procedure

1. Don a sterile pair of sampling gloves before handling the gauze pad. Sterile gloves are not needed for the Sponge-Stick.
2. Choose appropriate sampling locations and attach a sample template (if using) in the designated area or simply delineate the area with masking tape.
3. Document the surface area to be wiped.
4. Gauze pad procedures:
   a. Open a new sterile package of a gauze pad.
   b. Wet the pad with an appropriate volume of the sterile water or other sterile laboratory-specified buffer solution.
   c. Wipe the designated surface area inside the opening of the sample template.
   d. Wipe twice inside the template vertically, then horizontally using an "S" pattern to ensure complete surface coverage.
   e. Fold the gauze with the exposed side in.
   f. Place the gauze pad in an appropriate sterile sample container.
   g. Cap and seal the sample container, attach a label, and triple bag in sealable bags.
   h. Change sterile gloves prior to collecting the next sample.
5. Sponge-Stick procedures:
   a. Wearing a clean pair of gloves, open the sample bag, back the handle of the sponge out of the sample bag by pushing on the outside of the bag (to avoid reaching fingers inside of the sterile bag). Tear the bag open and grasp the handle behind the thumb-stop and remove from the sample bag using aseptic technique.
   b. Sample the surface area, being careful to cover the entire surface. For flat surfaces, apply gentle but firm pressure and use an overlapping "S" pattern to cover the entire surface with horizontal strokes, then vertical and diagonal strokes.
   c. Insert sponge into the sample bag. Hold the sponge from outside of the bag with thumb and forefinger and then bend the handle backward and forward to break the sponge handle at the score mark below the sponge edge. With the sponge head inside, fold the top of the bag over at least four times and secure by folding the wire toward the center of the bag.
   d. Label the transport bag and repeat steps a–c for collection of additional samples.

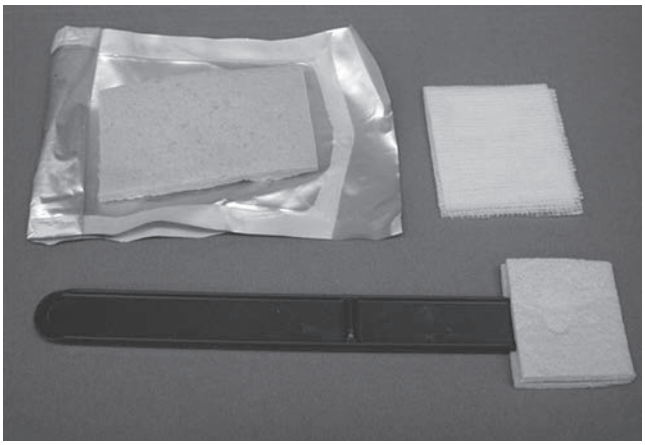

FIGURE 72-1 Sponges. Clockwise from *top left*: premoistened cellulose sponge (Solar Biologicals, Ogdensburg, NY); all-purpose gauze sponge (Kendall Healthcare, Mansfield, MA); Sponge-Stick (3M, St. Paul, MN).

best for flat, nonporous surfaces like walls, desks, and floors. Wipe sampling can be performed by using sterile gauze pads or sponges (Fig. 72-1). Wipe sampling is used to determine the extent and location of contamination, effectiveness of decontamination, and screening of specific items. Collection of wipe samples on rough, porous, or uneven surfaces may be difficult. If the surface is not flat, be sure to wipe any crevices or depressions well. The solution with which to wet the wipe is determined based on discussion with the laboratory and is dependent on the surface and the material to be sampled, and the method of analysis. The laboratory may, for QA/QC purposes, request a blank sample of the wipe and solution to be included with the samples as a negative control for each sampling event. These samples provide information about the handling, quality of the media, and other sources of contamination. If appropriate, a device used to monitor temperature during shipping may also be required by the laboratory.

Swab Sampling Swab samples work best for small nonporous areas of <100 cm^2, like crevices, corners, and hard-to-reach places (Box 72-7) (2). Several absorptive media are available, but noncotton (rayon, polyester, macrofoam) swabs are preferred. The swab to be used will be determined by the data quality objectives, input from the laboratory, and availability (Fig. 72-2).

Agar Contact Plate Sampling The agar contact method is used to sample cleaned and sanitized flat, nonabsorbent surfaces and is not suitable for visibly dirty and irregular surfaces (Box 72-8) (2). Contact plates (RODAC plates) are used to determine and count microorganisms present on surfaces and personnel (1). The method provides quantitative measurement of low numbers of microorganisms and cannot be used for heavily contaminated surfaces, because overgrowth will occur. Contact plates are constructed so that the agar medium is overfilled, producing a meniscus or dome-shaped surface that can be pressed onto a surface for sampling. A solid selective medium can be used, dependent on the microbial contaminant sought. Neutralizers can be incorporated in the medium if surface disinfectant residuals are present. After touching the surface to be sampled with the agar plate, the dish is covered and sent to a laboratory where it will be incubated at an appropriate temperature. In the laboratory, the presence and number of the microbial contaminants are determined by counting the colonies on the surface of the agar medium. One of the issues with agar contact plates is that they have a short shelf life.

BOX 72-7

Swab Sampling Procedure

Below is one possible procedure for collecting a swab sample on a nonporous surface. Please note that this protocol is not endorsed by any agency and a validated procedure has not been established.

Equipment and Apparatus

- Sterile sample containers with sealing lid, like a plastic centrifuge tube
- Sterile wrapped noncotton swab
- Wetting solution (if applicable) either appropriate sterile water, or other sterile laboratory-specific wetting solution in premeasured bottles or with measured sterile dropper
- Disposable, sterile sampling template with 100-cm^2 opening (optional)
- Sterile nonpowdered sampling gloves
- Sterile scissors
- Sealable plastic bags
- Sample forms and permanent marker

Procedures

1. Don a sterile pair of sampling gloves.
2. Choose appropriate sampling locations and attach a sample template (if using) in the designated area and photo document the template.
3. Document the surface area to be wiped.
4. Open a new sterile package of noncotton swab.
5. Wet the swab by dipping in a vial or tube of wetting solution and pressing against the side of the tube to remove the excess.
6. Wipe in an "S" pattern (vertically and horizontally) over the designated surface with the swab using firm strokes while rolling the swab to allow all surfaces of the swab to be used.
7. Place swab in appropriate sterile sample container, like a sterile centrifuge tube. It may be necessary to break, bend or cut the handle of the swab with the sterile scissors to ensure it fits into the sample container.
8. Cap the sample container, attach a label, and triple bag.
9. Change sterile gloves prior to collecting the next sample.

Porous Surface Sampling At this time, there are no validated sampling practices for suspected microorganisms from porous surfaces. The methods presented in this section are for porous sampling, which include high efficiency particulate air (HEPA) vacuum collection sock, microvacuuming, and bulk collection.

HEPA Vacuum Collection Samples of persistent biological materials deposited onto porous surfaces like carpets, fabrics, and draperies can be sampled with a portable

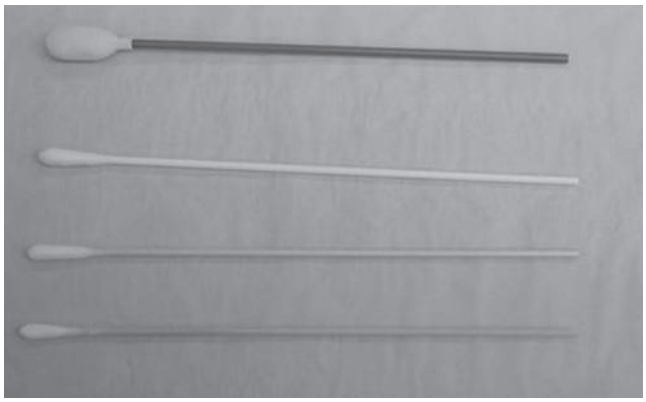

FIGURE 72-2 Swabs. From *top to bottom*: macrofoam applicator (Critical) swab (VWR International, West Chester, PA); cotton-tipped applicator swab (Baxter Healthcare Corp., McGaw Park, IL); polyester fiber-tipped applicator swab (Becton Dickinson and Company, Sparks, MD); rayon-tipped applicator swab (Hardwood Products Company, LLC, Guilford, ME).

HEPA vacuum with a collection sock filter designed to fit into the inlet nozzle of the vacuum cleaner (Fig. 72-3). The collection sock can be used to trap dust and bulk material, which is then sent for analysis. This method allows for the sampling of dust and other powdery substances from porous and nonporous surfaces (Box 72-9) (2). This method for bulk sampling can be used in postdecontamination and transitional sampling and to determine the extent and location of large areas of contamination (54). The major disadvantage of this method is the compromise of the collection efficiency by the initial loss of small biological particles through the sock filter and contamination of the HEPA filter. Collection efficiency increases when the sock filter is loaded with continued collection of dust.

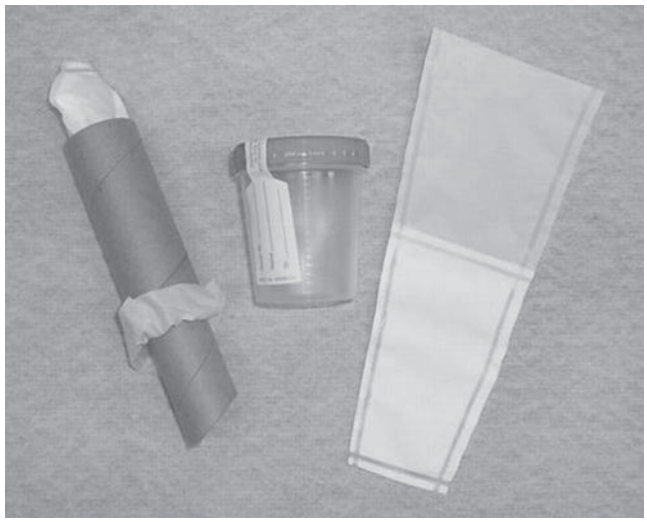

FIGURE 72-3 An X-Cell 200 HEPA vacuum sample kit with (left to right) disposable nozzle assembly, sterile sample container, and filter sock (Midwest Filtration Co., Cincinnati, OH).

Microvacuum Sampling The primary use of the microvacuum technique has been to determine the concentration of metals on a surface (63). However, the microvacuum sampling technique can be used as a surface sampling method to collect microorganisms that have been deposited on soft, rough, or porous surfaces (Box 72-10) (2). The microvacuum technique has not been validated for sampling microorganisms at this time and may not be the most efficient measure of microbial contamination on a surface (54). Microvacuum sampling can be used in postdecontamination and transitional sampling and to determine the extent and location of areas of contamination (54). The primary interference for bulk samples is large quantities of materials that may mask any microorganism that might be present in the sample. The use of dedicated sterile sampling equipment or decontamination of sampling equipment will minimize cross-contamination. Microvacuuming is carried out by using a collection nozzle attached to an air-sampling cassette or filter holder, and connected to a sampling pump. The sample can be collected within a sample template by moving the nozzle over the surface in an "S" pattern. Once the sample is collected, the cassette is then sealed and sent to the laboratory for analysis.

Bulk Sampling Bulk samples for microorganisms can be collected using a variety of methods and equipment (Box 72-11) (2). The sampling objective is to determine qualitatively if a bulk material, such as pieces of HVAC filters, devices, containers, personal items, clothing, is contaminated with microorganisms. This type of sampling can also be used as a tool for screening. Large quantities of dust and background bacteria may mask the target biological

BOX 72-8

Agar Contact Plate (RODAC) Sampling Procedure

Agar Contact Plate Sampling Procedure

Below is one possible procedure for collecting an agar plate sampling on a nonporous surface. Please note that this protocol is not endorsed by any agency and a validated procedure has not been established.

Equipment and Apparatus

- Sterile nonpowdered sampling gloves
- Sterile wrapped contact plate with appropriate agar medium.
- Parafilm® with a minimum width of 4 in.
- Sealable plastic bags
- Sample labels, forms, and permanent marker

Procedure

1. Don a sterile pair of sampling gloves.
2. Choose appropriate sampling location to be sampled with the contact plate and photo document.
3. Open the contact plate package taking precautions to maintain the sterility of the inner bag and its contents. Using aseptic techniques, remove the cover without touching the agar. Hold the lid during sampling so that it does not touch anything.
4. Firmly touch the agar to the surface to be sampled, using the same pressure for each sample. Do not move or slide the agar over the surface to be sampled, as this will spread the contamination and disturb the resolution of individual colony identification.
5. Replace the cover on the contact plate.
6. Label the contact plate with a sample label and wrap the plate with wax wrap Parafilm®.
7. Place the contact plate into a sealable bag, attach a label, and triple bag.
8. Store and transport the contact plate in a cooler but not directly on the ice, kept cold and delivered to the laboratory as soon as possible.
9. Change sterile gloves prior to collecting the next sample.

BOX 72-9

HEPA Vacuum Sampling Procedure

Below is one possible procedure for collecting a HEPA vacuum sample on a porous surface. Please note that this protocol is not endorsed by any agency and a validated procedure has not been established.

Equipment and Apparatus

The following equipment should be available in order to collect bulk samples:

- Sterile sampling gloves
- HEPA vacuum with a 1⅛;-in.-diameter hose attachment
- HEPA sample sock with cardboard inlet nozzle assembly
- Power source
- Sterile sample container of proper size
- Sealable plastic bags
- Sample forms and permanent marker

Sampling Procedure

1. For each sample collected, ensure that a new pair of sterile gloves is worn.
2. Place the cardboard inlet assembly into the inlet nozzle of the vacuum prior to inserting the HEPA sample sock into the nozzle. Fold the HEPA collection sock over the inlet nozzle.
3. Grasp the inlet nozzle and the assembly, securing the sample sock.
4. Turn on the vacuum and hold the nozzle close to the area being sampled without damaging the edge of the sample sock. Once the sample has been collected, turn off the vacuum and remove the filter sock from the nozzle touching only the blue portion of the filter sock.
5. Collect the sample in an area up to several square meters. Document the area that was sampled.
6. Do not let go of the filter sock while the vacuum is turned on. The filter sock will be sucked into the vacuum and the sample will be unusable.
7. Holding the blue portion, remove the filter sock from the assembly tube, roll or fold the top closed, and then place into a sterile sample container.
8. Label the sample container.
9. Double bag the sample container and label the outer bag.
10. Decontaminate the outer sample bag.
11. Photograph the sample at the sample location.
12. Change sterile gloves prior to collecting the next sample.

agent that might be present in the sample. The use of dedicated sterile sampling equipment for each sample collected will minimize cross-contamination. A validated method for nonporous surfaces (54) is available; however, it is not validated for porous surfaces. A solid bulk sample can be collected by placing the material into a sterile container. Prior to collecting a bulk sample, it is critical to discuss the material to be sent to the laboratory to ensure that the laboratory is able to accept and handle the sample. If the material to be sampled cannot be broken or cut into smaller pieces, discuss additional sample collection options with the laboratory. The laboratory will also provide information regarding the amount of sample that they require for analysis and the required QA/QC samples.

BOX 72-10

Microvacuuming Sampling Procedure

Below is one possible procedure for collecting a microvacuum sample from a porous surface. Please note that this protocol is not endorsed by any agency for sampling biological agents and a validated procedure has not been established.

Equipment and Apparatus

- Calibrated sampling pump
- Rotometer (air flow meter) or dry cell calibrator
- Sterile closed-faced 37-mm cassette with microvacuum nozzle preloaded with 0.45 µm sample filter made of mixed cellulose esterase (MCE) or Teflon
- Disposable, sterile sampling template with 100-cm^2 opening (to a maximum of 30 cm × 30 cm opening (63)).
- Flexible Tygon™ tubing
- Sterile tweezers
- Sterile sampling gloves
- Sealable plastic bags
- Sample forms and permanent marker

Procedure

1. Set up the sampling train by attaching one end of the Tygon™ tubing to the outlet of a filter cassette used for calibration and the other end to the manifold of the pump inlet.
2. Calibrate the pump with the rotometer or dry cell calibrator to the flow rate specified by the laboratory: >2.5 lpm (63) for MCE or Teflon filters.
3. Don sterile sampling gloves.
4. Use one preloaded cassette with either a Teflon or an MCE filter (65) and nozzle per sample. Remove the outlet and inlet end caps on the sample filter cassette. Attach the sample nozzle to the inlet side of the cassette.
5. Place the template in the selected sampling location.
6. Hold the collection nozzle at a 45 degree angle to the surface to be sampled. Vacuum the area inside the template, in a horizontal “S” pattern, followed by vacuuming in a vertical “S” pattern to ensure complete coverage of sample area. Record the rate at which nozzle is moved (~10 cm/s), approximately 1 minute for entire sample.
7. Once the sample has been collected, record pump flow rate.
8. Detach the sample filter cassette from the sample stand and remove the Tygon™ tubing. Place the cap on the outlet of the sample filter cassette. Remove the nozzle carefully and cap the inlet.
9. To prevent cross-contamination, use a dedicated collection nozzle for each sample.
10. Triple bag the sample filter cassette in sealable plastic bags.
11. Label properly.
12. Prepare the sample cassette for transport.
13. Change sterile gloves prior to collecting the next sample.

BOX 72-11

Bulk Sampling Procedure

Below is one possible procedure for collecting a bulk sample. Please note that this protocol is not endorsed by any agency. Please refer to ASTM Method # E2458-06 *(26)* for collection of powders from nonporous surfaces.

Equipment and Apparatus

The following equipment should be available in order to collect bulk samples:

- Sterile sampling gloves
- Disposable or decontaminated spade, spatula, scoop, or trowel
- Sterile forceps, scissors, scalpel, or sharp knife
- Sterile sample container of proper size
- Sealable plastic bags
- Sample forms and permanent marker

Sampling Procedures

1. For each sample collected, ensure that a new pair of sterile gloves is worn
2. Prior to initiating collection, document the area from which the bulk sample will be collected or from the object which will become the bulk sample.
3. All sample equipment must be sterile prior to use.
4. For solids, powders, or granular material, collect the laboratory-specified quantity of the bulk sample with a dedicated sterile spoon, trowel, or spatula and place material into a sterile sample container.
5. For large pieces of material that require analysis, the laboratory-specified quantity of material is collected with dedicated sterile scissors, scalpel, or knife by breaking, cutting, chipping, or shaving small pieces of the material into a sterile sample container.
6. Label the sample container.
7. Double bag the sample container and label the outer bag.
8. Decontaminate the outer bag.
9. Photograph the sample at the sample location.
10. Change sterile gloves prior to collecting the next sample.

Microbiologic Sampling of the Environment: Current Analytic Challenges Although significant research is being conducted, validated sampling collection methods do not exist for porous and nonporous surfaces. Overall detection limits for surface sampling methods are generally unknown and are dependent on many factors, which include variable collection efficiency of sampling devices, recovery efficiency from sampling devices due to variable extraction liquid and extraction method. Indeed, research investigators have determined that the sampling devices and processing methods have varying recovery efficiencies. It is critical to understand the collection efficiency of each sampling device from various types of surfaces to develop criteria for surface contamination. Results from the analyses of the surface samples should be interpreted based on the validity of the collection method, extraction method, and detection or identification assay. Interpretations during the various sampling phases should be based on (a) consistency in sample collection; (b) the number of samples collected; (c) the maximum sample area for which the method is validated; (d) sampling materials used; (e) sample stability; (f) the extraction efficiency for the sampling method; and (g) sensitivity of the detection or identification assay.

BOX 72-12

Validation Criteria Definition

Accuracy

The closeness of the results obtained to those predicted from a known concentration of microorganisms.

Precision

The agreement among individual results when applied repeatedly to multiple samplings across the range of the test. It is usually expressed as a standard deviation or coefficient of variation. It can be a measure of either reproducibility or repeatability.

Specificity

The ability to detect a range of the agent, which demonstrates whether the method is fit for the intended purpose. It should also be demonstrated to be compatible with the expected range of sample types.

Limit of detection

The lowest number of the agent that can be detected, but not necessarily quantified.

Limit of quantification

For assays where quantification of low levels of microorganisms is critical, it is the lowest number of microorganisms that can be determined with acceptable precision and accuracy.

Linearity

The ability to determine results that are proportional to the concentration of the agent within a given range.

Ruggedness

The degree of reproducibility of results from analysis of the samples under a variety of normal conditions (different analysts, instruments, lots of reagents, etc.). It can be expressed as a lack of influence of operational and environmental variables on the method.

Robustness

It is a measure of the methods capacity to remain unaffected by small but deliberate variations in the method parameters. It provides a measure of reliability during normal use.

Range

The interval between upper and lower levels that have been determined with acceptable precision, accuracy, and linearity.

(Data from Microbiology Guideline: AOAC International qualitative and quantitative microbiology guidelines for methods validation. *J AOAC Int* 1999;82:404–416; General Information <1225>. Validation of compendial methods. United States Pharmacopeia 26, National Formulary 27. Rockville, MD: The United States Pharmacopeial Convention, Inc., 2003:2439–2442.)

The following validation parameters to consider during a quantitative method validation are accuracy, precision, ruggedness, robustness, specificity, limit of detection, limit of quantification, linearity and range. Parameters to assess

during validation of qualitative methods are specificity, limit of detection, and ruggedness (Box 72-12) (2). Before approval of a validated method, it may be necessary to consider results from interlaboratory and intralaboratory validations to allow various analytical groups (experienced and nonexperienced) an opportunity to interpret and execute the method, impart deliberate documented minor changes, and utilize their own analytical materials and equipment. The qualitative method is generally validated to detect the presence of a low concentration of the agent in question (e.g., growth of the agent in selective cultures and PCR methods). The quantitative method is generally validated to enumerate the concentration of the agent from a specific sample area collected.

CONCLUSION

Though microbiologic sampling of the environment appears at first glance to be a simple task, each of the sampling strategies and methods discussed in this chapter is complex, and the success of the sampling endeavor depends on meticulous attention to details in sampling design and aseptic technique. Environmental sampling may never be extremely precise because of all the variables that come into play when utilizing culture methods. A good sampling strategy for the various investigation phases, a consistent approach, understanding the limitations of the different sampling methods, and knowledge of the target microorganism are the most important factors in obtaining the best possible information from a microbiologic environmental sampling event.

SECTION X

Epidemiology and Prevention of Healthcare-Associated Infections in Healthcare Workers

CHAPTER 73

Prevention of Occupationally Acquired Viral Hepatitis in Healthcare Workers

David K. Henderson and Susan E. Beekmann

Viral hepatitis was first recognized as an occupational hazard for healthcare workers nearly half a century ago when a blood bank worker acquired viral hepatitis after sustaining multiple needlesticks *(1)*. Since then, we have witnessed an explosion of knowledge in the fields of both basic virology and healthcare epidemiology. Five primarily hepatotropic viruses (hepatitis A–E, see Hepatitis Viruses, Chapter 46) have been identified and characterized, their modes of occupational transmission have been determined, and strategies for prevention have been developed. This chapter addresses the healthcare-associated epidemiologies of these five agents and does not specifically address the several additional agents that currently contribute to the viral hepatitis alphabet, including the agent called hepatitis French (origin) virus (HFV) (hepatitis F) *(2)*; the bloodborne "GB" agents (GB virus A [GBV-A], GB virus B [GBV-B] and GB virus C, [GBV-C] *(3,4)* which rarely cause hepatitis; and hepatitis G virus (HGV), a common, easily transmitted bloodborne agent that is closely related to GBV-C, which causes clinically mild, if any, hepatitis (5,*6–8*), and may not, in fact, be hepatotropic *(9)*. Until these "non-A–E hepatitis" viruses, and other putative hepatitis agents *(10–12)* are formally recognized as hepatitis viruses and have their respective epidemiologies delineated, general infection control practices for protecting healthcare workers from enterically transmitted or parenterally transmitted agents, as appropriate, are indicated. This chapter focuses on the etiology of occupationally acquired viral hepatitis, the epidemiology of these viruses in the healthcare setting, and the specific prevention and control strategies for each of the five hepatotropic agents identified above.

ETIOLOGY AND EPIDEMIOLOGY

The risk of occupational transmission of each of the hepatitis viruses differs according to the infective body substance, the modes of transmission, the occupations and work responsibilities of individual healthcare workers, the varying prevalences of infection in the patient population, healthcare workers' immune statuses, and the individual worker's compliance with infection control procedures. An overview of the five major hepatitis viruses, risks for occupational transmission in the healthcare setting, modes of occupational transmission, relevant prevention strategies and currently imprecise or unanswered questions is presented in Table 73-1. Factors affecting the risks for occupational transmission for each virus are discussed separately, below, in more detail.

Hepatitis A Virus

Although healthcare workers are generally not considered to be at substantially increased risk for acquiring hepatitis A virus (HAV) infection *(13–17)*, occupational transmission of this virus has been well documented and occurs, albeit rarely, under unusual circumstances. Most HAV transmission in healthcare settings occurs from index patients who are asymptomatic, from those in whom the infection is otherwise unsuspected and/or undiagnosed, from patients who are in the prodromal phase of the infection when viral shedding in the stool is maximal, in instances in which when infection control procedures are less than optimal, and/or in settings in which patients are incontinent of feces *(18–33)*. Occupational HAV transmission occurs primarily

TABLE 73-1

Major Hepatitis Viruses and Occupational Transmission to Healthcare Workers

Feature	*Hepatitis A (HAV)*	*Hepatitis B (HBV)*	*Hepatitis C (HCV)*	*Hepatitis D (HDV)*	*Hepatitis E (HEV)*
Occupational transmission problem	Rare	Common	Infrequent	Uncommon	Rare
Major mode of occupational transmission	Fecal/oral	Blood	Blood	Blood	Fecal/oral
Isolation precautions for patient	Standard Precautions	Standard Precautions	Standard Precautions	Standard Precautions	Standard Precautions
Prophylaxis for occupational exposure	IG	Hepatitis B vaccine and HBIG	None	Hepatitis B vaccine and HBIG for persons without HBV infection; none available for HBV carriers	Vaccine in development
Controversy/ alternative approaches/ unresolved issues	Adjunctive HAV immunization for individuals at-risk	Additional booster dose of HBV vaccine for healthcare workers who fail to maintain protective antibody levels	No postexposure prophylaxis, but some advocate either "preemptive therapy" or "watchful waiting" (see text)	None	None

IG, immune globulin; HBIG, hepatitis B immune globulin.

via the fecal–oral route, following direct or indirect contact with the index patient's fecal material and is generally only recognized when a cluster of cases occurs. Although healthcare workers can acquire HAV from contaminated food or drink *(34–36)*, occupational infection usually occurs following direct contact with infectious patients. Neonatal intensive care units may provide a unique setting for healthcare-associated/occupational transmission, because several reported outbreaks, some with widespread secondary transmission, have occurred in this setting *(20,22,23,28,31,37,38)*. Outbreaks in neonatal intensive care units have most frequently followed the rare occurrence of transfusion-acquired infection of a neonate. Unless staff members practice strict hand washing and environmental cleaning, neonatal and pediatric intensive care settings may provide optimal opportunities for fecal contamination of healthcare workers' hands and environmental surfaces. HAV can survive on workers' hands and this aspect of HAV epidemiology may contribute to the indirect spread of the virus to other patients and staff members *(39)*.

Although occupational HAV infection occurs rarely in US healthcare workers, seroepidemiological studies in other countries suggest that selected healthcare workers may be at increased risk for occupational infection. One study proposed that HAV is an occupational hazard in Germany, ranking third, with respect to morbidity statistics, among infectious occupational diseases, based on frequency of compensation *(40)*. Compared to the general population, medical occupational groups with the highest anti-HAV seroprevalences, in decreasing order, included medical charwomen, foodhandlers, pediatric nurses, other nurses, and physicians. Another study in Belgium found that healthcare workers in a pediatric hospital had a higher seroprevalence of anti-HAV than workers in general hospitals *(41)*, and a study in France reported a higher seroprevalence among nursing staff when compared to nonmedical employees *(42)*. A study of healthcare personnel in Korea found no evidence of occupational infection, an overall prevalence of prior infection in 28.3%, and a substantial increase in seroprevalence associated with increasing age *(43)*. Of interest, lower seroprevalences were identified among physicians between the ages of 25 and 39 *(43)*.

Various studies have investigated risk factors for occupational infection with HAV. Factors that facilitate fecal–oral spread enhance transmission. Fecal material from most normal HAV-infected patients is usually easily contained and presents a limited risk to staff members who practice good hand washing and rigorously follow infection control procedures. Conversely, patients who are incontinent of feces and those who have diarrhea present a much

higher risk. Factors associated with occupational infection include an index case with diarrhea or incontinent of feces *(19,21,22,24–27,29,30,32)*; an index case hospitalized during the prodromal period of maximal virus fecal excretion *(18,19,21,24–30,44)*; adult patients who have poor hygiene *(44)*; and less-than-optimal adherence to recommended infection control procedures, including lack of adherence to Standard and/or Contact Precautions *(29,33,38,44)*. One study identified four additional activities that may have enhanced fecal–oral spread in the occupational setting: sharing food with patients or their families, drinking coffee, sharing cigarettes, and eating in the nurses' office on an intensive care unit *(30)*. Another study *(31)* identified risk factors for transmission to staff during an outbreak in a neonatal intensive care unit, including caring for an infant with HAV infection, drinking beverages in the unit, and not wearing gloves when taping an intravenous line. This study also documented prolonged viral excretion in infected neonates; some infected infants excreted virus for 4 to 5 months after infection. This prolonged period of viral excretion in neonates and infants may also contribute to the risk for healthcare-associated transmission. Other studies in neonatal intensive care units found that risk of occupational infection was greater among staff members who did not routinely wash their hands after treating an infected infant *(38)* and among staff members who cared for the index (i.e., infected) case for longer periods of time *(28)*. Another outbreak investigation in a burn treatment center implicated eating on the hospital ward as the single most important risk factor for HAV infection among staff members *(45)*. Vomitus, bile-stained emesis, or bile-contaminated nasogastric suction material may also serve as a reservoir for HAV transmission *(21,25,29,46)*, since there is evidence that HAV is excreted in bile *(47)*. One study that involved an index patient who had neither diarrhea nor fecal incontinence identified intensive handling of infectious bile, rather than contact with feces, as the most likely mode of transmission *(46)*. Other likely factors contributing to this outbreak included inadequate terminal cleaning of equipment, food consumption in the unit, and inadequate hand-washing practices *(46)*. Recent studies have documented decreasing risks for HAV infection, in great measure due to improving sanitary conditions and aggressive vaccination of populations at risk (*43,48,*49).

Because most patients are hospitalized for hepatitis A only after they become jaundiced, (and at a time when viral excretion is often substantially reduced from peak excretion during the prodromal stage of infection), these patients are generally considered less infectious. Although fecal excretion of HAV may persist longer in children than in adults, quantitative determinations may be important to determine the risk of exposure to infected pediatric patients *(50)*.

Reported attack rates for occupationally acquired HAV have varied, ranging from a low of 2% of exposed susceptible staff members *(29)*, to 10% *(21)*, 12% *(24)*, 4% to 16% *(23)*, 3% to 30% *(28)*, and 21% to 50% *(25)*. Reasons for the wide variability in attack rates may include differing definitions of occupational exposure to the index case, differing levels of infectivity of source patients, differing intensity of exposures, and the effectiveness and timing of prophylactic immunoglobulin administration.

Hepatitis B Virus

Historically, the highest risk for occupationally acquired hepatitis among healthcare workers has been associated with exposure to hepatitis B virus (HBV); in fact, before the advent of the hepatitis B vaccine, HBV infection was *the* major occupational risk to healthcare workers *(51)*. In the 1980s, the annual incidence of HBV infection among healthcare workers in the United States was staggering. The Centers for Disease Control and Prevention (CDC) estimated that in the mid-1980s approximately 12,000 HBV infections occurred annually in healthcare workers who had frequent occupational exposure to blood or other potentially infectious materials, with an annual rate of infection between 4.89 and 6.63 per 1,000 exposed susceptible workers *(52)*. Of these 12,000 occupationally infected workers each year, CDC scientists estimated that 3,000 developed symptomatic clinical illnesses, more than 600 were hospitalized, and more than 250 of these healthcare workers died. CDC estimated that between 600 and 1,200 of these healthcare workers became chronic hepatitis B carriers. Since the HBV vaccine was developed and aggressive hepatitis B vaccination of healthcare workers in the United States has been promoted, HBV infections among healthcare providers has decreased dramatically to an estimated 400 annually by 1995 (53).

Numerous studies have documented that healthcare workers exposed to blood are at high risk for acquiring HBV infection. In one of the earliest studies, Williams et al. *(54)* investigated a large epidemic of hepatitis B infections among hospital personnel and found that clinical hepatitis attack rates and HBV antibody prevalence rates correlated with occupational exposure to blood from patients being treated with hemodialysis. Transmission was thought to occur by both accidental parenteral and so-called inapparent parenteral routes of inoculation of contaminated blood. Pattison et al. *(55)* studied workers in a large community hospital between 1972 and 1974 and found a significant association between frequency of blood contact and prevalence of HBV, but no association between frequency of patient contact and HBV prevalence. The first nationwide, cross-sectional seroepidemiological survey of occupationally acquired HBV infection among physicians was conducted by Denes et al. *(56)* in 1975 to 1976. These investigators found that infection rates were higher among those practicing in urban settings, that the risk for infection increased with the number of years in practice, and that infection rates were highest among pathologists and surgeons. Dienstag and Ryan *(57)* studied workers at a large urban hospital and found that the prevalence of HBV serologic markers increased as a function of contact with blood, years in a healthcare occupation, and age, but not as a function of contact with patients, years of education, previous needlestick, transfusion, or globulin injection. The highest seroprevalences were found among emergency room nurses, pathology staff members, blood bank staff members, laboratory technicians, intravenous teams, and surgical house officers. Similar high-risk occupations (emergency room, medical and surgical intensive care units, and dentistry–oral surgery) were identified by Jovanovich et al. *(58)* in a study conducted in an urban hospital.

Snydman et al. *(59)* conducted a multi-institutional seroepidemiological survey of hospital employees in 1980

and 1981 and found that the duration of employment for laboratory workers, surgical staff members, and medical staff members was associated with increased risk for having HBV markers. In this study, the highest gradient of risk in these occupations occurred during the first 5 years of employment. Another large multi-institutional study of nearly 5,700 hospital employees conducted by Hadler et al. *(60)* controlled for nonoccupational risk factors and confirmed the earlier findings of Dienstag and Ryan that occupational blood exposure, but not patient contact, was associated with risk for prior HBV infection. Hadler and coworkers also found that the frequency of needle accidents during daily work was directly related to HBV seroprevalence. The occupational group with the highest HBV infection rate was clinical laboratory and blood bank technicians, who routinely handled large numbers of blood specimens. In general, these and similar studies in the pre–HBV-vaccine era may be summarized by noting that healthcare workers who have occupational exposure to blood had a prevalence of HBV markers several times both that of workers who did not have blood exposure and that of the general population. This prevalence of HBV infection increased with increasing years of occupational exposure. HBV infection was related to the degree and frequency of blood exposure and not to the degree of patient contact. West reviewed studies evaluating the risk for HBV infection in healthcare providers and found the risk to be approximately four times elevated when compared to the risk for infection in the at-large adult population *(61)*. In West's review, physicians and dentists were found to be five to 10 times more likely to experience hepatitis B infection and surgeons, dialysis personnel, personnel providing care for developmentally disabled individuals, and clinical laboratorians to be at 10-fold or higher risks for HBV infection *(61)*.

The risk of occupational exposure to HBV depends on several other factors besides occupation and frequency of occupational exposures. The prevalence of HBV infection in the patient population also influences the risk for occupational exposure. Because HBV prevalence is generally higher in urban settings, workers in urban hospitals have been found to be at higher risk for HBV infection *(56)* than are workers in rural hospitals *(62)*. Renal dialysis patients (see also Chapter 63) who require frequent blood transfusions and have suppressed immune responses have long been known to be at high risk, both for acquiring HBV infection and for developing chronic HBV infections. For this reason, staff caring for dialysis patients are at increased risk for occupational HBV infection *(61,63,64)*. Workers in hospitals serving large numbers of other patient population groups at risk for HBV infection, such as intravenous drug users, homosexual men, prison inmates, the developmentally disabled, or immigrants from highly endemic areas, are also at higher risk for occupational exposure and infection with HBV *(65)*. Patients who are asymptomatic HBV carriers are the primary reservoir for HBV infection in the healthcare setting. Broad-scale testing to identify infected patients is neither practical nor cost-effective. In one study, testing patients who reported a history of hepatitis would have detected fewer than 20% of HBV-infected patients *(66)*.

The infectivity of the source material also influences the risk of acquiring HBV infection. Although hepatitis B surface antigen (HBsAg) has been detected in nearly all body fluids, blood is considered the most infectious and is probably responsible for most occupationally acquired infections. The infectivity of blood is generally correlated with the presence of increased circulating viral burdens, HBV DNA polymerase activity, or hepatitis B e antigen (HBeAg) in the blood. The risk for HBV infection after a percutaneous ("needlestick") exposure to blood from an HBV-infected individual has been estimated to range from 19% to 37% if the donor blood is HBeAg positive *(67,68)*. In the dental setting, saliva, particularly bloody saliva, is also considered to represent a substantial infectious risk.

The type of exposure to blood or other potentially infectious materials also influences the risk of acquiring infection. Percutaneous exposures, such as needlesticks or injuries with contaminated sharp instruments, are associated with the highest risks for occupational infection. Very small inocula of HBsAg-positive blood may produce infection, since the blood of acute or chronic HBV carriers may contain as many as 10^{13} virus particles of HBV per milliliter of blood *(51)*. Infectivity studies in chimpanzees have demonstrated that serum positive for HBeAg is infectious in dilutions up to 10^{-8} *(69)*. Despite the fact that percutaneous exposures are the most efficient route of infection, CDC estimates that fewer than 20% of HBV-infected healthcare workers recall an injury/exposure of this type *(70)*. Thus, other, so-called inapparent parenteral exposures account for a substantial fraction of occupational HBV infections. Preexisting cuts, dermatitis, other skin lesions, or mucous membranes may provide portals of entry for HBV infection. Blood-contaminated inanimate objects or environmental surfaces also have been implicated in occupational transmission in certain settings. In one study, sustaining paper cuts while handling laboratory computer cards in a hospital clinical laboratory was associated with an outbreak of HBV infection *(71)*. Before strict infection prevention measures were implemented in hemodialysis centers, environmental contamination with blood that subsequently resulted in contaminated workers' hands was hypothesized to facilitate HBV transmission *(72,73)*. Contamination of mucous membranes of the eye or mouth, which may occur with accidental splashes or pipetting accidents, also may result in HBV transmission *(74)*.

In the past 25 years, seroprevalence studies in healthcare workers have documented the importance of hepatitis B vaccine in preventing infections. Thomas et al. *(75)* studied 943 healthcare personnel in an inner city hospital. Their multivariate analysis identified only one risk factor—absence of HBV vaccination—to be independently associated with HBV infection in this population of healthcare workers. Similarly, Panlilio et al. *(76)* studied 770 surgeons for markers of HBV infection and found two risk factors—not receiving hepatitis B vaccine and practicing surgery for at least 10 years—for HBV infection. Another study in 114 operating room personnel in Pakistan also documented that nonvaccinated workers were more likely to be infected with HBV *(76)*. Supplementing these seroprevalence studies, Lanphear et al. *(77)* investigated the incidence of clinical HBV infection in hospital workers and found a dramatic decrease associated with increased immunity due to vaccination.

Hepatitis C Virus

Our current understanding of the role of hepatitis C virus (HCV) in occupationally acquired infections is less clear than for HAV and HBV and is complicated by the evolving understanding of the pathogenesis and immunopathogenesis of exposure and infection with this flavivirus (see also Chapter 46). Since the parenteral mode of transmission of HCV has been clearly established as a primary route of infection for transfusion recipients and intravenous substance users, by analogy to HBV, occupational transmission of HCV in the healthcare setting—including transmission from patients to staff, from patient to patient, and from infected providers to their patients—is likely to be linked to apparent and inapparent parenteral exposure to blood. To date, exposure to blood remains the primary vehicle for occupationally acquired HCV infection as is evidenced by the overwhelming majority of the cases of occupational infection that have been described in the literature *(78–94)*. HCV also has been transmitted by a punch *(95)*. HCV RNA has been detected in saliva *(96–98)*, and two cases suggest that transmission of HCV occurred following human bites *(99,100)*. Abe et al. *(101)* also provided experimental documentation of HCV transmission by saliva. When present in saliva, HCV titers are lower than in blood. The potential infectivity of saliva may have important implications for patient to provider transmission, primarily in the dental healthcare setting. HCV RNA also has been detected in a variety of other body fluids from infected patients, including menstrual fluid *(102)*, semen *(98,103,104)*, urine *(98)*, spinal fluid *(105)*, and ascites *(98)*. The relevance of these latter body substances to the transmission of HCV is unclear. One recent study demonstrated transmission of HCV as a result of a nurse providing care for a patient with severe epistaxis and concluded that the transmission occurred as a result of the exposure of the nurse's nonintact skin to the patient's blood *(106)*. In summary, blood is the body substance that presents the most risk for HCV transmission in the healthcare setting. Despite the fact that transmission of HCV resulting from exposures to body fluids other than blood has not yet been documented; presumably because viral titers in these fluids are substantially lower than in blood, other body substances may present measurable risks for occupational infection, particularly if the healthcare worker is exposed by the parenteral route and/or receives a large inoculum.

Parenteral exposures represent the primary mode of occupationally acquired infection, as is evidenced by the overwhelming majority of the cases of occupational infection that have been described in the literature *(82–94)*. However, two cases of HCV infection have been documented following mucosal exposures to blood *(107,108)* and one case has been associated with exposure of "nonintact skin" to blood *(106)*. Extensive HCV environmental contamination of instruments and surfaces in hemodialysis *(109–113)* and dental surgery settings *(114)* can occur, and such HCV environmental contamination has been suggested to play a role in transmission of HCV (115). However, to our knowledge, transmission of a specific HCV strain through environmental contamination has not yet been documented. Transmission resulting from environmental contamination should be an extremely unlikely consequence if proper sterilization and disinfection procedures are practiced and if current standards of infection control, particularly hand hygiene, are followed.

Numerous cases of healthcare-associated transmission from patient to patient (often as a result of cross-contamination from an index case, for example, in hemodialysis, from multidose vials for sequential patients, reuse of spring-loaded finger-stick devices, and contamination of endoscopes and other devices for invasive procedures) have been reported in the literature. The past 5 years have seen a disturbing increase in the detection of such cases *(116–126)*. A detailed discussion of this topic is beyond the scope of this chapter (see also Chapter 46).

Recognizing the epidemiological similarities between HCV and HBV, several investigators attempted to assess the risk of occupational infection by testing healthcare workers for the serological prevalence of HCV antibodies, when serologic tests for HCV became available. Interpretation of these studies must take into account both the limitations of the serological assays *(127)* and the inadequacy of assessing only the humoral immune response as a measure of exposure and HCV infection *(128)*. Many of the published studies employed the first-generation anti-HCV test that detects an antibody directed against a nonstructural HCV protein, anti-c100-3, and that has low sensitivity and specificity for diagnosing HCV infection when compared with second- and third-generation tests. Even later-generation anti-HCV antibody tests still may not detect 100% of infected persons, and tests designed to detect circulating HCV RNA may be necessary to identify some infected individuals. In addition, the anti-HCV tests have a high rate of false positivity in populations with a low prevalence of infection, and supplemental tests for specificity are necessary. The recombinant immunoblot assay (RIBA) or another supplemental HCV neutralization assay should be used to verify repeatedly reactive enzyme immunoassays. Even HCV RNA detection assays are problematic. These tests are subject to false-positive and false-negative results following improper collection, handling, or storage of test samples, and their interpretation is not conclusive: a single negative test may not indicate lack of infection but may be due to fluctuating RNA levels *(129)* and a single positive test should be repeated to exclude the high likelihood of contamination and a false-positive assay. In summary, the evolving diagnostic technology has complicated comparisons of HCV seroprevalence and incidence among the various published studies. Keeping these limitations in mind, Table 73-2 summarizes published studies of anti-HCV seroprevalence among many diverse types of healthcare workers (*75,76,130–155,*156,*157–176*).

In addition to the substantial variation in study design, the differences in healthcare worker populations studied, and the differences in the technologies used for detection, other considerations further complicate comparing and interpreting these studies. HCV seroprevalence varies geographically, so similar occupational groups from different locations cannot be compared directly, and local comparison groups are needed for determining if particular healthcare worker groups are at increased risk. Because blood donor seroprevalence data are readily available, blood donors were often used for comparison in these prevalence studies. However, blood donors are not a good comparison group, because they are preselected to avoid a history of

hepatitis as well as a history of risk factors for bloodborne infections *(177)*. Most of these studies were not designed to investigate risk factors for HCV seroprevalence, or had too few HCV-seropositive subjects to do so. Those studies that did identify risk factors for HCV infection found associations with increasing age *(141,162)*, years in healthcare occupations *(143,158,162)*, a history of blood transfusions *(140,162)*, and a history of prior needlestick injuries *(140,151)*. In aggregate, given the limitations of the study designs, testing methodology, and selection bias, these studies suggest that healthcare workers' risk of HCV infection is only minimally higher than that of volunteer blood donors and appears to be approximately 10-fold lower than the occupational/healthcare-associated risks posed by HBV in the healthcare setting.

Table 73-3 summarizes the results of HCV incidence studies conducted in various populations of healthcare workers who had sustained occupational exposures to HCV *(86,90,147,149,155,157,162,178–195)*. Although most of studies employed anti-HCV antibody testing as the primary detection system for HCV infection, nine of the studies used polymerase chain reaction (PCR) technology to attempt to detect HCV RNA as a marker for infection among individuals who had sustained parenteral exposures to blood from patients known to harbor HCV infection *(90,147,180,187,189–191,193,195)*.

Several factors contribute to the wide variance in the transmission rates (0–22.2%) observed in these studies, among them: different study designs and testing methods, widely differing sample sizes, variable populations of workers followed, different types of exposures, different infectivity of source patients, and potential geographical variability. Recognizing these limitations and acknowledging that the studies are not directly comparable, the pooled infection rate following percutaneous exposures was 1.9%. The risk for infection following other types of exposures has been less intensively studied, but, to date, no infections have been identified in the longitudinal studies following either mucous membrane or other less commonly occurring exposures. Monitoring for infection by measuring HCV RNA may be a more reliable marker for HCV viremia and infectivity *(181,196–198)*, but even when PCR monitoring is combined with antibody testing, the risk for infection may still be underestimated because neither of these technologies will identify individuals who mount only a brisk cellular response and quickly clear the infection *(128)*. Noting all of these limitations, if one pools the data from the nine studies that used RNA PCR testing, the calculated transmission rate for percutaneous injuries is somewhat higher (3.6%) than is found in the studies assessing incidence by anti-HCV antibody tests alone.

At least four cohort studies of hospital workers initially negative for anti-HCV have attempted to measure the incidence of HCV infection. In the first study, samples collected from 960 dental staff during 1979 to 1981 were retrospectively tested for anti-HCV and two were found to seroconvert, for an incidence of 0.15 per 100 person years of follow-up *(138)*. In the second, in a cohort of hospital staff in Cincinnati followed from 1980 to 1989, 6 cases of occupationally acquired non-A, non-B hepatitis occurred, for an incidence of 21 cases per 100,000 healthcare workers per year *(155)*. Four of the six cases were confirmed to be HCV infection. This incidence was approximately three times higher than that of nonhealthcare workers. The third study followed 765 hospital workers in Italy who were screened for HCV in 1986 and retested in 1992 *(159)*. One worker became infected, for an annual incidence of HCV infection of 0.02%. The fourth cohort study, conducted in San Francisco, observed a single seroconversion between 1984 and 1992, and found an incidence density rate of 0.08 per 100 person years (156). For perspective, this study also measured an incidence density rate of 3.05 per 100 person years for HBV among nonvaccinated susceptible workers and 0.055 for human immunodeficiency virus (HIV). A population-based surveillance system for acute viral hepatitis in Italy found that in 1991 healthcare workers were 2.95 times as likely to acquire acute hepatitis C compared to the general population, and in 1994 they were 1.72 times as likely *(199)*.

(Adapted from Henderson DK. Managing occupational risks for hepatitis C transmission in the health care setting. *Clin Microbiol Rev* 2003;16(3):546–568.)

The findings of a low seroprevalence of HCV infection among healthcare workers and the moderate risk of documented transmission by needlestick injury suggest that the occupational risk of HCV infection exists and is intermediate between the 0.3% per percutaneous exposure risk for occupational HIV exposure *(200)* and the 19% to 37% risk for parenteral exposure to an "e" antigen-positive, HBV-infected source *(67,68)*. The most probable reason for the lower risk is that titers of HCV circulating in blood are relatively low (probably 2–3 logs lower than HBV titers, as noted above) *(69,199)*, so that transmission by small inocula such as needlesticks or other injuries in the occupational setting is less efficient than is the case for HBV. However, because most HCV infections are persistent, the prevalence of HCV infection in some patient populations actually may be higher than for hepatitis B (201), providing a larger pool of potential sources for occupational infection. Because of the wide variability in HCV prevalence by geographic region and patient populations, occupational risk will necessarily vary by these conditions.

As noted above, recent studies of the immunopathogenesis of HCV infection suggest that none of the techniques that have been applied in the longitudinal studies of risk for occupational HCV infection may provide a true denominator of healthcare workers sustaining occupational HCV infections. Anecdotal case reports document HCV antigen circulation in individuals who never made anti-HCV antibody, despite the development of productive HCV infection *(202)*. Additionally, some investigators have suggested that both antibody tests and tests for circulating HCV nucleic acid underestimate the true denominator of exposures, further suggesting that the most sensitive measure of past exposure may well be assessment of specific cellular immunity directed against HCV *(128)*. As noted above, none of the longitudinal studies of healthcare workers measured cellular immune responses.

Further cohort incidence studies and exposure follow-up studies, with larger numbers of workers, employing both HCV RNA testing and sensitive measures of cellular immune

responses directed against HCV will be needed to define more precisely the occupational risk of HCV infection.

Hepatitis D Virus

Hepatitis D virus (HDV), formerly called the delta agent, is a defective virus that needs HBV as a helper virus (see also Chapter 46). Thus, HDV may infect healthcare workers either as a coinfection with HBV (i.e., a simultaneous exposure) or as a superinfection when healthcare workers already have HBV infection. The extent of HDV infection in healthcare workers has not been determined, because HDV antibody testing is not routinely performed *(203)*. Even if HDV antibody screening were routine, the prevalence would be difficult to determine, because infection may elicit only a transient and low-titered response *(204)*. Nevertheless, there is anecdotal evidence for occupational HDV transmission in a hemodialysis nurse *(205)*, and documented evidence for transmission to a surgeon following a deep needlestick injury *(206)*.

Because of its dependence on HBV, the epidemiology and mode of transmission of HDV are similar to those of hepatitis B. Worldwide, approximately 5% of HBsAg carriers are infected with HDV *(207)*. However, not all HBV-infected individuals have the same risk for HDV infection, because geographic and risk group distribution vary substantially. Patient populations that include HBV-infected persons from HDV-endemic areas, such as southern Italy, the Amazon basin, the Middle East, and certain Pacific islands, are more likely to be coinfected with HDV and, therefore, present a greater risk to healthcare workers. Among risk groups for HBV infection, HBV-infected hemophiliacs, intravenous drug abusers, and hemodialysis patients are more likely to be coinfected with HDV than are homosexual men. A major benefit of the efficacy of the HBV vaccine has been a significance decrease in HDV infections in high prevalence areas (49).

Hepatitis E Virus

The etiologic agent of the syndrome of enterically transmitted non-A, non-B hepatitis prevalent in India, Pakistan, Nepal, southwestern China, central Asia, the former Soviet Union, and parts of Africa and Mexico is now recognized to be the hepatitis E virus (HEV). HEV is not prevalent in the United States, although the disease has been imported from endemic areas by immigrants or travelers *(208–212)*. However, although still very rare, the first cases acquired within the United States have been reported *(213)*, and a new strain, called HEV US-1, has been identified as the cause in one instance *(214,215)*. Caution is required when interpreting results from seroprevalence studies; results of assays for antibody to HEV vary widely and are highly discrepant among populations in non–HEV-endemic areas *(216–218)*.

HEV, as is the case for HAV, is transmitted by the fecal–oral route. In the epidemic setting, fecal contamination of water is the most common vehicle for transmission *(219)*. Although person-to-person transmission can occur, infection in household contacts is uncommon *(220)*, suggesting that this mode of transmission is relatively inefficient. Some studies have suggested that animals may be a reservoir for HEV infection *(221)*. Medical staff members in refugee camps have become infected *(222)*. However, the exact mode of transmission in this report is unknown, and the fact that sanitation conditions in refugee camps differ significantly from those in most healthcare settings must be recognized. As with HAV, a period of viremia occurs during the prodromal phase of illness, before virus is shed in the feces, so bloodborne transmission is also possible *(223)*. Presumptive transmission of HEV to a doctor and two nurses has been reported following exposure to amniotic fluid, blood, and stool from a patient with acute hepatitis E acquired following travel to India *(224)*. Until more information becomes available, the risk for occupational acquisition of HEV by healthcare workers in most settings should be considered real, but rare, occurring only under distinctly unusual circumstances in the United States.

Some evidence suggests that hepatitis E may have a zoonotic reservoir, with pigs and possibly rats serving as reservoirs for human infection *(221,225)*. In fact, pigs have been identified as a potential reservoir, even in industrialized countries *(226,227)*. In support of this latter concept, one paper suggests a risk to surgical trainees who work with swine *(228)*. Critical information about hepatitis E and its etiology, epidemiology and prevention has been developed over the past 30 years, and serologic tests have been developed and used extensively to characterize HEV epidemiology. When the prior edition of this text was published in 2003, a candidate vaccine was already being evaluated in phase III clinical trials; nonetheless, no vaccine has yet been marketed. One study conducted in a high-risk population in an endemic area demonstrated that a recombinant HEV vaccine was highly effective in the prevention of hepatitis E (229).

PATHOGENESIS

Other than the clear association of needles, scalpels, and other medical "sharps" with the bloodborne hepatitis syndromes, the pathogenesis of these syndromes in the healthcare setting is not substantially different from the pathogenesis in the community. Chapter 46 thoroughly discusses the pathogenesis of these syndromes.

CLINICAL MANIFESTATIONS

Similarly, the clinical manifestations of the viral hepatitis infections arising as a result of occupational exposures in healthcare workers are not distinct from those in other adults (see also Chapter 46). An exception may exist for occupationally acquired HCV. One follow-up study suggested that, when hepatitis C develops following occupational exposure, the disease tends to be mild and transient *(180)* in contrast to posttransfusion-acquired hepatitis C, which tends to become persistent and chronic. Another study of community-acquired HCV infection, however, found that the frequency of development of chronic hepatitis is similar regardless of how the HCV infection is initially contracted but that severe chronic disease in the form of chronic active hepatitis is more common following transfusion-acquired infection (perhaps because of an inoculum effect) (230). Further studies are needed to confirm these preliminary observations.

DIAGNOSIS

The diagnosis of hepatitis infections in healthcare workers who have sustained occupational exposures is no different from diagnosis in a patient presenting with a hepatitis syndrome (see also Chapter 46). One diagnosis-related issue that is worthy of some emphasis (especially when the source patient is known) is that of determining the hepatitis infection status of the source patient. When the source patient is identifiable and the hepatitis infection status is not known, documenting the source patient's infection status will facilitate both risk assessment and the healthcare worker's postexposure management and follow-up and, in the event that the source patient is found to be infected with the same virus, will likely solidify the healthcare worker's compensation claim. As is done with postexposure testing of source patients for HIV infection, we feel strongly that such testing should be done with the informed consent of the source patient. State laws vary regarding the need for informed consent for testing. In occupational exposure settings, some states permit testing of available serum without consent. Hospitals and infection control committees should construct (and follow) policies that are consonant with their state and local laws. A major controversy currently exists concerning the use of periodic monitoring by RNA PCR of healthcare workers who have sustained occupational exposures to a source patient's blood for the so-called preemptive therapy or watchful waiting strategies (231) (discussed in more detail below).

PREVENTION AND CONTROL

As the hepatitis viruses differ in their modes of transmission and mechanisms of immunity, so will their methods of prevention and control. Components of a multidimensional prevention program include (a) education and training of staff members, (b) administrative controls (identification and isolation of infectious patients), (c) engineering controls (e.g., adequate hand-washing facilities, proper selection, and use of sharp disposal containers *(232)* and safety equipment such as protective needle-safety devices), (d) safe work practices and appropriate use of protective barrier equipment to minimize occupational exposures (practicing Standard [Universal] Precautions with all patients), and (e) employee immunization and postexposure management through occupational health services. Prevention of HAV and HEV infection focuses primarily on interrupting fecal–oral transmission, whereas HBV, HCV, and HDV are bloodborne pathogens requiring different precautions and strategies. Education and training of staff members regarding the methods of infection control and specific prevention strategies is the most important and fundamental component of prevention. When accidental exposures occur, appropriate postexposure prophylaxis, if available, should be administered. Postexposure prophylaxis strategies vary for each virus; currently, HAV and HBV are the only hepatitis viruses for which there are vaccines for preexposure prevention and immune globulins for postexposure prevention; however, as noted above, a hepatitis E vaccine has been shown to be safe and efficacious.

Hepatitis A Virus

To prevent occupational transmission of HAV, healthcare workers should practice good basic infection control techniques, particularly strict hand washing, with *all* patients. Because virus is shed in the feces in the highest concentrations during the incubation period and early in the prodromal period (when hepatitis A infection may not be suspected), identifying and isolating infectious patients may not be possible. In the neonatal or pediatric hospital setting in particular, HAV infections are usually asymptomatic and unsuspected. Hospitalized patients known to have had a recent exposure to known or suspected hepatitis A should undergo serologic studies, should receive appropriate immunoprophylaxis, and should be isolated appropriately. When a patient is known or suspected to have hepatitis A or has unspecified hepatitis consistent with a viral etiology, the CDC traditionally recommended enteric precautions through the first week after onset of jaundice *(233)*. The CDC's current guidelines recommend Standard Precautions for most patients with hepatitis A, but Contact Precautions for patients who are diapered or incontinent *(234)*. Contact Precautions should be maintained for the duration of the hospitalization for infants and children <3 years old, for 2 weeks after onset of symptoms in children 3 to 14 years old, and until 1 week after onset of symptoms for others. Standard Precautions dictate that gloves should be worn when handling all feces or feces-contaminated articles from all patients. Gloves should be worn routinely for contact with patients who have diarrhea or are incontinent of feces. To minimize inapparent contact with fecal material, healthcare workers should wash their hands after even minimal patient contact, and environmental contamination must be minimized by cleaning and disinfection procedures.

In the event of occupational exposure to HAV, postexposure prophylaxis with immune globulin (IG) is recommended *(65,235,236)*. Immunization with the hepatitis A vaccine is another reasonable postexposure immunoprophylaxis strategy, with or without the passive administration of immunoglobulin. As a practical matter, however, IG is seldom used during the primary outbreak, because the index case is often not diagnosed until after the first cluster of infections has occurred. In the healthcare setting, IG is more commonly employed to prevent secondary transmission. When administered before exposure or during the incubation period, IG protects against clinical illness (i.e., IG may not prevent infection but minimizes the clinical signs and symptoms of infection). Protective effects are greatest when administered early in the incubation period, and IG should be given no later than 2 weeks after exposure. Serologic screening of exposed workers for anti-HAV is not recommended, because screening is more costly than administering IG and would unnecessarily delay IG administration, compromising its efficacy. For postexposure prophylaxis, a single intramuscular dose of 0.02 mL/kg of standard lot immunoglobulin is recommended. Because the risk of occupational transmission in healthcare workers is so low, IG is not recommended for preexposure prophylaxis.

Inactivated hepatitis A vaccines have been marketed for more than 15 years *(237)* and the CDC's Advisory Committee on Immunization Practices (ACIP) has issued

recommendations concerning their use *(235,236,238)*. Because healthcare workers in general are not at high risk for HAV infection, preexposure use of the vaccine in healthcare workers has not been recommended by the ACIP. However, selected workers, such as those in laboratories or primate animal facilities who work with HAV, should be vaccinated. For outbreaks occurring in hospitals or institutions for developmentally challenged patients, the CDC still recommends aggressive use of IG, as there are no data concerning the role of hepatitis A vaccine in these settings, though some investigators (particularly those from outside the United States in settings in which the risk for transmission may be higher) have recommended it *(33)*. Because the vaccine should be administered at least 2 weeks prior to exposure to HAV, IG is still recommended for postexposure prophylaxis. In one of the authors' institution, however, the Occupational Medical Service occasionally makes exceptions to the CDC's general recommendations. If the exposed healthcare worker is likely to have additional future exposures to HAV and both immediate and long-term protection is desired, both the vaccine and IG may be administered. Vaccine should be administered with a different syringe at a different site from the IG; the ultimate antibody titer obtained is likely to be lower than when the vaccine is given alone. Both hepatitis A vaccines currently available in the United States require two doses, the second administered 6 months after the first (VAQTA) or 6 to 12 months after the first (HAVRIX). Vaccine protection has been shown to persist for at least 9 years *(239)*, is likely to last for at least 15 years, and possibly for as long as 50 years *(240,241)*.

One study has examined the cost-effectiveness of vaccinating medical students for hepatitis A and concluded that, although the cost per year of life saved was similar to that of many other medical interventions, in order to be cost saving, the incidence of hepatitis A infection would have to be at least 10 times higher than the present rate *(242)*. One selected set of healthcare workers who should be considered for hepatitis A vaccination includes individuals identified as having chronic liver disease (of any etiology, including HBV- and HCV-induced). One study documented the substantial risk of fulminant hepatitis and death among persons with chronic hepatitis C with chronic liver disease who acquired HAV infection *(243)*, and universal vaccination of all patients who have chronic liver disease of any etiology has been proposed *(238,244)*.

Fortunately, unlike HBV, HCV, and HDV infections, HAV does not result in a chronic infection state requiring difficult management decisions and long-term work restriction. Healthcare workers with hepatitis A infection should be restricted from patient contact and food handling until 7 days after onset of jaundice *(245)*.

Hepatitis B Virus

Of all the hepatitis syndromes, prevention efforts in the healthcare setting have focused most aggressively on occupational HBV infection. Results of these efforts are encouraging, but there are still opportunities for improvement. The CDC estimates that the incidence of HBV in healthcare workers declined from 17,000 per year in 1983 to approximately 400 annual infections in 1995 (53). This decline is generally attributed to the introduction of the hepatitis B vaccine in 1982, the institution of universal blood and body fluid Precautions (Universal Precautions) in 1987, and the issuance of OSHA's bloodborne pathogens standard in 1991 (53,*77,246–248*). The use of postexposure prophylaxis, and, to a much lesser extent, patient screening to identify those infected with HBV for special precautions, also may have contributed to decreased infections.

Because the source patients for most occupationally acquired HBV infections are never identified, all patients should be assumed to be infectious. This concept is the cornerstone of Universal/Standard Precautions and was originally developed in 1987 to address concerns about the transmission of HIV (see Prevention of Occupationally Acquired Human Immunodeficiency Virus Infection in Healthcare Workers, Chapter 74). All healthcare workers who have potential occupational exposure to blood or other potentially infectious materials must receive training in the various aspects of Universal/Standard Precautions: administrative and engineering controls, appropriate work practices, and use of protective barrier equipment to minimize occupational exposures. Such training is required both by the OSHA final rule on bloodborne pathogens *(70)* and by federal law. Engineering controls include the provision of hand-washing facilities and equipment designed to minimize percutaneous injuries, (e.g., impervious needle disposal units and self-blunting, shielded, or needleless devices). Work practices include appropriate hand washing, safe handling of needles and other sharp devices, and avoiding risky behaviors such as oral pipetting, recapping needles, and improper handling or disposal of needles and other sharp instruments. Employees must also know how and when to use appropriate protective barrier equipment, such as gloves, gowns, masks, and eye protection, to prevent occupational exposure to blood or other infectious substances. Employee training should also include safe disposal of infectious wastes, housekeeping practices to prevent environmental contamination, and first aid procedures and injury-reporting procedures to follow in the event of an occupational exposure. A summary of specific methods to reduce exposure to blood and other body fluids in the higher-risk operating room setting has also been published *(249)*.

HEPATITIS B VACCINE

Healthcare institutions are also required by the OSHA final rule to provide hepatitis B vaccine free of charge to all at-risk employees; workers who refuse the vaccine are required to sign a declination. Despite the fact that the vaccine provides the best available means of protection from hepatitis B, it has, unfortunately, been underutilized. The original hepatitis B vaccine licensed for use in the United States in 1981 was derived from human plasma and, the vaccine's proven safety and efficacy notwithstanding, vaccination programs were plagued with unfounded safety concerns about possible contamination with other bloodborne pathogens. Currently, the two US-licensed vaccines are marketed, and both are genetically engineered by inserting the gene for HBsAg into the yeast *Saccharomyces cerevisiae* and harvesting the HBsAg particles produced in culture. The recommended dose and schedule

for immunizing healthcare workers is 1.0 mL, injected into the deltoid muscle, at 0, 1, and 4 to 6 months. An adequate antibody response is generally considered to be at least 10 milli-International Units (mIU)/mL, which is approximately equivalent to 10 sample ratio units (SRU) by RIA or a positive test result by enzyme immunoassay (EIA) *(65)*.

Several factors affect the immunogenicity of the vaccine. Care must be taken to prevent freezing the vaccine during shipping and storage, or vaccine potency will be reduced. The vaccine manufacturer's recommended schedule should be followed. Satisfactory protection is obtained if the vaccine doses are administered at longer intervals, but optimal protection does not occur until the third dose. The response may be suboptimal if the vaccine is administered by gluteal injection, rather than being injected into the deltoid muscle. However, age of the recipient is probably the most important determinant of vaccine response. Vaccine response ranges from 90% to 95% among young adults to only 50% to 70% in vaccinees over 60 years of age *(250,251)*. Persons with immunosuppressive illnesses, such as renal failure and HIV infection, and persons with chronic diseases such as diabetes and chronic liver disease, also have diminished vaccine responses. Smokers have been found to have decreased immune responses compared to nonsmokers *(250,252–254)*, and obesity is also associated with diminished response *(250,254,255)*. Unlicensed, reduced vaccine dosages and intradermal routes of injection have been studied extensively, but the OSHA final rule stipulates that vaccine must be provided to healthcare workers according to current recommendations of the U.S. Public Health Service *(245)*.

Prevaccination antibody testing of potential vaccine recipients for evidence of existing immunity is not necessary, but may be sensible if the prevalence of prior infection in the population to be immunized is >10%. The decision to implement a screening program should be based on an institution-specific cost-benefit analysis considering the HBV seroprevalence rate among employees, the cost of serologic screening to the institution, and the costs of vaccination *(65)*. The issue of postvaccination anti-HBs testing has been more controversial. The decline in the occupational HBV transmission rate has been proposed as one argument against routine testing *(256)*. Although postvaccination assessment of antibody response was not recommended routinely in the past, testing was advisable for persons 50 years of age or older, those who were vaccinated with unlicensed dosages or routes of administration, those with immunosuppressive conditions or chronic diseases, and those whose subsequent management depended on knowing their immune status (such as dialysis staff members) *(65,250)*. In one of the authors' institutions, postvaccination testing is offered to anyone who desires it. The CDC's ACIP and the Healthcare Infection Control Practices Advisory Committee (HICPAC) now recommend that postvaccination testing be performed 1 to 2 months after the third dose for healthcare workers who have contact with patients or blood and are at ongoing risk for injuries with sharp instruments or needlesticks *(245)*. Other researchers have proffered what they believe to be a more cost-effective strategy of not performing postvaccination antibody testing, but instead providing postexposure testing and prophylaxis (257). Unfortunately, in our view, this approach has significant limitations. Workers who have inapparent or unreported occupational exposures would not benefit from this alternate strategy, nor would nonresponders be identified and counseled accordingly.

Workers who do not respond adequately to the primary series (nonresponders) may respond to additional vaccine doses. Nonresponders should be revaccinated with a second, three-dose series or be evaluated to determine if they are positive for HBsAg *(245)*. Revaccinated workers should be retested after completion of the second vaccine series. Nonresponders who are HBsAg-negative should also be counseled that they are susceptible to HBV infection, they should practice scrupulous Standard (formerly Universal) Precautions, and they need HBIG for postexposure prophylaxis (see below). CDC further recommends that workers in chronic dialysis centers who do not respond to the vaccine should be tested for HBsAg and anti-HBs semiannually *(258)*. Alternate vaccine formulations appear promising and may be effective in immunizing some nonresponders to current vaccines *(259)*.

The U.S. Public Health Service does not currently recommend either booster doses for workers who initially respond to the vaccine but whose antibody levels decline over time or periodic serologic testing to monitor anti-HBs levels *(245)*. Studies of duration of vaccine-induced immunity in healthy young adults have shown that between 28% and 50% of those who responded to vaccination lost adequate levels of antibody by 5 years, and 30% to 60% had no or low antibody levels by 8 years *(250)*. However, data suggest that, in the rare instances in which HBV infection occurs in adult vaccine responders, the infection is transient and does not result in clinical illness. Other studies have shown that there is excellent persistence of immunologic memory for up to 10 to 11 years following vaccination (53,*260,261*). Some institutions do offer booster doses of vaccine to healthcare workers who have previously responded to hepatitis B vaccination, who remain in at-risk professions, and whose anti-HBs antibody titers have dropped in the negative range (see Table 73-4).

Another important consideration is emphasizing the importance of vaccination of healthcare workers during orientation, training and/or before occupational exposures can occur. This approach has two advantages: it may increase vaccine acceptance and it will prevent infection in trainees who are unskilled and at increased risk of accidental injuries while learning techniques. Studies to determine vaccine coverage among healthcare workers have reported variable results. One study of randomly selected hospitals conducted in 1992 found that only 51% of eligible (and therefore presumably at-risk) employees were vaccinated with three doses of vaccine *(247)*. A large study of American and Canadian orthopedic surgeons found that the prevalence of vaccination decreased steadily with age, from 90% of 20- to 29-year-old surgeons to only 35% of those 60 or more years old *(141)*. Only 55% of hospital-based surgeons in a multicenter survey reported receiving all three doses of vaccine *(76)*. Another national study determined that only 66.5% of eligible employees had received three doses of the vaccine, although coverage was somewhat higher (75%) in workers with frequent exposure to potentially infectious body fluids (53). Hospitals with increased

TABLE 73-4

Guidelines for Management of Hepatitis Exposures to Blood and Other Potentially Infectious Materials at the NIH Clinical Center

Laboratory Results Obtained on Source (Donor) Patient[a]	*Exposed HCW's HB Vaccine Status*	*Exposed HCW's Laboratory Studies Ordered*[b]	*Exposed HCW's Laboratory Results*	*HCW Treatment*[c] *and Follow-Up*
$HBsAg^+$ or unknown, possibly $HBsAg^+$	Unvaccinated	HBsAg, anti-HBs, ALT/AST	$Anti\text{-}HBs^+$ $Anti\text{-}HBs^-$	None HBIG, begin HB vaccine series.[d] Obtain HBsAg, anti-HBs, anti-HBc, ALT/AST in 3 and 6 mo.
	Vaccinated, known nonresponder (anti-HBs–)	HBsAg, anti-HBs, ALT/AST	$HBsAg^+$ and $anti\text{-}HBs^-$ $HBsAg^+$ and $anti\text{-}HBs^-$	None HBIG and either: initiate revaccination as soon as possible or second HBIG dose in 1 mo. Obtain HBsAg, anti-HBs, anti-HBc, ALT/AST in 3 and 6 mo.
	Vaccinated, undocumented anti-HBs response	HBsAg, anti-HBs, ALT/AST	$Anti\text{-}HBs^+$ $Anti\text{-}HBs^-$	None HBIG and initiate revaccination as soon as possible. Obtain HBsAg, anti-HBs, anti-HBc, ALT/ AST in 3 and 6 mo
	Vaccinated, known responder (anti-HBs+)	Anti-HBs	$Anti\text{-}HBs^+$ $Anti\text{-}HBs^-$	None HB vaccine booster dose[e]
HCV PCR^+, $Anti\text{-}HCV^+$ or unknown, possible $anti\text{-}HCV^+$		Anti-HCV, ALT/AST; PCR for HCV RNA	$Anti\text{-}HCV^+$ $Anti\text{-}HCV^-$	None. If unvaccinated, begin HB vaccine series. Refer for follow-up If unvaccinated, begin HB vaccine series. Obtain anti-HCV, ALT/AST at 3 and 6 mo. Repeat HCV PCR at q2 week intervals for 6 mo. If positive, follow closely for resolution of infection (see text); After 4 mo of positivity, refer for consideration of IFN-alpha treatment.[e] Obtain anti-HAV. If anti-HAV neg., begin HA vaccine series.
AST/ALT abnormal, $anti\text{-}HCV^-$, NANBNC suspected, or unknown, possible NANBNC		Anti-HCV, ALT/AST	ALT/AST abnormal, NANBNC suspected ALT/AST abnormal or normal, NANBNC not suspected	None. If unvaccinated, begin HB vaccine series. None. If unvaccinated, begin HB vaccine series. Obtain anti-HCV, ALT/AST at 3 and 6 mo

[a] If the source of the exposure is known, obtain written, informed consent and order HBsAg, anti-HCV, and AST/ALT.
[b] If resources permit, obtain informed consent and freeze an aliquot of serum for future reference.
[c] Unless HCW is known to be positive for HBsAg or has adequate levels of anti-HBs, postexposure treatment should always include counseling and initiation of HB vaccine series (if unvaccinated or if HB vaccine series is incomplete), or administration of booster doses if indicated.
[d] Alternatively, if the employee refuses vaccine, administer HBIG as soon as possible and repeat in 1 month.
[e] Not a current USPHS recommendation.
HCW, healthcare worker; HBsAg, hepatitis B surface antigen; anti-HBs, antibody to hepatitis B surface antigen; anti-HBc, antibody to hepatitis B core antigen; ALT, alanine aminotransferase; AST, aspartate aminotransferase; anti-HCV, antibody to hepatitis C virus; HBIG, hepatitis B immune serum globulin, 0.06 mL/kg IM, as soon as possible (value beyond 7 days unknown); HB vaccine, hepatitis B vaccine; anti-HBs+, ≥10 SRU by RIA or positive by EIA; anti-HAV, antibody to hepatitis A virus; HA vaccine, hepatitis A vaccine; NANBNC, non-A, non-B, non-C hepatitis.
(Courtesy of Dr. James M. Schmitt, Occupational Medical Service, National Institutes of Health [modified].)

vaccination coverage often provided incentives, used employee performance measures (e.g., supervisors were notified if an employee refused vaccination, sanctions were imposed for refusing vaccination, or vaccination was required as a condition of employment), sent reminder notices when vaccine doses were due, and used a computerized tracking system. Clearly, we are making progress, but efforts are still needed to improve vaccine acceptance among healthcare workers. Although there is no precedent for federal law requiring workers to receive a vaccine, mandatory immunization of susceptible healthcare workers has been proposed as the best strategy to further prevent occupational and healthcare-associated hepatitis B infection. Many healthcare institutions and medical schools have adopted this strategy.

MANAGEMENT OF EMPLOYEES SUSTAINING OCCUPATIONAL EXPOSURES

The CDC recommends *(245,262)*, and the OSHA final bloodborne standard requires, that postexposure prophylaxis be provided to employees experiencing adverse exposures to hepatitis B. Healthcare institutions should have established protocols for providing immediate appropriate first aid for injuries and exposures, mechanisms for reporting employee injuries/exposures, and protocols to manage these exposures (263) (see also Chapter 74). Table 73-4 summarizes the management of employees following exposures to blood or other potentially infectious materials as practiced at the Clinical Center, National Institutes of Health (NIH) *(264)*. Although the complete protocol also includes other bloodborne pathogens, such as HIV and human T-cell lymphotropic virus, only the hepatitides are discussed here (see also Chapter 74). Management of exposures includes assessing the type, source, and circumstances of the exposure incident; evaluating the source (donor) patient for clinical, epidemiological, and laboratory evidence of hepatitis; and evaluating the hepatitis B vaccination history and hepatitis infection/immunity status of the exposed healthcare worker. Prophylactic treatment must be provided to susceptible healthcare workers as soon as possible following accidental occupational percutaneous or mucosal exposures to HBsAg-positive blood. A regimen combining hepatitis B immune globulin (HBIG) and hepatitis B vaccine will provide both short- and long-term protection and is the treatment of choice. At the Clinical Center, we often already know not only the vaccination status and HBV immunity status of the exposed healthcare worker but also the hepatitis status of many of the patients participating in research protocols. In many hospitals, this information will not be readily available and employee treatment may have to be initiated pending laboratory test results. The most current CDC recommendations *(262)* for prophylaxis should be followed. As soon as possible following the exposure, the vaccination status and immunity status of the exposed worker should be reviewed. If the exposed worker has not been vaccinated or has not completed vaccination, the vaccine series should be started and a single dose of HBIG (0.06 mL/kg) should be given as soon as possible, preferably within 24 hours of exposure. The vaccine should be administered in the deltoid at a separate site and can be given simultaneously with HBIG or within 7 days of exposure. If the exposed worker has already been vaccinated for hepatitis B and is known to have detectable antibody (anti-HBs ≥10 mIU/mL), no treatment is indicated. If the exposed worker has already been vaccinated and is known to be a nonresponder (anti-HBs <10 mIU/mL), either administration of a single dose of HBIG and initiation of revaccination is indicated, or a dose of HBIG should be given as soon as possible followed by a second dose 1 month later. If the exposed worker has been vaccinated but the employee's anti-HBs response status is unknown, the worker should be tested for antibody; if adequate no treatment is indicated; if <10 mIU/mL, a single dose of HBIG and a vaccine booster dose should be given. CDC recommendations *(245,262)* should be consulted for prophylaxis of healthcare workers when the source is HBsAg negative, not tested for HBsAg, or the status is unknown.

The Occupational Medical Service (Employee Health Service) plays an especially important role in the management of employees who have sustained occupational exposures to bloodborne pathogens. Counseling exposed employees is a crucial component of postexposure management. Counseling these employees is complex, labor-intensive, and often time-consuming and emotionally draining *(265)*. The counselor should collect the epidemiological details relevant to the exposure (i.e., how and why the exposure took place). In addition, the counselor should (a) provide the exposed healthcare worker with estimates (based on the literature) of the risk of infection associated with exposures of the type sustained by the worker, (b) discuss, in detail, the therapeutic postexposure management options (e.g., HBIG, vaccine), and the short-term and long-term side effects associated with these options, (c) discuss the plan for follow-up (and the importance of compliance with that plan), (d) discuss precautions that may be useful to avoid transmission to others should the injury result in infection, (e) provide emotional support for the exposed worker, (f) respond to any and all questions related to the exposure, and (g) encourage the exposed employee to call or return with additional questions *(265)*.

MANAGEMENT OF EMPLOYEES WHO ARE CHRONIC CARRIERS OF HEPATITIS B

The risk of HBV being transmitted from an infected healthcare provider to a patient is virtually nonexistent in the setting of routine patient care contact. A small but, nonetheless, real risk for provider-to-patient HBV transmission does exist for "invasive" patient contact (i.e., situations accompanied by some risk for the patient to be exposed to the blood of the healthcare provider). Personnel who have high circulating viral burdens, such as those who are HBeAg-positive HBV carriers, present higher risk to their patients. Through 1994, investigators at the CDC identified 42 instances of provider-to-patient HBV transmission (infecting over 375 patients) *(266)*. Almost immediately following the publication of this review, two additional clusters

of provider-to-patient transmission of HBV infection were reported that involved surgeons who were hepatitis B "e" antigen (HBeAg) positive *(267,268)*. These clusters of HBV infection from HBeAg-positive surgeons occurred, despite increased attention to infection control measures. In one of these clusters, four patients acquired clinical hepatitis B infection from an orthopedic surgeon *(268)*, and in the other, 19 patients of a thoracic surgery resident became infected *(267)*. No specific events or breaks in technique were identified in either cluster that could have led to the transmissions, although the surgical resident did not wear double gloves. In further investigations, the CDC had the resident perform laboratory simulations of tying surgical knots for an hour, which resulted in paper-cut–like skin lesions on the index fingers, and HBsAg and HBV DNA were detected in rinsings from his gloves. These lesions, combined with serous exudates and glove failure, could theoretically have caused HBV contamination of the patients' surgical wounds.

Since 1996, 10 additional reports of hepatitis B transmission from providers to patients have been published. These cases are generally associated with HBV infected surgeons; one case was associated with an infected dentist (*269,270*; I. Williams, CDC Personal Communication). A publication from the United Kingdom underscored the potential for transmission from providers who have high viral burdens, but are "e" antigen negative. Such providers are often infected with so-called precore mutants of hepatitis B *(269)*. This report underscores the importance of assessing the provider's circulating viral burden. One provider to patient case cluster was reported from Canada in 2000. In this cluster, 75 patients were infected during placement of subdermal EEG electrodes by an HBeAg-positive EEG technician *(271)*. No clear mechanism of transmission was identified in this epidemic. More recently, an orthopedic surgeon was found to have transmitted HBV to two patients; the surgeon was found to have a circulating viral burden of more than 1.7×10^7 virions/mL *(271a)*. Whereas such clusters continue to occur, (acknowledging that the United States does not have systemic surveillance measures to detect such cases) they appear to be occurring less frequently than in the past.

Historically, HB "e" antigen has been the most reliable marker for risk (i.e., high circulating viral burdens). In fact, historically, nearly all providers who have transmitted HBV to patients were "e" antigen positive. In 1997, UK public health authorities reported on four surgeons who had transmitted HBV to patients; all four were infected with HBV viruses that were precore mutants (i.e., these strains are genetically unable to express HBeAg but are still capable of assembling infectious virions) *(272)*. With the exception of providers who have been shown to transmit infection to patients, historically, no restrictions were placed on healthcare workers who were chronically infected with HBV *(273–275)*. Although contrary to previously issued guidelines and recommendations, new guidelines were issued by the CDC in July 1991 recommending that healthcare workers who perform "exposure-prone invasive procedures" be aware of their HBV infection statuses; those who are found to be HBeAg positive should not perform such procedures unless they have sought the counsel of an expert review panel and been advised under what circumstances (if any) they would be allowed to perform these procedures *(275)*. Further, these guidelines note that HBeAg-positive healthcare workers should inform prospective patients about their (i.e., the provider's) infection status *(275)*. Congress subsequently passed Public Law 102–141 mandating that states must implement either the CDC guidelines or create state guidelines and certify them as equivalent to the CDC Guidelines, as a condition for continued federal public health funding.

Consequently, local or state public health officials should be contacted to determine the regulations or the recommendations applicable in a given area.

The United Kingdom has implemented reasonably restrictive guidelines for providers infected with bloodborne pathogens. In the United Kingdom, providers who are infected with HBV and are "e"-antigen positive may not conduct exposure-prone invasive procedures; HBV-infected providers who are "e"-antigen negative, but have HBV DNA levels of $>10^3$ genome equivalents/mL may not conduct exposure-prone invasive procedures; and HBV-infected providers who are "e"-antigen negative, and have HBV DNA levels of $<10^3$ genome equivalents/mL may conduct exposure-prone invasive procedures, but must be retested at least every 12 months to assure that the level of viremia remains below 10^3 copies/mL (276). UK authorities have also recommended that HBV-infected healthcare providers who are HBeAg negative and who have pretreatment HBV DNA levels between 10^3 and 10^5 genome-equivalents/mL could be allowed to perform exposure prone procedures if they are successfully treated with suppressive oral antiviral therapy, such that their circulating viral burdens are suppressed below 10^3 genome equivalents/mL *(277)*. UK authorities are still wrestling with the development of an effective monitoring strategy to make certain that the circulating viral burden remains $<10^3$ genome equivalents/mL *(277)*. The differential sensitivity of available testing systems further complicates this issue.

A thorough discussion of the problems raised by excluding practitioners infected with bloodborne pathogens is beyond the scope of this chapter. These complex management issues have been addressed in detail elsewhere (278,*279–283*). The Society for Healthcare Epidemiology of America (SHEA) has recently issued updated recommendations regarding the management of healthcare workers infected with bloodborne pathogens (Table 73-5) (284). SHEA recommends that HBV-infected healthcare providers who are either "e" antigen positive or "e" antigen negative, but have circulating HBV burdens of greater than or equal to $<10^4$ genome equivalents/mL routinely double-glove for all invasive procedures, for all contact with mucous membranes or nonintact skin, and for all instances in patient care for which gloving is recommended, and that they not perform those Category III activities identified as associated with a risk for provider-to-patient HBV transmission despite the use of appropriate infection control procedures (284). SHEA recommends that healthcare providers who have circulating HBV burdens of genome equivalents per mL be allowed to perform those Category III activities identified as associated with a risk

for provider-to-patient transmission of bloodborne pathogens, so long as the infected provider: (a) is not detected as having transmitted infection to patients; (b) obtains advice from an Expert Review Panel about continued practice; (c) is followed routinely by Occupational Medicine, who tests the provider twice annually to demonstrate the maintenance of a viral burden of $<10^4$ genome equivalents/mL; (d) is also followed by a personal physician who has expertise in the management of HBV infection and who is allowed by the provider to communicate with the Expert Review Panel about the provider's clinical status; (e) consults with an expert about optimal infection control procedures (and strictly adheres to the recommended procedures, including the routine use of double-gloves and frequent glove changes during procedures, particularly if performing technical tasks known to compromise glove integrity [e.g., placing sternal wires]) and (f) agrees to the information in, and signs, a contract or letter from the Expert Review Panel that characterizes her/his responsibilities (284).

The management of practitioners who are chronically infected with bloodborne pathogens is complex for a variety of reasons. Because of the extremely limited data available, no single approach to this complex issue addresses all the relevant issues. Further, individuals who hold quite disparate positions with respect to the patients' right to know and the providers' right to privacy and medical confidentiality likely will have polar views of any individual approach to managing infected providers. Historically, science has provided the foundation for sentient public health policy. In many respects, the hepatitis B–infected practitioner has been "additional baggage" on the bandwagon of public sentiment being driven by societal anxiety about iatrogenic HIV transmission (278). Nonetheless, as additional data accumulate, the argument for considering the management of providers infected with each of the bloodborne viral infections on the evidence that relates specifically to that infection becomes increasingly more compelling. Hopefully, the guideline recently issued by SHEA (284) will provide some additional clarity for this complex problem.

Hepatitis C Virus

Unfortunately, unlike hepatitis B, there are no passive or active immunization products to prevent HCV infection. Prevention relies primarily on healthcare workers practicing Standard Precautions (which includes Universal Precautions) (see discussion in Hepatitis B Virus, above, and Chapter 74). Importantly, use of Universal Precautions has also been shown to decrease transmission to patients in a high-risk setting *(285)*.

MANAGEMENT OF EMPLOYEES SUSTAINING OCCUPATIONAL EXPOSURES TO HCV

The issue of postexposure prevention of HCV infection remains controversial. Testing for antibodies to HCV in source patients and in the exposed healthcare worker is subject to the limitations of serological testing discussed previously. The HCV antibodies identified in the currently available antibody assays are not neutralizing for HCV and are not protective, due to substantial HCV strain variability that permits multiple infections *(138,286,287)*. Therefore, anti-HCV identified in the "baseline" serum of an exposed employee does not indicate immunity. Conversely, HCV antibodies present in the source patient are not necessarily markers for infectivity of the source patient (although the source should be assumed to be infectious); such antibodies do not distinguish between acute, chronic, or resolved infection. Even third-generation anti-HCV testing will still not detect 5% to 10% of persons with HCV infection *(129)*. Direct detection of circulating HCV RNA by the PCR or other molecular method is probably the best approach to identify source patients who are HCV-infected and infectious. As noted above, even the PCR methodology is fraught with complexity.

CURRENT USPHS GUIDELINES

The CDC, in collaboration with HICPAC, has issued recommendations for follow-up of healthcare workers following occupational exposure to HCV *(288,289)*. These recommendations emphasize that institutions should have policies and procedures for follow-up of personnel who sustain percutaneous or permucosal exposure to anti-HCV-positive blood. Such policies should include, at a minimum: (a) for the source, baseline testing for anti-HCV; (b) for the exposed worker, baseline and follow-up (e.g., 6 months) testing for anti-HCV and alanine aminotransferase activity; (c) confirmation by supplemental anti-HCV testing of all anti-HCV results reported as repeatedly reactive by EIA; (d) recommending against immediate postexposure prophylaxis with IG or antiviral agents (e.g., interferon); and (e) education of workers about the risk for and prevention of bloodborne infections, including hepatitis C, in occupational settings, with the information routinely updated to ensure accuracy.

Several other potential interventions have been proposed for managing occupational exposures to HCV, including immunoprophylaxis with immunoglobulin, preemptive therapy of acute infection with immunomodulators, so-called watchful waiting with immunomodulators (231), and postexposure chemoprophylaxis (or chemoprophylaxis plus immunoprophylaxis with immunomodulators). Each of these approaches is worthy of additional consideration.

IMMUNOPROPHYLAXIS WITH IMMUNOGLOBULIN

The issue of postexposure immunoprophylaxis with IG also has been controversial, because no data demonstrate the efficacy of IG in this setting. Data from earlier trials of IG to prevent posttransfusion non-A, non-B hepatitis demonstrated mixed results (231,*290–292*). Although the CDC recommendations *(65)* once stated that "it may be reasonable to administer IG (0.06 mL/kg) as soon as possible after exposure," more recent data have led the U.S. Public Health Service's HICPAC no longer to endorse this practice *(288,293)*. In fact, neither of the authors' institutions offers postexposure treatment with immunoglobulin for occupational exposures to HCV. Although plasma pools for fractionation

to derive IG in the United States once included antibodies for HCV *(294)*, currently the United States and other countries screen plasma donors and exclude HCV-positive donors; thus, IG products no longer contain antibodies to HCV and therefore offer even less theoretical benefit *(289,295)*. Postexposure studies in experimentally infected chimpanzees have demonstrated that neither anti-HCV-negative intravenous immune globulin nor specially prepared hepatitis C immune globulin (containing significant titers of ant-HCV antibody) prevents HCV infection *(296)*.

POSTEXPOSURE IMMUNOPROPHYLAXIS WITH IMMUNOMODULATORS

Immediate postexposure, short duration interferon treatment has been attempted, but was not successful in preventing infection *(89)*. For several theoretical reasons (delineated in detail in reference (231)), and in spite of inferences in the literature suggesting its efficacy, no current rationale supports the use of immunomodulating substances in the immediate postexposure setting. One paper has examined this issue and found no evidence to support this approach *(297)*. As noted above, one could actually mount reasonable arguments as to why immunomodulators should not be administered in the very early phase of infection.

POSTEXPOSURE ANTIVIRAL CHEMOPROPHYLAXIS

Agent(s) with clearly defined antiviral activity against HCV (as compared with immunomodulatory activities) have yet to be made available in the healthcare market. Some agents that are designed to have specific anti-HCV activity are in the drug-development process. In the absence of data demonstrating both the relative safety (i.e., since the transmission risk is, at most, 2% to –3%, 97% to 98% of those given the agent would not need the treatment) as well as efficacy of anti-HCV agents, no recommendation can be made about their potential for use in the postexposure setting. Should some of these compounds be demonstrated to have specific antiviral activity against HCV (and to be reasonably safe), they could become candidates for postexposure chemoprophylaxis for occupational exposure to HCV (231).

PREEMPTIVE TREATMENT OF ACUTE HCV INFECTION VERSUS "WATCHFUL WAITING" AND TREATMENT OF ESTABLISHED HCV INFECTION

Another proposed postexposure management strategy, first suggested by Schiff in 1990, involves weekly monitoring of exposed persons for HCV RNA and initiating interferon treatment when infection is either first detected (i.e., "preemptive treatment") *(138)* or when it appears that the infection may become chronic *(298)*. The practicality of such an approach notwithstanding, definitive data are not yet available to document the efficacy of this approach, though many institutions in the United States are adopting this approach or some modification of it (299).

Perhaps one of the most compelling arguments for the use of one of the PCR monitoring strategies is the remarkable experience published over the past few years describing the treatment of patients who have the acute hepatitis C syndrome *(300–306)*. These studies have shown cure/resolution rates among patients who received treatment for their acute infections that are much higher than one would expect, based on the experience treating patients who have chronic HCV infection (*307,308,*309). In one of the studies of the therapy of "acute hepatitis C," HCV-RNA was undetectable and alanine aminotransferase levels were entirely normal in 43 of the 44 patients who were studied *(305)*. This 98% cure rate literally dwarfs any previously published study of the treatment of HCV infection.

Comparing the treatment of patients with the "acute hepatitis C" syndrome with those who are chronically infected may not be entirely appropriate. Immunological responses to HCV infection are complex; in fact, individuals who develop symptomatic acute hepatitis at the time of infection may represent a population of individuals who are capable of mounting more aggressive immunological responses to the infection. Other studies of therapy of "acute hepatitis C" have produced similar, but not quite so striking successes *(302,310,311)*.

Despite the fact that all of the studies describing the treatment of early or acute HCV infection have substantial limitations (discussed in detail in references (231,*298*)), the outcomes associated with the therapy of the "acute hepatitis C" syndrome almost uniformly suggest that treatment of acute HCV infection is advantageous. The NIH Consensus Conference on Hepatitis C concluded that patients identified with acute hepatitis C should receive immunomodulators *(306)*.

Following this approach, an institution's Occupational Medicine staff monitors healthcare workers who have sustained occupational exposures (at periodic intervals [e.g., 1–2 months] following an occupational exposure to HCV) using HCV RNA-PCR. In some institutions, if infection is definitively identified (as demonstrated by repeatedly positive HCV RNA detection from the serum of the exposed worker), interferon therapy is initiated. Regimens selected have varied. Jaeckel et al. *(305)* used a regimen of five million units of interferon alfa-2b subcutaneously daily for 4 weeks and then the same dose administered three times per week for an additional 20 weeks.

Others have suggested "watchful waiting," also using PCR monitoring. Following this strategy, the institution's Occupational Medicine staff would also monitor the exposed healthcare worker at 1 to 2 monthly intervals by HCV-PCR, and then closely follow individuals who become HCV PCR positive to see if chronic infection develops. One approach has been to recommend interferon treatment only for those who remain HCV-RNA-PCR positive and have elevated alanine aminotransferase levels 2 to 4 months into the course of their infections (231,*298,306*). This approach will allow a substantial fraction of individuals to resolve their infections spontaneously and would not put individuals who spontaneously recover at risk for the substantial toxicity associated with therapy with interferon *(298)*. Both these approaches have merit and

both have at least anecdotal support in the literature. The "preemptive therapy" approach has been used successfully in several instances *(91,187,189,195,312)* and unsuccessfully in others *(89)*. The case report describing failure of a postexposure interferon intervention provides indirect support for the "watchful waiting" strategy. In this case, the exposed individual received "postexposure prophylaxis" with interferon-alpha, five million units per day intramuscularly for 4 days, beginning on the day of exposure *(89)*. One month later, he developed elevated aminotransferase levels and was positive for HCV RNA by PCR, 11 weeks later, his anti-HCV antibody test was positive, and 6 months after the exposure his liver biopsy demonstrated chronic persistent hepatitis. The patient subsequently was treated with a 6-month course of interferon-alpha and was apparently cured *(89)*.

The CDC has not made formal recommendations concerning the use of either of these latter two strategies; however, as noted above, a substantial number of hospitals in the United States have adopted these strategies for managing occupational HCV exposures (299). Both the "preemptive therapy" and "watchful waiting" models represent entirely reasonable approaches to the management of occupational HCV exposure based on the currently available information, though, for the reasons cited above, we prefer the "watchful waiting" approach. Monitoring for HCV by PCR, monitoring alanine aminotransferase levels, and making management decisions based on these data and the individual's clinical status represent perhaps the most reasonable approach to postexposure management, in our view and seems, in our opinion, to represent a substantially improved strategy over the current USPHS recommendation to monitor anti-HCV antibody at 3 and 6 months following exposure *(262,313)*.

MANAGEMENT OF EMPLOYEES WHO ARE CHRONICALLY INFECTED WITH HEPATITIS C

The transmission of HCV from healthcare provider to patient has been reported uncommonly, albeit with some increased frequency in the past decade. As is the case for HBV carriers, individuals chronically infected with HCV are unlikely to transmit infection during routine patient contact. The risk for provider-to-patient HCV transmission during "invasive" patient contact (in which the patient may be exposed to the blood of the healthcare provider) is very small and, because of the lower titers of virus present in the circulation, is likely to be even lower than the risk for HBV transmission.

In the past 15 years, several instances of provider-to-patient transmission of hepatitis C have been reported (*314–327*,328,*329–334*). The first instance of provider-to-patient HCV transmission was reported from the United Kingdom in 1995 *(314)*. A postoperative cardiac surgery patient who had no risk factors for HCV infection developed acute hepatitis C infection, and one of the patient's surgeons was identified as HCV-infected. Only one of the surgeon's 278 patients who could be tested was infected with an HCV strain similar to the surgeon's *(325)*. The second case of provider-to-patient HCV transmission of HCV was reported from Spain *(315)*. Two postoperative cases of HCV infection were detected in cardiac surgery patients, prompting a retrospective evaluation of the patients of the chronically HCV-infected surgeon who had performed these cases. The look-back study identified 6 patients (of the 222 who could be tested) with HCV infection; 5 of these cases were caused by isolates closely related to the surgeon's isolate *(315)*. All of these five patients had undergone valve replacement surgery *(315)*. The third cluster (also from the United Kingdom) involved an HCV-infected gynecologist who was detected as transmitting HCV to a patient, resulting in an extensive look-back study that involved the testing of more than 4,500 patients, including 3,628 who had undergone "high-risk, exposure-prone procedures." Seven additional patients were found to have HCV infection caused by strains of HCV closely related to the surgeon's *(318,320)*.

Ross et al. *(330)* evaluated the 207 of 229 patients of a German orthopedic surgeon. Whereas 3 of the 207 were found to be HCV infected, only one was infected with an HCV strain similar to the orthopedist's *(330)*. This same team also evaluated patients of an HCV-infected obstetrician/gynecologist. One instance of transmission was detected among the 2,286 patients evaluated *(324)*. Three additional provider-to-patient HCV look-back studies are ongoing in the United Kingdom *(293,323)*. In the first of these studies, 3 of 1,900 patients were identified as having infection with a strain of HCV similar to that of the infected provider. In the second, 1 of 749 patients was found to be infected with a strain of HCV similar to the patient's provider, (328) and for the third, results have not yet been published *(323)*.

Several additional reports of provider-to-patient transmission of HCV implicate HCV-infected anesthesiologists. In one such case in the United Kingdom *(326)*, an HCV-infected anesthesiologist infected a patient during a procedure in which the anesthesiologist endotracheally intubated the patient, inserted a peripheral venous catheter, and provided general anesthesia. The anesthesiologist vehemently denied injection drug use *(326)*; however, in several similar cases described below, drug diversion was implicated as the cause of bloodborne pathogen transmission. Ross et al. *(329)* reported a cluster of five cases of HCV infection from an anesthesia assistant who was thought to have acquired acute HCV infection as a result of an occupational exposure to an HCV-infected patient in the operating room. In the course of 3 weeks, the assistant infected five patients. He vehemently denied intravenous substance abuse; however, the similarity of this case to the case described by Sehulster et al. *(331)* (discussed below) is striking. One important point about this cluster is the fact that the anesthesia assistant did not follow recommended infection control procedures in caring for his patients (i.e., Universal/Standard Precautions). He did not wear gloves, even when he had an open lesion on his hand.

The experience in the United States is strikingly at variance with the United Kingdom and European experience. Drug diversion by the infected provider played a pivotal role in four of the five reported instances of provider-to-patient HCV transmission in the United States. Williams et al. *(334)* reviewed the US experience *(334)*. The first instance of provider-to-patient HCV transmission in the United States involved an HCV-infected surgical technician who infected

approximately 40 of 346 patients over a 3-month period *(331,334)*. The surgical technician admitted diverting and self-injecting anesthesia medications from his patients and then used the same syringe to administer saline to patients. The second instance involved an anesthesiologist who was also suspected of using narcotics and diverting drugs from patients. He acquired HCV infection from one patient and subsequently transmitted the same strain to a patient during his acute phase of HCV infection *(322,334)*. The third case of HCV transmission is similar to the UK cases and involved an HCV-infected cardiac surgeon. The surgeon was found to have infected 14 of the 937 patients who could be evaluated from over a decade of surgical practice *(334)*. In the fourth case (again, an individual suspected of diverting patient narcotics), a nurse anesthetist transmitted HCV to 15 of 164 patients over a 4-month period coinciding with the acute phase of his own HCV infection *(334)*. The fifth instance of provider-to-patient transmission of HCV in the United States involved a surgical technician who diverted drugs and infected as many as 23 of her patients; she was convicted and sentenced to 35 years in jail (Joseph Perz, CDC, personal communication).

Thus, four of five detected instances of provider-to-patient HCV transmission in the US have been linked to diversion of patients' drugs to healthcare providers who were abusing injectable narcotics. Two additional cases, one from Spain, the other from Israel, emphasize the importance of narcotics abuse in provider-to-patient transmission of HCV. In the Spanish case, an opiate-addicted anesthesiologist infected more than 200 patients *(316,319)*. In the report from Israel, an opiate-using anesthetist infected 33 patients with HCV *(332)*.

The United Kingdom has recommended broad practice restrictions for HCV-infected providers who conduct exposure prone procedures, recommending that any provider who has circulating HCV RNA should be precluded from the conduct of such procedures *(335)*. Further, the United Kingdom recommended that trainees who are found to have circulating HCV RNA should be restricted from starting training in disciplines involving exposure-prone invasive procedures *(336)*. A European consortium could not reach consensus about HCV-infected providers and concluded, "on balance it is not recommended that exposure-prone procedures be forbidden for HCV-infected HCWs" (337). The SHEA guidelines published early in 2010 recommend that HCV-infected providers who have circulating HCV viral burdens of greater than or equal to 10^4 genome equivalents/mL routinely double-glove for all invasive procedures, for all contact with mucous membranes or nonintact skin, and for all instances in patient care for which gloving is routinely recommended, and that they not perform those Category III procedures identified as associated with a risk for provider-to-patient transmission of bloodborne pathogen infection despite the use of appropriate infection control procedures (Table 73-5) (284). SHEA also recommends that HCV-infected providers who have viral burdens of $<10^4$ genome equivalents/mL not be excluded from any aspect of patient care, including the conduct of Category III procedures, so long as the infected provider: (a) is not detected as having transmitted infection to patients; (b) obtains advice from an Expert Review Panel about continued practice; (c) is followed routinely by Occupational Medicine, who tests the provider twice annually to demonstrate the maintenance of a viral burden of $<10^4$ as well as by a personal physician who has expertise in the management of HCV infection and who is allowed by the provider to communicate with the Expert Review Panel about the provider's clinical status; (d) consults with an infection control expert about optimal infection control procedures (and strictly adheres to the recommended procedures, including the routine use of double-gloves and frequent glove changes during procedures, particularly if performing technical tasks known to compromise glove integrity [e.g., placing sternal wires]) and (e) agrees to the information in, and signs, a contract or letter from the Expert Review Panel that characterizes her/his responsibilities (284).

Hepatitis D Virus

Prevention of HDV in healthcare workers is best accomplished by preventing primary HBV infection. Although preliminary immunization studies in animals show some promise in limiting HDV infection *(338)*, no agents are currently available for active or passive immunization of healthcare workers who are already infected with HBV against HDV. This situation is worrisome, because workers who are already infected with HBV are at risk of developing severe acute illness and chronic liver disease should they acquire HDV superinfection *(204)*. This possibility provides an additional compelling reason for healthcare workers to become vaccinated against HBV. Preliminary experimental studies of treatment of chronic HDV infection with interferon alpha indicate that HDV replication may be inhibited, but this response may be transient. In one study, treatment for a year with high doses of interferon alfa-2a resulted in improvement in about half of treated patients, but relapse was still common *(339)*. Further long-term studies are needed to clarify the role of interferon alpha in the therapy of HDV infection *(340)*. Currently, the only preventive measure available for those infected with HBV is scrupulous adherence to Standard Precautions (Universal Precautions) to minimize occupational exposures to blood.

Hepatitis E Virus

HEV transmission to healthcare workers in most developed countries is extremely rare, although one study documented transmission to a trainee in urology who was operating on swine *(228)*. The diagnosis of HEV infection should be considered in travelers who have diarrhea and hepatitis and are returning from endemic areas. Precautions similar to those for preventing healthcare-associated acquisition of HAV should be adequate to prevent fecal–oral transmission. Workers in settings in which HEV may be present, such as refugee camps, should be especially careful to practice meticulous hand washing after patient contact and before eating and smoking *(222)*. Unlike HAV, no agents are currently available for immunization or passive immunoprophylaxis following exposure to HEV. An experimental vaccine has been successful in monkeys *(341)*, and a recombinant vaccine is currently in Phase III clinical trials *(221,225)*. IG manufactured in nonendemic areas is likely not to be protective because of a lack of antibody to HEV *(342)*, and the efficacy of IG from endemic areas is unknown. There is conflicting evidence that IgG anti-HEV protects against hepatitis E and HEV infection in monkeys and

TABLE 73-5

SHEA Guideline for Management of Healthcare Workers Infected with Bloodborne Pathogens[a]

Virus	*Circulating Viral Burden[b]*	*Clinical Activities[c]*	*Recommendation*	*Recommended Testing*
HBV	$<10^4$	Categories 1, 2, and 3	No restrictions[d]	Twice annually
	$\geq 10^4$	Categories 1, 2	No restrictions[d]	N/A
	$\geq 10^4$	Category 3	Restricted[e]	N/A
HCV	$<10^4$	Categories 1, 2, and 3	No restrictions[d]	Twice annually
	$\geq 10^4$	Categories 1, 2	No restrictions[d]	N/A
	$\geq 10^4$	Category 3	Restricted[e]	N/A

[a]These recommendations provide a framework within which to consider such cases; however, each such case is sufficiently complex that each should be independently considered in context by the expert review panel.
[b]Viral burdens are measured in genome equivalents per mL; currently available tests are not standardized. Individual institutions will need to make the best approximation of genome-equivalents per mL from available tests.
[c]See reference (284) for characterization of clinical activities.
[d]No restrictions recommended, so long as provider: is not detected as having transmitted infection to patients; obtains advice from an Expert Review Panel about continued practice; is followed routinely by Occupational Medicine, who tests the provider twice annually to demonstrate the maintenance of a viral burden of less than the recommended threshold, as well as by a personal physician who has expertise in the management of her/his infection who is allowed by the provider to communicate with the Expert Review Panel about the provider's clinical status; consults with an expert about optimal infection control procedures (and strictly adheres to the recommended procedures, including the routine use of double-gloves and frequent glove changes during procedures, particularly if performing technical tasks known to compromise glove integrity [e.g., placing sternal wires]); and agrees to the information in, and signs, a contract or letter from the Expert Review Panel that characterizes her/his responsibilities.
[e]These procedures permissible only when viral burden is $<10^4$ for both infections.
(Adapted from Henderson DK, Dembry L, Fishman NO, Grady C, Lundstrom T, Palmore TN, et al. SHEA guideline for management of healthcare workers who are infected with hepatitis B virus, hepatitis C virus, and/or human immunodeficiency virus. *Infect Control Hosp Epidemiol* 2010;31(3):203–232.)

humans. Earlier studies suggested that protective antibodies exist *(341,343)*, but a later study demonstrated that passive immunization with HEV antibodies was not protective *(344)*. No HEV-specific IG is currently available for protection from HEV.

CHAPTER 74

Prevention of Occupationally Acquired Human Immunodeficiency Virus Infection in Healthcare Workers

Susan E. Beekmann and David K. Henderson

In October of 2008, scientists from the Centers for Disease Control and Prevention (CDC) estimated that more than 1.1 million people were living with human immunodeficiency virus type 1 (HIV-1) infection in the United States, a prevalence of nearly 450 per 100,000 population *(1)*. Since the beginning of the acquired immunodeficiency syndrome (AIDS) epidemic in 1981 more than 1 million cases of AIDS had occurred in the United States, resulting in more than 560,000 deaths *(2)*. Established risk factors for infection include both homosexual and heterosexual contact, perinatal exposure and parenteral exposure. Parenteral exposure includes such specific risks as sharing needles during intravenous drug use and receiving blood, blood products, or tissues that are contaminated by HIV. Healthcare workers, in addition to these traditional risk behaviors, are at occupational risk for acquiring HIV infection following a parenteral or mucous membrane exposure to blood or blood-containing body fluids from HIV-infected patients.

Exposure to contaminated body fluids from HIV-infected patients and the potential for acquiring occupational HIV infection are issues that usually result in substantial healthcare worker anxiety. Even though the risk for occupational infection with hepatitis B virus (HBV) (see Chapter 73) in the healthcare environment has been documented since 1949 (3) and is associated with significantly more morbidity and mortality in the healthcare setting than is HIV, a clear focus on defining and minimizing healthcare workplace risks was not developed until the HIV epidemic was well underway *(4,5)*. Since the early 1980s, the subject of occupationally acquired HIV infection has received extensive media coverage, both in the lay press and in scientific forums. In this chapter, we attempt to frame these occupational risks in the context of available scientific knowledge in an attempt to provide a somewhat broader perspective regarding the risks for HIV transmission in society.

ETIOLOGY

HIV-1 is the only retrovirus that has been associated with serious occupational morbidity and mortality. Several cases of simian immunodeficiency virus (SIV) seroconversion have been reported *(6,7)*, but this virus has not yet been shown to cause disease in humans, and the SIV-seropositive laboratory workers remain well. Because several other human retroviruses have routes of transmission similar to those of HIV-1 (e.g., HIV-2, human T-cell lymphotrophic virus [HTLV] I *(8)*, and HTLV-II), occupational transmission of these viruses may someday be detected, although no reports of occupational infection with these other agents have been published. Nonetheless, risks of transmission associated with other retroviruses are likely to be extremely low, and current guidelines for prevention of transmission of HIV-1 are thought to be adequate to prevent transmission of all bloodborne viruses, including other retroviruses.

PATHOGENESIS

HIV derives a major survival advantage from its ability to target the immune system by infecting CD4+ T cells and by inducing a specific cytokine milieu. The wide range of immunologic abnormalities in HIV-infected patients results primarily from the impairment of T cell–mediated immunity. The virus produces billions of virions and T-cell turnover is estimated at a billion cells/day, accounting for the very rapid emergence of viral variants and the progressive nature of T-cell depletion. Even during clinical latency, this battle between countless virions and a continuous but slow repopulation with newly produced T-cells results in a highly activated immune system that attempts to control virus replication and renew itself. Several pathologic mechanisms have been suggested as resulting in T-cell loss, including indirect viral killing and activation-induced apoptosis. Highly active antiretroviral regimens can produce sustained reductions of plasma viral RNA to below detectable limits. Even in those with no detectable plasma RNA, viral DNA could be detected in lymph nodes and peripheral blood mononuclear cells (PBMCs) and virus could be grown from peripheral lymphocytes after removal of CD8+ cells and activation *(9)*. These observations that substantial viral replication occurs in lymphatic tissue during the period of clinical latency *(10)* while viral levels

in peripheral lymphocytes are undetectable or detectable at low levels *(11)* reinforce the insidious nature of the immunopathogenic effects of this virus. Disease progression is determined by the complicated interplay between viral and host factors, including different genetic polymorphisms of receptors, ligands, and key immune proteins that result in specific modulations of the host response to HIV infection (12). Inoculum size and certain inherent properties of the virus (e.g., syncytium-inducing viral phenotype) appear to confer greater overall HIV pathogenicity and may shorten the time to development of symptomatic HIV infection. In the 24 years since the introduction of zidovudine for the treatment of HIV, 25 drugs in six different classes used in varying combinations have resulted in predicted survival of nearly 40 years after combination antiretroviral therapy is initiated *(13)*. Combination antiretroviral therapy has been clearly linked with reductions in morbidity and mortality, with the most dramatic reductions coinciding with increases in the use of protease inhibitors *(14)*. Despite these therapeutic advances, reservoirs of HIV-1 have been identified that represent major impediments to eradication, including latent CD4+ T cells, hematopoietic stem cells of the monocyte/macrophage lineage, and dendritic cells *(15,16)*. Current antiretroviral therapy effectively suppresses but does not eradicate HIV infection *(17)*. The low rate of occupational infection following parenteral exposures to blood from patients known to be infected (i.e., ~3/1,000) may relate to the very low inoculum and/or to spontaneous clearance by cellular immune mechanisms. In one study, T-cells from six of eight HIV-exposed, but uninfected healthcare workers produced interleukin-2 when exposed to HIV peptide antigens *(18)*, and in a second study, cytotoxic T-lymphocytic responses to HIV envelope peptides were detected in 7/20 (35%) of healthcare workers who had sustained occupational exposures to HIV-positive blood compare with only 1 of 20 controls *(19)*.

Evidence has accumulated that infection of Langerhans cells, which are the dendritic cells of the epidermis, plays a pivotal role in early transmucosal and transepidermal transmission *(20)*. HIV infection of these Langerhans cells is regulated by surface expression of CD4 and HIV coreceptors, specifically CCR5. Langerhans cells, which represent only 2% to 3% of all epidermal cells, become infected very early (within 24 hours of exposure), and within an additional 24 to 48 hours this cell population has migrated from epithelial tissue to lymphoid tissue *(21,22)*. Within 5 days, HIV is detectable in peripheral blood in the SIV model. In addition, a molecule called DC-SIGN functions as an attachment factor and mediates capture of HIV by dendritic cells without infection of these cells *(20)*. HIV captured by dendritic cells maintains infectivity for 25 days *in vitro* in the absence of replication within dendritic cells, whereas free virus rapidly loses its infectious potential. Langerhans cells are the major epidermal cell type that is involved in transmission of HIV to lymphoid tissue *(23)*. Thus, the ability to block infection of dendritic cells or to block the handoff from dendritic cells bearing HIV on their membranes to susceptible T cells by HIV may importantly impact occupational transmission of HIV *(24)*. Recently, sequencing viruses in heterosexual transmission pairs and in acute HIV infection provided evidence that a single virus (or infected cell) initiated productive infection in close to 80% of the individuals tested, and two to five viruses in the other 20% (*25*,26). The greatest opportunities for prevention are strategies that target these initially small and genetically homogeneous foci of infection in the first week of infection (27). Additionally, since systemic HIV infection is not thought to occur immediately following exposure, a brief window of opportunity may allow modification of viral replication in the initial target cells or lymph nodes with postexposure antiretroviral treatment.

Once occupational transmission of HIV has occurred, the pathogenesis of infection is not thought to be different from that following other modes of transmission. As occurs with other HIV transmission modalities, some healthcare workers who have acquired occupational HIV infection have progressed quite rapidly to AIDS, while others remain asymptomatic after many years of infection.

DIAGNOSIS AND CLINICAL MANIFESTATIONS

The clinical and laboratory manifestations of HIV infection are generally no different for healthcare workers who acquire occupational infections than they are for persons infected through other routes. Findings that may be useful in establishing the diagnosis of HIV infection of healthcare workers are discussed in detail in the following paragraphs.

HIV-specific antibodies usually appear from 6 weeks to 4 months following exposure. An analysis of 51 seroconversions in healthcare workers determined that the estimated median interval from exposure to seroconversion was 46 days, with a mean interval of 65 days *(28)*. Serodiagnosis consists of screening enzyme-linked immunosorbent assays (ELISAs) followed by a diagnostic Western blot when the ELISA is positive. On evaluation using the Western blot technique, antibodies to the group-specific antigen/core (GAG) proteins (i.e., p18, p24, and/or p55) may be the first to appear, but antibodies to the envelope (ENV) (e.g., gp120, gp160, and gp41) and polymerase (POL) gene products (e.g., p31) develop thereafter, confirming the serodiagnosis of HIV infection. Rapid HIV antibody testing with high sensitivity and specificity (99.6% and 100%, respectively) and 20-minute turnaround time are now widely available with six rapid HIV tests approved by the U.S. Food and Drug Administration (FDA). Rapid testing may facilitate source patient testing and decrease the length of time healthcare workers take postexposure prophylaxis (PEP) pending the source patient HIV test result. Delayed seroconversion has been suggested following sexual exposures *(29,30)*, and the relatively low-inoculum exposures sustained by healthcare workers could result in latent HIV infection and delayed seroconversion. PEP does not appear to prolong time to development of HIV antibodies *(31)*. In 95% of healthcare workers who became infected after occupational exposures, seroconversion occurred within 6 months of the exposures *(31)* when routine testing has been performed. According to CDC, two cases of delayed seroconversion occurring in healthcare workers have been reported *(31)*. These healthcare workers had both tested seronegative for HIV at least 6 months following exposure, but were seropositive within 12 months after the exposure. One of these delayed seroconversions was associated with

concomitant exposure to hepatitis C virus (HCV), and this individual developed co-infection with hepatitis C that was rapidly fatal *(32)*. CDC models indicate that the upper 95th percentile of the distribution of time between exposure and seroconversion is 190 days, and that 5% of healthcare workers are estimated to seroconvert in <6 months following exposure *(33)*. Acute retroviral syndrome *(34–36)* associated with primary HIV infection has been a relatively common finding among healthcare workers in whom documented occupational HIV infection has occurred. This syndrome usually occurs 4 to 6 weeks after the occupational exposure. The CDC reported that 81% of healthcare workers experienced a syndrome compatible with primary HIV infection in a median of 25 days after exposure *(28)*. This clinical syndrome has been described as resembling acute infectious mononucleosis: fever, rash, malaise, myalgias/arthralgias, headaches, night sweats, pharyngitis, and lymphadenopathy have been documented *(34–36)*. Laboratory abnormalities have also been described, including reduced total lymphocyte count, elevated sedimentation rate, and elevated transaminases and alkaline phosphatase levels.

Core (i.e., p24) antigenemia may be detected coincident with the onset of symptoms and usually resolves within several weeks to months, as antibodies to p24 are produced and become detectable in the peripheral circulation *(37)*. One can also detect the presence of virus, either by culture or by polymerase chain reaction (PCR) in cerebrospinal fluid, PBMCs, and plasma before the development of an antibody response in persons who have sustained nonoccupational exposures *(35,38–40)*. Plasma HIV RNA levels are highest immediately after acquisition and then rapidly decrease *(41)*. These direct virus assays (including HIV p24 antigen EIA, PCR for HIV RNA, and the branched-chain DNA assay) consistently detect infections 1 to 2 weeks earlier than the most sensitive antibodies, but they still do not become positive until weeks or months postexposure and they may revert to negative following antibody seroconversion *(33)*. Interestingly, no association between plasma HIV RNA levels at the time of seroconversion and subsequent rate of CD4+ cell loss or AIDS progression has been detected *(41)*. The use of PCR to detect circulating viral RNA will likely supplant the use of the p24 antigen test, although the p24 assay turnaround time is much shorter than for the PCR assay in some centers.

Although direct virus assays have been used as ancillary tests in the diagnosis of occupational HIV infection, these tests should not routinely be used to detect infection in exposed healthcare workers *(33)*. These tests may be helpful in defined adjunctive circumstances, such as when the ELISA is positive but the Western blot is indeterminate, or when symptoms are consistent with the acute retroviral syndrome but serologic testing remains negative for more than several weeks. A negative direct virus assay should never be the basis for excluding infection. Although ultrasensitive direct virus assays are available (quantitation of HIV-1 RNA down to 50 copies/mL), the risk for false positive results increases accordingly.

Symptoms consistent with the acute retroviral syndrome signal that HIV antibodies will appear, usually within 1 to 10 weeks *(35)* if infection has indeed occurred. Healthcare workers who sustain occupational exposures should be educated about the symptoms of the seroconversion illness and should be instructed to seek urgent attention in the employee health clinic if these symptoms appear. In most occupational seroconversions, HIV seropositivity has not been documented as part of the routine serologic follow-up but has been detected after the healthcare worker seeks medical attention for an illness consistent with seroconversion. Nonetheless, the CDC recommends HIV antibody testing at 6 weeks, 3 months, and 6 months following the occupational exposure (*42*,43). The National Institute of Health (NIH) Clinical Center Occupational Medical Service also elects to check HIV antibody status at 12 months following exposure, although this is not routinely recommended by the CDC because of the rarity of delayed seroconversion events (*42*,43). Because of the anecdotal experience with delayed HIV seroconversion occurring following concomitant exposures to HIV and HCV, most authorities would recommend extending follow-up to 12 months following simultaneous exposures to hepatitis C and HIV.

EPIDEMIOLOGY

Occupational injuries and exposures to blood and body fluids continue to be commonplace in virtually every healthcare setting. Healthcare workers who sustain these injuries often react immediately with anxiety, fear, and concern over their risk for acquiring HIV. Framing the issue of HIV transmission risk is quite complex. Nonetheless, more than a decade of dealing with HIV infection in the healthcare workplace has led to a fairly extensive database characterizing these occupational risks.

Healthcare workers' perceptions of risk were initially affected by the news media and publicity regarding cases of occupational infection. The sensationalism that traditionally accompanied HIV-related issues in the media artificially inflated perceptions of occupational risk. We frequently find that both the lay public and, particularly, healthcare workers believe that large numbers of occupational HIV infections have been documented. Depending on the definition of "occupational infection" chosen for the analysis, one can arrive at quite disparate assessments of the number of occupational HIV infections documented in the United States (44). The number of cases of occupational HIV infections in healthcare workers has clearly decreased dramatically over the past decade.

Reports of Occupational Infections

A wide variety of sources have provided information about HIV infection in healthcare workers (44). Several general types of case reports have appeared in the literature, ranging from healthcare workers in whom HIV seroconversions have been documented following an occupational exposure to healthcare workers who are found to be seropositive but in whom the seropositivity cannot be linked to a discrete injury or exposure.

Documented seroconversions are generally defined as cases in which a healthcare worker sustains an injury with a device contaminated with blood from an HIV-seropositive or indeterminate source; the healthcare worker is documented to be HIV-seronegative at the time of the exposure, and then the healthcare worker develops

serologic evidence of HIV infection within the ensuing 6 months. Documented seroconversions are the source of the most detailed and reliable epidemiologic information about occupational infections and are, in fact, the standard against which other types of information about occupational HIV infection can be measured. Through June 30, 2009, 57 cases of occupational seroconversions had been documented either in the medical literature or in individual case reports to the CDC that meet the criteria established for this category of occupational infection (45,46). Of the 57 infected healthcare workers, 48 had percutaneous injuries, 5 had mucocutaneous exposures, 2 had both percutaneous and mucous membrane exposures, and 2 had unknown routes of exposure.

In addition to these documented seroconversions, a number of additional cases of HIV infection have been categorized by the CDC as "possible" occupational infections. This "possible occupational infection" category exhibits different demographics from the set of individuals who have documented occupational infections, and likely include individuals who have confounding community-based risk for infection (44). Since the overwhelming majority of these cases have been reported as anecdotes, these data provide only limited insight into the magnitude of risk for occupational infection (i.e., based on these data, one can state only that healthcare workers are at risk for occupational HIV infection). Some conclusions can be drawn, however, from the cases of documented seroconversions regarding the epidemiology of occupational infection. For example, by examining cases of documented seroconversion for circumstances of occupational exposure, one can gain substantial insight into the types of exposures likely to result in transmission of HIV. Even these relatively small databases provide evidence that the risk associated with mucocutaneous exposures appears to be lower than the risk associated with percutaneous injuries.

Data Describing the Magnitude of Risk of HIV Transmission in the Healthcare Setting

Longitudinal cohort studies of healthcare workers involved in the day-to-day care of HIV-infected patients and in the handling and processing of specimens from such patients provide the best available data regarding the magnitude of risk for transmission in the healthcare setting. A number of prospective studies have followed healthcare workers who have sustained documented exposure to blood or blood-containing body fluids from HIV-infected patients. In all of these studies, healthcare workers undergo baseline and follow up HIV serologic testing (at a minimum) any time a healthcare worker sustains a percutaneous exposure to blood from an HIV-infected patient. The average risk of HIV infection following percutaneous exposure to HIV-infected blood has remained at approximately 0.3% (95% confidence interval [CI] = 0.2–0.5%) for a number of years.

Similarly, other prospective studies have examined the risk associated with mucous membrane exposures to blood or body fluids from HIV-infected patients. Although mucous membrane exposures that resulted in HIV transmission have been reported anecdotally *(47,48)* no seroconversions have occurred following the mucous membrane exposures that were prospectively collected from enrollees in these longitudinal studies.

Factors that Might Influence the Risk of Transmission

Although these data are reasonably specific, and CIs around the calculated risks of transmission are narrow, we still lack sufficient information to predict which injuries will result in transmission of infection. Many of the percutaneous injuries that have been associated with documented seroconversions have been quite deep or extensive or have involved injection of a volume of blood into the healthcare worker, whereas other percutaneous injuries associated with transmission have been relatively minor. Mucous membrane or nonintact skin exposures that resulted in transmission have almost uniformly been quite extensive (e.g., the contact with blood has been for a prolonged period [>15 minutes] or has involved large areas of skin surface). Occasionally, injuries that one might intuitively think would have a higher than average risk for infection have not resulted in infection. For example, a healthcare worker at the Clinical Center, NIH, sustained a severe injury with a bone marrow aspiration needle that had been used on a patient with end-stage HIV disease; the needle actually penetrated through the palm and was visible from the dorsum of the worker's hand. This exposure did not transmit HIV infection.

The epidemiologic factors contributing to the risk for occupational infection have been explored using the case-control method (49). Thirty-three cases of occupational HIV seroconversion following percutaneous exposures to HIV-infected blood and 665 controls who did not seroconvert were studied by Cardo et al. (49) at the CDC. Multivariate logistic regression identified several risk factors associated with HIV transmission after percutaneous exposure: deep injury (odds ratio [OR] 15, 95% CI 6.0–41), visible blood on device (OR 6.2, 95% CI 2.2–21), procedure involving needle in artery or vein (OR 4.3, 95% CI 1.7–12), terminal illness in source patient (OR 5.6, 95% CI 2.0–16), and postexposure use of zidovudine (OR 0.19, 95% CI 0.06–0.52). Increased risk was associated with factors that are indirect measures of the inoculum size (i.e., the quantity of blood transferred in the exposure) or higher viral burden (i.e., source patient in the terminal stage of AIDS). Thus, although the average risk of HIV transmission following a percutaneous exposure is 0.3%, the risk of transmission following exposures involving large quantities of blood or high viral titers may be substantially higher than the average risk. Corroborating evidence for the factors identified by the case-control study was supplied by a laboratory study that demonstrated that more blood is transferred by deeper injuries and hollow-bore needles *(50)*. Mast and Gerberding *(51)* also determined that glove use reduced the transferred blood volume by nearly 50% in their laboratory model.

Despite our inability to predict with precision which exposures will result in transmission of HIV infection, the documented seroconversions have provided us with specific information about which body fluids have resulted in transmission. Of the 57 documented seroconversions, 49 exposures were to HIV-infected blood, 1 to visibly bloody pleural fluid, 4 to an unspecified fluid, and 3 to a concentrated viral preparation in a laboratory *(42)*. Thus, blood appears to be the major clinical risk associated with transmission. One case report documented transmission of HIV to a laboratory technician from Germany who sustained an

accidental splash of serum from an infected patient to his eye *(52)*. Transmission in this case was likely facilitated by failure to wash the eye and by concomitant conjunctivitis related to a contact lens present in his eye at the time of exposure. Blood, visibly bloody body fluid, and now serum clearly remain the primary risk for occupational transmission of HIV in the healthcare setting *(47)*.

The type and, likely, size of the needle or sharp object involved in the injury also appears to affect the risk of transmission. To date, to our knowledge, no cases of occupational infection have been definitively linked to an exposure resulting from a solid (i.e., suture) needle. Transmission has been associated with several types of hollow-bore needles (including injection needles and intravenous catheters) and other sharp objects (including contaminated broken glass, scalpels and an orthopedic pin *(47)*).

Finally, certain source patient variables, and, perhaps, even several factors relating to the recipient healthcare worker's status, likely affect transmission. Source patients with terminal HIV disease were found to be associated with higher risks of HIV transmission in the case-control study discussed previously (49). Although data regarding specific measurement of HIV viral burden were not available to the CDC researchers, the increased risk of HIV transmission from source patients who are in the late-stage of HIV infection likely is a surrogate marker for the source patient's circulating viral burden. Some also have postulated that the recipient healthcare worker's histocompatibility with the source patient (i.e., human leukocyte antigen [HLA] type, etc.) or any concurrent viral illnesses, such as Epstein Barr virus, cytomegalovirus infection, or infection with human herpesvirus-6 that results in increased CD4 expression, or the presence of chronic inflammation at or around the skin entry site, might also influence the risk of transmission. Despite this educated speculation, the numbers of cases of documented seroconversions with these data available are too few to permit adequate characterization of these risks.

Comparison of the Risk of HIV Transmission to the risk of Transmission of other Bloodborne Pathogens

When assessing the risk of acquiring occupational HIV infection, healthcare workers must be able to place that risk into the broader context of risks associated with other bloodborne pathogens such as hepatitis B and hepatitis C (see Chapter 73). Hepatitis B has long been recognized as a significant cause of healthcare worker morbidity and mortality; healthcare worker risks associated with hepatitis C have been documented and partially characterized in the past decade *(53–55)*.

The CDC estimated in 1987 that 12,000 cases of hepatitis B infection per year occurred among healthcare workers in the United States and that 500 healthcare workers were hospitalized each year because of the complications of occupationally acquired hepatitis B *(56)*. Additionally, prior to the full-scale implementation of hepatitis B immunization, approximately 200 workers died each year from occupational hepatitis B or its complications *(57)*. Subsequently, Mahoney et al. *(58)* found that the calculated number of HBV infections among healthcare workers declined from 17,000 in 1983 to 400 in 1995. This dramatic decline was associated with implementation of Universal Precautions policies, with licensure of recombinant-DNA hepatitis B vaccines, and with the implementation of the Occupational Safety and Health Administration (OSHA) Bloodborne Pathogens Standard *(59)*.

The risk associated with hepatitis C appears to be lower than the risk associated with hepatitis B: healthcare workers with frequent blood contact account for 1% to 2% of reported cases of hepatitis C infection *(60)*, and seroprevalence studies indicate that healthcare workers' risk of hepatitis C infection is only slightly higher than that of volunteer blood donors. Several small prospective studies have measured the risk of transmission after percutaneous exposure to average 1.9% (see Chapter 73) *(61)* with a range from approximately 0% (in six studies, summarized in reference *(54)*) to 22% *(62)*, depending on the size of the population studied and the assays used to test source patients and employees, among other important variables. Lower rates of transmission have been associated with the use of the (much less sensitive) first generation hepatitis C serologic test and with an interesting geographic distribution (see Chapter 73).

PREVENTION AND CONTROL

Despite the fact that several indirect pieces of evidence suggest that the administration of antiretrovirals as PEP may reduce the risk of HIV transmission (46,49,*63*), because of the toxicity and inconvenience of the agents administered as PEP, the attention of the healthcare community should be focused first on preventing occupational exposures as a means of preventing transmission of HIV. The U.S. Federal government has issued regulations that have just this intent. In 1991, the OSHA issued regulations *(59)* that were designed to ensure employer compliance with full implementation of Universal Precautions *(64)*. This "Bloodborne Pathogen Standard" also mandates that employers offer hepatitis B immunization to healthcare workers at risk for occupational exposure at no cost to the employee.

Primary Prevention of Exposures in the Healthcare Workplace

In the time that has elapsed since the initial cluster of cases of *Pneumocystis jiroveci* pneumonia was identified in Los Angeles in the summer of 1981 *(65)*, the CDC issued a series of guidelines with the goal of preventing transmission of HIV infection to healthcare providers (*4,42*,43,*56,64, 66–75*). The concept of "universal precautions," or use of blood and body-fluid precautions for the care of all patients was first proposed by the CDC in 1985 *(4)* and again in 1986 *(69)*. The August 1987 guidelines (frequently referred to as the Universal Precautions guidelines) consolidated and updated all previous CDC recommendations concerning the prevention of occupational infection with HIV *(64)*.

The 1987 Universal Precautions guidelines (summarized in Table 74-1) strongly emphasized the need for every healthcare worker to consider all patients as potentially infected with HIV or other bloodborne pathogens and to adhere to infection-control precautions for minimizing the risk of exposure to blood and body fluids from all patients. These guidelines have been updated by the Hospital Infection Control Practices Advisory Committee *(76)*. Universal Precautions

TABLE 74-1

Use of the Measures in Standard Precautions to Prevent the Transmission of HIV in Healthcare Settings[a]

- Standard Precautions should be consistently used for all patients since only serologic testing reliably identifies all patients infected with HIV or other bloodborne pathogens.
- Standard Precautions apply to blood and bloody body fluids, semen and vaginal secretions, tissues, cerebrospinal fluid, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, and amniotic fluid
- Appropriate barrier precautions should routinely be followed to prevent skin and mucous membrane exposure when contact with blood or other body fluids of any patient is anticipated
- Gloves are required for touching blood and body fluids, mucous membranes, or nonintact skin of all patients; for handling items soiled with blood or body fluids; and for performing vascular access procedures
- Masks and protective eyewear or face shields are required when droplets of blood or other body fluids might be generated that could contact mucous membranes (eyes, nose, mouth)
- Gowns are required when splashes of fluids might be generated
- Hand washing is required after contamination with blood or other body fluids and immediately after gloves are removed
- Precautions should be taken to prevent sharps injuries during procedures, during cleaning of instruments, and during disposal of used needles
- Needles should never be recapped, purposely bent or broken, or removed from disposable syringes
- Disposable syringes and needles, scalpels, and other sharps should be placed in puncture-resistant containers for disposal; these containers should be placed as close as practical to the area where sharps are being used
- Mouthpieces, resuscitation bags, or other ventilation devices should be available where their use can be readily anticipated
- Healthcare[b] workers who have exudative lesions or weeping dermatitis should refrain from all direct patient care
- Pregnant[b] healthcare workers should be especially familiar with and should strictly adhere to the concepts of Universal Precautions

[a]Standard Precautions are now used in place of Universal Precaution for prevention of the transmission of HIV and other bloodborne infections in healthcare settings (Siegel JD, Rhinehart E, Jackson M, et al. *Guideline for isolation precautions: preventing transmission of infectious agents in healthcare settings*, 2007).
[b]Recommendations not included in Standard Precautions.

and body substance isolation *(77)* are now amalgamated into a single set of guidelines called Standard Precautions *(76)*.

Although the use of Universal or Standard Precautions (see Chapter 90) has been advocated as a means to prevent occupational exposures to blood and other body fluids, neither the efficacy nor the cost-effectiveness of these admittedly labor-intensive and costly *(78)* precautions has been demonstrated definitively. Furthermore, Standard Precautions, with its emphasis on barrier precautions, may not prevent percutaneous injuries, which are the major risk associated with occupational infections, although appropriate handling and disposal of needles and other sharp objects is an integral component of these guidelines.

Studies of the efficacy of Standard Precautions have produced inconsistent results. At least one study has concluded that Universal Precautions training was associated with increased incidence of injuries *(79)*, whereas others have reported stable exposure rates *(80)*. Some studies have shown decreases in recapping or needle-disposal device-related injuries, but stable (or slightly increased) overall injury rates *(81–85)*. The studies indicating that implementation of Universal Precautions did not decrease overall injury rates almost uniformly suggest poor healthcare worker adherence to the components of Universal/Standard Precautions or failure to assess adherence to the precautions. Several other groups have reported trends toward fewer needlestick injuries in association with Universal Precautions *(78,86)*. Investigators at the Clinical Center, NIH, reported that implementation of Universal Precautions was associated with a significant decrease in both cutaneous *(87)* and reported parenteral exposures to blood (88). A review of published percutaneous injury rates per 100 employees found that injury rates following implementation of the Bloodborne Pathogens Standard in 1992 (see paragraph below) were lower than those based on pre-1992 data *(89)*. To the extent that these precautions are actually followed, they will very likely reduce occupational exposures to bloodborne pathogens. Ensuring adherence to the recommended precautions, however, is a challenging matter. Despite these controversies, Universal/Standard Precautions have been widely implemented and are now mandated by the OSHA *(59)*.

This mandate was published by the Department of Labor *(59)* as the "Occupational Exposure to Bloodborne Pathogens; Final Rule" in the Federal Register in December 1991 (the details of this Final Rule are summarized in Table 74-2). Employers, including hospitals and virtually any setting in which exposure to blood might occur, are now required to have in place an Exposure Control Plan that mandated implementation of Universal Precautions. In addition, a series of other requirements have been imposed, including extensive documentation and record-keeping regarding compliance with these regulations. Other requirements relate to engineering and work practice controls, use of appropriate personal protective equipment, detailed housekeeping standards, and requirements for "biohazard" labeling. Free hepatitis B immunization is now required for all employees with any potential for exposure; healthcare workers who decline vaccination must sign an "informed refusal," the content of which is specified in the Final Rule. Finally, the OSHA has established an obligatory federal standard of practice

TABLE 74-2

Requirements of the OSHA's Bloodborne Pathogens Standard

Hospitals and other healthcare employers are required to:

- Develop an exposure control plan that identifies employees with occupational risk of exposure to blood or body fluid
- Train all employees annually on occupational risks and methods to reduce risk of exposure
- Maintain records of employee training for 3 y and of medical evaluations for the duration of employment plus 30 y
- Use warning labels and signs to identify biohazards; red bags or containers are allowed to substitute for the label in many cases
- Implement engineering and work practice controls for worker protection, including specific requirements for:
  - Hand washing
  - Safe handling and disposal of sharps
  - Employee conduct in areas of potential exposure
  - Management, storage, and shipping of specimens
- Provide personal protective clothing and equipment
  - Employees must be trained how and when to use equipment
  - Cleaning, laundering, repair, and replacement is the employer's responsibility
- Maintain detailed housekeeping standards, including requirements for special handling and bagging of "contaminated" laundry
- Provide voluntary hepatitis B vaccine at no cost to employees
  - Prevaccination screening cannot be required
  - Employees declining vaccination must sign an "Informed Refusal," the content of which is specified
- Provide medical evaluation after exposure incidents
  - Ensure testing of the source patient when consent is obtained
  - Provide postexposure prophylaxis as recommended by the U.S. Public Health Service
- Institute additional precautions for HIV and HBV research and production facilities, where applicable

(Adapted from: 29 CFR 1910.1030. Available at *http://www.osha.gov/pls/oshaweb/owadisp.show_document?p_table=standards&p_id=10051)*

for employers when an employee is involved in an exposure incident; current recommendations of the U.S. Public Health Service must be implemented following an exposure incident.

Certain portions of the Final Rule were impatiently awaited by occupational medicine and healthcare epidemiology personnel, in particular the requirement to document compliance with the hepatitis B vaccination. Although the rates of occupational hepatitis B have decreased dramatically with the OSHA Final Rule and use of Universal Precautions *(58)*, absolute protection can only be assured with evidence of serologic immunity. Prior to publication of the OSHA Final Rule, the CDC estimated that only 30% to 40% of healthcare workers had been vaccinated *(90,91)*. In 1995, Agerton et al. *(92)* concluded that the OSHA Final Rule resulted in a greater awareness in healthcare workers of their risk for hepatitis B and an increase in the number of workers receiving the vaccine; nonetheless, only 51% of eligible workers had completed a vaccination series. Other portions of the Final Rule, such as the "exposure determination" requirement, in which employers must list all job classifications in which some employees have occupational exposure to blood, and then list every task and procedure performed by the employees in those job classifications, are remarkably onerous and have undoubtedly greatly increased the workload of healthcare epidemiology personnel with, in our opinion, little likely benefit to the employee.

Management of Occupational Exposures

Healthcare institutions have ethical and now legal responsibilities to develop and implement protocols for managing healthcare workers who are occupationally exposed to bloodborne pathogens. However, given the major gaps in the available scientific data regarding these issues, the optimal management of employees sustaining exposures remains elusive. Thus, this issue, which is particularly difficult for the healthcare workers who sustain the exposures, is likely to remain as problematic for hospital administrators, hospital legal staff members, healthcare epidemiologists, Infection Preventionists, hospital infection control committees, and employee health staff members, who often are responsible for development and implementation of policies and procedures designed to manage exposed employees.

In addition to the routine difficulties inherent in any occupational exposure, HIV-related exposures present the additional concern of secondary transmission of HIV to significant others. Healthcare workers who sustain occupational HIV exposures often react with profound anxiety and experience severe emotional and psychological stress. Managing these exposures is complex, labor-intensive, and often emotionally draining for the physician/counselor in the occupational health service *(93)*.

Postexposure management of occupational exposures should be routinely taught in professional schools and reinforced during healthcare epidemiology and occupational health interactions with healthcare workers (e.g., during orientation of new employees and during initial and recurring Standard Precautions training). Institutions should not defer disseminating this information until after an exposure; all healthcare workers should be aware of the appropriate procedures to follow irrespective of whether an exposure has occurred. The process of immediate

postexposure management should consist of three basic steps: administration of immediate first aid at the work site, informing one's supervisor of the event if the supervisor is immediately available, and immediately reporting to the Occupational Medical Service (or through another institutionally established reporting mechanism). We encourage our employees to report all exposures for two reasons: first, proper treatment (e.g., first aid and—when appropriate or desirable—postexposure chemoprophylaxis) can be administered, and second, reporting allows documentation of work-related exposures and facilitates workers' compensation claims when such claims are appropriate.

Although no data address the efficacy of immediate application of first aid in preventing transmission of occupational bloodborne infections, most authorities recommend administration of first aid immediately following an exposure as a logical action (*42*,43,*94*). Given a lack of data with which to make a scientific recommendation regarding first aid, selection of agents for decontamination (e.g., soap and water, chlorhexidine, iodophors, peroxide) should depend, in part, on which agents are most readily available. Although following an established institutional regimen seems an entirely reasonable approach, occupational medicine staff should explain that no data document the efficacy of these first-aid interventions in preventing occupational infection with bloodborne pathogens. In fact, an anecdotal report documents occupational infection with HIV despite the immediate application of first aid, including thoroughly rinsing the injury site (a cut from glass contaminated with blood from an AIDS patient) with undiluted bleach *(95)*. At the Clinical Center, NIH, our routinely recommended procedure is immediately to scrub the site of the injury or cutaneous exposure with a povidone-iodine solution and to attempt to "milk" the site of a transcutaneous exposure to express blood. Clinical Center guidelines also recommend that mucous membrane exposures affecting the mouth or nose be rinsed thoroughly with water or saline; exposures affecting the eyes should be rinsed thoroughly with water, saline, or sterile irrigants *(93,96)*.

Once the site has been decontaminated, the healthcare worker should inform his or her supervisor about the exposure (if the supervisor is in the immediate vicinity or can be reached within a minute or two) so that the supervisor can provide coverage while the employee is away from the area. The healthcare worker should then report immediately to the institution's employee health service. Reporting of exposures is essential both to ensure adequate care for the injured employee and to assist the institution in making necessary policy and procedural changes to minimize risks of injury to other employees. In order to facilitate reporting, a mechanism should be defined and widely publicized and must be capable of being activated at any time of the day. A number of institutions have implemented 24-hour-a-day hotlines staffed by expert clinicians who can coordinate both exposure reporting and employee management. Clinicians who provide first-line response to employees exposed to patients known or suspected to be HIV-infected should be prepared to provide state-of-the-art medical management of occupational exposures but also must be prepared for and capable of dealing with the extreme anxiety and occasional hysteria associated with these exposures.

Education and counseling are important components of the management of occupational exposures to bloodborne pathogens. Employees sustaining exposures to blood or body fluids from patients known or suspected to be HIV-infected need counseling regarding (a) the epidemiology, routes of transmission, and transmissibility of HIV, (b) the risk for occupational transmission of HIV following such an injury, (c) the importance of notifying the occupational health service of any acute febrile illness, and (d) techniques effective in minimizing the risk for transmission of HIV to sexual partners *(93)*.

Management of employees sustaining exposures to blood or body fluids from patients whose HIV status is unknown is confounded by the problems associated with testing the source patients. Each institution should develop a policy for the management of exposures when the source patient is either unable or refuses to consent to these tests that is consonant with State and/or local laws. Many states have laws that either permit testing of source patients in certain circumstances even if consent is refused or legally require informed consent for testing.

For institutions to achieve and maintain roles as healthcare worker advocates, the medical confidentiality and privacy of healthcare workers who sustain occupational exposures and/or infections must be preserved. Each employee who sustains an occupational exposure must be apprised fully of the procedures used for ensuring confidentiality and reassured that records will not be released without his or her consent. In order to maintain privacy, laboratory samples should never be submitted with identifiers that can be traced to an individual. Additionally, access to records of occupational exposures should be strictly controlled. We recommend that records of HIV, hepatitis B, and hepatitis C testing of employees be maintained separately from routine employee health records. Indeed, the OSHA requires the employer to obtain a copy of the evaluating healthcare professional's written opinion only, which must include a statement that the employee has been informed of the results of the evaluation and told about any medical conditions resulting from exposure that may require further evaluation and treatment. All other medical findings or diagnoses must be kept confidential and not included in the written report provided to the employer *(59)* (see Table 74-2).

Secondary Prevention of HIV Transmission—Postexposure Antiretroviral Prophylaxis Following Occupational Exposures

Ideally, primary prevention of occupational HIV infection would obviate the need for PEP. Unfortunately, neither implementation of Standard Precautions nor use of "safer" devices will prevent all injuries. Postexposure antiretroviral chemoprophylaxis has become the standard of care following at-risk injuries and exposures (*42*,43,*63,97,98*). Currently, the Public Health Service (PHS) recommends that PEP should be available as soon as possible following exposure (43), and the OSHA Final Rule mandates employer compliance with PHS recommendations *(59)*. Basic recommendations for PEP now include a two-drug regimen using two nucleoside analogs (zidovudine plus lamivudine or emtricitabine, or tenofovir plus lamivudine or emtricitabine) for 4 weeks (43). An expanded regimen

incorporating a third drug, usually a protease inhibitor (e.g., lopinavir/ritonavir [Kaletra]), is recommended for exposures that are associated with an increased risk for transmission (43). In instances in which resistance to antiretroviral agents incorporated in the basic regimen is anticipated, CDC has recommended using a combination of three agents to which the source patient's HIV isolate has not been exposed.

Whereas definitive evidence of the efficacy of chemoprophylaxis is still lacking, these recommendations for PEP were based on several pieces of evidence *(63,99)*. The retrospective case-control study results discussed previously in this chapter were initially presented in 1994 *(100)* and then in final form in 1997 (49). This study documented an association between use of zidovudine PEP and an 80% reduction in risk for HIV seroconversion *(101)*. This association was surprising and initially greeted with skepticism *(99)*, particularly since a retrospective case-control study design is not optimal for assessing the efficacy of PEP. Nonetheless, the association held true even with the addition of cases from the United Kingdom, France, and Italy. Although the magnitude of the protective effect may be altered with the future addition of more cases, the conclusion drawn from these data is that "…chemoprophylaxis may well be worthwhile after occupational exposure and may be a reasonable option after any type of exposure to HIV *(99)*." With a risk for infection of 0.2%, the sample-size requirements for a placebo-controlled trial are formidable. For example, assuming that a candidate agent is 80% effective and assuming a power of 80%, 17,110 healthcare workers would be needed for a double-blinded placebo-controlled trial to demonstrate significance at the 0.05 levels. Thus, definitive proof of the efficacy of postexposure, apart from the retrospective case-control study, is unlikely to ever be established.

Zidovudine was demonstrated to decrease the risk of maternal-infant transmission of HIV *(102)*. Only approximately 30% of the decrease in risk of vertical transmission following use of zidovudine prophylaxis was found to be attributable to a reduction in maternal viral burden, suggesting that newborns benefit from a substantial chemoprophylactic effect, effective preemptive therapy for HIV infection, or both *(103)*. Abbreviated zidovudine regimens have also been shown to be effective in decreasing the ratio of prenatal HIV transmission (*104*,105,*106*). Strikingly, in some of these studies, antiviral efficacy was demonstrated in instances in which only the infant received therapy (i.e., true PEP) (105,*107*), although a more recently published study recommends against infant-only treatment *(108)*. In addition, PEP has been shown to prevent or ameliorate retroviral infection in some animal studies *(109)*. Taken together, these pieces of evidence provide the foundation for the current U.S. Public Health Service recommendations (43).

Animal studies have provided insight—both to the safety as well as the efficacy of postexposure chemoprophylaxis regimens. Not surprisingly, given the fact that these agents are active at the level of nucleic acids, long-term studies of the chronic administration of antiretroviral agents to animals have identified toxicities, as well *(110–112)*.

Studies evaluating the efficacy of antiretroviral agents in preventing retroviral infections in animal models provide some of the best available evidence that these agents might, in fact, be of value in preventing occupational HIV infection. Whereas the results of the first such studies were relatively discouraging *(113–125)*, subsequent studies clearly demonstrated that antiretrovirals can prevent infection when the drugs are administered at, or shortly following, infection. Most of the initial studies demonstrated some drug effect (i.e., treated animals fared slightly better than controls, but all animals became infected) *(113–125)*. Beginning in 1992 *(126)*, studies in mouse and macaque models demonstrated the efficacy of chemoprophylaxis (*126–129*,130,*131*). Three sets of studies deserve special mention. The early studies of Ruprecht et al. *(132,133)* using the Rauscher murine leukemia virus (RMLV) model demonstrated as early as 1990 that either zidovudine or zidovudine plus alpha interferon could prevent RMLV viremia. Subsequent studies with this model demonstrated chemoprophylactic efficacy of zidovudine *(129)*. Böttiger et al. *(128)* studied 2,3′-dideoxy-3′-hydroxymethyl cytidine in a macaque model and showed that all treated animals that had been either injected intravenously or exposed intrarectally to either HIV-2 or SIV were protected, irrespective of the viral agent or the route of inoculation. Tsai et al. (130) administered a nucleotide analog agent, (*R*)-9-[2-phosphonylmethoxypropyl] adenine (PMPA, now FDA-approved as tenofovir), to several sets of macaques that had been infected intravenously with SIV. One set of animals was given PMPA at the time of infection, one set was given PMPA 4 hours after infection, and a third set was given the agent 24 hours after infection. All of the untreated control animals became infected, and none of the animals in any of the treatment groups developed any sign of SIV infection.

These animal models have also been used to evaluate factors that might modulate the efficacy of postexposure chemoprophylaxis. In the RMLV model the efficacy of antiretroviral prophylaxis is directly dependent on both the size of the viral inoculum administered and the presence of intact cellular immune mechanisms in the animals studied *(129)*. In the macaque model, Tsai et al. (134) demonstrated the importance of both the timely administration of chemoprophylaxis as well as the importance of the duration of therapy. In their model, all of the animals that were treated for a total of 28 days remained uninfected, whereas only half the animals treated for just 10 days were uninfected. In this model, none of the macaques treated for only 3 days were protected. These investigators also demonstrated that delay of treatment was detrimental in the model. None of the animals that received postexposure chemoprophylaxis within 24 hours of intravenous infection developed productive SIV infection, while only 50% of the animals treated at 48 hours after infection and 25% of animals treated at 72 hours after infection were protected from SIV infection.

The evidence provided by these animal studies is invaluable. The data clearly demonstrate that antiretroviral agents can prevent retroviral infections in these models. They do not, however, assure efficacy of prevention of HIV infection in humans.

Failure of chemoprophylaxis following occupational injuries to healthcare workers has been documented in at least 22 instances (*42*,43,*135*). Fourteen of twenty-three source persons were documented as having been

treated with antiretroviral therapy prior to the exposure. Antiretroviral resistance testing of source patient virus was performed in eight instances, and in four the virus was found to have reduced sensitivity to drug(s) used for PEP. Six additional cases of zidovudine failure following larger or direct intravenous inocula have occurred: two seroconversions occurred after direct intravenous inoculation of HIV-infected blood during nuclear medicine procedures *(136,137)*, another occurred after a deep stab injury inflicted on a prison guard *(138)*, the fourth case occurred following suicidal self-inoculation of blood *(139)*, and the fifth seroconversion occurred after transfusion of an entire unit of contaminated blood *(110)*. An additional case of suicidal self-inoculation was reported in which the exposed individual did not become infected after PEP with zidovudine, lamivudine, indinavir, ritonavir, and nevirapine. The authors suggest that the absence of infection was related to the small size of viral inoculum (2 mL blood with viral load <50 copies/mL), administration of PEP, and development of an HIV-specific T cell response *(140)*. Interestingly, genotypic resistance did not correlate with a lack of protection in the ACTG 076 study of zidovudine administration to attempt to prevent vertical transmission of HIV. Nonetheless, exposure to a strain of HIV with reduced sensitivity to the agents administered may influence the likelihood of failure of postexposure chemoprophylaxis. Other hypothesized reasons for the failure of PEP include a high viral titer or large inoculum exposure, time factors, including delayed initiation or premature discontinuation of PEP, host factors, including cellular immune responsiveness, and the source patient's virus, including the presence of syncytia-forming strains (141). Although anecdotal reports of failure provide useful insight into both injury circumstances and specific issues regarding administration of postexposure chemoprophylaxis, these reports indicate only that the efficacy of chemoprophylaxis is not 100% and do not, in themselves, prove lack of efficacy.

Delayed seroconversion following zidovudine prophylaxis has been a theoretical concern, since some of the animal data indicate that administration of zidovudine may merely delay viremia *(114)*. A review of zidovudine prophylaxis failure determined that 10 of 11 healthcare workers experienced an acute retroviral illness between 13 and 75 days (median 22 days) following the exposure, and all had seroconverted by 6 months following the exposure (141). These data are consistent with seroconversion data from healthcare workers who had not received PEP.

The role of resistant strains of HIV in the failure of chemoprophylaxis is unclear. A few reports of transmission of resistant isolates have been published *(142,143)*. Little et al. *(144)* reported in 2002 that the frequency of high-level resistance to one or more antiretroviral drugs increased from 3.4% (1995–1998) to 12.4% (1999–2000) among 202 subjects in 10 North American cities. Thus, the source patient's treatment history should be taken into account when determining the appropriate antiretroviral drugs for PEP. Data regarding perinatal transmission suggest that perinatal HIV transmission may be established by a relatively restricted number of virus particles and that drug-resistant forms may be less able to establish infection than wild type *(145,146)*. To further support this notion, several groups have found that virus with three-class multidrug resistance is infrequently transmitted which may reflect the poor replication capacity of these extensively mutated viruses *(147–150)*.

Combination regimens, particularly those using three or more drugs, have been proven superior to monotherapy or double nucleoside therapy in HIV-infected patients *(151–154)*. Current guidelines define highly active antiretroviral therapy (HAART) as the cornerstone of care for HIV-infected patients. HAART typically involves three or more drugs that inhibit the replication of HIV by various mechanisms (155). There are no data to address the efficacy of other antiretroviral agents added to the basic single-drug regimen for PEP. Theoretically, a combination of drugs with activity at different stages of viral replication could offer an additive preventive effect, particularly for occupational exposures with increased risks of transmission.

Currently, the routine use of three drugs for all occupational HIV exposures is not recommended (*42*,43). The PHS has concluded that the use of a highly potent regimen (i.e., three drugs) can be justified for exposures that pose an increased risk for transmission but that the additional potential toxicity may not be justified for lower risk exposures (*42*,43). The basic two-drug regimen is recommended for less severe exposures (e.g., solid needle and superficial injury) and HIV-infected sources with asymptomatic HIV infection or known low viral load (<1,500 RNA copies/mL). If the injury is more severe (e.g., large-bore hollow needle, deep puncture, visible blood on device, or needle used in patient's artery or vein) or the HIV-infected source has symptomatic HIV infection, AIDS, acute seroconversion, or known high circulating viral burden, then an expanded three-drug regimen is recommended. The two-drug basic regimens currently recommended by the PHS include: zidovudine plus lamivudine or emtricitabine, or tenofovir plus lamivudine or emtricitabine (see Table 74-3). Regimens including new classes of agents and newly marketed agents have been reported *(156–159)*. The addition of a protease inhibitor as a third drug for PEP following high-risk exposures is based on the demonstrated efficacy of these agents in reducing viral burden, as well as their interference at a different site of viral replication (i.e., after viral integration has occurred) than for nucleoside or nucleotide analog reverse transcriptase inhibitors. However, protease inhibitors have potentially serious drug interactions when used concomitantly with other medications. These agents also have serious side effects when used as an agent for combination PEP, including nephrolithiasis, hepatitis, and pancytopenia (*42*,43). Nonetheless, one analysis determined that triple-drug combination therapy following moderate-to-high risk occupational exposures was cost-effective for society *(160)*. Another analysis determined that the mean cost associated with administration of PEP was $706 (in 2003 dollars), with a reported range of costs to manage reported exposures from $71 to $4,838 *(161)*. If combination PEP is minimally more effective than zidovudine alone, then the added expense of including other drugs in the drug regimen is clearly justified. Mathematical modeling suggests that the optimal regimen would be a dual nucleoside regimen unless the background rate of viral resistance in the source population is >15%, in which case a three-drug regimen including a protease inhibitor would be favored *(162)*.

TABLE 74-3

Summary of Postexposure Prophylaxis Options for Healthcare Workers Exposed to HIV

Basic Regimen		*Expanded Regimen*
Two nucleoside analogs		Two nucleoside analogs plus one additional drug
	Indications	
Occupational HIV exposures categorized as "less severe" (e.g., solid needle and superficial injury) source with asymptomatic infection or low viral load		Occupational HIV exposures categorized as "more severe" (e.g., deep puncture and visible blood on device) source with symptomatic infection or high viral load, or known drug resistance
	Antiretroviral Agents	
Choice of one regimen	Zidovudine + lamivudine Zidovudine + emtricitabine Tenofovir + lamivudine Tenofovir + emtricitabine	*Choice of one regimen*
	Additional Agents for Expanded Regimen	
	Lopinavir/ritonavir or	Primary Choice
	Atazanavir Fosamprenavir Indinavir/ritonavir Saquinavir/ritonavir Nelfinavir Efavirenz	*Alternatives*

A significant number of healthcare workers begin PEP with two or more drugs after exposure to a source patient of unknown serostatus *(163)*. PEP continues until the ELISA result is available, which may take up to 5 days. CDC HIV PEP Registry data indicate that a healthcare worker taking only a few days of prophylaxis pending the source patient HIV test result is as likely as a healthcare worker taking the full 28 day course of prophylaxis to experience toxicity, since the median time to onset of symptoms was 3 to 4 days *(163)*. Use of a rapid HIV screening test (see "Diagnosis and Clinical Manifestations" section) will likely prevent the need for any medication and thus should decrease healthcare worker anxiety as well as drug toxicity, and decrease cost for the institution *(164,165)*.

Whereas studies of the administration of postexposure antiretroviral chemoprophylaxis have identified toxicity as a problem, the same studies have demonstrated a reasonable safety profile for PEP. For example, one multicenter collaborative study demonstrated safety of prophylaxis administered to healthcare workers following occupational exposure *(166)*. The zidovudine regimen used in this study consisted of 1,200 mg/day on days 1 to 3, followed by 1,000 mg/day on days 4 to 28 *(166)*. The study identified a mean decrease in hemoglobin values from 13.9 g/dL at baseline to 13.2 g/dL at 4 weeks for 105 healthcare workers who took zidovudine for at least 22 days. The maximum decrease in absolute neutrophil count was 1,200/mm^3 at week 4 following exposure. In this study, hematologic toxicities correlated neither with body weight nor with reported subjective toxicities. No objective nonhematologic toxicities were identified *(166)*. Symptoms of drug intolerance (nausea, fatigue, and headache) occurred in a substantial number of subjects *(167)*. Forty-nine percent of 674 subjects experienced at least one adverse effect (most commonly nausea) *(168)*; other investigators reported that subjective toxicities were experienced by 69% of 155 healthcare workers who took zidovudine for at least 1 week *(166)*. Despite the symptoms experienced by a majority of healthcare workers, laboratory evidence of significant objective toxicity was rare. The Italian Registry of Antiretroviral Postexposure Prophylaxis observed hemoglobin values in the 9.5 to 11 g/dL range in 3% of healthcare workers and a neutrophil count of <1,000 cells/mm^3 in two healthcare workers *(168)*. These same authors observed a transient increase of serum alanine aminotransferase to three times the upper limit of normal in seven healthcare workers. Prophylaxis was continued in each of these cases and all laboratory values returned to baseline within 1 to 2 weeks after a completed course of prophylaxis *(168)*. More recent studies have suggested improved adherence with the administration of newer regimens *(156,157,169,170)*.

An increasing body of evidence documents the toxicity of antiretrovirals other than zidovudine in uninfected healthcare workers and in patients with early (or primary) HIV infection. One study examined the effects of HAART on patients with primary HIV infection *(171)* Commonly reported side effects for protease inhibitors include nausea, diarrhea, headache, mild liver function test abnormality,

hyperglycemia, and nephrolithiasis *(42,172)*. A multicenter collaborative study for occupational exposures examined the safety and adherence with combination PEP regimens *(173)*. Thirty-six of fifty-four healthcare workers took two drugs (zidovudine plus lamivudine), 16 took three drugs (zidovudine plus lamivudine plus indinavir) and two workers took didanosine plus stavudine. Twenty-eight percent discontinued prophylaxis early because of symptoms. Liver function abnormalities developed in two individuals, and prophylaxis was discontinued in both cases. The first individual was also receiving isoniazid prophylaxis. The second individual was exposed concomitantly to HCV and HIV. This latter exposure resulted in acute hepatitis C infection; HIV was first diagnosed 12 months after the exposure *(173)*. Additional toxicity data are provided by a report of 10 healthcare workers receiving a three-drug combination regimen *(97)*. All 10 workers had some side effects, including gastrointestinal disturbance, fatigue, headache, and confusion. Three workers stopped PEP early because of symptomatology. Wang et al. *(163)* reported on the PEP experiences of healthcare workers enrolled in the HIV PEP Registry. Three hundred and eight of 492 (63%) enrolled healthcare workers took at least three antiretroviral agents. Three hundred and forty (76%) healthcare workers with 6 weeks of follow-up reported some symptoms while on PEP: nausea (57%), fatigue or malaise (38%), headache (18%), vomiting (16%), diarrhea (14%), and myalgias or arthralgias (6%). Median time to onset of each of the five most frequent symptoms was 3 to 4 days. Only 37 (8%) workers with 6 weeks of follow-up were reported to have lab abnormalities, most of which were unremarkable. Similar proportions of workers who took two drugs as compared with three drugs completed regimens as prescribed. However, significantly more healthcare workers taking three drug regimens reported adverse events. An additional report describing healthcare worker PEP experience indicated that 10/46 (22%) stopped treatment secondary to adverse events or symptoms *(174)*. Another review of individuals who received PEP reported that those who received zidovudine, lamivudine, and tenofovir or indinavir had increased rates of nausea and those who received zidovudine, lamivudine, and indinavir were more likely to complete the regimen than those who received a tenofovir-containing regimen *(170)*.

The immediate management of an occupational exposure should include the administration of first aid and rinsing and/or decontaminating of the exposure site as soon as is reasonably possible (i.e., as soon as patient and healthcare worker safety permits). At the Clinical Center of the NIH, we recommend the following management approach for healthcare workers who have sustained occupational exposures to HIV *(93,94)*. Wounds should be washed with soap and water, and then irrigated with sterile saline, a disinfectant or other suitable solution. Healthcare workers who have sustained a mucosal exposure involving the mouth and nose should flush the exposed area extensively with water or sterile irrigants. For exposures involving the eyes, the involved area(s) should be irrigated with clean water, saline, or sterile fluids designed as ocular irrigants. All exposures should be reported immediately to the employee's supervisor and to the institution's Occupational Medical Service. Each institution should work aggressively to develop mechanisms that facilitate both the reporting of exposures as well as the provision of follow-up care. The mechanisms should be widely publicized in the institution. Where feasible, institutions should offer access to consultants who are expert about the pathogenesis of HIV infection, the risk for occupational HIV infection, and the safety, efficacy, and known toxicities associated with the administration of antiretroviral agents. All institutional occupational medical systems must protect the confidentiality and medical privacy of the exposed worker. For healthcare workers who sustain documented occupational exposures to HIV, we advocate serologic studies at or as near to the exposure event as is possible (to document baseline seronegativity), with follow-up studies at 6 weeks, 3 months, 6 months and 1 year following exposure. All exposed workers should be offered the opportunity to take postexposure antiretroviral chemoprophylaxis (described above). Once the baseline serology, hematology, and chemistry studies are drawn, healthcare workers who elect chemoprophylaxis should be followed for signs of drug toxicity while on therapy. Studies that we routinely order for healthcare workers electing postexposure chemoprophylaxis are detailed in Table 74-4. Additional, supplementary studies, including direct measurement of the HIV viremia, are ordered if the healthcare worker develops symptoms suggestive of the seroconversion illness.

MANAGEMENT OF THE HIV-INFECTED HEALTHCARE WORKER

In July 1990, the CDC published a report of possible iatrogenic transmission of HIV to a patient during an invasive dental procedure *(175)* followed 6 months later by another report documenting identification of four additional patients apparently infected with HIV by the same dentist in Florida *(176)*. Two years later, a sixth patient was also identified as having been infected with the same strain of HIV as that from the dentist *(177)*. These events, as well as the drama surrounding the tragic stories of the infected patients of the dentist who have chosen to make their plights public, alarmed the public, and prompted calls for practice restrictions for HIV-infected healthcare workers.

Assessment of Risk for Transmission of HIV from Healthcare Worker to Patient

Discovery of the cluster of patients infected by the Florida dentist highlighted the need for additional data on the risk of HIV transmission from an HIV-infected provider to patients. These anecdotal cases of transmission, similar to the cases of transmission from patient to healthcare worker, indicate that provider-to-patient transmission is possible, but do not quantify the level of risk associated with infected providers. Scrutiny of the procedures that were performed by the dentist on the infected patients also provides little useful information, because some of the patients had no more than what would be considered "routine" (i.e., "noninvasive") dental work.

The second instance of transmission from provider-to-patient was reported from France *(178)*. An orthopedic surgeon most likely was infected with HIV in May 1983. The diagnosis of HIV infection and syndromic AIDS were made

TABLE 74-4

Summary of Laboratory Testing for Healthcare Workers Receiving Postexposure Prophylaxis

	HIV Antibody	*CBC with Differential*[a]	*Chemistry Panel*[b]	*Urine Pregnancy Test for Females*
Baseline	X	X	X	X
2 wk		X		
4 wk		X

Suspected acute retroviral syndrome[d]	X	X	X	
Suspected drug toxicity	X	X		

[a]CBC with differential should consist of a basic hematology panel with white blood cell differential and platelet count.
[b]Chemistry panel should consist of routine electrolytes, glucose, creatinine, SGOT (AST), SGPT (ALT), alkaline phosphatase, bilirubin, and amylase.
[c]Only if previous results indicate toxicity.
[d] Direct measurement of HIV by PCR or other technique also indicated in this setting.

simultaneously in March 1994. Nine hundred and sixty eight of 3,004 of the surgeon's patients who had undergone at least one invasive procedure by the surgeon were serologically tested for HIV. One patient, who had undergone two very lengthy hip procedures in 1992 and 1993, was determined to have newly acquired HIV infection. While no specific exposure incidents were recognized during the procedures, the patient was seronegative before the operation performed by the surgeon, and had a particularly prolonged duration of exposure to risk (the initial procedure lasted more than 10 hours). The surgeon's viral load could have been elevated at the time of the operation on this patient, and phylogenetic analysis indicated a close relationship between the patient's and the surgeon's viruses. The French National Public Health Network believes the case for transmission, based on the epidemiologic investigation and confirmed by viral sequencing, to be highly probable *(178)*.

A third possible case of transmission, in this instance nurse-to-patient, was also reported from France in 2000 *(179)*. Phylogenetic analysis strongly suggests an HIV-infected nurse as the source of infection, although the authors do not provide any epidemiological information as to the possible route of infection. The nurse was also co-infected with HCV, and both HIV and HCV were diagnosed 3 weeks after she provided care for the patient and transmission likely occurred. At the time of diagnosis, the source nurse had an HIV viral load of 1.8×10^5 copies/mL; her CD4 count was 94 per mm^3, and she was diagnosed with advanced hepatic cirrhosis with a blood clotting disorder *(180)*. Hepatitis C was not transmitted to the patient. Investigators suggest that the nurse's high viral load associated with severe blood clotting disorders may have enhanced the risk of HIV transmission, although the nurse reported no percutaneous blood injury. A lookback study reported testing 2,310 of 7,580 patients (30%), and no additional cases of HIV infection were identified *(180)*.

A fourth case of provider to patient transmission of HIV apparently occurred in Spain. In this instance a woman was apparently infected with HIV by her obstetrician/gynecologist during a caesarian section. A look-back evaluation identified 275 of the physician's patients on whom the practitioner had performed procedures. Of these, 250 could be tested, and no additional infections were identified *(181)*.

Based on our knowledge of routes of transmission from patients to providers, the primary risk for transmission of HIV is through exposure of the patient's bloodstream to blood from an infected provider *(182)*. Based on this assumption, most authorities have concluded that routine patient-care activities pose no measurable risk for transmission *(72,183)*. The CDC recommends that, if Universal/Standard Precautions and the correct infection control procedures are followed, infected healthcare workers should not be restricted from performance of routine patient-care activities including drawing blood or starting intravenous lines. In order to transmit infection, a sharp object would first have to be contaminated with the provider's blood and then would have to recontact the patient's tissues. Whereas a number of studies have described the risk for surgeons sustaining exposures during surgical procedures *(184–187)*, none of these studies attempted to assess the "recontact" risk. Two direct observational studies have attempted to address the patient's risk for exposure to a provider's blood during a surgical procedure *(188,189)*. In the first study, investigators from the CDC estimated that a surgical "sharp object" that had potentially injured a resident or attending surgeon had approximately a one in three chance of recontacting the tissues of the patient. This estimate was based on 28 "recontacts" following 88 observed injuries in surgeons; other authorities, including surgeons with years of operative experience, feel that this estimate of 32% may substantially overestimate the actual recontact risk. In the second preliminary study addressing potential for "recontact" injuries, occupational injuries during surgery were categorized as "definite" and "possible" *(189)*. These investigators found that three of nine "definite" provider injuries recontacted the patient, while two of seven "possible" injuries recontacted the patient.

In response to the Florida case cluster, CDC issued guidelines for HIV and HBV infected providers in July of 1991 *(72)*. From an implementation perspective, three aspects of these guidelines were challenging: (a) to implement the guideline, one needed to be able to characterize a subset of invasive procedures as "exposure-prone," (b) for infected providers to be able to conduct "exposure-prone" procedures, the provider would be required to notify patients prospectively of the provider's infection status, and (c) the guidelines required the convening of a Expert Review Panel but did not provide administrative or legal guidance about this function. These guidelines have not been modified since they were issued in 1991. The public anxiety associated with the Florida dentist case cluster prompted Congressional passage of a law (Public Law [PL] 102–141) requiring states to certify that they had implemented the July 1991 CDC/U.S. Public Health Service guidelines or their "equivalent." With the consultative assistance of several professional medical associations and professional societies, CDC attempted to develop a list of exposure-prone invasive procedures. Unfortunately no consensus could be reached. Ultimately, in 1992 Dr. William Roper, then the CDC Director, sent a letter to state health departments, noting that the states, not CDC, would certify the equivalency of their guidelines. As a result, substantial variability exists in state guidelines. Although the US guidelines have not been modified since their issuance, other countries have issued new guidances and several manuscripts have been published presenting various perspectives about this complex issue.

Guidelines issued from the United Kingdom provided one possible characterization of "exposure-prone" procedures *(190)*, and a manuscript published from the University of Virginia provided a second interpretation *(191)*. More recently, the Society for Healthcare Epidemiology in America (SHEA) published updated guidelines for managing the provider infected with bloodborne pathogens (192). The UK guidelines recommend that HIV-infected providers have their practices restricted *(72,190)*. Neither the US nor the UK guideline considers either the infected providers' clinical status or the HIV-infected provider's viral burden. The SHEA guideline recommends that HIV-infected providers who have circulating HIV viral burdens of $\geq 5 \times 10^2$ genome equivalents/mL routinely double-glove for all invasive procedures, for all contact with mucous membranes or nonintact skin, and for all instances in patient care for which gloving is recommended, and that they not perform those procedures identified as associated with a risk for provider-to-patient transmission of bloodborne pathogen infection despite the use of appropriate infection control procedures. The guideline recommends that HIV-infected providers who have viral burdens $< 5 \times 10^2$ genome equivalents/mL not be excluded from any aspect of patient care, including the performance of "exposure-prone" procedures, so long as the infected provider: (a) is not detected as having transmitted infection to patients; (b) obtains advice from an Expert Review Panel about continued practice; (c) is followed routinely by Occupational Medicine, who tests the provider twice annually to demonstrate the maintenance of a viral burden of $< 5 \times 10^2$ genome equivalents/mL; (d) is also followed by a personal physician who has expertise in the management of HIV infection and who is allowed by the provider to communicate with the Expert Review Panel about the provider's clinical status; (e) consults with an expert about optimal infection control procedures (and strictly adheres to the recommended procedures, including the routine use of double-gloves and frequent glove changes during procedures, particularly if performing technical tasks known to compromise glove integrity [e.g., placing sternal wires]); and (f) agrees to the information in, and signs, a contract or letter from the Expert Review Panel that characterizes her/his responsibilities (192).

The SHEA guidelines emphasize a "case-by-case" approach to this complex problem and note that whatever institutions decide, their approach has to be consonant with the State laws developed in the 1990s.

Lookback Notifications for Patients of Infected Providers

A series of retrospective "lookback" studies have provided additional, albeit indirect, information about the risk of HIV transmission from provider to patient. In all of these studies, patients have been offered HIV testing retrospectively after a healthcare provider has been determined to be HIV-infected. According to the CDC, 51 HIV-seropositive healthcare workers had prompted HIV antibody testing of 22,171 patients by January 1, 1995 *(193)*. To date, no additional iatrogenic infections have been documented in these studies. In fact, no HIV-infected patients have been identified for 37 of these infected healthcare workers; one or more HIV-infected patients were identified for 14 healthcare workers (the number of HIV-infected patients per healthcare worker ranged from 1–41). Of the 113 infected patients identified in these lookback studies, investigations have been completed for 110 patients. Twenty-eight were known to have been previously infected, 62 had established risk factors other than care by an HIV-infected provider, 15 had other potential chances for exposure (e.g., exchange of sex for drugs or money and/or multiple sex partners), and 5 had no risk identified. Genetic sequencing of the virus in the case of the infected Florida dentist indicated that six of the nine HIV-infected patients in the practice were infected with HIV strains that were closely related to those of the dentist *(194,195)*.

The large series of well publicized lookback studies that have been published from the United States *(196–206)* may imply that lookback studies are now a standard of care whenever an HIV-infected healthcare worker who has performed invasive procedures in his or her practice is publicly identified. Indeed, many of these studies were the response of an institution or public health agency to a public outcry precipitated by discovery of an infected provider. Epidemiologists and other professionals responsible for follow-up of an infected provider must bear in mind that the risk of transmission associated with patient contact and even most, if not all, invasive procedures is negligible, and many experts argue that these studies are of extremely limited utility. The CDC has concluded that the risk for transmission of HIV from a healthcare worker to a patient is very small, and that retrospective patient notification need not be routine *(193)*.

According to guidelines published by the Society for Hospital Epidemiology of America, lookback notification should be considered in the following circumstances: (a) after a proven case of transmission of HIV, hepatitis B, or any other bloodborne pathogen to an index case and (b) following a

serious breach in infection control practices during invasive procedures performed by an infected healthcare worker *(183)*. Lookback studies should not be undertaken for HIV-infected healthcare workers who do not perform invasive procedures. Two of the published lookback studies also detailed the costs incurred. Danila et al. *(198)* estimated that the costs associated with a study of an HIV-infected family physician totaled approximately $130,000, which was one-third of the entire annual Minnesota Department of Health budget for statewide AIDS and HIV surveillance. A second lookback study estimated that the total costs incurred by initial patient notification and testing were $158,500 *(206)*. Given the current efforts to control spiraling healthcare costs, lookback notifications may, in general, be an inappropriate use of diminishing resources.

Similarly guidelines from the United Kingdom National Health Service (*www.doh.gov.uk/aids*) advise that it is no longer necessary to notify every patient who has undergone an exposure-prone procedure by an infected healthcare worker because of the low risk of transmission and the anxiety caused to patients and the wider public. The National Health Service defines three categories of exposure-prone procedures; only for category 3 procedures where fingertips are out of sight for a significant part of the procedure and in which there is a distinct risk of injury (e.g., hysterectomies, caesarian sections, and open cardiac surgery procedures) is patient notification necessary.

Policy Issues

In summary, only four instances (nine patients infected by four healthcare workers) of iatrogenic HIV transmission have been documented in the 25 years since testing for HIV became widely available. Additionally, the published risk estimates, even with their inherent limitations, support the conclusion that the risk of HIV transmission from provider to patient is extremely small, perhaps negligible, even during invasive procedures. Clearly, we all face, and accept, risks of a much higher magnitude each day.

Another traditional concern of the medical establishment is that of *primum non nocere*. This concept is reinforced from each provider's first days as a student in a healthcare profession, yet we all recognize that doing no harm is impossible. The realistic goal is to minimize the harm that we do while keeping risks in appropriate perspective. Other risks, including such issues as the competence levels of practicing providers and provider substance abuse, undoubtedly result in a much higher level of patient morbidity and mortality than the risk associated with competent HIV-infected providers. Thus, to reduce patient risk, one could certainly marshal a cogent argument for implementing routine drug and alcohol testing and mandatory competence reviews of healthcare professionals rather than implementing mandatory HIV-testing programs.

A third issue of concern relates to disability law and the concept of "significant risk." The concept of significant risk was adopted in the School Board vs. Arline case *(207)*, in which the US Supreme Court determined that a disabled teacher who had chronic tuberculosis could not be discharged from her job because she was disabled as a result of her condition and did not present a significant risk for transmission of tuberculosis. This concept has been reaffirmed twice, in the Civil Rights Restoration Act of 1988 (PL 100–259, 134, Congressional Record H.587–8) and, more recently, in the Americans with Disabilities Act of 1990 (PL 101–336, 104 Stat. 327). Mandating practice restrictions in order to reduce a risk that is lower than other accepted risks would essentially undermine current disability law by legally redefining the concept of significant risk *(208)*.

The issues surrounding the management of providers infected with bloodborne pathogens are exceedingly complex. As more knowledge is gained about the risks for iatrogenic spread of hepatitis B, hepatitis C, and HIV, management strategies may become more straightforward. The constellation of problems associated with the management of HIV-infected healthcare workers will undoubtedly continue to haunt the medical profession for years to come. Obtaining data to aid decisions about the most appropriate management of infected providers will be extraordinarily difficult given existing societal perceptions and the magnitude of risk associated with infected providers. Nonetheless, as a discipline, the healthcare epidemiology community must assume leadership through educational efforts and by placing these risks into appropriate perspective with other risks, whether occupational, iatrogenic, or societal (192). Finally, based on our current understanding of the magnitude of risk for provider-to-patient transmission of bloodborne pathogens, we feel that prevention efforts should be focused on strategies to prevent occupational exposures to blood and body fluids. We believe the limited research capital available should be used to develop: (a) devices and procedures that minimize risks of injury, (b) interventions that influence improvements in practitioners' workplace practices, (c) better and more effective approaches to the education of healthcare workers and patients about risks and risk perception, and (d) sensible strategies to manage these risks.

CHAPTER 75

Vaccination of Healthcare Workers

Michael D. Decker, David J. Weber, and William A. Schaffner

It has been said that sanitation and vaccination have made the two greatest contributions to the health of mankind. This importance is mirrored within healthcare institutions. For healthcare personnel (HCP) and for their patients, sanitation (better known within hospitals as hygiene or infection control) may be the first line of defense against infectious agents, but HCP vaccination is an essential second line of defense to prevent spread of infection from patients to HCP, among HCP, and from HCP to patients.

Accordingly, ensuring the immunity of HCP to infection or disease caused by relevant infectious agents is an essential component of any healthcare institution's occupational health program, to accomplish two fundamental legal and moral duties: protection of the workers from the risks of the workplace, and protection of the patients from the risks posed by infectious HCP.

High rates of immunity among HCP are required if patients are to be protected from infection spread by HCP, as even a single infected worker can expose many patients. Unfortunately, it has proven impossible to attain the necessary high vaccination rates through purely voluntary programs. Screening has repeatedly shown substantial proportions of hospital staff to be susceptible to vaccine-preventable diseases, in the absence of a policy requiring immunity. For example, numerous studies of hospital workers in the early 1990s showed that 5% to 10% were susceptible to measles, despite national recommendations regarding measles immunity *(1–5)*. Indeed, the last major outbreaks of measles in the United States were predominantly fueled by spread within healthcare institutions. As cohorts born after the disappearance of epidemic measles enter the workforce, the proportion susceptible will increase unless immunity is confirmed and vaccinations provided to the susceptible. For example, a recent study reported that 9% of adult HCP hired at a cancer hospital between 1998 and 1999 were seronegative for measles antibody, compared with 4% of those of the same age hired between 1983 and 1988 *(6)*.

The problem of continued HCP susceptibility to vaccine-preventable diseases is not, of course, limited to measles. Even following adoption by the Occupational Safety and Health Administration (OSHA) of the Bloodborne Hazard Standard, with its requirement to offer hepatitis B vaccine to all exposed workers, substantial numbers of healthcare workers (HCWs) remain susceptible (particularly physicians, who typically are not employees and thus not subject to the standard). Similarly, surveys of HCP have reported low rates of acceptance of influenza immunization. Selected studies of hepatitis B and influenza vaccine coverage rates are shown in Table 75-1 (*7–23,*24,*25,26,*27).

Many institutions (and some jurisdictions) have adopted policies requiring the demonstration of immunity to selected diseases as a condition of service in various capacities or units. Although the proportion of institutions with such policies continues to increase, as recently as 1995, a survey of children's hospitals showed the following frequency of policies requiring measles, mumps, rubella, and varicella vaccination: medical students, 47% to 74%; resident physicians, 70% to 91%; hospital-based physicians, 40% to 55%; and private or community-based physicians, only 15% to 26% *(28)*.

Although one might argue that it is the worker's right to decline vaccination and accept the risk of infection, no one would argue that the worker has a right to infect patients. Accordingly, we consider "informed refusal" of vaccination to be permissible only for infections that are not expected to place the patient at jeopardy. (For employees, hepatitis B has been placed in this category as a matter of law by the Bloodborne Hazards Standard, despite numerous outbreaks of healthcare provider-to-patient transmission of hepatitis B; but physicians typically are not employees, and vaccination can be made a condition of admitting or other privileges, even if not a condition of employment.) For those vaccine-preventable infections among HCP that place patients at risk, we urge the adoption of policies that make demonstrated immunity (or valid medical waiver) a condition of employment (or privileges) in positions that would place the patient at risk in the event of HCP infection.

ORGANIZATION OF THE IMMUNITY (VACCINATION) PROGRAM

As alluded to above, it is important that the occupational health team understand that they need to operate an immunity program, not simply a vaccination program. The goal is to identify the susceptibilities of the workers to relevant infections and to take such steps (typically, vaccination) as may be appropriate to ensure their continued immunity.

TABLE 75-1

Hepatitis B and Influenza Vaccine Coverage of HCP: Selected Studies

Vaccine	*First Author*	*Year(s)*	*Study Location*	*HCP Evaluated*	*Immunization Rate*
Hepatitis B	Shapiro *(7)*	1991	3,411 orthopedic surgeons	Orthopedics	65%
	Panlilio *(8)*	1991–1992	21 hospitals	Surgical services	55%
	Agerton *(9)*	1992	150 hospitals, United States	All staff	51%
	Cleveland *(10)*	1992	US dentists	Dentists	85%
	Gyawali *(11)*	1994	London teaching hospital	Staff with blood exposure	78%
	Mahoney *(12)*	1994–1995	200 US hospitals	Staff eligible for hepatitis B vaccine	67%
	Simard *(13)*	2002–2003	425 US hospitals	At-risk HCP	81%, MDs/RNs; 71%, phlebotomists
Influenza	Weingarten *(14)*	1986–1987	Los Angeles hospital	House staff and nurses	3.5%
	Nichol *(15)*	1993–1994	Minneapolis hospital	Physicians and nurses	61%
	Zadeh *(16)*	1995–1998	Nursing homes, nine US states	All staff	46%
	Cui *(17)*	1996–1998	43 nursing homes, Hawaii	All staff	38%
	Russell *(18)*	1998	136 nursing homes, Alberta, Canada	All staff	30%
	Stevenson *(19)*	1999	Nursing homes, Canada	All staff	35%
	Seale *(20)*	2007	Two teaching hospitals in Sydney, Australia	1,079 HCP	22%
	Ballestas *(21)*	2008	Five hospitals in Perth, Australia, participating in a vaccination–rate improvement campaign	11,501 HCP	56–77% (29–51% in the precampaign year)
	Caban-Martinez *(22)*	2004–2008	National Health Interview Survey, U.S.	6,349 US HCP	46–49% overall; 38–42% for nurses
	Kent *(23)*	2007–2008	Health department staff, North Carolina	1,653 county public health workers	72%
	Ajenjo (24)	1997–2007	Large US health chain	26,000 workers (voluntary program)	Increased from 45% (1997) to 72% (2007)
	Babcock *(25)*	2008	Same large US health chain	26,000 workers (mandatory program)	98%
	Rakita *(26)*	2005–2009	Teaching hospital, Washington, United States	5,000 employees (mandatory program)	98–99%
	Palmore (27)	2009	NIH Clinical Center, Baltimore	2,754 HCP (mandatory program with exceptions)	88%

The services provided by the institution, and the characteristics of the patient populations served, need to be considered in determining these policies. Some infections (e.g., rubella and varicella) are much more likely to be associated with serious complications in adult HCP, and at the same time some infections that are common and often minor among HCP can be life threatening to patients with underlying chronic illnesses (e.g., influenza), immunosuppression (e.g., vaccinia), etc. The presence of special programs or populations (e.g., transplant units) will further alter the nature and scope of the vaccination and immunity policies. With these considerations in mind, the institution must decide which of the infections with potential for spread to, or through, HCP, warrant monitoring of HCP immunity; which warrant offering of immunization to the susceptible (with the option to decline); and which warrant mandatory immunization (or demonstrated immunity).

The institution has no obligation under the Occupational Safety and Health Act with respect to workers (e.g., volunteers, medical or other students, contract workers, etc.) who are not employees. Unfortunately, because microbes are unaware of this legal nuance, patient protection requires that the institution's vaccination and immunity policy apply to all workers, irrespective of their employment status, including workers with direct patient care responsibilities (e.g., nurses, respiratory technicians,

physical therapists, physicians, students), workers without direct patient care responsibilities (e.g., environmental service workers, security), contract or service workers, and emergency medical personnel.

All HCP new to a healthcare facility should receive a prompt review (within 10 working days) of their immunity with respect to vaccine-preventable diseases. Immunity is most commonly demonstrated by written documentation of immunization; for those persons requesting exemption on the basis of natural infection, serologic documentation of immunity should be required (the predictive value of a physician diagnosis is no longer adequate, given the current rarity of these diseases). Unless immune, the HCP should be appropriately immunized. As a general rule, serologic screening for immunity before immunization is neither necessary nor cost-effective. However, healthcare facilities might find certain screening programs to be cost-effective, given the cost of the screening test, the cost of the vaccine, and the prevalence of immunity in the local HCP population. In addition, facilities might wish to permit screening at the worker's request (either at the institution's or the worker's expense).

The institution may also wish to make available to HCP vaccinations that are not necessary for the protection of patients but that are indicated for other reasons. For example, the establishment and maintenance of immunity to diphtheria and tetanus toxins is universally recommended, and ensuring the timely provision of tetanus and diphtheria toxoid (Td; or, if not previously received, tetanus, diphtheria, and acellular pertussis [Tdap]) boosters through the occupational health service will eliminate concerns about tetanus prophylaxis in the event of (possibly unreported) occupational injury.

When vaccines are provided, appropriate information should be recorded in the employee's medical record (Table 75-2) and tracked electronically (either through a computerized employee vaccination registry or an electronic medical record). Computerized records greatly facilitate recall for boosting and identification of susceptibles in the event of an exposure or outbreak. Signed informed consent (or refusal, if appropriate) specific to each vaccine should be obtained before immunization. Vaccine information statements *(29)* must be provided for vaccines covered by the National Childhood Vaccine Injury Act (including measles, mumps, rubella, polio, diphtheria, tetanus, pertussis, hepatitis A, hepatitis B, *Haemophilus influenzae* type b, influenza, human papillomavirus, meningococcal conjugate, pneumococcal conjugate, and varicella vaccines). Vaccine information statements are also available for yellow fever and smallpox vaccines. Clinically significant or unexpected adverse events occurring after immunization should be reported to the Vaccine Adverse Events Reporting System *(30)*, as should any event listed by the vaccine manufacturer as a contraindication to subsequent doses of vaccine OR any event listed in the Reportable Events Table (available at *http://www.vaers.hhs.gov/reportable.htm*) that occurs within the specified time period after vaccination.

The immunization status of all HCP should be recorded in their employee medical record. A mechanism should be established to track immune status, including the need for and timing of repeat immunization, with effective recall and enforcement provisions.

TABLE 75-2

Data to Record When Providing Vaccines to HCP

Employee name
Employee identification number
Date of birth
Signed informed consent (or refusal, if relevant)
Date of immunization (or refusal)
Vaccine provided (or declined)
Name of vaccine manufacturer
Lot number of vaccine
Site of immunization
Route of immunization
Date of next scheduled dose or booster (if applicable)
Adverse events (if any)
Name, title, and address of person providing vaccine

VACCINES RECOMMENDED FOR HEALTHCARE WORKERS: GENERAL GUIDELINES

Recommendations regarding the vaccination of HCP have been issued by the Centers for Disease Control and Prevention (CDC) and its advisory bodies, the Advisory Committee on Immunization Practices (ACIP) and the Hospital Infection Control Practices Advisory Committee (HICPAC) (31–37), the American College of Physicians (ACP) *(38)*, the American Academy of Pediatrics *(39)*, and others (*40–42,*43). Many of these recommendations are updated periodically (see Table 75-3 for online sources of information).

All HCP should be immune to mumps, measles, rubella, varicella, and pertussis, and all HCP with potential exposure to blood or body fluids should be immune to hepatitis B (Table 75-4). Influenza vaccine should be offered to all HCP yearly (and strongly encouraged, if not mandated). In special circumstances, HCP or laboratory personnel should be offered immunization with other vaccines, including (no longer recommended) hepatitis A, quadrivalent meningococcal, inactivated poliomyelitis, rabies, typhoid, and vaccinia (Table 75-5).

Before the administration of any vaccine, the HCP should be evaluated for the presence of any condition that is listed as a vaccine contraindication or precaution *(44)*. If such a condition is present, the risks and benefits of vaccination need to be carefully weighed by the healthcare provider and the employee. The most common contraindication is a history of an anaphylactic reaction to a previous dose of the vaccine or to a vaccine component. Factors that are not contraindications to immunization include the following: breast-feeding or household contact with a pregnant woman (exception: vaccinia); reaction to a previous vaccination consisting only of mild-to-moderate local tenderness, swelling, or both, or fever less than 40.5°C; mild acute illness with or without low-grade fever; current antimicrobial therapy (except for oral typhoid vaccine) or convalescence from a recent illness; personal history of allergies (except a history of an anaphylactic reaction

to a vaccine component); and family history of allergies, adverse reactions to vaccination, or seizures *(38)*.

Special Conditions

HCP who are immunocompromised, pregnant, or have certain underlying chronic diseases can pose special considerations in the provision of immunizations (Table 75-6) *(45–59)*. Some routinely recommended vaccines (especially live virus vaccines such as measles, mumps, rubella, and varicella) may be contraindicated, and some vaccines that are not routinely recommended for HCP may be indicated (e.g., pneumococcal, meningococcal, and *H. influenzae* type b vaccines). In addition, for some indicated vaccines, higher antigen doses or postimmunization serologic evaluation may be indicated (e.g., hepatitis B vaccine in people with renal failure). When an otherwise mandatory vaccine is contraindicated for a given HCP, the worker should be individually evaluated for the possibility of altering his or her assignment to reduce risk to patients or to the HCP. The decision to reassign such a worker should be made in consultation with the employee.

Pregnancy Immunization of pregnant HCP raises a number of issues. For some live-attenuated and all inactivated or toxoid vaccines, the risks from immunization during pregnancy are largely theoretical (36,*38*). For such vaccines, the benefit of immunization outweighs the potential risks for adverse reactions, especially when the risk of exposure is high, infection would pose a special risk to the mother or fetus, and the vaccine is unlikely to cause harm. Furthermore, newer information continues to confirm the safety of vaccines given inadvertently during pregnancy.

No reliance should be placed on the presumption that certain vaccines "must have" been given in childhood or adolescence. HCP come from many countries, with differing vaccination programs; many children fail to receive various "routine" vaccinations, either through inadvertence or deliberate avoidance; and even if vaccinated, immunity may not have been produced. Accordingly, reliance should be placed only on objectively verifiable records of vaccination or serological assay. It is especially important that serological proof of immunity be obtained for all HCP without documentation of two separate vaccinations with rubella-containing vaccine, given the concern for both the worker and the patient populations regarding the consequences of this infection on the fetus.

Because of the theoretical risks, live attenuated viral vaccines (mumps, measles, rubella, and varicella) should be deferred for pregnant women. Pregnant HCWs may receive combined tetanus and Td (36,*60*). All women who are pregnant or will be pregnant during influenza season should receive influenza immunization *(61)*. If otherwise indicated, susceptible pregnant women may receive hepatitis A, hepatitis B, inactivated influenza, meningococcal, pneumococcal, rabies, typhoid Vi polysaccharide, and inactivated poliomyelitis vaccines (formulations containing trace or no thimerosal are preferable, when available) (36). Breast-feeding does not adversely affect the response to immunization and is not a contraindication for any of the currently recommended vaccines. The indications for using immune globulins in pregnant women are the same as those for women who are not pregnant.

USE OF VACCINES FOR POSTEXPOSURE PROPHYLAXIS OR OUTBREAK CONTROL

Those who have had to respond to the spread within their institution of a vaccine-preventable illness understand quite clearly how preferable it is to have previously vaccinated their HCP. The virtual impossibility of identifying and immunizing susceptible HCP sufficiently rapidly during an outbreak of measles, mumps, rubella, or varicella to avoid spread to another generation of susceptible HCP or patients offers a powerful inducement for policies requiring immunity before assignment to duty. Moreover, these vaccines are not known to provide protection when given to a susceptible person following exposure. In contrast, tetanus toxoid (Tdap is preferred, if not previously received) (*62*,63), hepatitis B vaccine *(64)*, vaccinia *(53)*, and rabies vaccine *(49)* are effective when given promptly following exposure, and hepatitis A vaccine may provide at least partial protection *(65)*. Varicella vaccine may provide protection if given within 72 hours of exposure, but it should not be relied on to prevent further transmission by exposed HCP because of incomplete efficacy *(66)*. Immunization of HCP with hepatitis A, meningococcal, or acellular pertussis vaccine may be indicated to control an institutional or community outbreak. In the event of widespread influenza activity, additional supplies of influenza vaccine may be difficult to obtain, adding further importance to a robust annual influenza vaccination

TABLE 75-4

Vaccines Strongly Recommended for All Persons Who Provide Healthcare to Patients or Who Work in Institutions that Provide Healthcare

Vaccine	*Recommendation*	*Schedule (Adults)*	*Major Contraindications*	*Special Considerations*
Hepatitis B	All HCPs at risk for exposure to blood or body fluids. Vaccinate unless laboratory evidence of immunity or prior receipt of three doses of vaccine with an appropriate schedule is documented.	1.0 mL IM (deltoid) at 0, 1, 6 mo; booster doses not necessary	Hypersensitivity to common baker's yeast.	Prevaccination serologic screening is not necessary. Perform post-vaccination serologic testing for HCPs at high risk for continued exposure. HCPs who have contact with patients or blood should be tested 1–2 mo after vaccination to determine response (see text).
Influenza	All HCPs should receive annual seasonal influenza vaccine. Consideration should be given to requiring vaccination (unless appropriately exempted) as a condition of presence within the healthcare institution. The Schedule and Contraindications shown are for trivalent inactivated vaccine (see Special Considerations).	0.5 mL IM yearly	Hypersensitivity to eggs (or thimerosal, for formulations containing thimerosal). No evidence exists of risk to mother or fetus when the vaccine is administered to a pregnant woman.	Trivalent inactivated vaccine is preferred over live attenuated intranasal vaccine for immunization of HCPs, due to the theoretical risk of spread to immunosuppressed and other at-risk patients.
Measles	All HCPs (including those born before 1957) who cannot document either receipt of two doses of live vaccine on or after their first birthday or laboratory evidence of immunity should receive a total of two doses of vaccine. MMR is preferred unless immunity to mumps and rubella is documented.	0.5 mL SC, second dose at least 1 mo later	Pregnancy; hypersensitivity to gelatin, neomycin, or eggs; immunocompromised state[a]; recent receipt of immunoglobulin.	Persons vaccinated during 1963–1967 with a killed measles vaccine alone, killed vaccine followed by live vaccine, or with a vaccine of unknown type should be revaccinated with 2 doses of live measles virus vaccine.
Mumps	Vaccinate (2 doses) unless born before 1957, laboratory evidence of immunity or laboratory confirmation of disease, or prior receipt of 2 doses of vaccine is documented. MMR preferred unless contraindicated or immunity to measles and rubella is documented.	0.5 mL SC, no booster	Pregnancy; hypersensitivity to gelatin, neomycin, or eggs; immunocompromised state[a]; recent receipt of immunoglobulin.	For unvaccinated personnel born before 1957 who lack laboratory evidence of mumps immunity or laboratory confirmation of disease, healthcare facilities should consider (and during an outbreak should require) 2 doses of vaccine.

(*Continued*)

TABLE 75-4

Vaccines Strongly Recommended for All Persons Who Provide Healthcare to Patients or Who Work in Institutions that Provide Healthcare (*Continued*)

Vaccine	*Recommendation*	*Schedule (Adults)*	*Major Contraindications*	*Special Considerations*
Pertussis	Recommended for all persons aged 11–65 who have not yet received a dose. All HCP with direct patient contact should receive Tdap as soon as feasible.	0.5 mL IM. Booster schedule not yet determined, but likely will be similar to Td.	Hypersensitivity to any component of the vaccine.	
Rubella	Vaccinate unless male born before 1957[b], laboratory evidence of immunity or laboratory confirmation of disease, or prior receipt of vaccine. MMR is preferred unless contraindicated or immunity to measles and mumps is documented.	0.5 mL SC, no booster	Pregnancy; hypersensitivity to gelatin or neomycin; immunocompromised state[a]; recent receipt of immunoglobulin.	For unvaccinated personnel born before 1957 who lack laboratory evidence of rubella immunity or laboratory confirmation of disease, healthcare facilities should consider (and during an outbreak should require) 1 dose of vaccine.
Varicella	All personnel should have evidence of immunity (see Special Considerations). Vaccinate unless physician-diagnosed disease, laboratory evidence of immunity or disease, or prior receipt of vaccine is documented. A personal history of disease is not acceptable unless reviewed and confirmed as unambiguous by a healthcare professional.	0.5 mL SC, second dose 4–8 wk later if ≥13 y of age	Pregnancy; hypersensitivity to gelatin or neomycin; immunocompromised state[a]; recent receipt of immunoglobulin. Avoid salicylate use for 6 wk after vaccination.	Susceptibles can be identified by serotesting all HCPs or only those with a negative or uncertain history of chickenpox; or, institutions may simply immunize all those with a negative or uncertain history.

Note: The package insert and ACIP recommendations should be consulted for specific guidance regarding indications, storage, administration, precautions, and contraindications.
[a]Persons immunocompromised because of immune deficiency diseases, human immunodeficiency virus infection, leukemia, lymphoma or generalized malignancy, or immunosuppressed as a result of therapy with corticosteroids (i.e., ≥2 mg/kg body weight or 20 mg/day of prednisone for ≥2 wk, alkylating drugs, antimetabolites, or radiation). Also see Table 75-6.
[b]Many authorities would also vaccinate males born before 1957 unless immunity is demonstrated.
IM, intramuscularly; MMR, measles, mumps, and rubella vaccine; SC, subcutaneously.
(Data from references 32, 33, 34, and 43.)

program. Outbreaks of measles or polio are now highly unlikely (except, perhaps, in distinct communities that reject vaccination), but either would trigger large-scale immunization drives. Finally, passive vaccination with immunoglobulin is useful for postexposure prophylaxis for hepatitis A, hepatitis B, measles, rabies, tetanus, varicella, and vaccinia. Unfortunately, postexposure prophylaxis (vaccine and/or immunoglobulin) is not available to prevent rubella or mumps following an exposure.

GUIDELINES FOR THE USE OF SELECTED VACCINES

The following subsections provide additional information regarding the vaccine-preventable diseases for which immunization of HCP is recommended, either universally (Table 75-4) or in special circumstances (Table75-5). For each vaccine, administration schedules and contraindications

TABLE 75-5

Vaccines that May Be Indicated for HCP or Laboratory Personnel

Vaccine	*Recommendation*	*Schedule*	*Major Contraindications*	*Special Considerations*
BCG (for tuberculosis prevention)	Indicated for HCPs only in localities where (a) multidrug-resistant tuberculosis is prevalent; (b) ongoing transmission to HCPs exists; and (c) full implementation of infection control precautions has been inadequate in controlling the spread of infection.	One percutaneous dose of 0.2–0.3 mL, given by multipuncture device; no booster recommendation	Immunocompromised state[a] or pregnancy	BCG vaccination of US HCP is discouraged as it would interfere with subsequent PPD screening programs and can result in complications.
Hepatitis A	Not routinely indicated for HCP. Persons who work with HAV-infected primates or with HAV in a research laboratory setting should be vaccinated.	Two 1.0-mL doses IM, 6–18 mo apart (*Vaqta*) or 6–12 mo apart (*Havrix*)	History of anaphylaxis to a previous dose; hypersensitivity to latex or neomycin.	
Meningococcal (serogroups A, C, Y, W135)	Not routinely indicated for HCP except personnel with laboratory or industrial exposure to *N. meningitidis* aerosols. May be useful during an outbreak due to a type included in the vaccine. Conjugate preferred (see Special Considerations).	0.5 mL IM; consider booster dose within 3 (polysaccharide) to 5 (conjugate) y if exposure continues	Conjugate: known history of Guillain-Barré Syndrome or latex allergy. Polysaccharide: Sensitivity to thimerosal (used in multidose presentation only) or to latex.	Although conjugate vaccines are not yet licensed for those >55 y, they have important immunological advantages and off-label use should be considered.
Poliomyelitis	All persons should be immune. Immune status should be confirmed for HCPs in close contact with people who may be excreting wild virus and laboratory personnel handling specimens that may contain wild virus.	Unimmunized adults: two doses of IPV given SC 4–8 wk apart, followed by a third dose at 6–12 mo	Hypersensitivity to 2-phenoxyethanol, formaldehyde, neomycin, streptomycin, or polymyxin B.	Use only IPV. OPV can, rarely, result in paralysis of recipients or their contacts (OPV is not available in the United States).
Rabies	Not routinely indicated for HCP except personnel working with rabies virus or infected animals in diagnostic or research activities	Preexposure: 1.0 mL IM on days 0, 7, and 21 or 28. Follow standard guidelines for postexposure prophylaxis	*Imovax*: None. *RabAvert (PCEC)*: Hypersensitivity to bovine gelatin, chicken protein, neomycin, chlortetracycline, or amphotericin B.	Postexposure prophylaxis boosters may be required despite primary immunization
Typhoid	Not routinely indicated for HCP except laboratory personnel who frequently work with *Salmonella typhi*	One 0.5-mL dose IM (Vi polysaccharide vaccine); booster doses of 0.5 mL every 2 y; *or* Four oral doses (Ty21a) on alternate days; revaccinate with the entire 4-dose series every 5 yr	History of severe local reaction or anaphylaxis to a previous dose of vaccine. Ty21a should not be administered to immunosuppressed[a] persons or to persons receiving antimicrobials.	Do not use the killed whole-cell vaccine. The Vi polysaccharide vaccine (*Typhim VI*) may be preferable because Ty21a (*Vivotif*) is a live attenuated product that poses a theoretical risk of transmission to patients by recently immunized HCPs.

(*Continued*)

TABLE 75-5

Vaccines that May Be Indicated for HCP or Laboratory Personnel (*Continued*)

Vaccine	*Recommendation*	*Schedule*	*Major Contraindications*	*Special Considerations*
Vaccinia	Not routinely indicated for HCP except personnel who directly handle cultures or animals contaminated with recombinant vaccinia or orthopox viruses (monkeypox, cowpox) that infect humans, or as part of "Pre-Event Vaccination Program" (see Special Considerations).	One dose administered with a bifurcated needle; boosters every 10 y	Pregnancy; breastfeeding; history of eczema in worker or close family contacts; other acute, chronic, or exfoliative skin conditions; immunosuppression in vaccine recipient or household contact; hypersensitivity to polymyxin B, streptomycin, tetracycline, neomycin, glycerin, or phenol.	Vaccine is available only from CDC Drug Services. A bioterrorism-related "Pre-Event Vaccination Program" was conducted among HCP in 2002 and early 2003 but is currently inactive.

Notes:
1. Excluded are vaccines not currently available in the United States for civilian use (e.g., anthrax, plague).
2. This table only considers indications related to occupational exposures of HCPs; these and other (e.g., Td, pneumococcal, etc.) vaccines may be indicated for persons, whether HCP or not, who meet certain exposure or risk criteria.
3. ACIP recommendations and the current package insert for the selected product should be consulted for specific guidance regarding indications, storage, administration, precautions, and contraindications.
[a]Persons immunocompromised because of immune deficiency diseases, human immunodeficiency virus infection, leukemia, lymphoma or generalized malignancy, or immunosuppressed as a result of therapy with corticosteroids (i.e., ≥2 mg/kg body weight or 20 mg/day of prednisone for ≥2 wk, alkylating drugs, antimetabolites, or radiation).
BCG, Bacille Calmette-Guerin; HDCV, human diploid cell vaccine; IM, intramuscularly; IPV, inactivated poliovirus vaccine; OPV, oral poliovirus vaccine; PCEC, purified chick embryo cell culture rabies vaccine; PPD, purified protein derivative (tuberculin); SC, subcutaneously.
(Adapted from Centers for Disease Control and Prevention. Immunization of health-care workers: recommendations of the Advisory Committee on Immunization Practices (ACIP) and the Hospital Infection Control Practices Advisory Committee (HICPAC). *MMWR Recomm Rep* 1997; 46(RR-18):7–9.)

are summarized in these tables, and recommendations concerning immunization of healthcare workers with special conditions are provided in Table 75-6. Management of the vaccine-preventable diseases themselves and management of exposures to those diseases (other than postexposure vaccination) are covered in detail in other chapters, to which readers will be referred.

In addition to those vaccines discussed below, there are other vaccines that are indicated only in certain parts of the world (e.g., Japanese encephalitis, tick-borne encephalitis, yellow fever) or that have no recognized application for HCWs (Hib, HPV, rotavirus); they are not discussed further.

Hepatitis A Vaccine

Background Hepatitis A virus (HAV) is highly endemic in the United States, with 13,397 cases (4.91 cases per 100,000) reported to the CDC in 1999 *(67)*, a figure that probably represents <10% of actual infections. The incidence of HAV varies by race (among US residents highest in Native Americans and Native Alaskans), location (in the United States higher west of the Mississippi River), and age. Globally, incidence and median age of onset are closely related to socioeconomic and developmental status, with higher rates and lower median ages of onset in less-developed countries. In the United States, schoolchildren 5 to 14 years of age have the highest reported incidence. However, infection in infants and young children often is asymptomatic, so the age distribution of reported cases may not be representative of the underlying age distribution of infection. Sources of infection include household or sexual contact with a person with HAV (22–26% of reported cases), with a child or employee in a day-care center (14–16%), or with an international traveler (4–6%) *(68)*. The majority of cases are sporadic, with no identified source. Food- or waterborne outbreaks classically account for only 2% to 3% of cases, but are becoming more common with globalization of the US food supply.

Hepatitis A results in substantial morbidity with significant costs caused by medical care and lost work time. Approximately 11% to 22% of people who develop recognized hepatitis A require hospitalization *(54)*. In the United States, an estimated 100 deaths per year are attributable to acute hepatitis A (there is no chronic infection).

Healthcare-Associated Outbreaks Although several cohort studies have failed to demonstrate HCP to be at increased risk for hepatitis A compared with control populations *(69–72)*, some European researchers have reported that HCP had higher than expected rates of seropositivity to hepatitis A *(73,74)*. A number of healthcare-associated outbreaks of HAV have been reported *(75–91)*. These reports suggest a common set of circumstances: a source patient who was not jaundiced, in whom hepatitis was not suspected, and who had fecal incontinence or diarrhea. Risk

Note: The package insert and ACIP recommendations should be consulted for specific guidance regarding indications, precautions, and contraindications.

[a]Severe immunosuppression can be the result of congenital immunodeficiency; HIV infection, leukemia, lymphoma, generalized malignancy, or therapy with alkylating agents, antimetabolites, radiation, or large amounts of corticosteroids.

[b]Recommendation is based on the person having the indicated underlying condition, not their status as HCP.

[c]Recommended for all women who are pregnant or will be pregnant at any time during the influenza season.

[d]Because of the theoretical risk of transmission to patients of the live attenuated agent contained in this vaccine, use of the alternative inactivated vaccine is preferred.

[e]Generally contraindicated in persons with HIV infection; recommended for children (no official recommendation for serosusceptible adults) with CD4+ >200/μL; consider reimmunization if initial immunization was given when CD4+ <200/μL and if CD4+ increases to ≥200 μL due to highly active antiretroviral therapy.

[f]All persons, whether HCP or not, should be immune unless specifically contraindicated.

[g]Immunization with IPV is recommended for unvaccinated HCP who have close contact with persons who may be excreting wild poliovirus. HCP who have a primary series of OPV or IPV who are directly involved with the provision of care to patients who may be excreting poliovirus may receive another dose of IPV. Except in the context of mass immunization to control circulating wild polio, use only IPV; OPV can, rarely, result in paralysis of recipients or their contacts (OPV is not available in the United States).

BCG, bacille Calmette–Guérin; HIV, human immunodeficiency virus; IPV, inactivated poliovirus vaccine; MMR, measles-mumps-rubella vaccine; R, recommended; C, contraindicated; UI, use if indicated.

(Adapted and expanded from Centers for Disease Control and Prevention. Immunization of health-care workers: recommendations of the Advisory Committee on Immunization Practices (ACIP) and the Hospital Infection Control Practices Advisory Committee (HICPAC). *MMWR Recomm Rep* 1997;46(RR-18):30.)

factors for HAV transmission to personnel include activities that increase the risk of fecal–oral contamination, including caring for a person with unrecognized HAV infection *(77–84)*; sharing food, beverages, or cigarettes with patients, their families, or the staff *(78,84–86)*; nail biting; handling bile without proper precautions *(84)*; and not washing hands or wearing gloves when providing care to an infected patient *(81,82,84,85)* (see also Chapters 46 and 73).

Vaccination Although current recommendations do not support routine immunization of United States HCP except in areas where hepatitis A is highly endemic (31), cost-benefit analyses have suggested that the cost of hepatitis A vaccination in HCP, per life-year saved, was similar to that of other standard medical interventions *(92)*. As with other special use vaccines, HCP should be encouraged to review with their local medical provider their own risks and benefits for hepatitis A vaccine.

Hepatitis B Vaccine

Background Exposure to blood-borne pathogens via parenteral or mucosal contact can expose HCP to the risk of acquiring numerous infections, foremost among these (in terms of risk, prevalence, and aggregate burden) being hepatitis B. Seroprevalence surveys conducted prior to the availability of hepatitis B virus (HBV) vaccine showed HCP to be at threefold to fivefold higher risk of HBV infection than the general US population *(93–96)*, with the risk of infection proportionate to the extent and duration of blood contact. The use of HBV vaccine among HCP, coupled with the institution of Universal (now Standard) Precautions and other preventive measures such as needleless devices and safety needles and syringes (e.g., self-sheathing needles), has markedly reduced that risk. Mahoney et al. *(12)* reported that HBV infection among HCP declined from 17,000 in 1983 to 400 in 1995. This 95% decline in incidence observed among HCP was 1.5-fold greater than the

reduction in incidence in the general US population during the same time period.

Healthcare-Associated Exposures HCP are at risk of hepatitis B acquisition for several reasons. First, HCP have high rates of exposure to blood *(97)*. For example, a 1988 survey of New York City surgeons found that 86% had at least one puncture injury in the preceding year *(98)*. A survey of US and Canadian orthopedic surgeons in 1991 found that 87.4% had a blood–skin contact and 39.2% a percutaneous blood contact in the previous month *(99)*. Second, the virus can persist in the environment, being able to survive drying and storage at 25°C and 42% relative humidity for at least 1 week *(100)*. Third, HBV is highly transmissible; the titer of infectious particles is extraordinarily high in the blood of actively infected persons. Consequently, rates of disease transmission after a percutaneous injury with a contaminated sharp range from 6% to 30% *(101–103)*. HBV infection also can be acquired via mucosal exposure, exposure to nonintact skin, or ocular exposure *(68)*, and has been transmitted to patients by a worker with severe exudative dermatitis while obtaining arterial blood gases *(104)*. Fourth, a substantial number of patients have inapparent infections; for example, a study of consecutive blood samples submitted to the chemistry laboratory of an urban hospital in 1987 revealed that only 28% of hepatitis B surface antigen (HBsAg)-positive specimens were labeled with a biohazard label as required *(105)*. Finally, many HCP remain unimmunized.

Many outbreaks of healthcare provider–to-patient transmission of hepatitis B have been described *(106–110)*. Transmission typically occurs during an invasive procedure, with the most important risk factors being e-antigen positivity of the HCP, degree of invasiveness of the procedure, the infected HCP not wearing gloves, or injury (often inapparent) to the infected HCP (see also Chapters 46, 73, and 76).

Vaccination OSHA has mandated since 1991 that all healthcare employees be offered hepatitis B immunization. Employees may refuse immunization but must sign a declination form. Employees who decline hepatitis B vaccine cite a desire to avoid medications, the perception that they are at low risk for occupationally acquired HBV infection, and concern about side effects *(111)*. Availability of educational materials directed at these issues may be helpful in minimizing refusals.

Protective serum titers of anti-HBsAg (≥10 mIU/mL) develop in 90% of healthy adults who receive three intramuscular (IM) doses of hepatitis B vaccine *(112–114)*. Independent risk factors for failure to seroconvert following HBV vaccine include smoking, female gender, higher body mass index, and older age *(115)*. The two currently available hepatitis B vaccines, Recombivax HB and Engerix-B, are equally immunogenic and are interchangeable; either can be used (in its recommended dose) to complete an immunization series begun with the other *(112)*. Immunogenicity is not reduced when hepatitis B vaccine is given with other vaccines. Pregnancy is not a contraindication to hepatitis B vaccine. All injections should be provided in the deltoid because gluteal injection can result in poor immunogenicity *(116)*.

The usual vaccination schedule consists of three doses administered at 0, 1, and 6 months. Acceptable alternative adult schedules include 0, 1, and 4 months and 0, 2, and 4 months. A schedule of 0, 1, 2, and 12 months should be considered for unimmunized HCP at high risk of HBV (e.g., hemodialysis workers, cardiac surgeons) *(117,118)*. All HCP at ongoing high risk for percutaneous or mucosal exposures should have an anti-HBsAg titer obtained 1 to 2 months after the third immunization *(119)*. HCP with postimmunization titers <10 mIU/mL should receive up to three additional IM doses of hepatitis B vaccine; serum antibody can be checked 1 to 2 months after each dose, with vaccination terminated if immunity is achieved. (Laboratories using test kits that simply report "positive" or "negative" must consult the product literature or manufacturer to determine the minimum antibody level able to return a positive result.) If protection is not achieved following the third additional (sixth total) dose, the HCP should be considered a nonresponder. Persons who are nonresponders after receiving the vaccine series should be tested for HBsAg (after the third or sixth dose of hepatitis B vaccine), as one of reasons for failure to respond to vaccine is active infection. This is especially a problem in HCP born in HBV-endemic countries who acquired hepatitis B perinatally or at a young age. HCP found to be HBsAg positive should be referred for care to a hepatologist or infectious diseases physician specializing in the care of chronic hepatitis B. In addition, current recommendations should be followed for managing and reporting HCP personnel who are HBsAg positive and perform invasive procedures (120). Following a blood-borne or mucous membrane exposure to an HBsAg positive source, nonresponding HCP should be tested for the presence of HBsAg and given hepatitis B immune globulin as indicated for postexposure prophylaxis.

Symptomatic hepatitis B is rare in immunized people who developed protective levels of antibody, even though there is eventual loss of detectable antibody in up to 50% of those people 5 to 10 years after immunization. For this reason, there is currently no recommendation for periodic boosting of HCP who have responded to hepatitis B vaccine *(66,121)*. Nonetheless, many institutions provide postexposure serologic testing of exposed HCWs and offer a booster dose of vaccine for those with antibody levels <10 mIU/mL, not because of medical need but in consideration of the anxieties of the exposed worker.

Influenza Vaccine

Background Influenza is characterized by the abrupt onset of fever, myalgia, sore throat, and nonproductive cough. During influenza epidemics, the hospitalization rate for the elderly and for persons with underlying health problems (especially cardiopulmonary) may increase twofold to fivefold compared with nonepidemic periods *(122)*. Of the 23 influenza seasons between 1972 and 1992, 19 were associated with excess mortality, 9 with more than 20,000 influenza-associated excess deaths, and 4 with more than 40,000 excess deaths *(123,124)*.

Influenza is a single-stranded RNA virus that occurs in three basic antigen types (A, B, and C) based on nuclear material. Type A infects humans and other animals (especially fowl, other birds, and pigs) and is antigenically characterized by two surface proteins, hemagglutinin (associated with cell attachment), and neuraminidase (associated with cell penetration). In recent years, most

influenza A human disease has been caused by viruses expressing hemagglutinin types H1, H2, or H3 and neuraminidase types N1 or N2. Infection with a strain expressing a given hemagglutinin and neuraminidase reduces the likelihood and severity of subsequent infection by strains expressing those types, but confers little or no protection against viruses expressing other types. Influenza A hemagglutinins and neuraminidases of given types undergo continual antigenic modification (antigenic drift, due to point mutations) that can reduce, sometimes markedly, the protection conferred by infection with an earlier strain of the same subtype, leading to epidemics. At unpredictable intervals, an influenza A strain undergoes a genetic shift (probably due to recombination events within an avian or porcine host that is simultaneously infected with a human and an animal strain) and produces a new subtype, to which there is no protection from infection with previous strains, leading to pandemics. In the past 125 years, there have been five pandemics, due to H3N2 in 1889, H1N1 in 1919 (the "Spanish flu"), H2N2 in 1957 (the "Asian flu"), H3N2 in 1968 (the "Hong Kong flu"), and novel H1N1 in 2009. In recent years, both H1N1 and H3N2 have circulated *(124)*. In addition, there have been isolated instances of human infection due to human–animal recombinant influenza A viruses (e.g., the Hong Kong chicken-market outbreak of H5 virus or the Netherlands H6 cases), but (perhaps due to aggressive containment efforts, or perhaps due to inherent characteristics) none have spread widely.

Influenza B infects only humans, predominantly children, and typically causes milder illness than does influenza A. Influenza B is genetically more stable than influenza A.

The composition of each year's influenza vaccine is determined about 6 months before influenza season each year (to allow time for manufacture), based on recommendations by the World Health Organization (WHO) and national advisory groups that monitor strains circulating worldwide. Unfortunately, new strains sometimes arise too late to be included in that year's vaccine.

Influenza virus appears to spread from person to person by small-particle aerosol transmission. Although aerosol transmission is well established, healthcare-associated transmission via fomites and contaminated hands remains possible. Influenza virus is shed for 1 to 2 days prior to onset of symptoms and for up to 5 days after onset of illness among adults and up to 7 days among children.

Healthcare-Associated Exposures Healthcare-associated acquisition of influenza is common *(125–146)*, typically in association with community outbreaks; HCP acquire infection from patients or in the community, and then spread infection to other HCP and patients, endangering patients and disrupting the provision of care *(125–129,147)*. Influenza infection among staff is common during the winter season and results in substantial absenteeism. Attack rates of 25% to 80% are often observed among both patients and staff during outbreaks. Similarly, healthcare-associated outbreaks within extended-care facilities (e.g., for the elderly) can result in substantial morbidity and mortality *(147–165)*.

The healthcare-associated spread of influenza cannot be prevented with measures instituted only when influenza is known to circulate, because identification of all patients with influenza is unlikely to be accomplished *(129)* and community indicators of influenza activity (e.g., visits to acute ambulatory care centers for upper respiratory illness) cannot be relied on to provide warning of influenza among hospitalized patients *(127)*.

On the other hand, a high influenza immunization rate among HCP has been shown to result in a decrease in the attack rate of influenza among patients *(166,167)*. For example, patients in facilities with more than 60% of the staff immunized experienced less influenza-related mortality and illness compared with patients in facilities without immunized staff *(166)*.

For all these reasons, routine annual influenza immunization of HCP is essential and has been recommended for many years. Recommendations for prevention and control of healthcare-associated influenza have been published and are summarized in Table 75-7 *(130,131,168–174)*. (see also Chapters 42 and 76).

Vaccination Influenza vaccine is recommended for all persons aged 6 months and older without specific contraindication (new ref), and a randomized, controlled trial in a general working population has demonstrated that providing influenza vaccine is cost-effective *(175)*.

Those who are at increased risk for complications of influenza because of age or underlying medical condition include all persons aged 6 through 23 months; all persons aged 50 years or older; residents of extended-care facilities or long-term-care facilities that house people of any age who have chronic medical conditions; adults and children who have required regular medical follow-up or hospitalization during the previous year because of chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression; persons aged 6 months to 18 years who are receiving long-term aspirin therapy and therefore may be at risk for developing Reye syndrome after influenza; and women who will be in the second or third trimester of pregnancy during the influenza season *(61)*.

Most pertinently, influenza vaccine is strongly recommended and is the standard of care for HCP, because they can transmit influenza virus to people at high risk, and moreover are needed for patient care during influenza outbreaks. The CDC specifically recommends immunization for the following HCP: physicians, nurses, and other personnel in both hospital and outpatient care settings; medical emergency-response workers; employees of nursing homes and long-term-care facilities who have contact with patients or residents; and providers of home care to people at high risk (e.g., visiting nurses and volunteer workers) *(61)*. Unfortunately, despite these recommendations, many HCP choose not to take influenza vaccine *(175–177)*. Reasons offered by HCP who decline influenza immunization have included desire to avoid medications, inconvenient vaccine administration, concern about side effects, belief that influenza can be caused by the vaccine, and belief that the vaccine is ineffective *(14,15,111)*. Institution-wide influenza immunization programs that are highly publicized, bring the program to the worker, take advantage of social or peer pressure, and reward participation have shown the greatest success, but still often struggle to vaccinate even half of the HCP having direct patient contact.

TABLE 75-7

Recommendations for the Prevention and Control of Healthcare-Associated Influenza

Prevention

1. Educate personnel about the epidemiology, modes of transmission, and means of preventing the spread of influenza;
2. Establish mechanism(s) by which hospital personnel are promptly alerted of an increase in influenza activity in the local community;
3. Establish protocols for intensifying efforts to promptly diagnose cases of healthcare-associated pneumonia;
4. Arrange for laboratory tests to be available to clinicians, for use when clinically indicated, to confirm the diagnosis of influ enza and other acute viral respiratory diseases promptly, especially during November through April;
5. Offer vaccine to outpatients and inpatients, beginning in September and continuing throughout the influenza season;
6. Vaccinate HCPs before the influenza season each year, preferably between mid-October and mid-November;
7. Isolate patients with known or suspected influenza in a private room, preferably under negative pressure;
8. Institute masking of individuals who enter the room of a patient with influenza;
9. Evaluate HCPs with febrile upper respiratory illnesses and consider removal from duties that involve direct patient care (use more stringent guidelines for staff working in high-risk areas, such as intensive care units, nurseries, or with severely immunocompromised patients); and
10. During community or hospital outbreaks, restrict hospital visitors who have a febrile respiratory illness.

Control of Healthcare-Associated Influenza Outbreaks

1. Early in the outbreak, perform rapid influenza virus testing and/or viral cultures on nasopharyngeal swab or nasal-wash specimens from patients with recent onset of symptoms suggestive of influenza;
2. Administer current influenza vaccine to unvaccinated patients and staff;
3. Administer antiviral prophylaxis to all uninfected patients in an involved unit for whom it is not contraindicated;
4. Administer antiviral prophylaxis to all unvaccinated staff members for whom it is not contraindicated and who are in the involved unit or taking care of high-risk patients;
5. If the cause of the outbreak is confirmed to be influenza and vaccine has been administered only recently to susceptible patients and personnel, continue antiviral prophylaxis until 2 wk after the vaccination;
6. To the extent possible, do not allow contact between those at high risk of complications from influenza and patients or staff who are taking antiviral treatment for an acute respiratory illnesses. Prevent contact during and for 2 d after the latter discontinue treatment; a failure to isolate patients treated with amantadine or rimantadine may result in the dissemination of drug-resistant strains; and
7. Consider restricting or curtailing visitation, elective admissions, and nonemergent cardiovascular or pulmonary surgery.

(Data from references 37 and *168*.)

In recognition of this dismal fact, there is an increasing trend of medical organizations recommending, and healthcare institutions requiring, mandatory influenza vaccination of HCP unless there is a medical contraindication to immunization *(178,179)*. As of early 2010, those recommending such policies include the Infectious Diseases Society of America, the ACP, the Association for Professionals in Infection Control and Epidemiology, and the New York State Department of Health. Institutions that have implemented such requirements include Virginia Mason Medical Center, the Clinical Centers of the National Institutes of Health, the Department of Defense, Hospital Corporation of America, Johns Hopkins Health System, University of Iowa Hospitals, Hospital of the University of Pennsylvania, Children's Hospital of Philadelphia, and the Cook County Health and Hospitals System *(180)*. Several institutions have published their experience and demonstrated achievement of vaccination rates exceeding 98% (*25*,*26*,27).

In light of these successful initiatives, institutions are encouraged to consider mandatory vaccination of HCP with direct patient contact. Institutions unable or unwilling to do so should consider introducing innovative methods of taking vaccine to workers, such as provision by mobile carts on hospital wards, offering vaccine to house staff and students in clinics and conferences, etc. *(169)*.

In June 2010, CDC published notice of the intent to provide an updated guidance that will emphasize a prevention strategy to be applied across the entire spectrum of healthcare settings, including hospitals, nursing homes, physicians' offices, urgent-care centers, and home healthcare. It will focus on the importance of vaccination, steps to minimize the potential for exposure such as respiratory hygiene, management of ill healthcare workers, droplet- and aerosol-generating procedure precautions, surveillance, and environmental and engineering controls *(181)*.

Measles-Mumps-Rubella Vaccine

Background The widespread use of measles-mumps-rubella (MMR) vaccine in the United States, coupled with the hemisphere-wide measles eradication program, led to record-low incidences of measles, mumps, and rubella. However, all three diseases continue to be reported, including small outbreaks of measles and large outbreaks of mumps, reflecting ongoing importations combined with pockets of susceptible populations (measles, mumps) or waning vaccine-induced immunity (mumps).

All three diseases are transmitted by the droplet route; measles, perhaps the most contagious disease known, also is transmitted by the airborne route. All three infections are contagious prior to development of clinically

recognizable illness. Moreover, a history of prior disease does not reliably predict prior infection and immunity, and consequently, many unimmunized HCP may falsely believe themselves immune.

Measles is highly dangerous; during the last major US outbreak, one of every 500 infected persons died. Rubella is less serious, but is of special concern because of its ability to cause congenital abnormalities in the fetuses of up to 90% of women with confirmed infection in the first trimester of pregnancy. Mumps is typically a mild illness in children, but meningoencephalitis, oophoritis, pancreatitis, and nephritis can occur, especially in adults, and epididymo-orchitis occurs in 20% to 40% of postpubertal men and may eventuate in testicular atrophy. Orchitis has been reported among male HCP who developed mumps as a result of hospital exposure *(182)*.

Healthcare-Associated Exposures Healthcare-associated measles is well documented in the literature *(183–215)* and has played an important role in the propagation of community outbreaks *(183–185)*. Measles was acquired in a medical setting by 1.1% of all cases between 1980 and 1984 *(186)* and 3.5% of all cases between 1985 and 1989 *(187)*, representing up to 53% of the cases in certain outbreaks *(184,188–193)*. Spread of measles has also occurred in outpatient settings, including emergency departments and physician offices, with transmission occurring even 75 minutes after the departure of the index case *(189,194–199)*. People who visited an emergency department have been shown to have a 4.9-fold *(200)* to 5.2-fold *(185)* higher risk of developing measles one incubation period later compared with those who did not have such visits. Healthcare-associated outbreaks have led to hospitalization of infected staff *(201)*, severe complications in infected patients *(202)*, and occasionally death of patients *(183,201)*. The cost of controlling a single outbreak has ranged from $28,000 to more than $100,000 *(183,201)*.

Healthcare-associated outbreaks of mumps have been reported infrequently *(182,216–220)*, but transmission from patient to patient *(216–218)* and from patient to healthcare provider *(182,217–219)* has been reported. In one case, it was suggested that an asymptomatically infected hospital nurse introduced mumps into a children's hospital *(216)*. During the 1986 to 1987 Tennessee mumps epidemic, six HCP in three different hospitals developed mumps after healthcare-associated exposure *(217)*. Healthcare-associated rubella also is well documented in the literature *(221–238)*. Sources of rubella infection have included both people with acute infection and infants with congenital rubella *(221–223)*. Healthcare-associated infection of pregnant staff members has led to the termination of pregnancy *(223,225)*.

Absence of a mandatory program requiring MMR immunity results in a subpopulation of susceptible HCP capable of propagating epidemics. Although these diseases presently are uncommon or rare, they are not eradicated, and introductions and local outbreaks of measles and mumps occur with regularity. These viruses are so communicable—especially measles—that rapid healthcare-associated spread will inevitably occur following each index case, unless exceptionally high vaccination rates are maintained (see also Chapters 51 and 76).

Vaccination All HCP should be immune to mumps, measles, and rubella. Immunity may be demonstrated through laboratory evidence of immunity (people with indeterminate levels should be considered susceptible) or evidence of appropriate immunizations *(239)*. Traditionally, birth before 1957 has been considered adequate for the presumption of immunity, but a recent study of healthcare workers born before 1957 who were newly hired in the period 2006 to 2008 revealed the following rates of serosusceptibility: measles 1.3%, mumps 3.7%, and rubella 2.9% (43). Given the consequences of rubella infection during pregnancy, hospitals should require proof of rubella vaccination or immunity even if birth before 1957 is accepted in lieu of proof of measles vaccination or immunity *(39)*. Moreover, hospitals that accept birth before 1957 as proof of measles immunity should assess the immunity of HCP born before 1957, in the same manner as for younger HCP, during a community or institutional outbreak of measles.

About 95% of subjects respond to a first dose of measles vaccine. However, measles is so contagious that it can propagate in a population that is 95% immune. Because nearly 95% of initial nonresponders will respond to a second dose, two doses of measles vaccine (MMR is preferred) are recommended to reduce the pool of susceptibles. Revaccination with MMR is also advisable for mumps control, because experience has shown that mumps outbreaks can propagate even in a highly vaccinated population *(240)*.

Meningococcal Vaccine

Background *Neisseria meningitidis* is responsible for 1,000 to 3,000 cases of invasive meningococcal disease annually in the United States, the majority of these in persons over 18 years of age (*241*,*242*,243). This relatively uncommon disease is notorious for its high rates of morbidity and mortality, and its ability to maim or kill a healthy person overnight. Even with the best medical care, fatality rates are 9% to 12% (up to 40% for meningococcal sepsis), and 11% to 19% of survivors of meningococcal disease experience serious sequelae such as hearing loss, neurologic disability, or amputation *(242)*.

There are five serogroups of *N. meningitidis* that are important in human disease (based on the capsular polysaccharide and denoted A, B, C, Y, and W-135). Humans are the only natural reservoir for *N. meningitidis*. The microorganism colonizes the nasopharynx and is carried by 5% to 10% of the population at any given point in time; carriage can give rise to type-specific antibody. Transmission is by droplet or nasopharyngeal secretions. Disease arises from invasion of capsule-producing strains in persons lacking specific anticapsular antibody.

In the United States, nearly all cases of invasive meningococcal disease are sporadic, but certain populations (including military recruits, college freshmen living in dormitories, and persons with terminal complement deficiencies or asplenia) are at elevated risk of invasive meningococcal disease, and small outbreaks occur regularly. Household or other close contacts are at 200 to 1,000 times the risk of developing meningococcal disease as is the general public *(244)*, and secondary attack rates in households average 2% to 5% *(245)*.

Effective vaccines exist for four of the five common serogroups (all but B). In developed countries, the older

polysaccharide vaccines have largely been replaced by newer, more effective conjugate vaccines. Two different quadrivalent conjugate vaccines are available in the United States and some other countries, and bivalent, trivalent, and quadrivalent polysaccharide vaccines and monocomponent (type C) conjugate vaccines are available in many countries. Polysaccharide vaccine should not be used if conjugate vaccine with equal or broader serogroup coverage is available.

Healthcare-Associated Exposures Although person-to-person transmission of *N. meningitidis* appears to require relatively prolonged close contact *(245,246)*, the existence of epidemics, the elevated secondary attack rates in households, the known elevated risk of disease among social clusters (military recruits, college freshmen, concertgoers, bar patrons, etc.) *(242)*, and especially the fearsome consequences of invasive meningococcal disease give rise to substantial anxiety among HCP caring for patients diagnosed with the disease. And indeed, healthcare-associated *(245,247–249)* and laboratory-based *(250)* transmission have occurred, but sufficiently uncommonly that vaccination is not routinely recommended for HCP *(247)* (see also Chapters 47 and 76).

Vaccination The ACIP has recommended that all adolescents aged 11 to 18 receive quadrivalent conjugate meningococcal vaccine, as should all persons aged 2 to 55 years at elevated risk of meningococcal infection (e.g., those with persistent complement deficiencies or asplenia, laboratorians or others with routine occupational exposure, travelers to or residents of endemic areas, military recruits, etc.) and any other persons wishing to avail themselves of this protection *(251,252)*. Persons who are at continued high risk and who were vaccinated at least 5 years previously should be revaccinated at 5-year intervals (253). In addition, institutions might elect to immunize selected staff members who have heightened likelihood of (or anxiety concerning) caring for patients with invasive meningococcal disease.

Pertussis Vaccine

Background In the United States, the reported annual incidence of pertussis declined from a high of 260,000 cases prior to routine vaccination to a low of some 1,300 cases in 1977 *(254)*. Subsequently, however, pertussis has progressively increased, with 13,506 cases reported in 2009 *(255)*. Most of this increase has occurred among adolescents and adults (due to waning vaccine-induced immunity). Heightened community prevalence of pertussis has led to dangerous increases in disease among infants too young to be fully vaccinated; it is in this group that most hospitalizations and fatalities occur *(256)*.

Because the initial phase of the disease resembles many viral respiratory infections and the classic whoop often is not seen with adult pertussis, the disease is commonly misdiagnosed (e.g., as bronchitis). However, studies using sophisticated diagnostic methods have demonstrated that *Bordetella pertussis* is a common cause of prolonged cough illness in adults *(257–259)*. Deville et al. *(260)* followed HCP for 5 years and found that 90% of subjects had serologic evidence of new infection during that period; 55% had evidence of two infections, 17% had evidence of three infections, and 4% had evidence of four infections.

Healthcare-Associated Exposures Many healthcare-associated pertussis outbreaks have been reported (*261–270,*271,*272*). Although the source case most commonly was an infected patient in whom pertussis was unrecognized *(261–263)*, infected HCP *(264,265)* and visitors *(266)* have also served as sources. Secondarily infected HCP, in turn, serve as the source for additional cases in the institution (*264,265,270*,271) or their own households *(262,264)* (see also Chapter 76). Costs associated with such outbreaks can be substantial (271).

Vaccination Pertussis immunization classically ceased around age 6 years, because adverse reactions to whole-cell vaccine among older persons were not tolerable. However, the development and worldwide licensure of highly effective adult-formulation tetanus, diphtheria, and acellular pertussis (Tdap) vaccines that are little more reactogenic than a standard tetanus-diphtheria booster has enabled a major expansion of the fight against pertussis *(273–280)*.

Tdap is recommended by ACIP for routine administration at age 11 to 12 years and for all persons aged 11 to 65 who have not yet received a dose, except during pregnancy; pending further data, it is recommended that Tdap be administered prior to pregnancy or immediately following delivery (63,*281*,282). It is particularly recommended that those who will have close contact with an infant receive Tdap. In addition, ACIP and HICPAC recommend that all HCPs with direct patient contact receive Tdap as soon as feasible (63).

In the event of a healthcare-associated outbreak, consideration should be given to administration of Tdap to all potentially exposed persons who have not yet received a dose (63,*280*).

Typhoid Vaccine

Background Typhoid fever now is relatively rare in the United States, with fewer than 500 cases reported annually. The disease remains common, however, in areas of the world where fecal contamination of food or drinking water occur. The majority of cases in Western countries occur among travelers to other countries *(283)*.

Healthcare-Associated Exposures Although *Salmonella* is a common cause of healthcare-associated infectious diarrhea, such cases in the United States usually involve the animal serotypes *(284–289)* rather than *Salmonella typhi (290–298)*. Transmission to HCP other than laboratorians working with *S. typhi* is distinctly uncommon (see also Chapter 76).

Vaccination Two modern vaccines exist, a live-attenuated oral vaccine (not recommended for HCWs, due to the theoretical risk of spread to patients) and a killed parenteral vaccine based on the capsular polysaccharide. A conjugate version of the latter vaccine has been developed but is not licensed. Vaccination is recommended for microbiology laboratorians who work frequently with *S. typhi*.

Vaccinia (Smallpox Vaccine)

Background Smallpox, one of the greatest killers of mankind, was eradicated as a natural disease in 1977 *(299)*. Unfortunately, it is now known that the Soviet Union weaponized smallpox during the 1980s, stockpiling enormous quantities of the virus whose present whereabouts are not known with certainty *(300)*. The consequent fear that smallpox might be used as a bioterror agent spurred efforts by the United States and other governments to reestablish stockpiles of smallpox vaccine (vaccinia). In addition, in 2002 to 2003 the United States promulgated a pre-event vaccination program designed to ensure the availability of immunized cadres that could respond to a smallpox release *(301)*. However, due primarily to concerns about vaccine adverse events *(299)* but also, perhaps, to doubts as to the likelihood of such an event, vaccine uptake among HCP was so low that the program was functionally suspended in 2003. Routine vaccination continues among deploying military personnel, certain rapid-response public health teams, and other select groups.

Healthcare-Associated Exposures Prior to the eradication of natural smallpox, the threat of healthcare-associated spread of infection was averted through universal vaccination. Subsequently, until the issue of bioterror protection arose, the only indication for the (somewhat hazardous) vaccination of HCP was to prevent the potentially more hazardous consequences of inadvertent infection with vaccinia among laboratorians and HCP occupationally exposed to vaccinia, recombinant vaccinia viruses, and other orthopoxviruses that can infect humans *(302)* (see Chapters 76, 101, and 104).

Vaccination In the United States, vaccinia is available to civilians only through the public health authorities. Vaccination against smallpox is recommended by the CDC only for laboratorians (or, presumably, other HCP) who work with orthopoxviruses (for this indication, contact CDC) and for public health and healthcare response team members (for this indication, contact your state or local health department). In addition, as noted, the Department of Defense routinely vaccinates deploying military personnel.

Varicella Vaccine

Background Varicella zoster virus (VZV) is the causative agent of varicella (chickenpox). Following acute infection, the virus remains latent in the trigeminal and dorsal root ganglia for life, and from there may erupt on occasion to cause herpes zoster (shingles) *(303)*. Although varicella is generally a mild disease in children, it is often more serious in adults, and substantial morbidity and mortality are common if infection occurs in neonates, pregnant women, or the immunocompromised *(303)*. VZV is most commonly transmitted from person to person by the droplet route, but true airborne transmission may also occur. The secondary attack rate of varicella among susceptible people in the household setting has ranged from 61% to 87% *(304–306)*. Herpes zoster is also infectious, although analysis of households suggests that the risk of transmission is lower than for varicella.

Varicella disease has declined sharply in the United States following incorporation of the varicella vaccine into the childhood vaccination schedule, with decreases in varicella-related hospitalizations and deaths *(307)*. Paradoxically, this heightens the importance of an institutional varicella immunity program, as those who escaped infection in childhood [in the prevaccine era, at least 5% of persons aged 20 to 29 *(308)*] and were left susceptible are likely to remain so, absent vaccination.

Healthcare-Associated Exposures Control of varicella is important in healthcare facilities because varicella and zoster are highly contagious, with many reported healthcare-associated outbreaks *(306,309–329)*; infection in adults frequently results in complications, including hospitalization *(310,330,331)*; infection in pregnant women is particularly dangerous, and may lead to both maternal *(303)* and fetal *(332–334)* complications; and immunosuppressed persons, who make up a progressively larger proportion of hospital inpatients, are at high risk of complications *(310,335–342)*.

Studies conducted prior to widespread varicella vaccination have indicated that a report of prior varicella by an HCP is predictive of immunity as measured by serology *(343)*. However, as exposure opportunities are reduced by childhood immunization programs, the proportion of such reports that are false positive must inevitably rise, and active screening will increasingly be necessary. A history of prior household exposure to VZV is not predictive of immunity *(344)*. Overall, a median of 3% of HCPs are susceptible to varicella *(312–314,329,345–349)*, absent an institutional immunization program. Among HCP with a negative or uncertain history of VZV infection, serosusceptibility has ranged as high as 47% *(309,312,313,346–350)*. Following healthcare-associated exposure to VZV, 2% to 16% of susceptible staff will develop clinical varicella *(309,310,312)* (see Chapters 43 and 76).

Vaccination Due to its high communicability and potential for serious consequences, the appearance of active varicella infection within a healthcare institution is an infection control emergency. In the absence of assurance of HCP immunity, the management of such VZV exposure incidents is burdensome and expensive. Accordingly, many institutions (particularly those with pediatric, obstetric, transplant, chemotherapy, or similar programs) have elected to require demonstrated immunity among HCP working with such patients. Decision and cost-effectiveness analysis methods have been used to demonstrate that immunization of HCP susceptible to varicella is cost-effective for healthcare facilities *(351–354)*.

We recommend that HCP be screened for VZV immunity at the time of initial employment (or, for current employees, at time of next tuberculosis or similar screening). HCP with a reliable history of VZV infection may be considered immune; all others should undergo serologic testing and, if negative, be considered for immunization with two doses of vaccine at least 4 weeks apart. Postimmunization serology is not recommended.

There appears to be virtually no risk of transmission of the vaccine virus from healthy people who do not develop

a rash postimmunization. HCP who develop an injection site rash may continue to work with nonimmunocompromised patients, provided that the lesions are covered. HCP with a generalized rash should be furloughed until the rash is resolved. In the authors' experience, this has been approximately 5 days. The rash should not automatically be assumed to be due to vaccine, especially if exposure to a case of chickenpox has occurred in the preceding 3 weeks.

CONCLUSION

All HCP should be immune to measles, mumps, rubella, and varicella. All those with the potential for exposure to blood or potentially contaminated body fluids should be immune to hepatitis B. Absent specific contraindication, those who are susceptible should be offered the appropriate vaccines; prevaccination serologic testing is not medically required but may be offered at the institution's discretion.

In addition, all HCP should be immunized annually against influenza. HCP also should receive Tdap (at least once), tetanus-diphtheria (thereafter), and pneumococcal vaccines as recommended for the general public. Hepatitis A vaccine may be indicated based on local or regional epidemiology. Finally, selected HCP may be candidates for other available vaccines, including meningococcus, polio, plague, rabies, typhoid, and vaccinia.

CHAPTER 76

Prevention of Occupationally Acquired Diseases of Healthcare Workers Spread by Contact, Droplet, or Airborne Routes (Other Than Tuberculosis)

Titus L. Daniels, Michael D. Decker, and William A. Schaffner

By virtue of their profession, healthcare workers are at greater risk of acquiring certain illnesses than are non–healthcare workers. This chapter discusses diseases spread by the contact or airborne routes for which healthcare workers are at elevated risk or that pose a particular problem for infection control and employee health staff. Notwithstanding the occasional healthcare-associated report, diseases that occur in the healthcare setting incidentally (e.g., food-borne illness arising in the hospital's cafeteria) are not considered. Similarly, only those diseases to which the immunologically normal healthcare worker is susceptible are covered.

Issues posed by the viral hepatitides and the human immunodeficiency virus (HIV) are covered in Chapters 73 and 74, respectively; tuberculosis is discussed in Chapter 38; infections of particular pertinence to laboratory workers are discussed in Chapter 77; infections pertinent to prehospital and posthospital healthcare workers are reviewed in Chapters 78 and 79; and issues consequent to bioterrorism are found in Chapters 101 to 104. Vaccinations of healthcare workers are detailed in Chapter 75. This chapter enumerates the remaining healthcare-associated airborne and contact-spread diseases for which healthcare workers are at elevated risk, reviews their epidemiology and prevention in healthcare institutions, and discusses some of the special challenges they pose for the infection control team. Pathogenesis, diagnosis, and therapy of these diseases are not addressed in detail, because they are discussed in other chapters of this text and elsewhere.

METHODS OF SPREAD

As Brachman *(1)* and others have pointed out, contact and airborne spread represent two ends of a spectrum. The spectrum begins with direct physical contact, as seen with bacterial pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA). Such person-to-person spread also includes most fecal–oral transmission. Disease may be transmitted by indirect contact, in which the victim encounters an intermediate object that previously was in contact with the source, as may occur, for example, through careless handling of contaminated equipment or used dressings. Disease can be spread via respiratory droplets expelled by a cough or sneeze; the cloud of expelled particles can impact persons or other objects within several feet, but the droplets do not travel farther before they settle to the ground. Finally, if respiratory droplets are sufficiently small, their moisture entirely evaporates while airborne, leaving any contained infectious particles suspended in the air. These droplet nuclei can be transported in the air over substantial distances. Under appropriate circumstances, other tiny particles (e.g., desquamated skin squames, fungal spores) may also be spread afar on the wind. Many diseases are spread by more than one of these routes. Additional pathways for the spread of disease include the blood-borne, common-source, and vector-borne routes. The diseases of transcendent importance that are spread by the blood-borne route are hepatitis B and C (Chapter 73) and HIV infection (Chapter 74). In the United States, healthcare workers generally are not at elevated risk of common-source or vector-borne diseases because of their occupation.

Humans long have pondered the origins of disease, and through the ages, the issue of airborne contagion has been raised many times. The Greek physician Galen stated, "When many sicken and die at once, we must look to a single common cause, the air we breathe" *(2)*. Hamlet bemoaned "this foul and pestilent canopy, the air," but 1,500 years after Galen, Sydenham said it was not the air itself, but "pestilential particles" carried by the air that conveyed disease *(2)*. Despite these prophetic speculations, Galen was responsible for establishing the dominance of the theory that deranged humors were responsible for disease, a belief to which Sydenham subscribed and which persisted until overthrown by the discoveries of the anatomists, pathologists, and microbiologists of the nineteenth century.

The discoveries of Louis Pasteur and others refocused attention on the possible spread of disease through the

air to such an extent that Tyndall was moved to write "the floating dust of the air … mingled with it the special germs which produce the epidemic, being thus enabled to sow pestilence and death over nations and continents" *(3)*. But soon, belief in the airborne spread of disease ebbed again because of the elucidation of the causes and modes of transmission of fecal–oral diseases, such as cholera; vector-borne diseases, such as malaria; and venereal diseases, such as syphilis. These discoveries had so reduced the attraction of the concept of airborne spread that by 1910, Chapin *(4)* stated in his *Sources and Modes of Infection*, "Bacteriology teaches that former ideas in regard to the manner in which diseases may be airborne are entirely erroneous; that most diseases are not likely to be dust-borne, and they are spray-borne only for 2 or 3 ft."

There opinion lay for 20 years, not overturned even by the great influenza pandemic until Wells *(5)* articulated the concept of droplet nuclei, infectious particles that can remain suspended in the air for many hours after the droplet itself has evaporated and that can be carried a considerable distance on air currents. Wells promptly proceeded to test his theory by placing ultraviolet lights in selected classrooms of two schools *(6)*. In a subsequent measles epidemic, the attack rate was dramatically higher in the control classes. Riley later collaborated with Wells to demonstrate the airborne transmission of tuberculosis *(7,8)*. Similar experiments, coupled with more sophisticated epidemiologic observations of outbreaks, have established the importance of the airborne route of spread for many diseases.

VIRAL INFECTIONS

Common Respiratory Viruses

Few healthcare workers would rank the common respiratory viruses first on a list of the diseases to which their work exposes them, but we would speculate that these illnesses cause more disruption and lost productivity than all the others we discuss combined.

Influenza The prototype of these illnesses is influenza. Influenza epidemics occur with distressing frequency within healthcare institutions, with predictable consequences; increased absenteeism or reduced efficiency of staff members and increased mortality, morbidity, and length of stay among the patients. Indeed, immunization of healthcare workers results in significantly reduced morbidity (43% reduction in influenza-like illness) and mortality (44% reduction) among geriatric patients in long-term-care facilities *(9)*.

The capacity of influenza for explosive spread was demonstrated by an outbreak among 53 persons stranded aboard a grounded airliner for 3 hours: within 3 days, 72% of the passengers were ill with influenza A *(10)*. When the "Asian" influenza A pandemic of 1957 reached the Oklahoma City Veterans' Hospital, 19 (39%) of 49 patients on the neurologic ward were affected, three of whom died; all but one of the physicians on the ward were "incapacitated" *(11)*. During the same epidemic, eight (62%) of 13 unvaccinated staff members studied at the New York Hospital developed influenza, as compared to 7 (35%) of 20 vaccinated staff *(12)*. Influenza A/Bangkok (H3N2) produced illness in one third of patients and staff members on affected wards at a Chicago hospital *(13)*. The same strain of influenza caused a 70% increase in absenteeism during a 2-week period among employees of a Winnipeg, Canada, hospital, which incurred excess sick-leave costs of $24,500 (1,980 Canadian dollars) *(14)*. Reports of healthcare-associated outbreaks of influenza B appear to be less common than reports of influenza A. This finding may merely reflect the greater prevalence of influenza A, although one report of hospital surveillance during an influenza B epidemic found no clusters of disease despite 25 cases detected by culture *(15)*.

Influenza is spread via infected nasopharyngeal secretions. Attempts in 1918 to transmit the pandemic strain failed because of improper technique; it was not until 1937 that Smorodintseff and associates demonstrated experimental transmission by droplets *(16)*. Spread is believed predominantly to involve respiratory droplets, as well as direct person-to-person spread through contact with infected secretions. Airborne spread is possible, but not as well documented as with such diseases as tuberculosis and varicella. Mingling of the occupants, a vigorously coughing source patient, and a nonfunctioning ventilation system were associated with the airliner outbreak, and thus, it may have been entirely caused by droplet spread.

Given the opportunities for exposure to influenza during a community outbreak, the only realistic approach to prevention among healthcare workers is through immunization. Unfortunately, achieving high immunization rates among healthcare workers has proven difficult *(17–19)*, with rates often less than 50% (20). Hospital-wide influenza immunization programs that are highly publicized, bring the program to the worker, take advantage of social or peer pressure, and reward participation find greater success, but still fail to maintain vaccination rates above 90%. Mandatory influenza vaccination programs appear to have the greatest effect on sustaining acceptable influenza vaccination rates among healthcare personnel (21). In an established outbreak, cohort isolation may help prevent spread to other patients *(22)* but likely would be of little benefit to the work force, given the ubiquitous opportunities for exposure during an outbreak. The neuraminidase inhibitors have traditionally afforded protection against influenza A (H1N1, H3N2) and influenza B, should a worker at high risk of complications be unable or unwilling to participate in the immunization program. In recent years, however, some influenza A (H1N1) strains have become resistant to oseltamivir. A combination of oseltamivir with an adamantine or zanamivir alone may be used if prophylaxis is indicated. Current recommendations for the prevention and treatment of influenza are available from the Centers for Disease Control and Prevention (CDC) and should be consulted prior to prescribing antiviral therapy *(23)*. Infected employees should not work in order to prevent spread to patients and others. (For more information on influenza, see Chapter 42.) (Note: All references to specific forms of isolation precautions, such as Standard, Droplet, or Airborne Precautions, refer to the "2007 Guideline for Isolation Precautions: Preventing Transmission of Infectious Agents in Health Care Settings," by the Hospital Infection Control Practices Advisory Committee of the United States Public Health Service (24)) (see also Chapter 90).

Parainfluenza Parainfluenza infections are most problematic among infants and young children, and spread on pediatric wards is well documented. These outbreaks often involve the staff *(25,26)*; an outbreak investigated at the Children's Hospital National Medical Center was shown to affect six of 17 neonates along with 18 of 52 nursing personnel *(26)*. Although the disease is relatively mild among older children and healthy adults, it can be a problem in long-term-care facilities, affecting both patients and staff, with patient deaths reported *(27)*. Of the various strains of parainfluenza virus, type 3 appears to be implicated more often in healthcare-associated outbreaks. The spread of parainfluenza often is indolent *(28)*, and the virus appears to be relatively hardy; droplets may contaminate environmental surfaces with virus that survives for many hours *(29)*.

Spread of parainfluenza virus is by direct contact and by large droplets, which may create the potential for indirect contact spread. Airborne spread is plausible but has not been demonstrated. Immunity is not durable and reinfection occurs throughout life. Thus far, efforts to develop vaccines have not been fruitful. Thus, protection of the healthcare worker rests on identification and isolation of cases with use of Contact and, perhaps, Droplet Precautions.

Respiratory Syncytial Virus Respiratory syncytial virus (RSV) is the most important respiratory pathogen of infants and young children, in whom it is the predominant cause of bronchiolitis and pneumonia *(30,31)*. Community-based outbreaks occur every winter and spring, and essentially the entire population has serologic evidence of infection by age 3 years. Immunity is short-lived and reinfection can occur annually. Thus, RSV spreads readily to healthcare workers. The disease is mild in previously infected adults, who may be asymptomatic or experience symptoms of the common cold *(31)*. Despite their mild illness, however, infected healthcare workers can serve as a source of infection for pediatric *(32,33)* and other *(27,34–37)* patients in whom infection may be dangerous.

Hall et al. *(32)* studied healthcare-associated RSV during a community outbreak and found that 45% of infants hospitalized 1 week or more acquired infection as did 10 of 24 staff members. Indeed, in the absence of effective barrier precautions, 30% to 60% of healthcare workers caring for RSV-infected children acquired infection *(38,39)*.

RSV infection appears to be acquired through inoculation of the eyes or nose by direct and indirect contact with infectious respiratory secretions *(31,39)*. Use by caregivers of eye–nose goggles markedly reduces spread of the disease *(38,40)*, probably by preventing self-inoculation via contaminated hands; others have shown similar benefit through use of gloves and gowns *(41)* or gloves, gowns, and masks *(42)*. To curtail both direct and indirect contact spread, use of Standard and Contact Precautions is appropriate. As is so often the case, scrupulous hand washing is the key to prevention of infection (see also Chapter 91).

Adenovirus The adenoviruses are responsible for a variety of syndromes: typical upper respiratory infections (e.g., cough, coryza, pharyngitis), particularly of children; febrile acute respiratory disease of military recruits; epidemic keratoconjunctivitis; pharyngoconjunctival fever; and, uncommonly, pneumonia *(43)*. Spread can be explosive, particularly in closed groups, such as military recruits or shipyard workers.

A number of outbreaks of epidemic keratoconjunctivitis have been documented in healthcare facilities. Most often, these outbreaks involve spread to patients exposed to contaminated ophthalmologic equipment or solutions or to a caregiver's unwashed hands *(44–52)*. Healthcare workers have acquired conjunctivitis not only through care of patients with conjunctivitis but also through care of patients with other adenovirus infections such as pneumonia *(53)* when appropriate isolation precautions were not observed (see also Chapter 90).

Although less common, outbreaks of respiratory disease resulting from adenovirus are more serious. A 1980 outbreak at Children's Hospital in San Diego, California, involved six patients (of whom four died) as well as 300 (78%) of 383 employees, of whom 15% developed conjunctivitis, 28% diarrhea, and 72% upper respiratory symptoms *(53a)*. The outbreak was terminated by strict isolation, cohorting, furlough of ill employees, and closure to new admissions. A smaller but similar outbreak in a neonatal intensive care nursery resulted in two patient deaths and infection of nine patients and ten staff members *(54)*. An outbreak in a pediatric long-term-care facility resulted in 11 deaths and 28 cases (46% attack rate) among patients; 22% of staff members (23 of 106) acquired illness *(55)*. An outbreak in another pediatric long-term-care facility following infection in one infant spread to involve two staff members and 10 (30%) of 33 patients, of whom two died *(56)*.

Although respiratory illness is rarely serious among adults, it may be more severe among residents of long-term-care facilities *(27,57)*. The infection can be fatal among the immunocompromised *(58)*. Serotype 14 has recently emerged and may be associated with more severe respiratory illness, even among the less infirm. An outbreak of severe respiratory disease in a military training facility affected 48% of trainees (551/1147), resulting in 23 hospitalizations (4 requiring admission to an intensive care unit [ICU]) and one death *(59)*.

Good evidence supports the spread of adenovirus by direct contact, indirect contact, droplets, and (predominantly among children) the fecal–oral route. Airborne spread is plausible, but we are not aware of a healthcare-associated outbreak that cannot be explained by contact or droplet spread. Airborne spread does not appear to be necessary to explain epidemics among military recruits *(59,60)*, given their prolonged close contact and the opportunity for droplet spread. Contact Precautions should be used for patients with adenovirus conjunctivitis; Droplet Precautions should be added for those with adenovirus respiratory infection. Environmental decontamination can be difficult, because the adenovirus is unusually hardy; alcohol and chlorhexidine are not reliable agents for disinfection *(61)*. A variety of vaccines have been used with success in the military, but none is available for civilian use (see also Chapter 48).

Rhinovirus and Coronavirus The rhinoviruses and coronaviruses cause the common cold—coryza, with variable cough, and pharyngitis. More than 100 serotypes of

rhinovirus are known (virtually ensuring the opportunity each year to encounter a virus to which one is not yet immune), as well as an as-yet-undetermined number of coronaviruses. Although the rhinoviruses and the usual coronaviruses are virologically distinct, they are clinically and epidemiologically similar enough to be considered together. Widespread community outbreaks caused by these viruses occur every winter, with low-level spread throughout the year. As every parent knows, incidence rates are highest among young children and decline with increasing age among adults (apart from a higher incidence among adults with young children). Schools and homes are the major foci of dissemination *(62)*. Given the ubiquitous opportunities for exposure and the usually benign outcome, healthcare workers may not view the common cold as a target for infection control. The frequency of infection, though, is not trivial. In a prospective analysis of healthcare workers with respiratory illness, nearly 40% were found to be infected with rhinovirus. Of those infected employees, one quarter provided care for high-risk patients *(63)*.

Transmission does occur between patients and caregivers, however, with outcomes that are burdensome for caregivers and potentially serious for selected patients, such as the immunocompromised, the very young *(30)*, or the elderly *(64)*. For example, Valenti et al. *(33)* investigated an outbreak of viral respiratory disease in a neonatal intensive care unit (NICU) and determined that one half of the cases were caused by RSV and one half were caused by rhinovirus; respiratory illnesses were similarly serious in the two groups of infants *(33)*. The investigation showed that the infants acquired their infections from their caregivers, 31% of whom had been ill in the preceding week. Unlike other viral respiratory infections, rhinovirus infections do not appear to be significantly more dangerous among the healthy elderly *(27)*, although lower respiratory tract involvement has been seen *(65)* and can have severe consequences among those with chronic pulmonary disease *(64)*.

During infection, rhinovirus is present in high titer in nasal secretions but only in low titer, if at all, in oral or pharyngeal secretions *(62)*. Volunteer studies have shown that infection is acquired readily via the nose or conjunctiva but poorly via the oral route. Although the virus is relatively hardy and can survive drying on environmental surfaces for several hours, the overwhelmingly most important route of spread is nose to hand to nose or eye. Prevention of spread of infection to or from workers is best accomplished through use of Standard Precautions, with particular attention to hand washing. Workers should be encouraged to stay home at times of profuse catarrh.

Severe Acute Respiratory Syndrome (SARS) Coronavirus

Severe acute respiratory syndrome (SARS) emerged in southern China late in 2002 and spread rapidly to Hong Kong, Singapore, Taiwan, Vietnam, and Canada *(66)*. Few cases were documented in the United States. A new coronavirus was quickly established as its cause. Although definitive information concerning the nuances of transmission is lacking, it is clear that droplet and close contact spread occur, sometimes with astounding efficiency from so-called super-spreaders. Aided by a large, distinctive, and malfunctioning sewage system, transmission from virus excreted in feces may have occurred in a high-rise housing complex in Hong Kong. The role of conventional fecal–oral transmission and the role of environmental contamination remain uncertain.

Healthcare-associated transmission to healthcare workers (with some fatal results) was a prominent feature in virtually every country experiencing the disease *(66–71)*. The United States was spared almost all healthcare-associated spread. This may have been the happy consequence of intensive education by the CDC, the good fortune of not having a super-spreader enter the country, or other unknown factors.

Much of the healthcare-associated spread of SARS was attributed to inconsistent observance of strict Airborne Precautions and inconsistent use of personal protective equipment, particularly during aerosol-generating activities. Droplet Precautions have been shown to be effective in reducing transmission risk. If SARS recurs, the fastidious use of isolation and personal protective equipment will be critical to avoiding spread of the virus to healthcare professionals.

Enteric Viruses

Coxsackievirus, Echovirus, Poliovirus, and Miscellaneous Enteroviruses The enteroviruses cause a variety of syndromes, including aseptic meningitis, encephalitis, poliomyelitis, herpangina, epidemic myalgia, upper and lower respiratory disease, hand–foot–mouth disease, conjunctivitis, pericarditis, and myocarditis *(72)*. In the United States, enterovirus infections occur almost exclusively between May and November, peaking in the summer months *(73)*. Many enterovirus infections are associated with exanthems. These viruses are so common, and their manifestations so varied, that recognition of transmission or identification of the causative agent often occurs only when a distinctive outbreak occurs.

Enterovirus infections are common in children, for whom they are generally mild. Infections are more likely to be serious among infants and adults, who experience a greater frequency of cardiac or neurologic involvement *(72)*. For example, an outbreak of echovirus 30 in a day-care center came to attention when 13 parents developed aseptic meningitis *(74)*. Similarly, in an outbreak of coxsackievirus B5 infection in a newborn nursery, illness was sporadic and mild among full-term infants but more prevalent and severe among premature infants; two nurses developed severe pleurodynia and fever *(75)*. A New Zealand hospital experienced a dual outbreak involving echovirus 11 and coxsackievirus B3 *(76)*. Eleven infants and 12 staff members developed meningitis; about one-half the infections were healthcare associated. Modlin *(77)* reviewed 16 nursery outbreaks of echovirus and found hospital personnel to be involved in nine cases. In a unique outbreak of hand–foot–mouth disease in Utah, 17 (13%) of 136 operating suite personnel—but no patients—developed clinical disease resulting from contact spread following illness in an index surgical technician *(78)*.

All enteroviruses reside in the gastrointestinal tract, and thus most spread is by direct contact involving the fecal–oral route. Standard Precautions should be supplemented by Contact Precautions for diapered or fecally incontinent individuals. Although many of these viruses

can be recovered from the oropharynx during illness and have been experimentally transmitted by coughing *(72)*, use of Droplet Precautions is not routinely recommended. As always, hand washing is likely the most important single preventive strategy.

Poliovirus infection has been eradicated from the Western Hemisphere *(79)*. Until worldwide eradication is achieved, occasional imported cases may be seen in the United States. However, the risk of spread will remain confined to sects that shun immunization unless immunization efforts wane in this country. The use of live attenuated oral poliovirus vaccine (OPV) has been abandoned in the United States. The risk of vaccine-associated disease was once seen at a rate of about one case per 2.6 million doses *(80)*. In countries where OPV is still used, a risk of vaccine-associated paralytic disease exists in contacts of OPV recipients, raising a theoretical concern of infection in a healthcare worker, although we find no evidence that such an event has ever occurred. In addition, transmission should be prevented by Standard Precautions. Thus, verification of primary poliovirus immunization of healthcare workers is recommended only for (a) those working with poliovirus in the laboratory; (b) those who might care for, or handle specimens from, a patient excreting wild poliovirus; or (c) in the event of an outbreak (see also Chapters 24 and 50).

Rotavirus, the Norovirus, and Related Viruses Rotavirus is the principal etiologic agent of infantile diarrhea and is responsible for up to one half of all episodes of acute diarrheal disease in infants and young children. The Norwalk-like viruses, a growing group of similar yet genetically diverse members of the Caliciviridae, consist of Norovirus (formerly, Norwalk virus) and a host of other small (27 nm, as compared to 70 nm for rotavirus) round-structured viruses (SRSVs) such as the Snow Mountain, Hawaii, and Marin County agents *(81)*. These agents appear to be responsible for two-thirds of all nonbacterial gastroenteritis *(82)*. An additional but much smaller proportion of viral gastroenteritis is attributable to the astroviruses, other caliciviruses, and minireoviruses. The coronaviruses (especially including the toroviruses *(83)*), adenoviruses, enteroviruses, and parvoviruses, discussed elsewhere in this chapter, can also cause gastroenteritis.

Several healthcare-associated outbreaks of rotavirus have been documented in neonatal or pediatric units, usually initiated by admission of children involved in a community outbreak *(84–91)*. Although each of these outbreaks involved substantial healthcare-associated spread of infection to hospitalized infants and children, no healthcare workers were reported to acquire illness. Several rotavirus outbreaks among geriatric populations have also been reported *(92–94)*. In contrast to the experience with pediatric outbreaks, infection and illness occurred among staff members in each of these geriatric outbreaks. Another outbreak, involving somewhat less-elderly patients on a cardiology ward, also involved the staff *(95)*, as did an outbreak on an obstetrics unit *(96)*. Whether this difference in likelihood of illness among staff members reflects random chance, differing host adaptation of viral strains, or systematic differences in infection control practices is unclear. Routine use of rotavirus vaccine in infancy will reduce the likelihood of the introduction of these viruses into healthcare facilities.

Rotavirus is spread by the fecal–oral route, principally via the hands of healthcare workers. The virus is highly stable, but environmental contamination does not appear to be an important pathway of transmission in an outbreak. Similarly, despite occasional isolation of the virus from pharyngeal secretions, airborne spread does not appear likely. Standard Precautions should be sufficient, supplemented by Contact Precautions for diapered or incontinent patients. Of interest, quaternary ammonium disinfectants appear to be ineffective against rotavirus; bleach or phenolics should be used if rotavirus environmental contamination is a concern *(97)*. (For additional information on enteric viruses, see Chapters 24 and 50.)

Noroviruses and other SRSVs cause explosive outbreaks of gastroenteritis in the home, school, community, and nursing home settings, particularly in the winter and spring. The gastroenteritis is marked by sudden onset of vomiting and diarrhea. Rates of secondary spread are high, and disease often involves school-aged children, parents and caregivers, and some young children. Of 270 outbreaks reported to the CDC from July 2000 to June 2004, 31% involved nursing homes and hospitals *(98)*. In a Tennessee outbreak, 55% of patients and 61% of the nursing staff in a long-term-care hospital became ill in a 10-day period *(99)*; an outbreak in a similar facility in Los Angeles involved 55% of residents and 25% of staff members *(100)*. Although attack rates have been higher among patients than staff in most outbreaks, this outcome is not always the case. In a recent North Carolina outbreak, 31% of staff and 11% of patients were ill *(101)*. A 3-week outbreak at a 600-bed Toronto, Canada, hospital involved 27% of the 2,379-person staff, as well as 10% of their household contacts *(102)*. The outbreak appeared to be centered in the emergency room, where 69% of the staff and 33% of visitors acquired illness; an extensive investigation suggested spread of infection by the airborne route. Investigation of a cruise-ship outbreak the following year similarly suggested a role for airborne or droplet spread *(103)*. Investigators of several subsequent outbreaks have concluded that airborne or droplet transmission occurred *(100,104–106)*, although some commentators remain skeptical *(81,107)*. Caul *(108)* has pointed out that, based on electron micrographic studies, each ounce of vomitus contains 30 million viral particles; only 10 to 100 are required to cause infection. Projectile vomiting associated with Norovirus gastroenteritis may aerosolize infectious droplets. This view is supported by data such as those of Chadwick and McCann *(104)*, who found that staff members exposed to nearby vomiting had a fourfold elevated risk of illness; nearby vomiting and close patient contact remained as the only significant independent predictors in a multiple logistic regression. Numerous outbreaks were reported to the CDC in 2006 to 2007, especially in long-term-care facilities. Two newly identified cocirculating norovirus strains that emerged in 2006 likely accounted for the increased burden of disease *(109,110)*.

The appropriate choice of isolation precautions for Norovirus and related gastroenteritis is somewhat contentious; Standard Precautions may not be sufficient. Although unproven, the plausibility of Droplet spread and the epidemiologic evidence supporting that route of transmission appear to be sufficient to warrant Droplet Precautions when confronted by forceful vomiting caused

by Norovirus-like agents. The evidence that environmental contamination plays a role in disease transmission is insufficient to recommend Contact Precautions, although, as is recommended for rotavirus, Contact Precautions should be considered in the event of fecal incontinence or other gross soiling. Healthcare-associated outbreaks may require cohorting and furloughing of involved staff members until they are well; most affected institutions have employed elaborate environmental decontamination, the need for which is unproven, but perhaps prudent (see also Chapters 24 and 50).

Hepatitis A The hepatitis A virus causes an acute, self-limited infection whose clinical manifestations vary with age. Children typically experience mild or no illness; adults commonly develop malaise, nausea, vomiting, and icterus. Fulminant hepatitis and death are rare (0.1–0.5%) *(111)*. The disease is clinically indistinguishable from several other viral hepatitides, and serologic diagnosis is required.

Healthcare-associated transmission is thought to be unusual. Most healthcare-associated outbreaks arise following admission of a patient not suspected to have hepatitis A, who either has subclinical infection, is in the prodrome, or is serologically false negative because of immune deficiency *(112)*, emphasizing the need to follow Standard Precautions for all patients. For example, three physicians caring for a 21-month-old girl with unsuspected anicteric hepatitis A became infected and ill; another developed subclinical infection *(113)*. Of 58 susceptible workers exposed to a patient who had vomiting, diarrhea, and fecal incontinence during the 8 days preceding jaundice, six (10.3%) acquired infection *(114)*. An outbreak in one NICU affected 13 infants, 22 nurses, 8 other staff, and four household contacts *(115)*; an outbreak in another NICU involved four infants and ten staff members. Investigations of such outbreaks have repeatedly identified two sets of behaviors as risk factors for worker infection: (a) a failure to wash hands, wear gloves, or both *(114–116)*; and (b) eating, drinking, or smoking in the patient care unit *(115,117,118)*.

Hepatitis A is transmitted almost exclusively by the fecal–oral route. A brief viremic phase occurs, during which blood-borne transmission is possible; airborne transmission has been alleged in at least one report *(119)* but is unlikely. The virus is present in high concentrations in the stool, and Standard Precautions should be supplemented with Contact Precautions in the case of fecal incontinence (including diapered infants).

Excellent vaccines have been developed and licensed. Although considered indicated among US healthcare personnel only for susceptible individuals in areas where hepatitis A is highly endemic *(120)*, cost-benefit analyses have suggested that the cost of hepatitis A vaccination in healthcare workers, per life-year saved, was similar to that of other standard medical interventions *(121)* (see also Chapter 46).

Herpes Viruses

Infections caused by the herpes viruses are among the most common diseases of humans. The herpes viruses are not cleared following primary infection but, rather, reside permanently in target tissue. The viruses remain capable of reactivation, which might result in clinical disease on a regular basis (herpes simplex), occasionally (varicella zoster virus [VZV]), or only in the face of immune compromise (cytomegalovirus [CMV]). The herpes viruses have been incriminated as risk factors for several neoplasms, and those that are lymphotropic alter immune function during active infection.

Herpes Simplex Virus Herpes simplex virus (HSV) infection is common. In the United States, by age 45, 70% to 80% of the population has acquired antibody to HSV-1, the strain associated with oral lesions; 15% to 20% of whites and 40% to 60% of blacks have antibody to HSV-2, the strain associated with genital lesions. Infection with either strain is lifelong; following primary infection, the virus travels along sensory nerves and becomes latent within sensory ganglia. In a recurrence, the virus reactivates, travels peripherally from the ganglia along the nerves, and reestablishes cutaneous infection *(122)*. Of importance to the healthcare worker, active virus can also be demonstrated in oral or genital secretions when no cutaneous or mucosal lesion is evident.

Although herpes virus can cause a variety of clinical syndromes, only one is routinely of pertinence to the healthcare worker: whitlow, a term derived from the middle-English whit flaw, or a flaw in the quick of the nail. Both HSV-1 and HSV-2 can cause whitlow; prior oral or genital infection does not necessarily protect one from acquiring a new infection of the finger *(123)*. Workers with frequent exposure to oral secretions, such as dental workers, respiratory care personnel, and anesthesia staff members, are at greatest risk *(124–128)*. Oral transmission can occur during mouth-to-mouth resuscitation *(129)*, and at least one outbreak has been reported involving transmission between nurses and patients in a pediatric ICU with further household spread *(130)*.

Under most circumstances, compliance with Standard Precautions should ensure protection from infection with HSV. Workers should glove (both hands) before contact with any oral secretions, including before airway suctioning. Contact Precautions should be considered when dealing with neonatal, disseminated, or severe primary herpes infection (see Chapter 44). Workers with whitlow should be restricted from contact with patients or their environment, and restriction from contact with high-risk patients may be appropriate for workers with orofacial herpes lesions.

Varicella Zoster Virus The VZV is the etiologic agent of chickenpox; reactivation of the latent virus in previously infected persons produces the disease known as herpes zoster (shingles). Chickenpox is common among children, in whom the disease is generally mild; severity of illness increases with age of the subject. Despite repeated epidemics in schools, a small proportion of adults escape childhood infection and remain susceptible. Nearly all healthcare workers (98–100%) with a clinical history of chickenpox are immune as measured by serology *(131)*, but 4% to 47% (median, 15%) of those with a negative or uncertain history of prior chickenpox are susceptible *(131)*. In one study, the rate of susceptibility was higher among those <35 (7.5%) than those more than 35 years of age (0%) *(132)*. Primary infection in susceptible adults can (but usually does not) cause serious disease, including varicella pneumonitis,

which can be fatal. Two groups are at special risk from primary varicella infections: the immunocompromised, among whom the mortality rate may approach 20%; and newborns whose mothers develop primary infection from 5 days before to 2 days after giving birth. The combination of absent transplacental antibody and massive exposure places these infants at high risk, and the mortality rate can approach 30% *(133)*.

Countless healthcare-associated outbreaks of VZV infection have been reported; indeed, it would be surprising to learn of a hospital caring for pediatric patients that has been spared. The high communicability of VZV, the routine presence in the hospital of immunocompromised patients at risk of serious or fatal disease if infected, and the presence of a core of susceptible healthcare workers make the management of VZV exposure one of the most challenging tasks of the infection control worker. This task is complicated by the fact that VZV is one of the few agents of healthcare-associated infection capable of true airborne spread *(134–142)*. Airborne spread of VZV can arise from patients (or personnel) with primary infection *(141)*, from patients with disseminated zoster *(136–138)*, or rarely from patients with localized zoster *(140)*. Of course, the infection can be transmitted by contact as well as through the air.

Management of VZV exposure incidents is burdensome and expensive. In a 1-year period at their hospital, Krasinski et al. *(143)* recorded 95 VZV infections (93 inpatients, two staff members), resulting in six exposure incidents involving 156 patients and 353 staff members. Fifty-one patients and 101 staff members denied prior VZV infection, but serology confirmed 5 and 11, respectively, to be susceptible. Three secondary infections occurred, six courses of varicella zoster immune globulin (VZIG) were administered, and 13 staff members were furloughed, at a cost of 356 hours of infection control staff time and $41,500. Similarly, Weber et al. *(144)* documented exposures in 121 patients and more than 300 staff members in a single year, of whom 11 and 49, respectively, were serosusceptible; costs of managing these exposures totaled $55,934. Given the frequency of VZV exposure incidents and the burden they impose, it is not surprising that the appropriate management of exposure events has been much debated *(137,145–154)*.

Immunization of susceptible employees is now the cornerstone of the varicella control program and is cost effective *(131,155,156)*. Susceptible employees can be identified by serotesting all employees, serotesting only those with a negative or uncertain history of chickenpox, or by foregoing serotesting and simply immunizing all those with a negative or uncertain history; the choice of strategy will depend on the institution's assessment of the relative costs of vaccine and serology, the rate of seronegativity in its employees, and the risk it is willing to accept of missing the detection and vaccination of a susceptible person *(131,157)*.

Immunization of staff does not address all concerns. Although seroconversion is not ensured following vaccination, postvaccination serology is not helpful and is not recommended *(120)*. In addition, vaccinees can develop a mild generalized rash and may pose a risk of infection to susceptible patients. The institution should develop policies concerning management of vaccinated employees who develop a rash illness or who are subsequently exposed to varicella. Employees with chickenpox, as well as immunosuppressed employees with zoster, must be excluded; otherwise, healthy employees with covered zoster lesions may work, except with high-risk patients.

When an exposure event occurs, unvaccinated susceptible employees with exposure (i.e., those who have provided care without the required precautions) are furloughed from the 8th to the 21st days following exposure *(120)*. Only employees known to be immune are assigned to care for patients with active VZV infection. Contact Precautions are used for all patients with VZV infection, and Airborne Precautions are added for those with primary varicella or disseminated zoster. Finally, exposed susceptible patients are discharged as soon as possible; if not discharged by the 8th day following exposure, they are placed in isolation through the 21st day or until discharged. VZIG is considered for exposed susceptible persons with impaired immune responses, including pregnant females (see also Chapter 43).

Epstein–Barr Virus The Epstein–Barr virus (EBV) is the principal causative agent of infectious mononucleosis and has been implicated as a cause of Burkitt's lymphoma and nasopharyngeal carcinoma. From 30% to 95% of children have antibodies to EBV by age 6; the proportion is higher in less-developed countries. After children, young adults are the most commonly infected group, in whom infection is more likely to be symptomatic *(158)*.

Transmission appears to require exchange of saliva and otherwise does not occur even with prolonged close contact. Few reports suggest healthcare-associated spread. Ginsburg et al. *(159)* reported an outbreak of infectious mononucleosis at an outpatient clinic in which five (17%) of 29 staff members developed clinical disease with serologic confirmation of recent EBV infection. The only possible route of transmission identified by the authors was the communal use of poorly washed coffee cups. One additional report noted the development of mononucleosis, reported to be serologically confirmed, in five (17%) of 29 laboratory workers; three had been involved in performing mononucleosis tests on serum specimens.

EBV is apparently transmitted rarely, if ever, in the healthcare setting, and no supplement to Standard Precautions is indicated in the care of patients infected with EBV.

Cytomegalovirus Nearly everyone acquires CMV infection at some point in life; age at first infection follows a pattern similar to that previously described for EBV, with larger proportions of children infected earlier in life in less-developed countries. Infection is most often asymptomatic or associated with nonspecific symptoms, but in less than 1% of cases may cause mononucleosis, hepatitis, or respiratory, gastrointestinal, or neurologic disease. As with the other herpes viruses, CMV infection is lifelong, and subsequent immunocompromised permits the virus to reactivate and cause respiratory, gastrointestinal, ophthalmologic, or other disease. In addition, CMV is one of the five classic teratogenic infections; primary or subclinical recurrent maternal infection during pregnancy can cause transplacental infection and neurologic damage to the fetus. Most fetal infections result from recurrent, rather than primary,

maternal infection; the risk of fetal infection is about 1% for pregnant women with CMV antibody *(160)*.

Concern regarding fetal CMV infection has stimulated substantial anxiety among healthcare workers, although to our knowledge, no healthcare-associated outbreak of CMV has ever been reported. Numerous studies of seroprevalence and seroconversion rates have been performed among nurses and other staff members who care for young children (*161,162,*163,*164–171)*; although some studies found some elevation in risk (often not reaching statistical significance), none concluded that healthcare workers incurred a material additional risk as compared to the risk associated with routine home and community life. In recent years, anxiety concerning CMV appears to have subsided. This reaction may reflect reassurance by the cited data and by the adoption of Standard Precautions—or perhaps distraction by other concerns such as HIV and pandemic influenza. CMV is excreted in urine and saliva, as well as stool, tears, breast milk, semen, and cervical secretions *(160)*. Droplet or airborne spread does not appear to occur, even during mechanical ventilation *(172)*. Adherence to Standard Precautions is adequate to protect the worker (see also Chapter 45).

Human Herpesviruses 6–8 Human herpesvirus 6 (HHV-6) has been identified as the causative agent of *roseola infantum* (also known as exanthem subitum and sixth disease). Roseola, the last of the classic exanthems of childhood to be differentiated, occurs commonly in children between the ages of 6 months, after waning of maternal antibody, and 4 years, by which age almost all children are seropositive. Within this age range, HHV-6 is a common cause of febrile illness, accounting for 20% of emergency room visits by infants 6 to 12 months old *(173)*. Reactivation during the year or two following primary infection was found in 16% of subjects *(173)*, and the occurrence of occasional outbreaks *(174)* suggests that reinfection of children is possible. Primary infection of adults is rare, because most acquire immunity in childhood, but when it occurs, it can produce lymphadenopathy, hepatitis, or a mononucleosis-like syndrome *(175)*. Serious or fatal HHV-6 reactivation has been demonstrated in recipients of bone marrow and, to a lesser extent, liver transplants. However, no evidence of transmission to healthcare workers exists as yet; thus, no infection control measures beyond Standard Precautions are needed. Serologic studies show that infection with human herpesvirus 7 is widespread in childhood. The virus may be another cause of *roseola infantum*; otherwise, its clinical significance is uncertain. Human herpesvirus 8 seems to resemble EBV in its ability to transform lymphocytes, and appears to be important in the cause of Kaposi's sarcoma *(176)* and has produced bone marrow failure in patients with kidney transplants *(177)*. Standard Precautions are indicated.

Herpesvirus Simiae Herpesvirus simiae, also known as simian herpesvirus B, is enzootic in rhesus, cynomolgus, and other macaque monkeys in whom it behaves much as HSV-1 does in humans. The disease can be transmitted to humans by the bite of a monkey; of 23 patients known to have symptomatic infections prior to 1987, 18 died of encephalitis. Only one known instance of spread from human to human has been reported, but it is noteworthy for occurring in the course of providing nursing care: the wife of a monkey handler repeatedly applied cortisone cream both to her husband's wound and to her own excoriated dermatitis; he died, but she received acyclovir and her disease did not progress *(178)*. Standard Precautions appear to be sufficient to prevent transmission to the healthcare worker *(179)*.

Other Major Childhood Viruses

Measles Measles, perhaps the most contagious disease extant, is an acute exanthematous infection caused by the rubeola virus *(180)*. It has been known since ancient times and was ranked first among the exanthems by the 19th-century nosologists *(181)*. Illness begins with cough, coryza, and fever; an enanthem (Koplik's spots) and a maculopapular exanthem follow. Measles is the most dangerous of the common exanthematous diseases of childhood. Even in healthy children, the disease can progress to pneumonia or, less commonly, encephalitis; bacterial pneumonia can also complicate the course. Chronic complications include subacute sclerosing panencephalitis. Measles infection is more serious in adults and in immunocompromised individuals. A safe, effective live attenuated vaccine exists, and its widespread use has interrupted the endemic transmission of measles in the United States *(182)*.

The exceptional communicability of measles permitted continued epidemics in past years, despite relatively high immunization levels. Measles outbreaks typically involve one or both of two groups: (a) infants too young to be immunized and young children who escaped immunization, and (b) young adults (including healthcare workers) with primary vaccine failure (about 2–5% of vaccinees). These problems have been addressed with substantial success by vigorous immunization campaigns *(183)* and by implementing a two-dose immunization schedule, which gives a second opportunity to immunize those who failed to seroconvert when first vaccinated (184,*185*). History makes it clear, however, that any slippage in immunization rates will lead to a resurgence of measles consequent to importations from areas of the world where active transmission continues *(182)*.

Reports of measles infections among healthcare workers caused by healthcare-associated outbreaks once were frequent *(185–195)*, and the frequency of such events climbed during the 1980s. For the 5-year period 1980 to 1984, 241 cases of measles (1.1% of all cases from 1980 to 1984) were acquired in healthcare settings; of the 241 cases, 24% were among staff members *(188)*. In the next 5-year period, 1,209 medical-setting cases were identified (3.5% of all cases during the period); 28% of the infections occurred in staff members *(187)*. Most of these cases represented a failure to immunize, not a failure of vaccine; only 20% of staff members for whom immunization status was known were documented to have received even one dose of vaccine. From 1985 through 1991, 2,997 measles cases were acquired in medical facilities, representing 4% of the total in that period *(196)*. As measles has been brought under greater control, the mean age of patients has shifted upward (27% of cases from 1993 to 1995 were in persons older than 20 years of age), and the proportion of cases acquired in medical settings increased (to 14% for the

period 1992–1995) *(197)*. In the United States, healthcare-associated acquisition of measles by healthcare workers in the 21st century has been essentially eliminated.

Healthcare-associated measles was a serious matter, involving substantial risk to patients and staff. During 1988, Children's Hospital in Los Angeles admitted 37 patients with measles *(193)*. Six cases were unsuspected, exposing 107 patients and 24 staff members. Twelve patients and seven employees developed measles; one patient died, and two workers were hospitalized with pneumonia. Eight hundred workers required vaccination, and 211 workdays were lost. Others have recounted the disruption and expense associated with these outbreaks *(190,192,198)*. In addition to jeopardizing healthcare workers and inpatients, healthcare-associated outbreaks can play an important role in propagating measles in the community (*191,193,199,200)*.

Like varicella, measles is spread readily by the airborne route. In 1937, Wells placed ultraviolet lights in selected classrooms of two schools *(6)*. In a subsequent measles epidemic, the attack rate was dramatically higher in the control classrooms, indicating causation of measles by an airborne agent susceptible to inactivation by ultraviolet light. Analyses of other outbreaks have confirmed the potential for airborne spread (*194,201,202)*, and Airborne Precautions should be used for patients known or suspected to have measles. Isolation strategies, however, clearly do not eliminate the risk of healthcare-associated measles; healthcare workers must be immune. Authorities now are willing to categorize as immune all persons born before 1957 *(196,197,203–205)*. From 1985 through 1991, 29% of healthcare workers reported with measles were born before 1957. Numerous serosurveys support the view that persons in this older group are less likely to be susceptible than younger persons *(206–212)*. Thus, because of the absence of endemic measles in the United States today, the 1957 demarcation is practical.

Immunization program costs can be minimized by devising program strategies that optimize the balance between obtaining preimmunization serology (to immunize only the susceptible) and immunizing without serology (a less expensive alternative if most will need immunization) (*180,207,213,214)*. The ideal measles prevention program would require that regardless of age, every worker with patient contact show documentation of receipt of two doses of measles vaccine after the first birthday, at least 1 month apart, or serologic evidence of immunity. Immunization would be required, as necessary, to satisfy this standard. However, substantial practical difficulties are encountered with this approach. Many workers properly immunized in childhood cannot document that fact and, thus, would require either serologic screening or two immunizations. If serologic screening is pursued, rubella immunity also should be assayed; more workers are susceptible to rubella than to measles (*205)*, and primary vaccine failure could have occurred with either antigen. Finally, a program incorporating serologic screening incurs substantial overhead associated with tracking of results and recall of employees.

The CDC's Advisory Committee on Immunization Practices (ACIP) recommended in June 2009 that all healthcare workers born after 1956 be required to provide laboratory evidence of immunity, laboratory confirmation of disease, or documented proof of receipt of two doses of vaccine; those born before 1957 should be considered for two doses of vaccine without proof of immunity (215). In an outbreak of measles, two doses of MMR vaccine is recommended for those born before 1957 who lack laboratory evidence of immunity. A simpler alternative approach is to give one injection of combined measles-mumps-rubella (MMR) vaccine to every employee who cannot document immunity or adequate prior immunization. Although this approach is not as comprehensive as the ideal program, the shortfall in immunization coverage would be limited to those persons who were susceptible to measles prior to this immunization, who failed to respond to this immunization, and who would have responded to a second injection given a month later. Data from Willy et al. (*211)* suggest that this strategy would leave 0.7% more of the work force susceptible (or equivocal) than would the ideal program (6.1% initially susceptible, 14.1% nonresponders to first vaccination, 81.8% responders to second vaccination). In comparison, programs that do not immunize persons born before 1957 leave 1.6% (*211)* to 6.4% *(206)* of employees susceptible; those that immunize only new hires can be expected to have substantial numbers of susceptible employees for many years.

Regardless of program strategy, MMR vaccine should be used. As discussed later, the consequences of healthcare-associated rubella can be disastrous, and many healthcare workers remain susceptible to mumps. No ill effects ensue from immunizing those already immune, and persons not yet immune require immunization. Individuals responsible for employee immunization programs will find helpful the previously cited program analyses *(209,210,216,217)*, the analysis of vaccine response by Willy et al. *(211)*, and the detailed recommendations published in a 1994 consensus paper *(218)* and recommendations provided by the ACIP (215) (see also Chapter 75).

Rubella Rubella (German measles) is another of the common exanthematous infections of childhood. Categorized as "third disease" when it was clinically differentiated from measles and scarlet fever 100 years ago, rubella is less contagious than measles and substantially less dangerous (except to the fetus). Postnatal acquired infection is commonly mild, and complications are rare apart from arthritis or arthralgia, which can affect up to one third of women (children and men are relatively spared). The arthritis may take several months to resolve and rarely may become chronic (*219)*.

The importance of rubella derives from its potential for devastating damage to the fetus. Depending on fetal age, infection may result in fetal death, heart defects, deafness, cataracts or glaucoma, retardation, and a host of other congenital maladies. The risk of fetal damage declines with maturity, from a high of 60% during the first 2 months of pregnancy. Once a susceptible woman is exposed, no intervention is likely to alter subsequent events favorably. Prevention of congenital rubella syndrome depends on establishing prior immunity.

Several healthcare-associated rubella outbreaks have involved staff members and patients *(214,220–229)*; Hispanic patients and staff are apparently particularly susceptible.

Such outbreaks can have substantial consequences. For example, a healthcare-associated outbreak in Boston involved 47 healthcare workers, one of whom terminated her early pregnancy *(227)*; rubella in an obstetrics clinic nurse exposed 151 obstetrics patients and 44 employees *(224)*; an obstetrician and two other staff members of a prenatal clinic developed rubella, exposing 56 susceptible pregnant women and infecting 2 *(223)*; 15 cases of rubella among staff members of an obstetrics service led to exposure of 231 pregnant women, of whom 25% were susceptible *(229)*. The national immunization program has substantially curtailed circulation of wild rubella virus, and such outbreaks have become rare. At the same time, however, the reduced circulation of wild virus has reduced the opportunity for women who escaped childhood immunization to acquire natural immunity prior to entering the childbearing years. The potential for rubella outbreaks among hospital personnel clearly remains should a case be introduced; serosurveys indicate that 4% to 6% of new hires are susceptible *(230,231)*, and 19% of practicing obstetricians surveyed in 1994 had neither been immunized nor been demonstrated to be immune by serology *(232)*.

Persons infected with rubella are infectious from 10 days before until 5 days after rash onset. Rubella is believed to be spread by respiratory droplets; airborne spread is plausible but has not been demonstrated. Droplet Precautions are recommended for management of patients with rubella, but as with measles, infections can be expected among employees despite isolation precautions unless the employees are immune. Pregnant, nonimmune workers should not care for patients infected with rubella (24).

A safe, effective live attenuated virus vaccine was introduced in 1969. Although the vaccine can cause a febrile illness as well as transient arthritis, these effects are less common, milder, and shorter-lived than with natural infection. Congenital rubella syndrome has not been demonstrated following vaccination, but the vaccine virus can cross the placenta; therefore, the vaccine should not be given to women who might be pregnant or become pregnant within 3 months. As discussed with respect to measles, employee health programs likely will find it more cost-effective to immunize with MMR all those who cannot document prior immunization than to perform serology for both measles and rubella *(196)*. Either approach, however, is less expensive than managing the consequences of an outbreak such as those previously described *(209,227)* (see also Chapter 51).

Mumps Mumps is an acute viral infection that, in unimmunized populations, occurs predominantly among school-aged children. Illness begins with nonspecific symptoms of a viral syndrome, followed by acute nonsuppurative parotitis that may be unilateral or bilateral. The swelling may be painful and accompanied by fever, but it resolves within a week. Other glands may be affected; epididymo-orchitis occurs in 20% to 40% of postpubertal men and may eventuate in testicular atrophy. Rarer manifestations include meningoencephalitis, oophoritis, pancreatitis, and nephritis *(233)*. A safe and effective live attenuated virus vaccine has been available since 1967. However, use of mumps vaccine was not required in many jurisdictions until relatively recently, and a substantial population escaped immunization *(203,234)*. Mumps is much less contagious than measles, varicella, or rubella, and many adults remain susceptible. Outbreaks of mumps have occurred in healthcare facilities with transmission from patient to worker *(235–237)* and from healthcare worker to patient *(238)*. Mumps is spread by droplets and by contact with saliva, which is infectious for up to 9 days prior to the parotitis. Droplet Precautions are recommended and should be implemented for 9 days after swelling onset. Prevention of healthcare-associated transmission is best accomplished by an immunized population, including healthcare workers. A policy of immunizing with MMR all persons who cannot document adequate prior immunization would obviate the need to perform yet another serology (see also Chapter 51).

Parvovirus The parvoviruses cause infections marked by bone marrow suppression and reductions in blood cell counts in a number of species. Parvovirus B19 is the cause of (a) erythema infectiosum, the fifth of the classic exanthems of childhood; (b) transient aplastic crisis in patients with chronic anemias; and (c) fetal infections, leading to hydrops or abortion. Erythema infectiosum is a generally mild illness marked by a "slapped cheek" facial rash and variable, often lacy, extremity rash. Arthritis and arthralgia may occur, most often in adults *(239)*.

Outbreaks in schools and the community are common. Patients with erythema infectiosum are no longer infectious by the time the rash appears, but patients with transient aplastic crisis or immunodeficiency are viremic while ill. Healthcare-associated outbreaks with spread to healthcare workers have been described *(240–242)*, but the risk to healthcare workers is low *(243)*, particularly as compared to school or day-care employees *(244,245)*, who are more commonly in contact with children incubating erythema infectiosum. Indeed, apparent healthcare-associated outbreaks may merely reflect transmission outside the hospital during a community-wide outbreak *(246)*. Parvovirus is believed to be spread by direct contact, blood, and respiratory droplets; true airborne spread has not been demonstrated, and the possible role of fomites is undefined. Standard Precautions are sufficient for care of uncomplicated erythema infectiosum but should be supplemented by Droplet Precautions for patients with transient aplastic crisis or other parvovirus syndromes (see Chapter 51).

Rare and Exotic Viruses

In this section, we briefly consider a number of viral infections that rarely, if ever, are encountered in US hospitals. Some are relatively benign but might be capable of spread to healthcare workers. Others have frightening reputations that are undeserved, because they have no demonstrated potential for spread to healthcare workers. A few have earned their formidable reputations and require caution, particularly including some of the hemorrhagic fever (HF) viruses.

Hemorrhagic Fever Viruses The viruses known to cause HF in humans differ in their structure and genetics but share the ability to cause a generalized illness that can be severe, marked by involvement of visceral organs (e.g., hepatitis, nephritis, carditis) and by thrombocytopenia or other coagulation defects that lead to disseminated intravascular

coagulation or other bleeding diatheses. Humans likely are not the primary hosts for any of these viruses, with the possible exception of dengue. The two most important routes of exposure are insect bites (yellow fever, dengue, Rift Valley fever, Crimean-Congo HF, Kyasanur Forest disease, and Omsk HF) and exposure to infectious rodent urine either directly or, more often, via contaminated airborne dust (Lassa fever, Argentine HF, Bolivian HF, and Hantaan and related HFs); the natural route of exposure is not known for Marburg and Ebola HFs *(247–251)*. Laboratory-acquired infections have been reported for Hantaan HF *(252)* and Kyasanur Forest disease *(253)*, but person-to-person transmission is not known to occur with yellow fever, dengue, Argentine HF, Bolivian HF, Rift Valley fever, Hantaan HF, Kyasanur Forest disease, or Omsk HF, and these diseases are not discussed further here (the hantavirus group is discussed in the next section).

Lassa Fever Of the four HFs with known potential for healthcare-associated spread, the best known is Lassa fever. The disease was first recognized following infection of three nurses at a missionary hospital in Nigeria, of whom two died *(254)*. The next year, an outbreak in the same community led to the death of a missionary physician who became infected through a cut received while performing an autopsy on a presumed Lassa fever patient *(255)*. Two years later, an outbreak in a Liberian missionary hospital led to illness in three patients and seven staff members; one nurse and all three patients died, for a case fatality rate of 36% *(256)*. However, subsequent studies have shown that the disease is endemic in West Africa, with infection rates of 10% to 20%, and that 90% to 95% of these infections are mild or inapparent *(257)*. Thus, the extraordinary precautions recommended and implemented by the CDC with the first case imported to the United States *(258)* were significantly relaxed in later recommendations *(259–261)*, because it became apparent that attention to barrier precautions prevented healthcare-associated infections *(259,261,262)*.

Outcome of Lassa fever is correlated with the degree and persistence of viremia; exceptionally high titers of virus can be found in blood. Prevention of healthcare-associated transmission must focus on avoidance of inoculation or aerosolization of blood. Primary human infection arises from inhalation of dust or aerosols contaminated with infected rodent urine. Person-to-person transmission of Lassa fever has occurred both in the household and the hospital setting, but initial fears of droplet or airborne transmission have not been substantiated. Because spread by direct contact is a possibility, it is appropriate to supplement Standard Precautions with Contact Precautions (see also Chapters 47 and 103).

Marburg Virus In 1967, several hundred African green monkeys imported from Uganda for medical research arrived in Marburg, Germany. Subsequently, 25 researchers working with monkey kidneys or tissue cultures became ill with a viral HF; seven died, as did 13 of the monkeys *(250,251)*. Six close contacts of the researchers also acquired illness; none died. The causative agent was determined to be a unique filamentous virus (filovirus). The virus has been identified in only a few subsequent sporadic cases of infection in Africa, several of which involved person-to-person transmission to medical staff members *(263,264)*. The natural reservoir and routes of transmission remain unknown *(265)*. The disease is clearly transmissible by the respiratory route from laboratory specimens, but person-to-person infection appears to require close contact. In the first known case of Marburg HF imported into the United States, none of the approximately 260 contacts (220 of whom were healthcare personnel) had evidence of a compatible illness. Six of the index patient's travel companions had serologic testing performed, which failed to reveal evidence of disease, supporting the notion that close, prolonged personal contact is likely necessary for person-to-person transmission, at least for sporadic disease *(266)*. During an epidemic of Marburg HF in the Democratic Republic of the Congo, between October 1998 and September 2000, 6 of 48 healthcare workers who cared for patients infected with Marburg virus were later discovered to be seropositive *(267)*. However, poor adherence to Standard Precautions was noted to be widespread. Pending further data, use of Contact Precautions and careful attention to Standard Precautions (especially with respect to blood) appear appropriate. Tissue and laboratory specimens should be handled with caution and processed so as to ensure containment (see also Chapters 47 and 103).

Ebola Virus Two simultaneous outbreaks of viral HF in neighboring regions of Sudan and Zaire in 1976 heralded the existence of yet another African HF virus *(268)*. Of the identified cases in Sudan and Zaire, 55% and 88%, respectively, died, reflecting substantial differences in the two viral subtypes *(250)*. The outbreaks were accompanied by healthcare-associated and household spread, but investigation of the only other known human outbreak, 2 years later, showed that person-to-person transmission required blood exchange or close personal contact *(269)*.

The Ebola virus is similar to the Marburg virus, joining it as the only other member of the filovirus family. As with Marburg virus, the natural reservoir of Ebola virus remains unidentified. Monkeys are susceptible and experience a high mortality rate *(270)*, which suggests that they are not among the natural hosts. The discovery of Ebola virus epidemics among medical research monkeys held in United States and Philippine primate centers caused considerable alarm and prompted strict new screening and quarantine regulations *(271,272)*. This Reston subtype of Ebola virus was highly virulent for monkeys, but it produced only subclinical infection among the exposed humans *(273)*.

More than 25 years had passed since the last recognized outbreak of human disease caused by Ebola virus when a large new outbreak involving the Zaire subtype began in early 1995 in Kikwit, Zaire. As in previous outbreaks, provision of medical care without use of standard infection control precautions led to an explosive healthcare-associated outbreak, with many worker and patient deaths at Kikwit General Hospital; job-specific attack rates ranged from 31% for physicians to 10% for nurses to 4% for other workers *(274)*.

Disease is spread by contact with infected blood or tissues; parenteral exposure is particularly lethal. Although epidemiologic and pathologic evidence suggest that aerosol

spread is possible *(273)*, the importance of this route is uncertain. Standard Precautions should be supplemented with comprehensive Contact Precautions; Droplet Precautions are not known to be necessary but their use, particularly when dealing with the highly lethal Zaire subtype, should depend on the clinical circumstances (see also Chapters 47 and 103).

Both Ebola and Marburg virus can persist in tissues for several months following acute infection, emphasizing the need for careful handling. As with Lassa and Marburg viruses, it is recommended to supplement Standard with full Contact Precautions.

Crimean-Congo Hemorrhagic Fever The fourth of the HFs shown to spread from person to person, Crimean-Congo HF, was first described among Russian troops in Crimea in 1944. Found in the Balkans, Siberia, China, the Middle East, and Africa, the virus is normally transmitted by ticks but can be spread by close contact, and several healthcare-associated outbreaks have occurred *(248,251,275–277)*. Healthcare-associated transmission can be prevented by attention to barrier precautions *(276)*; Contact Precautions should also be used (see also Chapters 47 and 103).

Other arenaviruses have been associated with sporadic secondary transmission *(278)*. For example, Sabiá virus has infected at least two laboratory workers *(279)*; although transmission to healthcare workers as a consequence of clinical duties has not been reported, enhanced infection control precautions have been proposed for care of such patients *(279)*.

Hantavirus Group Hantaan and related viruses are the etiologic agents of the HF with renal syndrome seen in Korea (Korean HF), China, Siberia, and southeastern Europe. Spread is through inhalation of dust or aerosols contaminated with infected rodent urine or, rarely, a rodent bite; person-to-person transmission is unknown. In June 1993, a previously unrecognized syndrome consisting of nonspecific viral symptoms progressing rapidly to respiratory failure, interstitial pulmonary edema, and death was described among residents of the southwestern United States *(280)*. Investigation showed the causative agent to be a previously unrecognized hantavirus (now named the Sin Nombre virus). Although the syndrome is new, the reservoir (the deer mouse) and route of transmission appear to be typical of the hantavirus family *(281)*. The deer mouse resides in much of the United States, and cases of hantavirus pulmonary syndrome have been described in various locales *(282,283)*. Little evidence supports healthcare-associated spread, and Standard Precautions should be sufficient.

Human Papillomavirus A large number of papillomaviruses produce various forms of warts and other epithelial tumors. Spread is believed to be by close contact and would be prevented by Standard Precautions. However, one interesting report showed the presence of intact papillomavirus deoxyribonucleic acid (DNA) in the vapor produced by laser treatment of warts and other verrucae *(284)*. Whether human infection at any site could arise from such an exposure is speculative, but prudence suggests ensuring proper exhaust of the vapor.

Pox Viruses Smallpox, a colossus of death, no longer strides the earth but lies imprisoned under heavy guard in Russia and Atlanta, awaiting final destruction *(285)*. Only as smallpox neared defeat by the milkmaid's friend, vaccinia, did smallpox reveal beyond doubt its ability to attack not only those nearby, via contact, but also distant victims through the air; to prove its prowess, it claimed as its final victim, a photographer infected in her office, by air wafted from a nearby research laboratory *(286,287)*.

Vaccinia too, its task completed, had largely disappeared, although vaccination continued for laboratorians working with orthopox and vaccinia viruses *(288)*. After the terrorist attacks of September 11, 2001, smallpox bioterrorism preparedness activities included a program of vaccinating public health workers and some hospital workers. This program is further discussed in Chapter 103.

Vaccinia can be passed from person to person by contact with the active vaccinial lesion, but no viremia is present in the normal host *(289)*, and respiratory spread does not occur; Contact Precautions are sufficient. The theoretical possibility of airborne spread exists with the progressive vaccinia that can occur in the immunocompromised, although it has not been demonstrated; should such a case be encountered (or smallpox be unleashed once again), Airborne Precautions would be indicated.

The large genome of vaccinia makes it attractive as a carrier of inserted genetic material, the hybrid then being used to infect a patient and thereby accomplishing gene therapy. This process raises numerous infection control issues, which are discussed in detail elsewhere *(290)* (see also Chapter 69). Vaccination of clinical staff working with patients given vaccinial recombinants may be appropriate.

Monkeypox produces a disease that is similar in appearance to smallpox but is not readily transmitted from person to person *(289)*. During the summer of 2003, an outbreak of monkeypox occurred in the United States among persons who had purchased imported exotic pets (Gambian giant rats among them) and prairie dogs that had become cross-infected at the animal distribution facility *(291)*. No transmission to healthcare providers was detected. CDC's ACIP suggested that vaccinia vaccine (smallpox vaccine) might be a useful preventive measure among potentially exposed healthcare workers. Not much, if any, vaccine was used for that purpose. Molluscum contagiosum and orf require close contact for transmission *(292)*; Standard Precautions are sufficient.

Rabies and the Other Encephalitis Viruses Vector-borne encephalitis viruses include (a) eastern, western, and Venezuelan equine encephalitis virus; (b) St. Louis and tick-borne encephalitis viruses; (c) the California encephalitis virus group (including La Crosse and Jamestown Canyon viruses); (d) Powassan, Louping Ill, and Negishi viruses as well as West Nile virus. Most strains are spread by mosquitoes, some by ticks; primary host species include horses, birds, deer, rodents, and pigs. None of the viruses are transmitted from person to person, although some have infected laboratory workers exposed to aerosols *(247,248,293)*.

West Nile virus arrived in the United States in 1999, causing an outbreak of meningoencephalitis among largely elderly residents of New York City *(294)*. Over succeeding

mosquito transmission seasons, it has spread stepwise across the entire United States. Although the vast majority of human infections are acquired from mosquito bites, transplacental transmission to a fetus, transmission via breast milk, and acquisition from an infected organ donor as well as from transfused blood have been documented. No special risk to healthcare workers has been shown.

Lymphocytic choriomeningitis (LCM) virus, related to the Lassa fever virus, shares its characteristic of being spread by exposure to infectious rodent urine; rodent bites have also been implicated. Unlike Lassa virus, LCM virus is not known to spread from person to person. Several outbreaks of LCM have affected medical center staff, but all have been attributable to contact or presence in the same room with rodents being used in research *(249,295–298)*.

Rabies, one of the most feared diseases, is a viral zoonosis transmitted to humans through the bite of an infected mammal. Rabies is the most uniformly fatal infection known; survival is nearly unprecedented once symptoms begin. Consequently, anxiety among healthcare workers is intense once a patient has been diagnosed with rabies, and scores or even hundreds of healthcare workers are commonly administered rabies prophylaxis following diagnosis of a patient. Although rabies virus can be isolated from a variety of human tissues and fluids, including saliva, a well-documented instance of person-to-person transmission of rabies has never occurred, apart from corneal transplantation *(299,300)*. One report describes two possible cases in Ethiopia of human-to-human transmission (both involving saliva: one bite and one kiss), but these cases were not laboratory confirmed *(301)*.

No evidence supports droplet, airborne, or environmental transmission from human sources for any of these agents; therefore, Standard Precautions are sufficient. Healthcare workers involved with a rabies case do not need prophylaxis unless mucous membranes or nonintact skin were exposed to potentially infectious body fluids *(299)*. Preexposure immunization is indicated for those working with rabies virus or likely to come into contact with potentially rabid animals (see also Chapter 47).

Prions

Prions are poorly understood, small, protein-containing particles that can be detected in the brain in certain pathologic states and appear to be responsible for a number of slowly progressive neurodegenerative diseases. These transmissible spongiform encephalopathies include Creutzfeldt–Jakob disease (CJD), kuru, Gerstmann–Sträussler–Scheinker disease, and fatal familial insomnia in humans, and scrapie, bovine spongiform encephalopathy (mad cow disease), transmissible mink encephalopathy, and related diseases in animals. Purified prion material derived from the aforementioned diseases can induce the disease in a healthy host when injected (or, in the case of kuru, when ingested). No one has been able to demonstrate nucleic acids in prions, and their reproduction might involve an alteration in a protein normally encoded by the host *(302)*.

Person-to-person spread of CJD has occurred in connection with corneal transplants *(303)*, dural grafts *(304)*, contaminated neurosurgical instruments *(305)*, and cadaver-derived growth hormone *(306)* or gonadotropin *(307)*. Kuru is acquired by ingestion of infected human brain, and new-variant CJD is a rare sequela to ingestion of beef products from cattle with mad cow disease *(308)*. The evidence strongly indicates that CJD and related diseases do not spread by the airborne or contact routes, and Standard Precautions are sufficient when caring for patients with these diseases. However, prions are extremely resistant to inactivation and retain infectivity even in formalin-fixed tissue. Patient specimens and contaminated equipment (e.g., needles, surgical instruments) must be handled with particular care, and detailed recommendations have been offered for their decontamination *(309)* (see also Chapters 47 and 80).

CHLAMYDIAL, RICKETTSIAL, AND MYCOPLASMAL INFECTIONS

Chlamydiae

Like the viruses, members of the order Chlamydiae are obligate intracellular parasites. Three species have been identified: *Chlamydia trachomatis,* the cause of trachoma and lymphogranuloma venereum; *Chlamydia psittaci,* the agent of psittacosis; and *Chlamydia pneumoniae,* previously called the TWAR agent, which causes an atypical pneumonia. (The first two recognized isolates were identified at the University of Washington and were obtained from a Taiwanese child in 1965 and a student with acute upper respiratory infection in 1983.) Humans are the natural hosts of *C. trachomatis* and *C. pneumoniae,* whereas *C. psittaci* is a pathogen of animals, particularly psittacine birds (parrots), and infects humans only secondarily. *C. trachomatis* is spread by contact with infected secretions, and Standard Precautions are sufficient to protect healthcare workers.

C. psittaci is spread through the air, but it is uncertain whether person-to-person transmission occurs. Several healthcare-associated outbreaks have been described in the literature that were attributed at the time to psittacosis *(309a,309b,313)*, but they either antedated the recognition of *C. pneumoniae* (to which bird owners are as susceptible as anyone else) and might well have been caused by the latter agent *(310)*, or rested on serologic results that were less than fully conclusive *(311,312)*. *C. pneumoniae* has been implicated in outbreaks of pneumonia in various closed communities such as classrooms and military barracks; healthcare-associated outbreaks appear to be very rare. In at least one outbreak, serologic data support the impression of healthcare-associated spread of chlamydial pneumonia, but whether the species was accurately identified is unclear (*313*).

Although droplet spread of chlamydial pneumonia cannot be excluded, current evidence does not appear to justify imposition of Droplet Precautions; Standard Precautions should suffice (24).

Rickettsiae

The rickettsiae are also obligate intracellular parasites. Those of the genus *Rickettsia* all have nonhuman mammalian reservoirs, are transmitted to humans by insect vectors, and survive only briefly outside a host. The lone member of the genus *Coxiella* behaves quite differently. *C. burnetii*,

the etiologic agent of Q fever, is a gram-negative coccobacillus that can sporulate and thereby survive outside the host for extended periods *(314)*. Q fever (so named because its cause was a query) is a zoonosis of ungulates (e.g., sheep and cattle) that can cause an acute and chronic febrile illness in humans. Humans are highly susceptible; a single microorganism can cause disease. Outbreaks of Q fever have occurred not only among those who work with ungulates but also those nearby. Included among the latter group have been a number of healthcare workers exposed to sheep used in research at their medical centers *(315–320)*. Laboratory workers are also at risk *(321)*; indeed, the first recognized case of Q fever in the United States was acquired occupationally by a National Institutes of Health physician *(322)*. However, despite the fact that *C. burnetii* can be isolated from human milk, placenta, and blood, no evidence indicates transmission to healthcare workers during normal clinical duties, and Standard Precautions are sufficient.

Mycoplasmas

The members of the *Mycoplasma* and closely related *Ureaplasma* species are the smallest free-living microorganisms known. Because they have fastidious growth requirements, they are difficult to culture on artificial media and are found in nature only in close relation with their hosts. Of the numerous mycoplasmas isolated from humans and potentially involved in human disease, only one has been associated with outbreaks among healthcare workers: *Mycoplasma pneumoniae,* a prominent cause of the atypical pneumonia syndrome.

M. pneumoniae infections occur sporadically or as outbreaks in closed populations such as families, schools, and military barracks *(323)*. Younger persons are more susceptible and tend to have milder disease. Outbreaks among staff members have been described in healthcare institutions in Finland, Ohio, Texas, and New York *(324,325)*. Transmission is believed to be by respiratory droplets, and Droplet Precautions should be followed.

BACTERIAL INFECTIONS

Bacterial Enteric Infections

Salmonellae The salmonellae are aerobic gram-negative bacilli that inhabit the intestinal tracts of humans and animals. Some strains are specific to humans or other species, whereas others have a broad host range. Salmonellae routinely cause gastroenteritis but can induce a wide variety of diseases in humans. *Salmonella typhi,* the causative agent of typhoid fever, produces the most serious illness in humans, but many of the animal salmonellae can produce serious or fatal disease, particularly in the elderly *(326)*.

Salmonella was once a common cause of healthcare-associated infectious diarrhea, particularly in newborn and pediatric units, which accounted for 50% of reported healthcare-associated cases *(327)*. Between 1963 and 1972, 28% of reported *Salmonella* outbreaks in the United States occurred in healthcare institutions *(328)*; case–fatality ratios were <1% in most hospital units but rose to 3% in pediatric units, 7% in nurseries, and 9% in nursing homes.

Healthcare-associated outbreaks often involve healthcare workers *(329–332)*, who occasionally become chronic carriers. One unusual healthcare-associated outbreak involved spread of *Salmonella* infection from patients to nursing home laundry workers who handled soiled sheets without use of gloves or other barrier precautions and who routinely ate in the laundry room *(333)*.

Salmonella is spread by the fecal–oral route and, notwithstanding the rare report suggesting alternative routes of spread *(334)*, Standard Precautions are sufficient to protect the worker. In addition, soiled laundry must be handled in accord with established recommendations, and food should not be consumed in work areas (see also Chapters 24, 34, and 50). Two excellent typhoid vaccines, one oral, one parenteral (as well as an older parenteral vaccine that should no longer be used), are now available, and immunization is indicated for laboratorians working with *S. typhi*.

Shigella *Shigella* species are the principal etiologic agents of bacillary dysentery; *S. dysenteriae* causes the most severe disease, whereas *S. sonnei* has been the most common isolate in recent years. Shigellosis is easily transmitted, because the infective dose is 100 microorganisms or fewer. The disease is marked by abdominal cramping and watery diarrhea that becomes bloody or mucoid, usually accompanied by fever. Illness typically lasts 1 week but can be prolonged *(327,335)*. Healthcare-associated outbreaks of *Shigella* are much less common than are *Salmonella* outbreaks but can be a particular problem in long-term-care and custodial institutions for children and for the elderly *(336–340)*. In each of the cited outbreaks, staff members acquired infection from patients and often facilitated the spread of infection.

Shigella species are transmitted solely by the fecal–oral route, and Standard Precautions normally are sufficient to protect the worker. Because of the low infective dose, Contact Precautions should be used when managing diapered or incontinent patients.

Cholera *Vibrio cholerae* causes cholera, a toxin-mediated profuse watery diarrhea that can cause prostration in the first hour and death from dehydration in the second. Cholera, described in ancient Greek and Sanskrit texts, circled the globe in six successive epidemic waves during the19th and early 20th centuries. Epidemic cholera returned in 1991 in South America, establishing a new endemic focus *(341)*.

Spread of cholera is by the fecal–oral route. On rare occasions, humans may become carriers. Healthcare-associated transmission to patients has occurred *(342,343)*, but little evidence indicates transmission to healthcare workers. As with other highly transmissible gastroenteritides, Standard Precautions should be supplemented with Contact Precautions when caring for diapered infants or fecally incontinent patients (see Chapter 50).

Other Bacterial Agents of Diarrhea *Clostridium difficile* secretes a toxin that causes pseudomembranous colitis. Risk of the disease is substantially elevated in patients whose normal bowel flora have been depleted by treatment with antibiotics, particularly broad-spectrum cephalosporins *(344). C. difficile* is an important healthcare-associated pathogen spread by direct and indirect contact *(345,346)*, and

Standard Precautions should be supplemented with Contact Precautions. Healthcare workers might acquire the microorganism occupationally, but normally would not be expected to manifest illness. However, full-blown pseudomembranous colitis has been reported in staff members who were taking a bowel-active antibiotic during a healthcare-associated outbreak of disease *(347,348)* (see Chapter 37).

Escherichia coli is the most common of the aerobic enteric bacteria that colonize the normal intestinal tract. There are numerous strains, some of which can be important causes of enteric disease. Enteroinvasive *E. coli* microorganisms behave like *Shigella* and cause dysentery; enterotoxigenic strains cause a cholera-like illness; the enterohemorrhagic *E. coli* O157:H7, often associated with undercooked ground beef, causes bloody diarrhea. All strains are spread by the fecal–oral route and require Contact Precautions only when managing diapered or incontinent patients. Similar precautions are recommended for the bacterial diarrheas not discussed here.

Bacterial Diseases Spread by the Respiratory Route

Diphtheria Diphtheria, described by Hippocrates, has been a fearsome disease; an epidemic in New England in the early 18th century killed one third of all children, and in the early 1920s diphtheria was the leading cause of death of Canadian children aged 2 to 14 years *(349)*. Epidemics occurred at approximately 25-year intervals until modern times; the disease has nearly been eradicated through use of diphtheria toxoid vaccines. The causative microorganism is *Corynebacterium diphtheriae,* a gram-positive bacillus for which humans are the only known reservoir. The microorganism colonizes the respiratory tract or skin wounds, where it may be asymptomatic or produce mild inflammation. The microorganism does not invade, but if it is infected by the toxin-encoding bacteriophage, it can liberate a toxin that interferes with ribosomal protein synthesis, causing local accumulation of killed cells and inflammatory residue (the pseudomembrane), myocarditis, neuropathies, and nephritis. Skin carriage can be common in certain groups; for example, 86% of diphtheria cases among urban alcoholics in Seattle, Washington, were cutaneous *(350)*. Spread of the microorganism to others occurs more readily from those with skin carriage than from those with pharyngeal carriage *(351)*.

Adequate antibody to the toxin largely protects from the serious consequences of infection but does not eradicate carriage of the microorganism. Because introduction of toxigenic strains into the community can result in disease if immunization levels are inadequate, it is pertinent that 22% to 62% of US adults under 40 years of age and 41% to 84% of persons 60 years and older lack protective levels of diphtheria antitoxin *(352)*. The possible consequences of widespread adult susceptibility to diphtheria were illustrated in Russia and other former Soviet states, which experienced a massive outbreak of diphtheria in the 1990s following decreased childhood immunization programs, resulting in 140,000 cases and 4,000 deaths *(353)*. Although diphtheria has become rare in the United States and Western Europe, outbreaks involving patients and staff members have occurred in healthcare institutions *(354,355)*. Serotesting during one hospital outbreak found 37% of staff members to be susceptible. Diphtheria is spread both by respiratory droplets and by direct contact. Droplet Precautions are appropriate for cases with respiratory tract disease, and Contact Precautions should be implemented for those with cutaneous diphtheria. Employee health programs should ensure that employees have been immunized within the past 10 years with tetanus and diphtheria toxoids (Td) adsorbed, for adult use (184).

Pertussis Guillaime Baillou described an outbreak in Paris of a disease he called "quinta" in 1578; in 1679, Thomas Sydenham renamed the disease pertussis, meaning violent cough. The disease is highly contagious and spreads via respiratory droplets. When *Bordetella pertussis* microorganisms enter the respiratory tract, they attach via their fimbriae to cilia, causing ciliary stasis, cell death, and shedding of respiratory mucosal cells. Because they do not invade, they largely escape cellular host defenses, continuing to produce local damage and, through their toxins, systemic disease, until the host finally is able to clear the microorganisms. The onset is insidious, seeming like a typical cold or upper respiratory infection with little fever. Within a week or so, a cough appears that progresses within another week or two to paroxysms. In a paroxysm, the patient may produce up to a dozen short coughs with no intervening inspiration; cyanosis and vomiting often occur. Finally, after perhaps expelling some thick mucus from the bronchial tree, a desperate inspiration through a narrowed glottis produces the characteristic whoop. This phase continues for up to 4 weeks and then gradually subsides; nonparoxysmal cough may persist for as long as 6 months. Pertussis is one of the most contagious of the infectious diseases, and is a significant health problem worldwide, with more than 60 million cases and 500,000 to 600,000 deaths annually *(356)*.

Pertussis can be an important cause of respiratory disease in adults *(357–364)*, who experience a less severe syndrome marked by a debilitating cough that persists for many months. One quarter to one-fifth of adults with persistent cough have laboratory evidence of recent pertussis infection *(365,366)*. A number of hospital outbreaks have been reported in which staff members became infected by symptomatic patients and subsequently spread disease to other patients and adult contacts *(367–373)*, and studies have demonstrated both the prevalence and the incidence of pertussis among healthcare workers *(374–376)*. Unfortunately, adverse reactions to conventional whole-cell pertussis vaccine are common and severe among adults; for example, significant local reactions were noted in as many as 97% of adult recipients of whole-cell pertussis vaccine in one hospital outbreak *(371)*. Because standard pertussis vaccine is not given beyond age 6, antibody wanes with age, and adolescents and adults become increasingly susceptible to pertussis. In turn, they act as a reservoir of disease able to expose and infect infants not yet immunized *(373,374,377)*. These factors are thought to be important in the current epidemic of pertussis: there were 7,796 cases of pertussis reported in 1996, the highest total in nearly 30 years *(378)*.

Acellular pertussis vaccines have been available for use in children and are now licensed for adult use. To mitigate the healthcare worker's role in pertussis epidemics,

employee health programs should utilize tetanus-diphtheria acellular pertussis (Tdap) vaccine. It is recommended that adults substitute a one-time dose of Tdap for a Td booster, providing at least 2 years have elapsed since the prior Td immunization (184). In the event of an outbreak, consideration should be given to mass immunization with Tdap of all potentially exposed persons who cannot document prior receipt of Tdap.

Droplet Precautions should be used when managing known or suspected pertussis infection. Erythromycin or its more recent derivatives (e.g., azithromycin) can be used for prophylaxis of exposed healthcare workers and others *(373)*, but may fail (*379)*; work restrictions are appropriate for symptomatic employees (380).

Streptococcus *Streptococcus pyogenes* (group A *Streptococcus*) is one of the most common and dangerous bacterial pathogens. Group A streptococci colonize the throats of 15% to 20% of schoolchildren; anal, vaginal, scalp, and other cutaneous carriage also occurs. The microorganism commonly causes acute pharyngitis and cutaneous infections, including erysipelas, and was the most common cause of puerperal sepsis in the days before Semmelweis. The group A streptococcus can cause fatal deep infections, including pneumonia, sepsis, myositis, and necrotizing fasciitis, and it can cause nonsuppurative sequelae, including rheumatic fever and nephritis *(381)*.

Streptococcal toxins are responsible for streptococcal toxic shock syndrome and for scarlet fever (second disease, the only classic exanthematous disease of childhood caused by a bacterium). Most reported healthcare-associated outbreaks of group A streptococcal disease have involved transmission from healthcare workers to patients, resulting in wound (382) or skin and soft tissue *(383)* infections. Healthcare workers can acquire colonization or infection from patients, most commonly resulting in pharyngitis *(384–386)*. Invasive disease resulting from patient to healthcare worker transmission has also been reported, resulting in toxic shock syndrome with associated pneumonia *(387)* or necrotizing fasciitis *(388,389)*.

Group A streptococcus is spread by respiratory droplets, as well as by direct and indirect contact with contaminated sources such as respiratory secretions, food, and drink *(384)*. Reports have also apparently documented the airborne spread of group A streptococci *(16)*, but such events are probably rare. Contact Precautions should be used for persons with purulent wound infections (including burns), unless the infections are minor and well contained by bandages. Droplet Precautions should be implemented until completion of the first 24 hours of effective antibiotic therapy in patients with severe group A streptococcal wound infection and those with respiratory tract infection, including pharyngitis, pneumonia, or scarlet fever (which is most commonly associated with pharyngeal infection). Infected workers should be excluded from patient care and treated, as should asymptomatic carriers who have been epidemiologically implicated in transmission (24,*390,391*).

Pneumococcus *Streptococcus pneumoniae* is a major cause of bacterial pneumonia, sinusitis, otitis media, and meningitis, and can cause a host of other serious infections. Previously uniformly susceptible to penicillin, pneumococci increasingly manifest reduced susceptibility or resistance to penicillin, erythromycin, and even third-generation cephalosporins *(392–394)*. Unlike group A streptococci, pneumococci elaborate few toxins; their ability to cause disease resides in their capacity to reproduce in host tissues and to stimulate a vigorous inflammatory response.

The pneumococcus colonizes the nasopharynx in 5% to 10% of adults and 20% to 40% of children *(395)*. Infection is seasonal, increasing in the winter months, and more likely at the extremes of age. Outbreaks of pneumococcal disease usually occur in circumstances of prolonged close contact *(396–401)* and are uncommon but not unprecedented in hospitals *(396)*; several nursing home outbreaks have been documented *(402–406)*. Spread is by respiratory droplet but, as noted, usually requires prolonged close contact. In most cases, Standard Precautions will be sufficient, but Droplet Precautions are recommended when the infecting pneumococcus is resistant to antibiotics.

Healthcare workers are not a group recommended to receive the present polysaccharide polyvalent pneumococcal vaccine. Conjugate pneumococcal vaccines, which link the capsular polysaccharide to a carrier protein and thereby stimulate the T-cell–dependent arm of the immune system, are used routinely in young children *(402)*.

Meningococcus *Neisseria meningitidis* has a fearsome reputation as the causative agent of epidemic cerebrospinal fever and, indeed, is capable of producing rapidly fatal sepsis or meningitis. However, the microorganism is not nearly as communicable as fables (and television) portray. Epidemics of meningococcal disease occur throughout the world, and transmission undoubtedly occurs with prolonged close contact *(407,408)*. Household or other close contacts are at 200 to 1,000 times the risk of developing meningococcal disease as is the general public *(409)*; secondary attack rates in households average 2% to 5% *(407)*. However, although healthcare-associated *(407,410–412)* and laboratory-based *(413)* transmission has occurred, such transmission is distinctly unusual and appears to be more likely to occur with meningococcal pneumonia *(410,412,414)* than with meningitis or sepsis *(407)*.

Transmission is by respiratory droplets, and Droplet Precautions are appropriate for patients with invasive meningococcal disease, particularly pneumonia, until 24 hours after institution of effective therapy. Chemoprophylaxis should be offered to workers having prolonged close contact or contact with respiratory secretions without appropriate barrier protection and might consist of orally administered ciprofloxacin (or equivalent), 500 mg once, or rifampin, 600 mg twice daily for 2 days. Chemoprophylaxis is not recommended for those individuals who have had only casual contact with an infected patient. Healthcare workers are not a group routinely recommended to receive the meningococcal vaccine, unless at persistent risk of exposure (e.g., certain laboratorians) (415) (see also Chapter 47).

Haemophilus Influenzae *Haemophilus influenzae* is a gram-negative bacillus indigenous to humans, commonly carried in the pharynx and, less often, the conjunctivae and genital tract. In past years, *H. influenzae* type b (Hib) was the most common cause of meningitis among children

between 1 month and 2 years of age. However, following licensure of the conjugate Hib vaccines *(416)*, invasive Hib disease among children has virtually disappeared *(417)*. Pneumonia caused by *H. influenzae* occurs among adults but tends to be restricted to those with lung disease, alcoholism, or other compromise. Healthcare-associated outbreaks of type b and nontypable *H. influenzae* have been reported *(418–422)*, but spread to healthcare workers appears to be unlikely. Use of Droplet Precautions for patients with invasive *H. influenzae* infections is recommended to prevent spread of the microorganism to other patients, particularly unimmunized children, the elderly, and the immunocompromised.

Plague "The hand of the Lord was against the city with a very great destruction: and he smote the men of the city, both small and great, and they had emerods in their secret parts." 1st Samuel 5:9

Yersinia pestis, the causative microorganism of plague, is a gram-negative bacillus that is zoonotic among rodents. Although some of the pestilences described in First Samuel and other books of the Bible may have been the disease we now know as plague, the first epidemic ascribed with confidence to that disease was the Great Epidemic of Justinian, which took the lives of 25% of the population of the Roman Empire in 542 A.D. *(423)*. Two more great epidemics swept the world in the 14th (the "Black Death") and late 19th (the "Bombay Plague") centuries. In modern times, plague persists in endemic foci in the western United States, Southeast Asia, east Africa, and South America. In the United States, 362 cases of human plague were reported from 1944 to 1993. The disease is slowly becoming more widespread and, in the last decade, has been reported from Texas, Oklahoma, and every contiguous state in or west of the Rockies. As suburban development has extended, the household has become the most common site of exposure, and domestic cats allowed to roam in endemic areas have become important sources of transmission to cat owners and veterinarians *(424)*.

There are three distinct forms of plague. Bubonic plague is characterized by markedly swollen and tender inguinal, axillary, or other lymph nodes (buboes), and is typically spread by the bite of a flea (or similar pest). Bubonic plague commonly eventuates in sepsis. However, septicemia can occur directly, without development of a bubo, and is called septicemic plague. Finally, pulmonary involvement permits direct human-to-human spread of the disease, causing pneumonic plague. In the absence of prompt antibiotic therapy, fatality rates for bubonic, septicemic, and pneumonic plague are 70%, 100%, and 100%, respectively; even with antibiotics, 33% of patients with septicemic plague die, three times the rate of those with bubonic plague *(425)*. The outbreak of pneumonic plague in India in late 1994 served as a reminder that the disease remains dangerous; of 276 persons hospitalized in the first 3 weeks of the outbreak with a diagnosis of plague, 56 (20%) died *(426)*.

Pneumonic plague is spread by respiratory droplets. Because any case of plague may progress to pulmonic involvement, all patients with plague should be placed on Droplet Precautions until the patient has received an effective antibiotic for 24 to 48 hours *(427)*; persons known to have respiratory tract disease should remain on Droplet Precautions for at least 72 hours following initiation of effective therapy. Care should be taken with laboratory specimens not to create aerosols, but otherwise they may be handled normally (see also Chapter 47).

Brucellosis Brucellosis is a zoonosis due to any of several species of *Brucella*. Like typhoid fever, brucellosis is an enteric fever characterized by fever (undulant if untreated), malaise, headache, and possibly, lymphadenopathy, visceromegaly, and depression; most organ systems can become involved. Nearly all cases occur in persons with close contact with infected animals. Airborne transmission in the laboratory *(428,429)* is a potential problem if proper safeguards are not followed (see Chapter 77), and transmission to nurses and physicians caring for infected patients has occurred *(429)* but is rare. Standard Precautions are sufficient to prevent transmission during clinical care.

Legionellosis Healthcare-associated outbreaks of legionellosis (either pneumonia or Pontiac fever) attributable to environmental sources have been reported on multiple occasions, as detailed in Chapter 36. Although the exposure of staff members to these environmental sources is often similar to that of patients, overt disease is rare among staff members even when common among patients, reflecting the relationship between pulmonary or other compromise and development of clinical disease. Nonetheless, serologic surveys of hospital staff members support the hypothesis that subclinical or mild disease occurs among healthy staff members in an outbreak resulting from an environmental source *(430–432)*. Despite suggestions in the early literature *(432)*, no good evidence supports person-to-person spread of *Legionella* infection, and cautious prior CDC recommendations for "secretion" precautions *(433)* have been withdrawn; Standard Precautions suffice (24).

Bacterial Diseases Spread by Contact

Staphylococcus aureus *Staphylococcus aureus* is a gram-positive microorganism that intermittently colonizes normal human skin and, particularly, the nares. The microorganism is hardy and survives well on environmental surfaces. Healthy mucous membranes and skin are adept at preventing invasion by *S. aureus,* but a break allows invasion that can lead to serious local, metastatic, or systemic infection. The increasing prominence of MRSA has heightened concern among clinicians, infection control workers, and other staff members. Transmission of MRSA is not considered to differ from that of methicillin-susceptible *S. aureus*.

Colonization with *S. aureus* becomes more likely as exposure and opportunities increase *(434)*. Colonization of healthcare workers with MRSA is likely in direct proportion to its prevalence in their environment *(435,436)*, except when contact precautions are followed (437). In turn, the likelihood that healthy workers will acquire staphylococcal infection of minor wounds, or that staphylococci will invade through minor wounds to cause serious illness, increases with their prevalence of carriage *(434,438–441)*.

Spread of staphylococci is almost exclusively by direct and indirect contact, notwithstanding demonstration of the possibility of airborne spread *(442,443)*. Prevention of spread depends on appropriate attention to Standard

Precautions supplemented by Contact Precautions when environmental contamination is likely (e.g., staphylococcal scalded skin syndrome; exfoliative dermatitis; furunculosis, especially in children; infected burns, especially if large) or when dealing with MRSA (see also Chapters 28 and 29).

Vancomycin-Resistant Enterococcus Infection control workers who once had MRSA nightmares now dream about vancomycin-resistant *Enterococcus* (VRE). Indeed, VRE is a legitimate source of anxiety (see also Chapter 33), and it can be transmitted readily from patient to patient on the hands of healthcare workers, but it poses no personal threat to the workers themselves.

Syphilis *Treponema pallidum*, the causative agent of syphilis, is a spirochete for which humans are the only known natural host. The microorganism causes a complex and chronic infection that begins with the primary skin or mucosal lesion (chancre), progresses to secondary dissemination throughout the body, and then becomes latent. Ten to 30 years later, 10% to 20% of patients with untreated disease will progress to tertiary disease with cardiovascular, neurologic, gummatous, or other complications *(444)*.

T. pallidum is a fragile microorganism that survives poorly apart from the body. Transmission is by contact with the chancre, mucous patches, condylomata lata, nasal discharge of babies congenitally infected, or other moist sources in primary and secondary stages of the disease. Prior to the routine use of gloves, primary infection of the hands of physicians and other healthcare workers was occasionally recognized *(445)*, but such events are now exceedingly rare *(446,447)*. Standard Precautions are sufficient to prevent transmission.

Gonorrhea *Neisseria gonorrhoeae*, the causative agent of gonorrhea, is a gram-negative diplococcus that primarily infects columnar or cuboidal epithelium. Consequently, the major risk of healthcare-associated transmission to healthcare workers involves conjunctivitis, usually due to inoculation of the eye by a contaminated finger. Although pharyngeal infection occurs, subsequent respiratory transmission does not appear to be a concern. The skin lesions of disseminated gonococcal infection rarely contain viable microorganisms *(447)*.

Unwitting transmission to a healthcare worker is most likely in association with unrecognized disease in patients admitted for other reasons. A particular concern is gonococcal ophthalmia neonatorum, which may occur despite prophylaxis and may remain unrecognized for days. Once again, Standard Precautions are sufficient to prevent transmission.

FUNGAL INFECTIONS

With rare exceptions, fungi are not transmitted from person to person, and healthy workers are not at risk of acquiring fungal infection from patients. Of the deep fungal infections, histoplasmosis, blastomycosis, and coccidioidomycosis have caused outbreaks among healthy persons, but workers in healthcare institutions are no more likely to be involved in such outbreaks than workers in other kinds of facilities in the same geographic area.

Symptomatic infection with *Cryptococcus*, *Aspergillus*, or *Mucorales* rarely or never occurs in normal hosts, and in any event, the microorganisms are abundant in nature. However, *Coccidioides* (and perhaps others of the dimorphic fungi) can germinate and grow in the filamentous form if patient drainage is left undisturbed for several days in bandages and casts; once aerial structures have developed, they are capable of releasing infectious spores *(448)*. Otherwise healthy workers can become sensitized to *Aspergillus* antigens and experience allergic bronchopulmonary aspergillosis when exposed to air from, for example, contaminated humidifiers (one possible cause of "sick building syndrome"), but healthcare workers are not at particularly elevated risk of such exposures.

Sporotrichosis, chromomycosis, or mycetoma could be transmitted by means of a contaminated sharps injury, but neither airborne nor contact spread is plausible. *Candida* is a normal human commensal that can cause opportunistic illness (e.g., thrush, vaginal candidiasis) in otherwise healthy persons, but such infections are usually endogenous. Person-to-person transmission occurs on rare occasions (e.g., newborn thrush, balanitis), but the usual circumstances are not applicable to healthcare workers.

The fungal infections most readily transmitted from person to healthy person are the dermatophytoses, as we are repeatedly reminded by the advertisements for athlete's foot tonics. Although rare, healthcare-associated outbreaks of ringworm and other dermatophyte infections have occurred and involved staff members *(449,450)*. Standard Precautions should be sufficient to prevent spread of fungal infections to the healthy worker.

PROTOZOAL AND PARASITIC INFECTIONS

Amebiasis, giardiasis, cryptosporidiosis, isosporosis, microsporidiosis, enterobiasis, hymenolepiasis, strongyloidiasis, and many of the other diseases caused by intestinal protozoa and helminths are transmitted by the fecal–oral route and, thus, could be transmitted by contact between a patient and an unwary worker. Proper attention to Standard Precautions and hand washing will prevent such infections. Certain of the blood and tissue parasites are well known to be transmitted to healthcare workers by needlestick (especially malaria, but leishmania, trypanosomiasis, or babesiosis could be transmitted similarly), through laboratory accidents (especially toxoplasmosis), or through other blood-to-blood exposures *(451)*, but otherwise, person-to-person transmission does not occur *(452)*. Transmission of trichomoniasis from patient to patient by contaminated fomites is possible, but the requisite genital contact should not occur among staff.

Pneumocystis carinii is a protozoan (or perhaps fungus) that appears to be ubiquitous, because 70% to 80% of children have antibodies by age 4 years *(453)*. Transmission appears to be by air, and several healthcare-associated outbreaks have been reported *(454,455)*. Nonetheless, immunocompetent workers are not at risk (nor are most immunocompromised workers, because they already carry the microorganism, but such workers should avoid exposure). Standard Precautions are sufficient for all these infections.

The parasites with demonstrated ability to cause healthcare-associated outbreaks involving staff and patients are the ectoparasites. Healthcare-associated transfer of pediculosis (head, body, or pubic lice) is possible, but unlikely, because sharing of clothing or bedding (or direct pubic contact) is generally required for transmission *(455)*. In contrast, numerous healthcare-associated outbreaks of scabies have occurred *(452,453,455–459)*, and such outbreaks can be widespread and persistent. *Sarcoptes scabiei,* the itch mite, burrows into the skin and lays eggs; sensitization to mite antigens leads to intense pruritus. Disease is transmitted by direct or indirect contact. Infestation in the normal host involves one to two dozen mites; immunocompromised hosts (e.g., those with alcoholism, Down syndrome, leprosy, or acquired immune deficiency syndrome [AIDS]) can develop "Norwegian" or crusted scabies marked by proliferation of thousands of mites, resulting in hyperkeratotic and crusted skin. Such persons are highly contagious. Management of a healthcare-associated outbreak is difficult and stressful *(456–461)*. If infestation is widespread, all potentially involved persons must be treated simultaneously (within 24 to 48 hours) on two occasions 1 week apart, and all routes of indirect contact (laundry, shared lockers, etc.) must be identified and managed. Fortunately, the mite survives only 48 hours outside the body, permitting decontamination of fomites by storage. Prevention largely depends on a high index of suspicion regarding dermatitis, particularly in immunocompromised patients. Those patients known or suspected to have scabies should be managed with Contact Precautions until properly treated.

Several healthcare-associated outbreaks of infestations caused by pigeon mites have been reported. The disease can mimic scabies, but unlike the itch mite, the pigeon mite can survive for months between meals *(455)*. Workers or, more often, patients can become infested, usually through proximity to ducts, air conditioners, or cracks that lead to pigeon roosts.

Myiasis is seen not uncommonly as a presenting condition in inner-city emergency rooms and can occur as a healthcare-associated infestation of wounds or mucus membranes. However, transmission to workers is not possible.

NONINFECTIOUS DISEASES

Some diseases are spread to healthcare workers by air or by contact but are not infectious. These diseases fall into two principal categories: allergic and toxic.

Diseases Caused by Allergic Reactions

Serious allergic reactions to latex are increasingly being recognized among patients and staff *(462–474)*. An estimated 7% of surgeons and 35% of spina bifida patients have immunoglobulin E antibodies to latex. Numerous allergic reactions have been reported, many severe, and several healthcare workers have had to leave practice. For highly sensitized workers, direct contact with latex is not required; anaphylaxis has been induced when someone nearby changed gloves *(466)*. Early signs of sensitization to latex should prompt an immediate switch to vinyl or other gloves before such extreme sensitization occurs. (See also Chapter 93).

Hypersensitivity pneumonitis can occur in response to numerous fungi and likely to bacterial components as well *(475)*; such reactions may be important in certain cases of "sick building syndrome." Numerous outbreaks of infection attributed to airborne or droplet dispersal of bacteria by humidifiers and air handling systems have occurred among patients who are susceptible because of intubation, presence of wounds, indwelling devices, and so on *(442,476–478)*. Infection of healthy staff by such routes is not known to occur, but the potential for hypersensitivity pneumonitis exists. Prevention depends on proper attention to maintenance and sterile precautions.

Finally, workers highly sensitized to certain drugs can be at risk from exposure to those drugs; for example, the simple flushing of a syringe containing penicillin might adversely affect a worker with high-level penicillin allergy. Employees of pharmaceutical manufacturers have had allergic reactions to drug dusts, but fortunately, modern-day hospital pharmacists do not use mortar and pestle nearly as often as their predecessors.

Diseases Caused by Toxic Exposures

Healthcare workers are exposed to a remarkable variety of chemicals that are known to be toxic by the contact or respiratory routes; ethylene oxide, glutaraldehyde, formaldehyde, xylene, chemotherapeutic agents, pentamidine, ribavirin, and anesthetic gases are among the substances with known toxic potential, most of which are subject to regulation by the Occupational Safety and Health Administration. Depending on the substance, workers must be provided with appropriate training and personal protection, material safety data sheets must be provided, warning labels must be displayed, environmental and personal exposure levels must be monitored, and proper disposal must be ensured. Because many of these toxic substances are pertinent to infection control, the infection control worker should be familiar with the staff and operations of the industrial safety program of the institution.

ORGANIZATIONAL ISSUES

Special Populations

Specific policies should be developed to address certain sensitive issues: (a) healthcare workers infected with blood-borne pathogens such as Hepatitis B, Hepatitis C (see Chapter 73), HIV (see Chapter 74); (b) workers with immune compromise, of whatever cause; and (c) pregnant employees. Pregnant employees often object to providing care to patients with selected infections out of fear that doing so will pose a risk to the fetus. This concern is almost never justified, and pregnant employees should not be routinely excluded from care of any particular patients *(117)*. On the other hand, women who are or might become pregnant should be counseled concerning the importance of complying with established precautions, particularly when dealing with patients infected with agents having known potential for complicating pregnancy (*117*,479). The Society for Healthcare Epidemiology of America has developed guidelines for the management of healthcare workers infected with Hepatitis B, Hepatitis C, or HIV (480).

Vaccination Program

Organization of the employee health service is detailed in Chapter 93, and we will not duplicate that material here except to stress the importance of a comprehensive and well-documented vaccination program. The employee health service should maintain a vaccination registry that documents all vaccinations ever received by all employees; the value of these data in the event of an exposure event or outbreak is enormous. In addition, the institution should, in its own self-interest, ensure up-to-date vaccination (or documented immunity) of all employees with respect to diphtheria, tetanus, pertussis, hepatitis B, measles, mumps, rubella, varicella, and influenza. Other vaccines may be indicated for certain employees (e.g., laboratory researchers or those working in special units), and if indicated should be provided at no cost, such as vaccinia, rabies, hepatitis A, polio, and typhoid (see also Chapter 75).

SUGGESTED READINGS

The topics of this chapter have been the subject of several comprehensive reviews or guidelines (24,*110,122,133, 180,219,233,247–250,289,292,293,302,314,323,326, 335,341,349,381,395,425,*480–482), which may provide additional information.

CHAPTER 77

Prevention of Occupationally-Acquired Healthcare-Associated Infections in Diagnostic Laboratories

Thomas J. Kirn, Susan E. Boruchoff, and Melvin P. Weinstein

Laboratorians who work in medical diagnostic laboratories or biological research laboratories are at increased risk of infections resulting from occupational exposures to pathogens (*1–4*,5). This group includes an estimated 500,000 individuals in the United States (6). Visits to the laboratory by clinical staff, improper biological waste disposal, person-to-person transmission of laboratory-acquired infections (LAIs) and point-of-care medical testing may lead to additional exposures and allow dissemination of infectious agents outside of the laboratory. Clearly, measures to ensure the safety of laboratory workers are required and must be strictly adhered to by laboratory personnel (7). Changes are likely to occur in the number and/or composition of potential infectious agents to which laboratory workers are exposed, as global climates change, medical and surgical interventions evolve, and bioterrorism attempts occur. Therefore, safety measures must adapt to these new demands, and protocols to prevent LAIs are increasingly important. The most noteworthy recent event that illustrates this point is the challenge many laboratories faced while responding to the new occupational risk that the 2009 H1N1 Influenza A outbreak posed to healthcare workers (*8*,9). This chapter focuses on the microorganisms that are likely to cause LAIs, modes of spread of such agents in a laboratory setting, and methods that are commonly employed to minimize risk to laboratory workers.

EPIDEMIOLOGY OF LABORATORY-ACQUIRED INFECTIONS

LAIs may be defined as all symptomatic or asymptomatic infections resulting from (usually occupational) exposure to an infectious agent in a laboratory setting (5). There is an extensive literature dating back to the end of the 19th century that describes a wide variety of bacteria, viruses, fungi, and parasites that have caused LAIs. Despite this, the true incidence of LAIs is unknown, since LAIs are usually reported as individual case reports or compiled through laboratory surveys. In addition, these reports of LAIs often lack sufficient detail or precision to allow extrapolation of incidence or other epidemiologic factors. Finally, in some instances, it is difficult to determine if an infection was truly laboratory acquired, as opposed to community acquired (e.g., respiratory virus infection), unless an obvious laboratory accident or similar exposure was tightly linked to the onset of infection.

The most extensive LAI surveys in the United States were conducted by Sulkin and Pike between 1949 and 1970 *(10–12)*. More recent surveys reviewed LAIs in Utah, U.S. public health laboratories, and among subscribers to the ClinMicroNet forum (*13, 14*,15). Based on the earlier data sets, Wilson and Reller estimated that the annual incidence of LAIs in the United States was between 1 and 5 per 1,000 employees (16). More recently, Singh estimated the increased relative risks of infection in laboratory workers compared to the general population for *Brucella* spp. (RR = 8,012), *Neisseria meningitidis* (RR = 40.8), and *Escherichia coli* O157:H7 (RR = 8.6) based on ClinMicroNet survey data (15,17). In the same survey, the relative risks for *Shigella* and *Salmonella* infection were not elevated in laboratory workers, despite the fact that a large number of LAIs were caused by these two agents (15,17).

More systematic surveys of LAIs were performed in the United Kingdom between 1970 and 1995 *(18,19)*. The most recent retrospective survey of occupationally acquired infections in 397 laboratories (1994–1995) in the United Kingdom found an overall incidence rate of 16.2 per 100,000 person years, compared with 82.7 infections per 100,000 person years in a similar survey conducted in 1988 to 1989, suggesting that control measures may be reducing the incidence of such infections *(19)*.

Because of the lack of adequate modern data on LAIs, control measures are proposed and implemented based on extrapolation of prior experience with one infectious agent to others, the epidemiology of relevant microorganisms in nonlaboratory settings, and hazard analysis (6,*13*). Although laboratory workers will always be at some risk for infection, adherence to safety measures is expected to significantly reduce the risk. It is important to note that most reports focus on the occupational risk associated with handling patient specimens and performing microbiologic cultures. By contrast, few reports document the spread of laboratory pathogens from the laboratory to other hospital

areas or to the community *(20)*. Thus, it appears that the risks associated with diagnostic laboratories are mainly those of infection of laboratory workers from microorganisms reaching the laboratory from patient specimens, and much less of microorganisms spreading to the community from the laboratory.

IMPORTANT ETIOLOGIES OF LABORATORY ACQUIRED INFECTIONS

The factors that influence occupationally acquired infections in laboratories are related to host susceptibility and behavior, the virulence and availability of the pathogen, and the work environment (5). In the past, *Brucella* species, *Mycobacterium tuberculosis, Coxiella burnetii,* hepatitis B virus (HBV), *Francisella tularensis,* and *Salmonella* species caused most LAIs (6,*11*). During the 1980s, *M. tuberculosis, Salmonella* species, *Shigella* species, HBV, and hepatitis C virus (HCV) were the most frequent microorganisms causing infection in laboratory workers *(13,14,18)*. A list of selected microorganisms that have caused laboratory infections during the past decade is provided in Table 77-1, and discussion of the most frequently encountered microorganisms follows. A more complete compilation can be found in selected publications in the reference list (*2*,6,7,21).

Bacteria

Over 37 bacterial species account for approximately 43% of LAIs, making bacteria the most frequent cause of LAIs in diagnostic laboratories *(10)*. The risk of transmission of *M. tuberculosis* and *Mycobacterium bovis* in healthcare facilities and clinical laboratories has long been recognized *(28)*. Since 1953, the tuberculosis case rate in the United States has declined nearly tenfold, from 53 cases per 100,000 to 5.6 per 100,000 in 2001, and decreased 40% compared with the most recent peak year of 1992 (http://www.cdc.gov/tb/statistics/reports/2008/default.htm). Historical surveys have demonstrated an incidence of tuberculosis among laboratory workers up to nine times greater than in the general population *(29,30)*. The greatest risk of laboratory-acquired mycobacterial infection is associated with exposure to aerosols generated during handling of liquid specimens, preparation of frozen sections, and performing autopsies, although a few LAI mycobacterial infections have been attributed to direct parenteral inoculation (7,*31*). The relatively low inoculum of *M. tuberculosis* required to establish infection in humans *(32)* makes unprotected exposure to this microorganism in the laboratory quite risky. Although respiratory specimens are most frequently implicated as the source of laboratory-acquired mycobacterial infection, the presence of acid-fast bacilli in specimens other than respiratory secretions (e.g., gastric aspirates, cerebrospinal fluid (CSF), urine, exudates, and tissue) may also result in healthcare-associated transmission to healthcare workers (HCWs) and autopsy personnel *(33)*.

Historically, the second most frequent of the bacterial causes of LAI have been *Brucella* spp., which have caused approximately 24% of all reported LAIs and 11% of LAI-associated laboratory worker deaths in the United States (*34,35*,36,37,*38*,39,*40*). *Brucella* spp. are highly infectious and often cause infections in multiple research or clinical laboratory workers following a single laboratory accident (36,37,*40*). While protocols for proper handling of known *Brucella* isolates in clinical microbiology laboratories are typically in place, misidentification of this microorganism frequently occurs, leading to laboratory staff exposures (36,41). *Brucella* spp. are believed to be transmitted in the laboratory primarily via aerosolization or direct contact. Often, however, it has been impossible to determine the mechanism of transmission. Rare cases of person-to-person transmission have been reported, and in some instances, individuals with very low risk exposure (nonlaboratorians that have made short visits to the laboratory) have contracted brucellosis *(20)*. *F. tularensis* is rarely encountered in the clinical laboratory. However, like *Brucella* spp., it is a fastidious, slow-growing gram-negative coccobacillus that may be difficult to identify early enough to prevent accidental exposures (42).

Bacillus anthracis is a gram-positive spore-forming rod that is a rare cause of human infections in the United States. *B. anthracis* represents a unique risk among potential LAI agents, because the spores it produces are extraordinarily hardy and contaminated surfaces (or hands) are difficult to disinfect with routine procedures. Laboratory-acquired

TABLE 77-1

Selected Microorganisms Involved in Laboratory Infection Episodes Reported in Medical Journals During the Period 2000–2010 by Microorganism Group

Microorganism	*Type of Laboratory*	*Year of Publication*	*Reference*
Bacteria			
Brucella spp.	Diagnostic, Research	2008, 2004, 2001, 2000	(15,*22,34*, 37,*38*)
Toxigenic *E. coli*	Diagnostic	2008, 2005	(15,*53*)

Shigella spp.	Diagnostic	2008	(15)
Mycobacterium spp.	Anatomic	2001	*(33)*
Rickettsiae	Research	2001	*(55)*
Viruses			
West Nile Virus	Diagnostic	2009, 2002	*(25,26)*
Vaccinia	Research	2008	*(27)*

anthrax has most recently been documented in a laboratory worker handling specimens from the 2001 bioterrorism-related anthrax outbreak that occurred in the United States *(43,44)*. In this case, the lab worker acquired cutaneous anthrax from exposure to microorganisms present on the surface of contaminated vials.

Burkholderia pseudomallei, the microorganism responsible for melioidosis, is cited as a rare cause of LAIs but has been associated with a fatal outcome *(45)*. Direct contact with microbiologic cultures or specimens, ingestion, autoinoculation, and exposure to infectious aerosols and droplets all have been implicated in transmission of *B. pseudomallei*. *N. meningitidis* is another infrequent cause of LAIs that has been associated with fatal outcomes *(46)*. In a recent survey, 16 worldwide cases of probable laboratory-acquired *N. meningitidis,* with eight fatal outcomes, were identified between 1985 and 2001, including six US cases between 1996 and 2000 *(47)*. All cases (16/16) occurred among clinical microbiologists who, in most cases (15/16), performed isolate manipulation without respiratory protection *(47)*.

The agent of whooping cough, *Bordetella pertussis*, has caused at least 12 LAIs in the past 30 years, with six probable cases in the United States from 1996 to 2001 (2,5). The source isolates for the US cases were recovered from blood or CSF in five of the six cases and middle ear fluid in the sixth case.

The enteric bacterial pathogens, *Salmonella* species and *Shigella* species, are commonly reported causes of LAIs, while many additional cases likely go unreported (*2,13,19*,21,*48*). In older surveys, *Salmonella typhi* has caused more reported fatalities than any other LAI, while in more recent studies *Shigella* sp. was identified as the most frequent bacterial cause of LAIs (*11,13*,15,*19*). Infections generally occur from handling laboratory specimens and microbiologic cultures or occasionally from ingestion of intentionally contaminated food *(49)*. Gastroenteritis resulting from *Vibrio* species, *Campylobacter* species, enterotoxigenic *E. coli* and *Clostridium difficile* are infrequently reported (15,*50–53*).

The agent of Q fever, *C. burnetii,* is rare in the United States, so the risk for diagnostic laboratory-acquired Q-fever infection in this country is minor compared with that in many other parts of the world. The microorganism is present in blood, urine, feces, milk, and tissue specimens and resists drying. Most LAIs from *C. burnetii* arise from aerosols generated in animal research laboratories, although there are a few reports of parenteral and mucous membrane transmissions (*2*,21,54).

Before 1960, psittacosis was "among the most commonly reported laboratory-associated infections," but only sporadic cases have been reported in the past 20 years (*2*,21). Psittacosis case fatality rates are high compared with those of infections resulting from other agents. *Chlamydia psittaci*, the agent of psittacosis, may be present in tissues, feces, nasal secretions, and blood specimens. Few infections occur from exposure to *Chlamydia trachomatis* and generally result from mucous membrane exposure.

Leptospira interrogans, the cause of leptospirosis, can be present in urine, blood, and tissues of infected patients. Ingestion, accidental parenteral inoculation, and contact of skin or mucous membranes with cultures or infected specimens have all led to infection in laboratory workers. Likewise, LAI with syphilis has been documented, and its agent, *Treponema pallidum,* can be present not only in blood but also in cutaneous, mucous membrane, and other lesions. Laboratory spread of this microorganism follows from parenteral inoculation, contact of mucous membranes or broken skin with infectious clinical materials, and possibly infectious aerosols. Accidental parenteral inoculations are likely sources for laboratory-acquired rickettsial infections, but several infections with typhus have been associated with aerosols or infected airborne particles, and cases of Rocky Mountain Spotted Fever probably have occurred by this route as well *(19,48)*. LAIs from *Rickettsia typhi, Rickettsia coronii,* and *Orientia tsutsugamushi* have also been reported *(2,55)*. Because most diagnostic clinical laboratories do not perform cultures for rickettsia, these infections are more likely to be a risk in research laboratories.

Viruses

The blood-borne viruses (HIV, HBV, HCV) pose the infection risk of greatest concern to hospital workers (6,7,*56*,57). As of September 2007, the Centers for Disease Control and Prevention (CDC) had received reports of 57 HCWs in the United States with documented occupationally acquired HIV seroconversion, and 140 additional reports classified as possible occupational transmission (*http://www.cdc.gov/ncidod/dhqp/bp_hcp_w_hiv.html*). These individuals include 19 laboratory workers (16 clinical laboratory workers and 3 nonclinical laboratory technicians). Forty-eight of the fifty seven documented seroconversions were from percutaneous exposures, five were mucocutaneous, two were both, and two had an unknown route of exposure. Forty-nine HCWs were exposed to HIV infected blood, three to concentrated virus, one to visibly bloody fluid, and four to unspecified fluid. Twenty-six of these individuals had developed acquired immunodeficiency syndrome as of the date of the report.

The risk of infection from HIV, HBV, and HCV following occupational exposure to infected blood is related to the concentration of the virus in blood. HBV can be present in concentrations of 10^8 to 10^9 infectious particles/mL, while the concentrations of HIV and HCV are 10^0 to 10^4 and 10^2 to 10^3 particles/mL, respectively (7,57). The risk of infection following a percutaneous exposure is approximately 18% for HBV, 1.8% for HCV, and 0.3% for HIV. Following the mandatory requirement that employers provide HBV vaccination at no cost to their employees, the incidence of HBV infections in HCWs decreased 95% from 1983 to 1995 *(58)*. The 1% to 2% prevalence of HCV infection among HCWs appears no greater than the rate observed in the general population (7,57).

Although the blood-borne viruses are found in many different body fluids and tissues, the transmission of HCV, HIV, and HBV is most often associated with blood or visibly bloody body fluids. Since the 1990s, biosafety measures have emphasized the reduction of infection from blood-borne pathogens in all HCWs. The risk of acquiring a blood-borne infection is influenced by the prevalence of infection in patients, the amount of blood involved, the type of exposure, the concentration of pathogen in the blood or body

fluid, and the availability of postexposure prophylaxis (57). In addition to infections from human immunodeficiency virus (HIV), HBV, and HCV, blood-borne transmission of at least 20 other agents has been reported (7,*59*).

Most viral LAIs, other than infections from the blood-borne viruses, occur in animal research laboratories following exposure to aerosols or contamination of skin and mucous membranes (5). Arenavirus, Sabia virus, West Nile virus, and other viruses causing hemorrhagic disease have caused such research laboratory infections *(60–62)*. Lymphocytic choriomeningitis virus infections in laboratory workers occur in diagnostic facilities when cell cultures become contaminated with the virus, leading to possible aerosolization or skin or mucous membrane contamination. Specimens suspected of harboring the agent of smallpox, variola major, should not be cultured but rather shipped directly to CDC or a state health laboratory (63,*64*).

Respiratory viral infections acquired in the laboratory are probably underreported, because it is difficult to document occupational acquisition. These viruses can be aerosolized by manipulation of specimens or cultures. In contrast, the agents that cause viral gastroenteritis are rarely transmitted to laboratory workers. Infections with the hepatitis viruses that are principally transmitted by the fecal–oral route are also uncommon causes of LAI; it is hypothesized that since the shedding of Hepatitis A, and probably Hepatitis E, is diminished by the time a patient is symptomatic, there is a decreased risk of transmission in the healthcare facility *(1)*.

Fungi

Laboratory-acquired fungal infections have been reported infrequently since 1980. Generally, fungal infections are acquired from the inhalation of the conidia of the thermally dimorphic fungi *Coccidioides immitis, Histoplasma capsulatum,* or *Blastomyces dermatitidis,* and there is one reported case of infection with *Penicillium marneffei* (5,6,54,*65*). Occasionally, cutaneous infections occur following accidental inoculation *(66,67)*. Coccidioidomycosis and histoplasmosis are the most frequently reported laboratory-acquired fungal infections (6). Arthroconidia from laboratory cultures of *C. immitis* easily become airborne, whereas spherules from tissue are much less likely to be aerosolized. Laboratory-acquired histoplasmosis also results primarily from handling laboratory cultures. The infective conidia are small and likely to become airborne, resist drying, and can cause infection after small inocula are inhaled. Less frequently, pulmonary infection resulting from *B. dermatitidis* has followed inhalation of the conidia by laboratory workers.

Parasites

Laboratory-acquired parasitic diseases are exceedingly rare. However, parasitic diseases are receiving increasing attention because of world travel and increased susceptibility in immunocompromised individuals *(68)*. Over 300 cases of parasitic LAIs have been reported, including malaria, leishmaniasis, trypanosomiasis, and toxoplasmosis *(10,68)*. The two most frequently reported infections from accidental exposure are from *Trypanosoma cruzi* and *Toxoplasma gondii*. The rate of occurrence of laboratory accidents during work with *T. gondii* is reported to be one accident per 9,300 hours of exposure resulting in one infection per 24 person years, while the infection rate for working with *T. cruzi* is calculated to be one infection per 46 person years *(68,69)*. The clinical spectrum of these infections has ranged from asymptomatic to fatal (one case for each microorganism). Herwaldt *(56)* also reported on infections caused by *Plasmodium* species (34 cases) and *Leishmania* species (12 cases). Most of the infections associated with blood and tissue protozoa occurred from parenteral exposure, but acquisition via skin and mucous membrane exposure and ingestion have also been reported. Only 21 cases of LAIs with intestinal protozoans have been reported, involving *Cryptosporidium parvum, Isospora belli,* and *Giardia lamblia*. Fewer reports have involved the helminths, including *Schistosoma* species, *Strongyloides* species, and *Ancylostoma* species. The most probable route of infection was ingestion of contaminated material, although a few cases were associated with aerosols or skin penetration.

RESERVOIRS AND MODES OF SPREAD

LAIs may be transmitted via a variety of modes including inhalation, ingestion, inoculation, and contamination of skin and mucous membranes (6,21,54). Perhaps the most likely mode of transmission is accidental inoculation of skin or soft tissue with needles or other sharps such as scalpels and broken glass from specimen containers. Nearly all pathogenic microorganisms can produce infection by this route and, as noted above, this is the most frequent route of transmission for blood-borne pathogens such as HIV or the hepatitis viruses (7). Hopefully, the accidental percutaneous inoculation of infectious material by laboratory personnel will decrease with the increased use of plastic collection tubes, needleless systems, and engineered safety devices. As a rule, needles should not be used in the laboratory unless there is no other alternative.

Although the intact skin is an excellent barrier to penetration by microorganisms, minor cuts and abrasions are common and may serve as portals of entry in the absence of penetrating trauma. Contamination of mucous membranes by splashes and sprays of infectious material can lead to the laboratory transmission of HIV and other pathogenic agents to laboratory workers (5,7). In animal research facilities, bites and scratches from infected animals present a risk for transmission of an agent.

As in patient care areas, transmission by hand to skin and mucous membranes of the mouth, eye, and nose can cause LAIs *(70)*. Ingestion may occur following mouth pipetting, transfer of microorganisms on contaminated fingers or pencils, accidental splashes, or consumption of food and beverages in the laboratory. The laboratory environment is contaminated during the workday from routine specimen processing and other work practices that produce aerosols or splatters, and this results in contamination of the hands (21,71). Indirect contact with microorganisms can occur when work benches and other environmental objects (e.g., specimen containers, test requisitions, instruments) or surfaces become contaminated with microorganisms. Accidents or spills also can lead to contamination of the workbench or other equipment,

which may lead to contamination by hand contact. The importance of avoiding poor personal hygiene practices, such as applying cosmetics and adjusting contact lenses in the laboratory, must thus be stressed. Cases associated with contamination of food, drink, or tobacco products have declined significantly, because attention has been paid to eliminating eating, drinking, and smoking in the laboratory.

Transmission within the laboratory via airborne spread is also of great concern (7,*64,72*). Many laboratory procedures generate aerosols, droplets, or droplet nuclei that can cause infection when inhaled by the laboratory worker. Droplet nuclei are small (<5 μm in diameter) and therefore tend to remain suspended in air and move throughout the room on air currents and reach the alveoli of the lungs when inhaled *(73)*. They therefore may pose a risk to individuals working in other parts of the laboratory at the time the aerosol is generated. Relevant procedures that generate aerosols include use of bacteriology loops for transferring cultures and flaming them afterward; pipetting (especially with fixed automatic pipettes or during mechanical resuspension of material achieved by repeated pipetting); using syringes and needles; opening tubes and bottles; using centrifuges and blenders; performing autopsies; harvesting viral cultures; lyophilizing; and breaking culture plates, bottles, and tubes. These work practices also produce droplets that contaminate counters or floor surfaces, permitting transmission from these surfaces to hands. Microorganisms in blood droplets can survive for several days after drying on work surfaces or instruments (54). Specific bacteria that may be transmitted by airborne droplets or aerosols were discussed above and include *M. tuberculosis*; *Corynebacterium diphtheriae; N. meningitidis; B. pertussis; Streptococcus pyogenes;* and the potential agents of bioterrorism, *B. anthracis, Yersinia pestis, Brucella* species, *F. tularensis,* and *B. pseudomallei* (*2*,7,21,63,*74*).

It is important to note that the potential bacterial agents of bioterrorism may be transmitted by multiple exposure routes, including aerosols, contamination of skin and mucous membranes, ingestion, and percutaneous inoculation. Infections often occur when laboratory workers do not recognize or suspect the pathogen and neglect to take necessary safety precautions (41). The practice of "sniffing" plates for characteristic odors associated with a specific bacterium should therefore be curtailed *(2)*. In addition to aerosol transmission, laboratory-acquired brucellosis has occurred from direct skin contact with cultures or with other infectious material, percutaneous inoculation, and spray onto mucous membranes. These same transmission routes are important for *B. anthracis,* the agent of anthrax; *F. tularensis,* the cause of tularemia; *C. diphtheriae,* the agent of diphtheria; and *Y. pestis,* the agent of plague. All of these bacteria should be handled with biosafety level (BSL) 2 and 3 safety precautions *(64)*.

GUIDELINES FOR PREVENTION

Ensuring laboratory safety is included in the standards of the Occupational Safety and Health Administration (OSHA), which are driven by the premise that the employer must provide a safe workplace (*56*,57,*75–78*). Compliance with current OSHA standards is subject to review by the agency's inspectors; thus, these regulations are perhaps of greatest importance to clinical diagnostic laboratories. Other groups, such as the CDC *(79,80)*, the National Institutes of Health (21), the College of American Pathologists (CAP), and the Clinical and Laboratory Standards Institute (CLSI), all provide guidelines or regulations regarding laboratory safety. OSHA, the National Institute for Occupational Safety and Health (NIOSH), the CAP, and the Joint Commission include safety among their checklists for laboratory inspectors. State and local licensing inspections and federal inspections for participation in Medicare also focus on safety issues (7).

Guidelines for laboratory safety from these groups cover exposures to chemical agents, fire, and other aspects, but the highlight of each is the prevention of LAI. The following discussion is guided by these various regulations and guidelines and centers on the clinical diagnostic laboratory. The prevention of infection in autopsy, surgical pathology, and research and referral laboratories follows the same general plan considered here, but its implementation varies dramatically in each site according to the work done and the microorganisms involved (7).

Each laboratory must assess its specific risk from handling infectious material and design an exposure control plan to minimize these potential risks. Safety practices, usually containment measures, are designed to reduce or eliminate the exposure of laboratory workers to infectious material (7,21). These practices vary with the pathogenicity and infectious dose of the agent, the routes of transmission, the work performed, and the availability of treatment or prophylaxis (21,81,*82*). The CDC/National Institutes of Health guidelines recommend four levels of biosafety, and each successive level suggests increased occupational risk and more stringent containment practices. These classifications are similar to those adopted by the World Health Organization (WHO) based on increasing level of risk to the individual and community and availability of effective treatment and prevention *(83)*. Laboratories that use, receive, or store select agents must address, in addition to BSL 2 to 4 safety practices, security and reporting issues *(84)*. Additional safety practices are necessary for work in research and anatomic laboratories (7,*85–87*).

OSHA regulations for prevention of infection emphasize engineering controls, work practice modification, and personal protection by immunization and protective equipment *(72,88)*. Guidelines based on CDC recommendations for the clinical diagnostic laboratory can be placed in these same general categories and compared for BSLs 2 and 3. Most guidelines are common to both BSLs 2 and 3, whereas some are unique to level 2, and others are specific to level 3 protection (refer to Tables 77-2–77-4 for a comprehensive description of specific practices). Many of these elements are pertinent to other hospital areas and to laboratories; such policies are discussed in detail in other chapters and are reviewed only briefly here. Several elements of infection prevention are more relevant to the laboratory than to other areas, and these are discussed at greater length in the following sections.

Engineering Controls

Airflow handling is an essential element in several clinical care areas of a hospital where microorganisms likely to be spread by airborne transmission are encountered,

TABLE 77-2

Control Measures for Prevention of Laboratory-Acquired Healthcare-Associated Infections that are Common to BSLs 2 and 3

Engineering Controls

1. Only needle-locking syringes or disposable syringe-needle units are used for injection or aspiration of infectious materials
2. Needles and syringes or other sharps are used only when there is no alternative, such as for parenteral injection, phlebotomy, or aspiration of fluid from diaphragm bottles
3. Syringes that resheath the needle, needleless systems, and other safe devices are used when possible
4. Plasticware is substituted for glassware whenever possible
5. Used disposable needles are carefully placed in conveniently located puncture-resistant containers. Nondisposable sharps are placed in a hard-walled container for transport to a processing area for decontamination, preferably by autoclaving
6. Cultures, tissues, and specimens of body fluids are placed in containers that prevent leakage during collection, transport, handling, processing, storage, or shipping
7. Materials with high concentrations or large volumes of infectious agents may be centrifuged in the open laboratory only if sealed rotor heads or centrifuge safety cups are used and if these rotors or safety cups are opened only in a BSC
8. An eyewash facility is readily available
9. Rugs are not used, because proper decontamination following a spill is difficult
10. Bench tops are impervious to water and resistant to acids, alkali, organic solvents, and moderate heat
11. Laboratory furniture is sturdy, and spaces between benches, cabinets, and equipment are accessible for cleaning
12. Open windows are fitted with fly screens
13. A method for decontamination of infectious or regulated laboratory wastes is available (e.g., autoclave, chemical disinfection, incinerator)

Work Practice Modification

1. Hands are washed after handling infectious material, after removing gloves, and before leaving the laboratory
2. Food is stored outside the work area in cabinets or refrigerators designated for this purpose only
3. Mouth pipetting is prohibited; mechanical pipetting devices are used
4. All procedures are performed carefully to minimize splashes or aerosols
5. Work surfaces are decontaminated at least once a day and after any spill of viable material
6. All cultures, stocks, and other regulated wastes are decontaminated before disposal by an approved decontamination method such as autoclaving
7. Materials to be decontaminated outside of the immediate laboratory are placed in a durable, leak-proof container and closed for transport
8. Materials to be decontaminated off-site from the laboratory are packaged in accordance with applicable local, state, and federal regulations before removal from the facility
9. An insect and rodent control program is in effect
10. A biosafety manual is prepared or adopted
11. Personnel are advised of special hazards and are required to read and follow instructions on practices and procedures
12. Personnel receive appropriate training on potential hazards associated with the work involved, the necessary precautions to prevent exposures, and exposure evaluation procedures. Annual updates, or additional training as necessary for procedural or policy changes, are provided
13. A high degree of precaution always is taken with any contaminated sharp items, including needles and syringes, slides, pipettes, capillary tubes, and scalpels
14. Used disposable needles are not bent, sheared, broken, recapped, removed from disposable syringes, or otherwise manipulated by hand before disposal; they are placed in appropriate containers (see above)
15. Broken glassware is not handled directly by hand but is removed by mechanical means (e.g., brush, dustpan, tongs, forceps)
16. Containers of contaminated needles, sharps, and broken glass are decontaminated before disposal according to local regulations
17. Laboratory equipment and work surfaces are decontaminated with an appropriate disinfectant routinely, after work with infectious materials is finished, and especially after contamination by infectious material (e.g., spills, splashes)
18. Contaminated equipment is decontaminated before it is sent for repair or maintenance or packaged for transport
19. Spills and accidents resulting in overt exposures to infectious materials are reported immediately to the laboratory director

Personal Protection

1. Personnel receive appropriate immunizations or tests (e.g., tuberculin skin test) for the agents potentially handled or potentially present
2. Medical evaluation, surveillance, and treatment are provided as appropriate, and written records are maintained following any exposure to infectious agents
3. Persons who wear contact lenses in laboratories should also wear goggles or a face shield

(*Continued*)

TABLE 77-2

Control Measures for Prevention of Laboratory-Acquired Healthcare-Associated Infections that are Common to BSLs 2 and 3 (*Continued*)

4. Protective laboratory coats, smocks, gowns, or uniforms designated for laboratory use are worn while in the laboratory
5. Protective clothing is removed and left in the laboratory before leaving for nonlaboratory areas and is either disposed of in the laboratory or laundered by the institution, never taken home by personnel
6. Gloves are worn when hands might contact infectious materials, contaminated surfaces, or equipment. They are disposed of when contaminated, removed when work with infectious materials is complete, and are not worn outside the laboratory
7. Disposable gloves are not washed or reused

[a]As defined by the Centers for Disease Control and Prevention with the National Institutes of Health (21) and the OSHA *(88).*

especially *M. tuberculosis* and dimorphic fungi *(78)*. In the laboratory, however, the potential for encountering BSL 3 microorganisms that can be spread by air is so much greater that certain standards and guidelines beyond those that apply to the rest of the institution are mandatory (*72*,89). Aerosolization can result from the use of blenders, both low- and high-speed centrifuges, and automatic pipettes, as well as improperly flamed loops used for inoculation of microbiologic cultures. Other standard and seemingly innocuous laboratory procedures such as pipetting, accidentally dropping infected liquids on a counter, and inoculating a tube with a syringe all can generate aerosols. If one adds to this the presence in clinical specimens of microorganisms prone to spread by the airborne route (see above), the need for control of aerosols becomes crucial. Thus, building design that ensures inward directional airflow into the laboratory from corridors and hallways ("negative pressure") and similar engineering for direct exhaust of the air without recirculation are crucial for laboratories handling airborne pathogens. For BSL 3 laboratories, airflow is monitored to ensure that the ventilation system does not fail *(72, 90)*. Air ventilation in the autopsy suite is also critical; the room should be under negative pressure, provide 12 air exchanges per hour, and be exhausted directly to the outside (7).

Biologic safety cabinets (BSCs) are designed to contain the highly infectious agents that are transmitted by an airborne route through infectious splashes or aerosols generated by microbiologic procedures (7,*72,91*). There are three types of BSCs (Classes I, II, and III). Class I BSCs draw room air through the cabinet and discharge it outside, through HEPA filters. While this type of cabinet protects the user from harmful materials inside, it is unsuitable for

TABLE 77-3

Requirements for BSL 2 that Differ from those for BSL 3[a]

Engineering Controls

1. Properly maintained BSCs, preferably class II or other appropriate personal protective equipment or physical containment devices are used for procedures that could create infectious aerosols or splashes. These may include centrifuging, grinding, blending, vigorous shaking or mixing, sonic disruption, opening containers of infectious materials whose internal pressures are different from ambient pressure, and harvesting infected tissues
2. Each laboratory contains a sink for hand washing

Work Practice Modification

1. Access to the laboratory is limited or restricted when work with infectious agents is in progress
2. Eating, drinking, smoking, handling contact lenses, and applying cosmetics are not permitted in the "work area" (laboratory for level 3)
3. Only persons who have been advised of the potential hazard(s) and meet specific entry requirements (e.g., immunization) enter the laboratory
4. When the infectious agents in use in the laboratory require special provisions for entry (e.g., immunization), a hazard warning sign incorporating the universal biohazard symbol is posted on the access door to the laboratory work area. The sign identifies the agent, lists names and telephone numbers of responsible persons, and indicates the special requirements for entering the laboratory

Personal Protection

1. Face protection (e.g., masks, goggles, faceshield) is used for anticipated splashes or sprays of infectious materials when the microorganisms must be manipulated outside the BSC
2. When appropriate, considering the agents handled, baseline serum specimens for personnel are collected and stored. Additional serum specimens may be collected periodically, depending on the agents handled or the function of the facility.

[a]As defined by the Centers for Disease Control and Prevention with the National Institutes of Health and the OSHA (21,*88*).

TABLE 77-4

Requirements for BSL 3 that Differ from those for BSL 2[a]

Engineering Controls

1. The laboratory is separated from areas with unrestricted traffic flow. Passage through two sets of self-closing doors is the basic requirement for entry. A clothes change room (shower optional) may be included in the passageway
2. A ducted exhaust air ventilation system is provided. This system creates directional airflow that draws air from clean areas into the laboratory toward contaminated areas. The air is not recirculated to any other area of the building. It is discharged to the outside with filtration and other treatment optional. The outside exhaust must be dispersed away from occupied areas and air intakes
3. The high-efficiency particulate air (HEPA)-filtered exhaust air from class II or class III BSCs is discharged directly to the outside or through the building exhaust system (for class II cabinets, exhaust air can be recirculated if the cabinet is tested and certified at least every 12 months). Discharged air to the building exhaust system is connected in a manner that avoids any interference with air balance of the cabinets or building exhaust system
4. Properly maintained BSCs are used (class II or III, as appropriate)
5. Continuous flow centrifuges or other equipment that may produce aerosols are contained in devices that exhaust air through HEPA filters before discharge into the laboratory
6. Laboratory doors are kept closed when testing or experiments are in progress
7. Each laboratory contains a sink for hand washing. The sink is foot, elbow, or automatically operated and is near the laboratory exit door
8. The interior surfaces of walls, floors, and ceilings are water resistant, so they can be easily cleaned. Penetrations in these surfaces are sealed or capable of being sealed to facilitate decontamination
9. Windows in the laboratory are closed and sealed

Work Practice Modification

1. Eating, drinking, smoking, handling contact lenses, and applying cosmetics are not permitted in the laboratory ("work area" for level 2)
2. Persons who are at increased risk of infection or to whom infection may be unusually hazardous are not allowed in the laboratory. Access is restricted to persons whose presence is required for program or support purposes
3. Only persons who have been advised of the potential hazard(s), meet specific entry requirements (e.g., immunization), and comply with all entry and exit procedures enter the laboratory
4. When infectious materials are in the laboratory, a hazard warning sign incorporating the universal biohazard symbol is posted on all laboratory and animal room access doors. The sign identifies the agent, lists names and telephone numbers of responsible persons, and indicates any specific requirements for entering the laboratory, such as the need for immunizations, respirators, or other personal protective measures
5. The laboratory director ensures that, before working with microorganisms at BSL 3, all personnel demonstrate proficiency in standard microbiologic practices and techniques and in the practices and operations specific to the laboratory facility. This might include prior experience in handling human pathogens or cell cultures or a specific training program
6. All manipulations involving infectious materials are conducted in BSCs or other physical containment devices within the containment module. No work in open vessels is conducted on the open bench
7. All potentially contaminated waste materials (e.g., gloves, laboratory coats) from laboratories are decontaminated before disposal or reuse
8. Spills of infectious materials are decontaminated, contained, and cleaned up by appropriate professional staff members or others properly trained and equipped to work with concentrated infectious material
9. Animals and plants not related to the work being conducted are not permitted in the laboratory

Personal Protection

1. Outside of a BSC, appropriate combinations of personal protective equipment are used (special protective clothing, masks, gloves, face protection, or respirators) in combination with physical containment devices (e.g., centrifuge safety cups, sealed centrifuge rotors) for manipulation of cultures or other materials that may be a source of infectious aerosols
2. Face protection (goggles and mask or face shield) is worn for manipulations of infectious materials outside the BSC
3. Protective laboratory clothing such as solid-front or wrap-around gowns, scrub suits, or coveralls must be worn in, and not worn outside, the laboratory
4. Reusable laboratory clothing is to be decontaminated before being laundered
5. A laboratory policy exists that addresses the collection and storage of baseline serum specimens for personnel WHICH are collected and stored for all laboratory and other at-risk personnel. Additional serum specimens may be collected periodically, depending on the agents handled or the function of the facility

[a]As defined by the Centers for Disease Control and Prevention with the National Institutes of Health and the OSHA (21,*88*).

microbiology laboratories because plates and other media within the cabinet are not protected from room air contaminants. Most routine clinical laboratories use Class II BSCs that provide protection to the user and prevent external contamination of the materials inside the cabinet by recirculating HEPA filtered air into the cabinet. An effective containment system for handling BSL 2 and 3 agents requires that the BSC is properly maintained, that the BSC be certified annually or whenever the cabinet is moved, and that well-trained employees use good microbiologic technique (7). More detailed characteristics of each type of cabinet and procedures for their correct use have been reviewed and extensively described elsewhere (7,*72,78*).

Other engineering controls for decreasing the risk associated with handling infectious material include safety engineered devices and instruments, sharps containers, safety containers for centrifuges, plastic containers and collection devices for specimens, mechanical pipettes and diluters, bench tops impervious to liquids, and personal protection equipment (7,*92*).

Work Practice Modification

Laboratory workers cannot *a priori* identify specimens that contain infectious agents and, therefore, must practice Standard Precautions. Thus, the concept that all patients and all laboratory specimens are potentially infectious and capable of transmitting infection is practiced in all healthcare settings (7,*93,94*). These guidelines represent the first level of protection of the laboratory worker from a wide variety of pathogens. Hand washing is a fundamental procedure to reduce duration of exposure and transmission of an infectious agent within the healthcare facility, including the laboratory. Adequate hand cleansing using traditional soap and water or an alcohol-based gel should occur before leaving the laboratory, after removing gloves, and after obvious hand contamination *(95)*. Some practices that promote the transfer of microorganisms from surfaces to hands to mucous membranes are universally prohibited in the laboratory. These include eating or storing food, drinking, applying cosmetics or contact lens, smoking, chewing gum, and mouth pipetting. Workers with skin lesions or dermatitis on the hands or wrists should not handle potentially infectious materials without adequate protection (96).

Personnel who collect and transport specimens should be adequately trained. Whether transported by hand or pneumatic tube, specimens should be placed in a leak-proof primary container. This primary container is placed in a leak-proof secondary container, usually a sealable plastic bag. Secondary containers and specimen storage areas should be labeled with a biohazard label to alert individuals to the potential infectious hazard. Needles should be removed before transporting a syringe to the laboratory.

Specimen processing in microbiology requires special steps to prevent infection and should be performed in a BSC. For example, when entering a blood culture bottle with a needle and syringe, the vial should never be held in the worker's hand and the bottle should be placed behind a splashguard or in a BSC. Similarly, unfixed slides should always be handled as if they contain infectious materials (7). Special steps are needed for dealing with the potential hazards associated with the use of diagnostic instruments (7).

Prompt decontamination of spills is particularly important in the laboratory. Most laboratory spills involve blood, other body fluids, or microbiologic media that often contain high concentrations of protein. Because many disinfectants are less active in the presence of these proteins, the bulk of the spilled liquid must be adsorbed before disinfection (7,96). For large spills of microbiologic cultures, the spill is flooded with an appropriate disinfectant and left to stand for 20 minutes before cleanup (7). Phenolic disinfectants are not recommended for use on contaminated medical devices that come in contact with laboratory workers but may be used on laboratory instruments, floors, and countertops. Also, instrument parts made in part or wholly of aluminum are corroded by sodium hypochlorite, so other disinfectants are preferred for disinfection of laboratory instruments containing these parts.

Surface cleaning of the laboratory bench or other surfaces must be meticulous, because these surfaces are likely to be contaminated with potential pathogens (71). Many surfaces (countertops, floors, equipment, centrifuges, etc.) become contaminated by microorganisms during routine processing of clinical specimens and cultures. These surfaces should be carefully disinfected at the completion of work and after accidental spills to prevent contamination of laboratory employees and visiting medical personnel who may unknowingly carry the agent to other parts of the facility or the community (71). All unnecessary material should be removed from these surfaces to facilitate proper cleaning and disinfection.

Waste disposal and handling of biologic materials at the end of processing are especially important topics for the laboratory, because of the volume of the materials involved and because the processing of the specimens often involves amplification of the potential pathogen *(97)*. The laboratory is a major generator of potentially hazardous waste, and should have procedures to segregate materials for discard into designated containers such as "routine," "chemical," and "biohazard" waste for proper decontamination and disposal. Fortunately, the same procedures used in other parts of the facility apply to laboratory waste.

Surveillance of accidents and exposures is a key feature of infection control in all hospital areas but is especially important in the laboratory. The essential components of postexposure management include incident reporting, wound management, evaluation of the transmission risk, and consideration of postexposure prophylaxis (7,*56*,57). Every incident, no matter how trivial the injury or exposure, must be reported to the supervisor, including the date and time of exposure, the details of the accident, information on the source person, and medical evaluation of the injured employee. The immediate reporting of the incident establishes a time relationship, in the event that an infection develops, and permits preventive measures to be implemented. OSHA regulations require that the facility's exposure control plan include hepatitis B vaccination at no cost to the employee, postexposure evaluation and follow-up, communication of potential hazards to employees, and appropriate records and reporting (7,56,57,*98*).

Follow-up for the individual is vital. Procedures for medical follow-up of exposure to blood-borne pathogens are dealt with in separate chapters (see Chapters 73 and 74). Equally important is the periodic and regular analysis of the incidents that occur in a given laboratory. Laboratory, Occupational Health, and Infection Prevention

personnel should cooperate in the compilation and analysis of incident report data to search for common patterns, to eliminate identified risk factors, and to modify laboratory procedures to minimize occurrence of these incidents *(99)*.

The shipment of infectious material is regulated by national and international rules and regulations promulgated by the U.S. Department of Transportation, International Airline Transport Association, and the WHO *(83)* and are beyond the scope of this chapter.

Personal Protection

Immunization Laboratory workers must be encouraged to participate in the same immunization program that is offered throughout the institution (7,*100*). This includes, at a minimum, provision of HBV immunization at no cost to the employee. The laboratory worker may be at greater risk of exposure to body fluids containing one of the hepatitis viruses, so it might be worth the special effort to emphasize immunization to laboratory employees. Immunizing trainees against HBV is particularly important, because the risk of infection often is high during training.

Bacillus Calmette–Guérin (BCG) vaccine is made from an attenuated strain of *M. bovis*. It is not routinely offered to hospital workers in the United States, because a positive tuberculin skin test when the vaccine is effective is thought to be a hindrance to surveillance for natural tuberculosis and because adverse effects are associated with immunization (e.g., abscess at the injection site). However, it may be considered for laboratory employees who process large volumes of specimens containing *M. tuberculosis*. Other possible vaccines for laboratory workers include meningococcal polysaccharide vaccine, rabies vaccine, polio vaccine, and typhoid vaccine. Vaccines for anthrax and/or smallpox may be considered for workers in research or BioThreat response laboratories. Primary prevention in the laboratory should focus on biosafety practices, but these vaccines are a consideration for personnel who work with these agents on a frequent and regular basis (see also Chapter 75).

Personal Protective Equipment Gloves, masks, and gowns are used throughout a hospital to protect workers from contact with blood and other potentially infectious materials. The laboratory is no exception to this practice, because all specimens handled in the laboratory are considered potentially infectious. Laboratory workers must be trained in the appropriate use, limitations, and disposal of personal protective equipment. In general, only powder-free latex or other nonlatex gloves should be used in the laboratory as part of the Standard Precaution guidelines. Puncture-resistant gloves should be available in the autopsy suite or when handling scalpels and other sharps. In addition to protective clothing, laboratory workers should wear face shields or work behind splashguards when removing stoppers or withdrawing samples from specimen tubes (7). When extensive soaking by potentially infectious material is a possibility, waterproof coats, gowns, or aprons should be worn. Respiratory protection in the form of NIOSH-approved masks (e.g., N95 particulate respirator, with prior formal testing to confirm mask fit) is recommended when working with *M. tuberculosis* or other similar BSL 3 microorganisms (7,21). Shoes should cover the feet to protect the skin from spills or dropped sharps. All personal protective equipment, including laboratory coats, gowns, or other protective covers, should not be worn outside the laboratory area.

ACKNOWLEDGMENT

This chapter contains information presented in Chapter 82 of the third edition of this book by David E. Sewell.

CHAPTER 78

Prevention of Occupationally Acquired Infections in Prehospital Healthcare Workers

James M. Melius

Prehospital healthcare workers now number over 200,000 workers employed to provide this type of healthcare *(1)*. This estimate does not include the large number of volunteer prehospital healthcare workers or the police and fire fighters who also may be required to provide emergency medical assistance as part of their jobs. Many of these prehospital healthcare personnel work for modern well-equipped emergency medical systems in major metropolitan areas. Others volunteer their time for local rescue companies with very limited resources, often in rural areas. Some are full-time professional healthcare workers dedicated to a career in emergency medical services, whereas others may only provide voluntary services for a few hours per month or may only occasionally have to provide emergency medical care as part of their full-time jobs as firefighters or police officers.

Working in the prehospital environment is in many ways similar to providing care in hospitals and other healthcare facilities. Prehospital healthcare workers encounter a variety of seriously ill patients with many types of illness, and, like other healthcare workers, emergency medical workers face an increased risk of acquiring a number of different infectious diseases as a result of their work. The potential risk of a bioterrorism incident expands the number of conditions that must be considered.

Prehospital healthcare workers usually spend only a short time with each patient. This limited contact undoubtedly lowers their risk of acquiring a patient-related infection. However, a number of other factors may increase this risk.

In responding to traffic accidents or entering the homes of their patients, these workers provide medical care in many different settings over which they have little control. In most situations, they do not have complete information on the patient's medical condition. This lack of control of their work environment and the incomplete diagnostic information have significant implications in preventing the transmission of infectious diseases from the patients to these workers.

Another important difference from many other healthcare workers is the variety of types of organizations that employ these workers and the lack of programs within those organizations for providing infection control services. In some cases, the organizations may lack the resources or the commitment for the operation of good infection control programs. Although infection control programs for prehospital workers have improved in recent years, there are still large disparities among different organizations.

This chapter provides an overview of the infectious diseases risks faced by prehospital healthcare workers and of the methods useful for their prevention. These preventive steps are quite similar to those used in other healthcare settings. Therefore, this chapter emphasizes preventive approaches especially important to prehospital healthcare workers rather than reiterating infection control procedures described elsewhere in this book. Finally, the chapter briefly discusses approaches for organizing better preventive programs for these workers.

PREHOSPITAL HEALTHCARE

Prehospital healthcare workers include many thousands of healthcare workers in many organizational settings. Some work full time as emergency medical care workers for private or public providers. Others spend most of their time conducting other tasks (e.g., fire fighting) but must occasionally provide emergency medical care. Others volunteer their services, spending a few to many hours every week with volunteer rescue squads (usually in rural areas).

These workers also differ in their medical training. Some have years of specialized training for their careers and frequent updating of their medical training. Others have only very limited emergency care training and little continued training because of their other job requirements.

The common tasks performed by these workers include the provision of emergency medical care outside the hospital (or healthcare facility) setting and the transport of these patients to healthcare facilities. The types of patient being cared for obviously vary among different prehospital care providers. Some mainly transport patients who are not critically ill, whereas others mainly respond to trauma incidents. Geographic location and many other factors obviously affect the potential exposure of these workers to people with communicable diseases.

The workplace for prehospital healthcare providers can be viewed as including four settings: (a) the accident scene or other place where initial care for the patient is provided, (b) the transport vehicle, (c) the healthcare facility receiving area (usually emergency room), and (d) the facility in which the responder is stationed (e.g., hospital,

fire house). From the perspective of infection control, the third setting is not discussed in this chapter. However, it should be noted that emergency medical providers may be at some risk for acquiring infections even after arrival at the healthcare facility.

The site of the initial care (e.g., patient's residence, accident scene) is probably the most problematic of the four locations. In contrast to most other healthcare workers, the emergency medical responder usually has little information about the patient's condition when initially providing medical care at the scene. Thus, the responder is usually not aware of whether the patient has a communicable disease. Collection of some diagnostic information is obviously a critical aspect of providing initial emergency care, but information about a specific infectious disease often will not be obtained. Often, a specific infectious disease will not be diagnosed until after the patient has been hospitalized.

In providing care, the responder usually must rely on verbal information from the patient or the family that may not fully reflect the patient's medical condition. In some cases, the patient may be unconscious and otherwise unable to provide any information, and knowledgeable family members may not be present. In the absence of specific diagnostic information, the responder must depend on his or her initial physical assessment of the patient, perhaps with additional knowledge such as the likelihood of the patient having an infectious disease because of the geographic location (i.e., how common is the disease in that area).

The responder not only lacks diagnostic information but must also provide emergency medical care at the site. In many cases, this care must be provided at the patient's residence. The responders may have a very limited work area and poor lighting, making certain procedures, such as starting intravenous lines, difficult. In addition, the patient may be combative or otherwise difficult to manage, further increasing the risk of this type of procedure. For airborne communicable diseases, there may be increased risk of exposure, because the responder must work in a residential environment in which the patient has been staying. This area may lack adequate ventilation and may have contaminated surfaces.

An accident or trauma scene may pose additional dangers. In addition to the limited space, poor lighting, and other problems, the trauma scene may have broken glass and other sharp objects that could contribute to the spread of blood-borne pathogens. In some cases, the responder may have to spend a long period stabilizing the patient until the patient can be extricated from a motor vehicle. Taking proper infection control precautions in a confined space with a seriously injured patient may be quite difficult.

Another aspect of providing emergency care at the scene that is obvious but is especially important is that all protective equipment that is needed at the scene must be carried by the responders. If they do not bring the necessary equipment with them, the equipment must either be retrieved from their transport vehicle or from their station or not used at all. Anticipating what will be needed and then providing ready access to that equipment can be quite challenging. The availability of equipment may be particularly problematic for responders who most often fulfill other duties (e.g., law enforcement or fire fighting) but are also expected to provide emergency medical care.

The situation in transport vehicles is somewhat better. The patient is usually stable enough to be transported. Better medical and monitoring equipment is also available. However, this setting also has a number of problems. First, patients often must be rapidly transported to the hospital and may often be in very critical condition. Medical care and procedures such as starting intravenous lines must be conducted very quickly. Most transport vehicles have very little room, further compounding this problem. Transport also may cause problems because of the movement of the vehicle during transport. This is obviously a problem while trying to perform procedures during transport (e.g., insertion of intravenous lines). Another potential problem is that most emergency transport vehicles are poorly ventilated. Most ventilation either comes from opening windows or from the vehicle's heating or cooling systems, which often simply recirculate most of the air in the vehicle *(2)*. Recent studies have also demonstrated the potential for surfaces in the transport vehicles to be contaminated with methicillin-resistant *Staphylcoccus aureus* and other bacterial pathogens that may be a source of risk for both the patients and the prehospital healthcare workers (3,4).

Another site where emergency medical responders work is their station. In some cases, this may be a hospital. In others, it may be a fire house or a similar structure. Some responders may even work from their homes (e.g., rural volunteer units). This location is most important in terms of infection control in that responders must often return to that site to clean their equipment. Proper equipment and practices for this setting are obviously important.

OCCUPATIONALLY ACQUIRED INFECTIONS

Prehospital healthcare workers share many of the risks of occupationally acquired infections with healthcare workers in other settings. Although most of their contacts with infectious patients are relatively brief, the lack of information about the patient's conditions and difficult environmental conditions may increase their risk relative to the more controlled hospital environment.

There is relatively little documentation of the actual risk of occupationally acquired infections among emergency medical providers. Hepatitis B has probably received the most attention *(5)*. However, other infections have occasionally been reported. For example, there is a case report of toxic shock syndrome in a firefighter from a *Streptococcus pyogenes* infection acquired from cardiopulmonary resuscitation of an infected child *(6)*.

Although somewhat dated, the most complete documentation of the infectious diseases risk for prehospital healthcare workers comes from a survey of the emergency medical service in Portland, Oregon *(7)*. Using verbal and written exposure reports and other sources, the author documented 256 reported infectious disease exposure incidents over a 2-year period (1988–1989). The incidence of reported exposures was 4.4 per 1,000 emergency medical service

calls. Of these, approximately 24% involved respiratory exposure and 47% involved exposure of intact skin. Approximately 29% involved the exposure of nonintact skin or mucous membranes to blood or other body fluids or needlesticks. Fourteen incidents involving either needlesticks or exposure of nonintact skin or mucous membranes to blood or other body fluids were reported over the 2-year period. Although difficult to generalize to other emergency medical settings, these data do provide some sense of the scope of infectious diseases exposures for prehospital healthcare workers.

A survey of emergency medical service workers serving three inner-city emergency departments focused only on occupational blood contact *(8)*. Based on 62 self-reported blood contact incidents while transporting 2,472 patients, the study estimated that each worker had 12.3 blood contacts per year, including 0.2 annual percutaneous exposures. Bleeding patients were the main source of the exposures. A more recent study in Rhode Island used first-responder visits to Emergency Departments for blood or body fluid exposures found an average incidence rate of 23.29 visits per 100,000 ambulance runs (9).

Some older surveys of prehospital healthcare workers for hepatitis B markers provide some indication of these worker's risk for that disease. A study of 59 Seattle, Washington, paramedics found that 25% had evidence of antibody to hepatitis B surface or core antigen *(10)*. A similar survey of 338 Houston, Texas, paramedics found the prevalence of hepatitis antibodies to be approximately 26%, whereas a survey of Boston, Massachusetts, paramedics and emergency medical technicians found the prevalence to be approximately 28% *(11,12)*. A recent review article summarizes much of the available literature on hepatitis B and C risks for public safety workers including the marked decrease in Hepatitis B infection (13).

There is little documentation of the prevalence or the incidence of other occupationally acquired infections in prehospital healthcare workers. Based on the type of work, one would expect them to be potentially at risk for the same types of infections as other healthcare workers (especially emergency room workers) (see Chapters 73, 74, and 76). However, the incidence of particular infections is difficult to estimate.

ATTITUDES

Studies of emergency medical workers in the late 1980s and early 1990s showed significant concerns about the risk for acquiring blood-borne infections such as HIV, and many preferred not to treat HIV-infected patients *(14)*. More recent studies have found similar concerns among prehospital healthcare workers about pandemic influenza (15,16). An Australian study reported that 43% of prehospital healthcare workers would refuse to work during a pandemic (15). A similar study in the United States found that 12% would not report to work voluntarily during an influenza pandemic, and this would increase to 52% if risk of disease transmission to their family existed (16). To what extent these attitudes may have changed based on these workers' knowledge about and experiences during the recent H1N1 pandemic is not known.

Legal Requirements

Requirements for qualifications and training for prehospital healthcare workers vary from state to state. Most states do not have specific regulations regarding infection control practices and training, although many receive some training in this area and may be held to some general standard of practice. However, in the last few years, the federal government has gotten more involved in regulating infection control practices through occupational safety and health regulation, initially in the area of blood borne infections and more recently with airborne infections. Although the scope of this regulation (see Chapters 74 and 97) clearly covers prehospital healthcare workers, legal coverage of the standard varies. Many states do not provide occupational safety and health regulation or enforcement for public employees. The federal Occupational Safety and Health Administration (OSHA) does not cover public employees if the state does not provide such coverage. Coverage for volunteer rescue squads or fire departments also varies from state to state. More recently, OSHA has issued enforcement guidelines for protecting healthcare workers from the risk of tuberculosis. A more comprehensive infection control standard has been proposed and is currently under review.

One very troublesome issue for prehospital healthcare providers has been the issue of notification of providers after they have transported and cared for patients with infectious diseases. Although confidentiality protection for HIV-infected patients has contributed to this difficulty, other factors are also important. The infected patient may not be diagnosed for some time after admission. Most often, the prehospital care provider is not employed by the healthcare facility in which the patient is diagnosed, and infection control staff members in that facility may not be aware of the potential exposure of the prehospital care provider. Difficulties in communication and patient confidentiality further complicate this situation.

The Ryan White Act passed by Congress in 1990 mandated the development of a notification system for all prehospital care providers. For potentially fatal infections spread by airborne routes, healthcare facilities were required to notify the prehospital care provider if a patient whom he or she had transported was diagnosed with such an infection. For blood-borne infections, prehospital healthcare providers were allowed to inquire about a patient's diagnosis through a designated liaison if the prehospital healthcare provider was significantly exposed (e.g., needlestick) while transporting the patient. The law included a mechanism for review of the significance of the exposure and for protecting the confidentiality of the patient. The Department of Health and Human Services has now implemented this portion of the legislation. This requirement has helped to improve communication between prehospital care providers and hospitals regarding these issues.

PROGRAMS

Although infection control activities for prehospital healthcare workers are essentially the same as for other healthcare workers, some issues should be emphasized.

First, emergency medical providers are often unaware of the patient's diagnosis when arriving at the site of care or during transport to a healthcare facility. Therefore, standard protocols for the application of infection control procedures are especially important. Standard adherence to Universal Precautions (now Standard Precautions in healthcare facilities—see Chapters 73, 74, and 90) for all patient care activities is an obvious example. Another approach would be to initiate certain precautions for specific types of patients triggered by their symptoms or by knowledge of the presence of specific infectious diseases in their service area (17). Assuming that all infectious patients can be individually identified at the scene is not good practice. Any selective protocols need to be simple and easy to apply.

Second, proper protective equipment must be available for use at the scene. This includes equipment such as masks and gloves needed during patient care and equipment for disposal. Requiring used needles to be brought back to the station for disposal increases the risk for these providers *(8)*. Use of self-capping intravenous catheters for prehospital emergency care workers has been shown to result in a marked decrease in reported needlestick injuries *(18)*. The responsible parties need to ensure that necessary equipment is available. Proper equipment for cleaning used equipment in the station is also important. Cleaning such equipment in an area used for food preparation (e.g., responder's home or in a fire house) is not good practice. Proper procedures for medical waste disposal also need to be followed.

Third, proper infection control practices need to be adapted to the situation when the responder may have other job duties such as law enforcement or fire fighting. If the responder may arrive at the scene equipped for one type of duty but then must act as an emergency medical responder, proper equipment needed for infection control must still be provided.

Adequate training is extremely important (19). The application of standard practices throughout the provider organization is critical, because the providers usually will not base their use of precautions on prior knowledge of whether the patient has an infection. All staff members need to be appropriately trained and familiar with the infection control practices for the organization.

The threat of a bioterrorism attack will pose additional challenges to the development and delivery of infection control programs for prehospital workers. The bioterrorism threat will require additional training and other resources. Meeting this challenge will also place more emphasis on the need for improved administration of the infection control programs for these organizations and on the necessity for better and more rapid communication with public health authorities.

ORGANIZATION OF SERVICES

Perhaps the most difficult issue with the implementation of infection control programs for prehospital care providers is the organization of these services given the different types of organizations in which these responders work (20). Other than hospital-based responders, the organization and provision of the necessary training and medical services needed for a good infection control program must be implemented by the provider organization. The following suggestions apply mainly to other types of organizations (e.g., fire departments, rescue squads).

First, given the growing importance and complexity of good infection control programs for these workers, one person in each organization must be made fully responsible for this program. Implementation of program elements can be delegated to others in the organization, but there needs to be a single position responsible for the overall program. This responsibility includes training, procurement and placement of proper equipment, and medical follow-up. This person must seek input from all parts of the organization to ensure that the infection control program is being properly implemented. Joint labor–management health and safety committees are one means for obtaining this input.

Second, there needs to be some liaison with a medical provider capable of providing the medical care and advice needed for the infection control program. This could be the infection control staff at the major hospital serviced by the responder. It could also be the emergency medical department providing emergency medical training or consultation for the responder organization. This medical liaison is critical for two functions. First, they can assist with infection control training and provide consultation on specific issues. Second, they can provide the medical consultation needed for issues related to immunization, surveillance programs, and incident follow-up. Although both are important, the latter best illustrates the need for such a medical liaison. Prompt follow-up medical care is critical after an incident such as a needlestick injury. Attempting to arrange such follow-up without any planning or preparation puts a great burden on the person at risk. It is far better to have developed a comprehensive medical program as part of the overall infection control program.

Many prehospital care providers have limited finances and are already strained by the requirements of providing good medical service. Additional training and immunizations may add to the financial strains, but such assistance is critical to the development and operation of a good infection control program.

CONCLUSIONS

Although there are few data on the extent of occupationally acquired infections among prehospital healthcare workers, their risk appears to be similar to that of other emergency care workers. The development of good infection control programs for these workers is hampered by the nature of the work and the diversity of organizations providing such care. However, sound infection control programs for these workers have been developed and should be beneficial.

CHAPTER 79

Prevention of Occupationally-Acquired Infections in Posthospital Healthcare Workers

Charles W. Stratton IV

Infectious diseases can be transmitted from one human to another by a number of different mechanisms. Some of these mechanisms such as aerosolized respiratory droplets pose a direct threat to persons nearby, whereas others involve direct contact or exposure to biologic specimens from infected patients. Consequently, healthcare workers are recognized as being at risk for contracting an infection from patients or patient specimens (*1*,2,*3–6*). Such risks for occupationally acquired infections in healthcare workers have long been appreciated, as is evident by the protective clothing once worn during the plague epidemic of the 14th century (Fig. 79-1). The 2009 H1N1 influenza A pandemic *(7)*, the severe acute respiratory syndrome (SARS) outbreak *(8)*, the threat of bioterrorism *(9)*, and the ongoing acquired immunodeficiency syndrome (AIDS) epidemic *(10)* have all focused considerable attention on occupationally acquired infections. Such attention has resulted in Centers for Disease Control and Prevention (CDC) infection control guidelines for H1N1 influenza *(11)*, SARS *(12)*, Public Health Service (PHS) regulations for select agents and toxins *(13)*, and Occupational Safety and Health Administration (OSHA) regulations for blood-borne pathogens *(14)*. The reemergence of tuberculosis *(15,16)* similarly has resulted in CDC guidelines *(17)* and federally mandated regulations *(18)*.

Several important references related to reducing the risk of occupationally acquired infections in healthcare workers are readily available. The Clinical and Laboratory Standards Institute (CLSI) offers Document M29-A3, "Protection of Laboratory Workers from Occupationally Acquired Infections" (19). The CDC also offers guidelines for infection control in hospital personnel (20). These guidelines include recommendations for nonpatient healthcare personnel, management of exposures, prevention of transmission of infections in microbiology and biomedical laboratories, and prevention of latex barrier hypersensitivity reactions.

More persons in the United States today are employed in the healthcare sector than in any other industry *(21)*. Historically, most of these workers have been employed in the hospital setting. Thus, occupationally acquired infections in healthcare workers have received the greatest attention for workers in the hospital setting. Hospitals have developed comprehensive infection control programs and occupational health services that address the prevention of occupationally acquired infections. However, the horizons of infection control continue to expand in the 21st century *(21,22)* due to the recognition that the risk of infections transmitted from patients to healthcare workers is not limited to hospital workers but extends to out-of-hospital healthcare workers *(22)*. Today, healthcare is delivered in outpatient, transitional care, long-term care, rehabilitative care, home care, and private office settings *(21,23)*. The out-of-hospital setting is receiving increasing attention, and infection control requirements and activities have been established (*24*,25). This chapter covers the prevention of occupationally acquired infections in posthospital healthcare workers.

EXAMPLES OF POSTHOSPITAL HEALTHCARE WORKERS AND THEIR RISK FOR OCCUPATIONALLY ACQUIRED INFECTIONS

The definition of posthospital healthcare workers continues to expand and evolve *(21,23)*. Outpatient healthcare workers and medical personnel at reference laboratories, for example, can be either prehospital or posthospital healthcare workers. Following are examples of common categories of posthospital healthcare workers and their risk for occupationally acquired infections.

Pathologists and Medical Technologists

Although pathologists and medical technologists generally work in the hospital setting, they may be involved in either hospital care or posthospital care. For example, pathologists and medical technologists who are involved in surgical pathology, cytology, and clinical laboratories are usually involved in hospital care, whereas pathologists and morgue personnel involved in autopsies could be considered posthospital healthcare workers. Moreover, some pathologists and medical technologists work in reference

FIGURE 79-1 Protective garb worn by healthcare workers in the Middle Ages to protect themselves against plague.

laboratories that are not associated with a hospital. As nonhospital-associated freestanding operations, these reference laboratories most often do not have the assistance of hospital infection preventionists (IPs) and, hence, may fall short in providing protective measures appropriate to the infectious risks. The use of such freestanding reference laboratories for testing of specimens from hospitalized patients and for testing of specimens from patients in the prehospital and posthospital setting is increasing. This, in turn, has resulted in potential infectious risks for personnel involved in the packaging, handling, and transport of medical specimens. Accordingly, the PHS and CLSI have developed regulations and guidelines for proper procedures for the handling and transport of diagnostic specimens and etiologic agents (*13*,*26*). Moreover, the CLSI, the CDC, and the National Institutes of Health (NIH) address biosafety issues in microbiology and biomedical laboratories (19,*27*). All pathologists and medical technologists have unique risks for occupationally acquired infections because of contact with patient specimens. The risk for pathologists and medical technologists involved in clinical laboratories is covered in Chapter 77. The risks for pathologists who perform autopsies (19,*28,29*) are addressed in this chapter. Biosafety considerations for autopsies are important topics that often are not addressed by hospital infection control committees.

Home Healthcare Workers

Cost containment has shifted a great deal of medical care from the hospital setting to the outpatient setting. Accordingly, infection control issues in the home care and hospice setting are now being addressed (30). Although the home setting is considered to have fewer infection risks, studies have not confirmed this (31). Clearly, some patients receiving home healthcare have infections and, thus, pose a risk for home healthcare workers (30,*31*). Home healthcare patients are often elderly and may have unrecognized tuberculosis *(32)*. AIDS patients are another group of patients commonly cared for in a domiciliary setting *(33)*. Such infection risks in the home healthcare setting are only beginning to be studied. Research is needed to delineate such risks and to identify ways to minimize or prevent these infections from being transmitted to home healthcare workers. The topic of infection control in the home healthcare setting is discussed in Chapter 99.

Residential Long-Term Healthcare Workers

The number of persons entering assisted-living facilities and nursing homes for residential long-term care is substantial and is increasing. Many of these nursing home, residential care, and assisted-living patients enter such facilities directly from the hospital. The need for residential long-term care facilities to provide comprehensive infection control programs is well recognized (*34*,35). A number of infectious diseases problems are common to long-term care facilities and often are unappreciated *(36)*. A typical presentation of infections is generally acknowledged and may lead to delays in diagnosis and treatment of infections such as tuberculosis. The physical plant of many long-term care facilities is often a factor; many residents live in confined settings with few private rooms, and rooms appropriate for isolation often are not available. Finally, many long-term care facilities experience rapid turnover of personnel, and residential long-term care workers frequently have less training than those in the hospital setting. Long-term care facilities need a well-developed infection control program that in part identifies and minimizes the risk of occupationally acquired infections. Such programs can be developed best with the assistance of the hospital-based IP (37) (see Chapter 98).

Outpatient Healthcare Workers

The delivery of healthcare continues to shift from the hospital setting to the outpatient setting *(23)*. For example, an increasing number of surgical procedures are done on an outpatient basis, and postoperative complications are now seen by emergency departments (35). Thus, many outpatient healthcare workers can be considered posthospital workers and share the risks of posthospital healthcare workers *(36)*. The Joint Commission (TJC) is actively reviewing infection control programs for outpatient services that are affiliated with hospitals and has published standards for ambulatory surgery centers (37).

Rehabilitation Facility Workers

Another shift in providing healthcare has been the establishment of rehabilitation facilities. Follow-up care of many illnesses is now carried out in these facilities, and healthcare-associated infections are common *(38)*. Healthcare workers in these facilities have similar risks to hospital workers, yet these rehabilitation facilities may not be associated with a hospital and have access to IPs and policies. Surveillance and infection control measures, nonetheless, are needed (35).

Dialysis Facility Workers

Freestanding dialysis facilities have become very common. Clearly, the risk for many blood-borne pathogens in such facilities is high *(39)*. These centers may not have access to IPs and policies; however, surveillance and infection control measures clearly are needed. Accordingly, the CDC has published guidelines and recommendations for the prevention and control of dialysis-associated infection (40).

Healthcare Laundry Workers

Freestanding healthcare laundries serving multiple hospitals have been established in many cities. The risk for these workers is high for certain infections, including blood-borne pathogens because of the presence of sharp objects such as needles *(41)*. Workers in these laundries also are at risk for scabies. Laundries may not have access to IPs and policies. Guidelines and recommendations for the prevention and control of infections in the laundry setting are included in the CDC guidelines for infection control in healthcare settings (42).

Funeral Home Workers

The risk for exposure to infectious agents during autopsies is becoming better known and has resulted in guidelines for performing autopsies to minimize this risk *(17,28,29,43)*. In particular, guidelines designed to minimize the risk of human immunodeficiency virus (HIV) infection *(44,45)* and tuberculosis *(46)* have been published. Funeral home workers can be considered posthospital healthcare workers and share some of the same risks as a pathologist performing an autopsy *(47)*. A study of funeral practitioners has noted a low rate of occupational exposures and a high rate of hepatitis B vaccination in comparison with prior studies, which suggests both improved education for and compliance with the recommendations for preventing transmission of blood-borne pathogens in the workplace *(48)*. Such efforts should be continued.

Trash Haulers and Landfill Operators

The potential for exposure to infectious diseases in trash haulers and landfill operators is a very important issue *(49,50)*. Although minimal *(51,52)*, the risk is real and should be controlled. The proper disposal of medical waste is a key factor in controlling this risk; CLSI Document GP5-A "Clinical Laboratory Waste Management: Approved Guideline—Second Edition" addresses this topic (53), and federal law now requires compliance *(54)*.

EPIDEMIOLOGY OF OCCUPATIONALLY ACQUIRED INFECTIONS

Although quite a few pathogens can be transmitted to a worker in the healthcare setting, there are relatively few mechanisms by which such transmission can occur. The most common and important mechanisms of transmission are exposure to aerosols, exposure to blood or body fluids via direct contact or inoculation, and hand-to-mouth transmission. These are reviewed in some detail.

Exposure to Aerosols

The transmission of *Mycobacterium tuberculosis* occurs mainly by inhalation of droplet nuclei *(55)*. The influenza A virus may be spread by droplet nuclei *(7)*. Finally, there is also evidence that in some cases the coronavirus responsible for SARS has been spread by droplet nuclei *(8)*. These droplets are airborne particles and must be <5 μm in size to reach the alveolar spaces. Droplet nuclei can be produced when persons with upper and lower respiratory tract infections or with laryngeal infections speak, sneeze, cough, or sing. If these persons are in a healthcare setting such as a nursing home, and the diagnosis of tuberculosis, influenza A, or SARS is unknown, they become a risk to healthcare workers. Multidrug-resistant tuberculosis, SARS, and the 2009 H1N1 influenza A pandemic have refocused infection control efforts on airborne transmission of infection *(56–58)*. Consider, for example, the findings of a study investigating the potential for airborne distribution of influenza virus in an urgent care medical clinic *(59)*. This study collected airborne particles from an Urgent Care Clinic using stationary National Institute for Occupational Safety and Health (NIOSH) 2-stage cyclone aerosol sampler. The presence of airborne influenza A, influenza B, and respiratory syncytial virus (RSV) was determined using real-time quantitative polymerase chain reaction (PCR). The results of this study demonstrated that airborne particles containing influenza and RSV RNA were detected throughout this healthcare facility. Moreover, these airborne particles were small enough to remain airborne for an extended period of time and to be inhaled deeply into the respiratory tract *(59)*.

Clearly, airborne transmission of infection is important. Healthcare workers in laboratories are also at risk for airborne pathogens, because there are certain manipulations with patient samples that may produce an aerosol. An important example of such a manipulation is dropping of fluids containing microbial suspensions (e.g., urine containing *M. tuberculosis* microorganisms because of renal tuberculosis) onto a hard surface, producing an aerosol. Working with *Neiserria meningitidis* cultures is also considered a risk, and microbiology technologists should be immunized against this pathogen.

The risk of aerosolized *M. tuberculosis* from patients with unsuspected tuberculosis to posthospital healthcare workers such as home healthcare, nursing home, and clinic healthcare workers has become quite clear with the resurgence of tuberculosis in the United States. This risk increases in settings such as outpatient clinics where many sick people congregate in waiting and treatment rooms or halls and is also increased in communities where the incidence of HIV and/or tuberculosis is high. Outbreaks of tuberculosis among healthcare workers have occurred *(60–62)*; some have involved multidrug-resistant *M. tuberculosis (61,62)*. This risk can best be appreciated by considering the tuberculosis skin test conversion rates among healthcare workers that have ranged from 0.11% to 10% *(63,64)*. This risk increases considerably in healthcare workers who are exposed to persons from countries where tuberculosis is endemic, to HIV patients, and to patients known to have tuberculosis; the skin test conversion rates in such settings have ranged from 18% to 55% *(65,66)*. Transmission of tuberculosis to healthcare workers can be a major problem requiring prevention and control *(66)*. This problem is covered in great detail in Chapter 38.

A less well-appreciated, but equally important, risk for posthospital healthcare workers such as pathologists and funeral home workers is the risk for aerosolized transmission of infectious agents when working with deceased patients *(67)*. In addition to the risk of dropping body fluids containing microbial suspensions, a number of other procedures associated with autopsies produce an aerosol. For example, the Rokitansky method, in which the abdominal and thoracic organs are eviscerated as a unit, continues to be commonly used at autopsy. However, this method involves blunt blind dissection in both cavities, which is cumbersome and creates unnecessary aerosols. The CLSI now recommends removing organs singly (the Virchow technique) to avoid the more hazardous aerosolization risk associated with complete evisceration by the Rokitansky method (19). The CLSI also recommends that organs not be photographed until they have been fixed in formalin to decrease the risk of aerosolized microorganisms. Unfortunately, this does not provide complete protection against aerosolized *M. tuberculosis* because this pathogen survives fixation in formalin, although the fixation does decrease the number of mycobacteria and thus lessens the degree of infectivity *(68)*. The need to saw the calvarium is perhaps the most problematic autopsy procedure, because it unavoidably creates an aerosol. Aerosolization can be minimized by doing this procedure inside a plastic bag or plastic head frame, using a hand saw (difficult to do), or having a vacuum attached to the oscillating saw.

Another important risk factor for aerosolization during an autopsy is the use of side-arm faucet water aspirators to remove pleural or peritoneal fluids from these body cavities, because these aspirating devices produce an infectious aerosol. Side-arm faucet water suction devices should not be used in autopsy suites or in funeral homes. Instead, they should be replaced by surgical-type vacuum reservoirs that are attached to the hospital vacuum lines that have appropriate traps, filters, and regulators *(69)*.

Air flow in the autopsy suites (but not funeral homes) has been addressed by the American Society of Heating, Refrigerating, and Air Conditioning Engineers and by the CDC *(17)*. Adequate air flow is an important means of minimizing the risk of aerosolized pathogens. Both groups recommend that autopsy suites have at least 12 total air exchanges per hour and that autopsy room air be exhausted directly to the outside. In addition, the College of American Pathologists recommends that autopsies on high-risk patients be done only in rooms with good ventilation *(69,70)*.

It is important to have a clear understanding of what constitutes good ventilation. There are three important engineering factors that allow good ventilation/control of air within a room. First, negative pressure in the room should be maintained with respect to surrounding areas. This means that air should move from an area of low infectivity (i.e., outside the room) to an area of higher infectivity (i.e., inside the room). Second, the number of air changes in the room should be increased, which can substantially decrease the risk of the transmission of aerosolized pathogens by dilution and removal of these pathogens. Good ventilation also dictates that within-room mixing of air (i.e., ventilation efficiency) is adequate. This is usually accomplished by placing air supply outlets in the ceiling and exhaust inlets near the floor. This provides a downward movement of clean air, which travels through the breathing zone to the floor area for exhaust. Third, there should be adequate exhaust to the outside. Because the air in a high-risk room such as the autopsy suite is likely to be contaminated with infectious droplet nuclei, it should not be recirculated within the room or within the building. Instead, this potentially contaminated air should be exhausted to the outside, away from intake vents, people, and animals. An episode in a medical examiner's office in Syracuse, New York, *(62)* illustrates this point. Two workers in the Onondaga County medical examiner's office were infected by *M. tuberculosis* after they were exposed during autopsies on cadavers of prison inmates who had been infected with *M. tuberculosis* before death. In addition to the two workers who contracted clinical manifestations of tuberculosis, the tuberculin skin tests of 30% of the staff in the medical examiner's office converted to positive; this included a secretary whose desk was right under the ventilation system that circulated air from the morgue. The examiner's office responded to this episode by installing a new ventilation system, adding ultraviolet treatment of the air in the morgue, and initiating a respiratory protection program for personnel who worked in the morgue. Chapter 84 provides additional information on the design and maintenance of ventilation systems and prevention of airborne infections.

If adequate ventilation is not possible, healthcare workers who have any possibility of being exposed to aerosolized infectious particles should participate in a respiratory protection program. This is accomplished by wearing particulate respirators. A standard surgical mask is not a particulate respirator because lack of a tight face seal allows particles between 1 and 3 μm to be inhaled. Disposable particulate respirators are available. There are two types: the dust/mist filter, which excludes particles of 2 μm, and the fume filter, which excludes particles 0.6 to 1.0 μm. The CDC has published guidelines for the use of particulate respirators that include training, fit testing, care, and maintenance *(17)*; OSHA requires that a fume filter be used in particulate respirators *(18)*.

Exposure to Blood or Body Fluids via Direct Contact or Inoculation

It is well appreciated today that exposure to blood or body fluids via direct contact or inoculation can result in the transmission of a number of pathogens, of which the best known examples are hepatitis B virus (HBV) and HIV. The risk of HIV has increased the awareness of this problem. Numerous incidents of exposure of healthcare workers to HIV-infected blood have been evaluated in multiple prospective studies. These studies have identified HIV infections, usually involving individuals who had been punctured with needles; seroconversions are rare in staff members with intact skin. The rate of infection with HIV in healthcare workers after exposure to HIV-infected blood is approximately 0.3% *(71)*. It is instructive to review these seroconversions in healthcare workers analyzed by the CDC *(71)*, including six from prospective studies. Of the 34 individuals with

seroconversion, 12 were nurses, 11 were laboratory workers, 4 were physicians, and the other 7 were from other occupational groups. All underwent HIV seroconversion within 1 year of exposure, which had been mucocutaneous contact or percutaneous inoculation with blood or fluids containing HIV. Of the 28 percutaneous inoculations, 14 occurred while drawing venous blood and 2 occurred while drawing arterial blood; 5 of these were associated with carrying out intravenous infusions. Of the remaining injuries, two had occurred while injecting laboratory specimens, one while holding a specimen vial and two while manipulating a transvenous pacemaker. The remaining injuries were a result of other or unknown causes. Most of these percutaneous inoculations occurred after unexpected movement by a patient, a coworker, or equipment (seven exposures); inadequate needle disposal (nine exposures); and recapping of needles (seven exposures). Thirteen of these twenty-eight occurred through the workers' gloved hands. Of the five mucocutaneous exposures that resulted in seroconversion, one involved pressure hemostasis with an ungloved hand, three occurred during accidents involving blood spillage, and one involved an individual who was sprayed with concentrated virus. The CDC has concluded that the most frequent cause of occupational transmission of HIV or HBV is injury by a needle contaminated with the virus *(71)*. However, other mechanisms such as virus-contaminated body fluids being splashed on mucosal membranes and, to a lesser degree, skin clearly are important. Finally, but most importantly, postexposure prophylaxis with antiretroviral therapy with zidovudine (ZDV) has been found to be associated with a >80% reduction in the risk of occupational infection *(72)*. Prophylaxis clearly is important (73,*74*). For this reason, the PHS recommends that ZDV, lamivudine, and sometimes a protease inhibitor such as indinavir should be given prophylactically within 1 to 2 hours of a high-risk exposure to HIV *(74)* (see also Chapter 74).

PREVENTION

Prevention of Exposure to Blood and Body Fluids

Strategies are needed to reduce the occupational exposure to infectious agents by inoculation and/or direct contact. These are summarized in Table 79-1. Chapters 73, 74, and 76 cover healthcare-associated infections in healthcare workers caused by infectious agents acquired by exposure to blood and body fluids or by direct contact with other infectious substances. Specific risks associated with autopsies and appropriate preventive measures are discussed further in this chapter.

Autopsy protocols (19,*28,29,43–46,62,67–70,75*) should include measures to prevent or minimize exposure of the prosector and his or her assistant to potentially contaminated tissues and body fluids by direct contact or via inoculation. These measures should also prevent other areas of the autopsy suite from becoming contaminated so that bystanders, housekeeping personnel, and others will not be exposed to contaminated tissue and fluids. In short, autopsy precautions should be directed at the prevention of needlesticks, accidental cuts, and splash or direct contamination of mucous membranes or skin in any person who for any reason enters the autopsy suite. A rational approach to the safe conduct of autopsies includes (19,*28,29,43–45*) performance of autopsies by experienced and well-trained personnel, use of appropriate safety-oriented devices, a safe work environment, appropriate work practices, appropriate vaccination against vaccine-preventable diseases such as hepatitis B, and Standard Precautions (formerly Universal Precautions). These are discussed in greater detail.

Experienced and Well-Trained Personnel It is logical to assume that the risk of accidental injury is greatest among the inexperienced. This has been confirmed by a study wherein a laceration injury occurred in 1 of every

TABLE 79-1

Strategies for Risk Reduction from Occupational Exposure to Infectious Agents by Inoculation or Direct Contact

Strategy	*Comment*
Improved education/training on the safe handling and disposal of needles	This is an approach that will most rapidly reduce risks
Modifications of work-practice habits involving the way devices are used	The proper education/training should lead to such changes in habit
Improvements in personal protective equipment to include design, comfort, and availability and use and aimed at providing a better barrier between the blood/body fluids of a patient and the healthcare worker	Although this is a slower process than education, it can be done in a short period; education and training on the use of personal protective equipment obviously is needed to ensure its proper use
Engineering controls that are designed to eliminate the problem	Examples are needle-free devices for intravenous access and devices that cover a needle after use; these are the least rapid strategies to implement
Administrative controls and policies to ensure the implementation of such controls	Examples are postexposure management procedures and vaccination against HBV; these, like education and training, can be implemented quite rapidly

11 autopsies conducted by pathology residents. In contrast, one such injury occurred for every 53 autopsies performed by staff pathologists *(76)*. In addition, there should not be time constraints (self-imposed or otherwise) that could lead to hurried carelessness. For this reason, many pathology departments do not routinely conduct autopsies after 4 p.m.

There must be a sufficient number of experienced and well-trained personnel. Most autopsies are done with two persons, the prosector and his or her assistant. A logical recommendation is to have a third person (19,*29*). This third person functions as a circulator and does not directly participate in the autopsy procedure. Thus, the prosector and his or her assistant are "dirty," whereas the circulator remains clean, avoiding direct contact with contaminated tissues and body fluids. The circulator's tasks include the following:

1. Preparation of the 0.5% sodium hypochlorite solution from commercial bleach solution by diluting the latter 1:10. This solution is used to swab surfaces and/or to soak instruments.
2. Preparation of plastic biohazard bags for bagging soiled linens from the stretcher and for the gowns and scrub suits, which are deposited in plastic bags after the autopsy has been finished. Other plastic bags are prepared for waste such as gloves, masks, and foot covers, which will be incinerated. All bags must be labeled with a biohazard tag as per OSHA regulations *(14)* and with the disposition (incineration or laundering). Many medical centers now have colored bags to indicate the disposition (e.g., red for incineration, orange for laundering).
3. Assistance in the collection of all specimens by bringing clean containers to the table in which specimens may be placed. Also, the propane gas cylinder can be lit for the searing spatula. The circulator should do all paperwork such as laboratory requisitions. The circulator also ensures that specimen containers are washed clean and wiped with 0.5% sodium hypochlorite solution, the caps and covers are tightly fastened, the containers are labeled with biohazard tags and the deceased's name and hospital number, and the containers are placed in waterproof bags for transportation to the various laboratories for further processing and studies. Finally, the circulator attaches the accompanying laboratory requisitions to the proper specimens.
4. Assistance in providing any instruments or other supplies to the prosector.
5. Recording the organ weights and other descriptive notes, often using dictating equipment.
6. Adjusting the lamp and microphone over the autopsy table.
7. Communication with physicians, nursing supervisors, funeral directors, and other relevant personnel so that the telephone receiver does not get contaminated by the prosector.
8. Handling of containers in which tissues for fixation are to be placed to avoid contamination of the outer surface of the container.
9. Wiping up any drops of blood or body fluids that may fall on the floor around the autopsy table. Gloves should be worn. Paper towels and 0.5% sodium hypochlorite solution are used. This minimizes any soiling of the autopsy floor.

Use of Appropriate Safety Devices Safety devices for the routine autopsy have become an important aspect of Standard Precautions and are well documented and described (*14*,19). Particularly important in the autopsy suite are personal protective items. Eyes should be protected by goggles or face shields. Eye glasses are often worn instead of goggles or face shields but provide only minimal protection for the eyes. Goggles under which eye glasses can be worn are available. Surgical caps and masks should be worn for the performance of the autopsy. The mask is particularly important for the prevention of tuberculosis. These masks should not be the standard surgical mask but instead a disposable particulate respirator. OSHA, of course, requires a fume filter that excludes particles 0.6 to 1.0 μm in size. A number of pathologists use and are very pleased with powered respirators. Scrub suits should be worn. These should have long sleeves with either attached or separately provided water-repellent sleeves. The scrub suit must not be worn outside of the autopsy suite. Surgical gowns have been recommended (19). These should be waterproof disposable gowns with disposable forearm guards. A waterproof apron must be worn. Protective shoes should be worn. These are not to leave the autopsy suite. Waterproof shoe coverings should be worn over these shoes; these should be disposable. Two pairs of gloves are recommended because latex loses its integrity after a period of use *(77)*. Frequent changing of the outer pair is recommended. Many prosectors now use a fine-mesh metallic glove or a Kevlar "fish" glove. The latter was developed for workers cleaning fish and is very flexible and not clumsy. These Kevlar gloves can be purchased more cheaply from a sporting goods store than from a laboratory safety catalog. If such gloves are not worn routinely, they should be worn for high-risk procedures such as removing the pelvic organs or cutting the ribs. Ribs should not be cut through the bony portion but instead should be incised medial to the costochondral junction. Uncalcified cartilage, unlike bone cuts with spicules, will not scratch or puncture the skin if there is unexpected contact. A safe yet practical approach to gloving is a pair of tight-fitting latex surgical gloves underneath Kevlar gloves, with a larger pair worn on top of the Kevlar gloves. The outer pair should be changed frequently.

Other safety devices concern the use of instruments and their design. There should be only one blade in the dissection field at any given time. Blades with rounded ends are available. Changing blades should not be attempted with forceps and clamps, because these contribute to flying blades. When an oscillating (Stryker) saw is used, a vacuum device can be attached to minimize aerosols. Alternatively, a damp towel can be held over the saw by a second person or a clear plastic bag can be used to contain the entire procedure. Many prosectors now recommend that the cranium be opened with a hand saw, although this is exceedingly difficult. Blunt needles are available for aspirating body fluids.

Safe Work Environment It is the responsibility of each medical center to provide an adequately equipped and safe morgue facility. Of utmost importance is proper ventilation. Good lighting is important. A shower should be available in both the men's and women's locker rooms. All surfaces

should be of a material that is easy to clean (e.g., stainless steel); contaminated surfaces should be promptly cleansed and treated with an appropriate disinfectant. Floors and walls are best painted with enough coats of epoxy paint to seal such materials as cinder blocks, bricks, tile, and concrete. The floors should have drains connected with appropriate traps and filters to the hospital drainage system. High-pressure hose sprays should be avoided during the autopsy cleanup procedure. Similarly, side-arm faucet water aspirators that use the Bernoulli principle to create an inexpensive suction device should be avoided, because these may create an infectious aerosol. Instead, surgical-type vacuum reservoirs that are properly connected to the hospital system should be available.

Appropriate Work Practices Work practices and attitudes regarding the transmission of infectious diseases during the autopsy are evolving and are being shaped by new scientific evidence. For example, Bankowski et al. *(78)* described the postmortem recovery of human immunodeficiency virus type 1 (HIV-1) from the plasma and mononuclear cells of patients with AIDS. Recovery of infectious HIV-1 from 51% of blood samples of deceased AIDS victims should prompt pathologists and morticians to reevaluate policies regarding Standard Precautions and the handling of known HIV-1–infected cadavers. Of particular interest in this comprehensive evaluation is the authors noting that time from death until specimen acquisition was the only factor significantly associated with recovery of HIV-1. No HIV-1 was recovered from cadavers sampled more than 21 to 25 hours after death. Thus, delaying an autopsy for 24 hours may markedly decrease the potential HIV-1 infectivity. However, it is clear that the risks are not entirely eliminated by postponement of the autopsy. Infectious HIV has been recovered from tissue, bone, and blood after a postmortem interval of 6 days and from an unfixed spleen specimen stored at 20°C for 14 days after death *(79)*. Unfortunately, a 24-hour delay in the autopsy would not be well received by funeral directors and embalmers who already have identified significant delays in obtaining autopsied cases from hospitals *(80)*.

Hepatitis B Vaccination Healthcare workers with occupationally acquired HBV infection have died from this infection *(81)*. Despite all the concern about autopsies in the AIDS era, among the greatest risks to pathologists continues to be viral hepatitis *(82)*, both hepatitis B and hepatitis C. The prevalence of anti–hepatitis B antibody in pathologists is 27%, exceeded only by surgeons at 28% *(83)*. Accordingly, there are now available guidelines for prevention and strategies for surveillance for these and other blood-borne viruses *(84–86)*. The risk of acquiring HBV infection from occupational exposure depends on the nature and frequency of exposure to blood or to body fluids containing blood *(87)*. The risk of infection is at least 30% after a percutaneous exposure to blood from a hepatitis B e antigen-seropositive source *(88)*. Unlike HIV-1, hepatitis B vaccination is readily available, and all pathologists who are seronegative for hepatitis B should be vaccinated. Vaccination for hepatitis B has been shown to effectively prevent healthcare-associated hepatitis B *(89)*, and the CDC now recommends such vaccination *(90)* (see Chapter 73).

Standard Precautions The concept of Standard Precautions is quite simple. This concept recognizes that medical history and examination cannot reliably identify all patients with blood-borne pathogens; therefore, blood and body fluid precautions should be used *consistently* for *all* patient specimens. This approach is recommended by the CDC and is referred to as "universal blood and body fluid precautions" (now contained within Standard Precautions). All patient tissues, blood, and body fluids should be considered potentially infectious. This concept is further discussed in Chapters 73 and 74.

The concept of Standard Precautions is extremely important to undertakers and mortuary workers *(48,62)*. Although all deceased patients known to have a contagious disease should have the body bag marked with a biohazard or blood precautions tag to warn funeral directors and other mortuary personnel, not all cases of transmissible infectious diseases are identified at the time of death. The greatest risk for mortuary workers is the injection and distribution of embalming fluid, which displaces the natural body fluids. This procedure carries the risk of needlestick injuries, direct contact with displaced body fluids, and aerosolization of displaced body fluids. Therefore, mortuary workers should follow the same precautions as outlined for the autopsy.

After the introduction of Universal Precautions in 1986, with reaffirmation by the CDC in subsequent publications *(91,92)*, a modified approach *(93)* was published in 1988. The difference between these two proposals is that, initially, all body fluids were treated as if they were equally infectious; the modified approach excluded certain body fluids unless they were contaminated with blood. This topic has been further updated on a CDC/NIOSH web site (94). Experience has revealed that compliance with Standard Precautions is not ideal, with perceived risk and appropriate education as important factors in compliance *(95–99)*. Nonetheless, these guidelines remain prudent today and are summarized in Table 79-2.

It is important to realize that these guidelines are only for blood-borne infections and do not address transmission of aerosolized infectious pathogens. It was initially estimated that the cost of Universal Precautions would be between $1 and $10 per patient admitted to hospitals in the United States *(100)*. Subsequent data *(101)* found that the cost of implementing the CDC Universal Precautions in a university hospital was closer to the $10 per patient estimate. Finally, it should also be realized that no data confirm the efficacy of these guidelines. Nonetheless, they are sensible if they are followed correctly.

Prevention of Diseases Transmitted by Hand-to-Mouth Contact

Although airborne transmission and direct contact and inoculation of infectious pathogens are the most common risks for occupationally acquired infections in posthospital healthcare workers, hand-to-mouth transmission is nevertheless an important mechanism in the pathogenesis of these infections. Basically, the mechanism consists of a healthcare worker contaminating his or her hand(s) with an infectious agent from a patient and then transferring this pathogen to his or her mouth. As might be anticipated, most of these infections involve pathogens that cause diarrheal illnesses, although

TABLE 79-2

Modified Recommendations for Standard Precautions

Following the precautions with:
- Amniotic fluid
- Blood and other body fluids containing visible blood
- CSF
- Pericardial fluid
- Peritoneal fluid
- Pleural fluid
- Semen
- Synovial fluid
- Tissues
- Vaginal secretions

It is not necessary to follow the precautions with the following body fluids unless they are contaminated with blood:
- Feces
- Nasal secretions
- Sputum
- Sweat
- Tears
- Urine
- Vomitus

It is not necessary to follow the precautions with the following body fluids unless they are contaminated with blood:
- Feces
- Nasal secretions
- Sputum
- Sweat
- Tears
- Urine
- Vomitus

viral hepatitis is another infection that can be transmitted by hand-to-mouth contact (i.e., fecal–oral contamination).

Fecal–oral contamination occurs, because many patients have poor personal hygiene and soil the environment, after which poor hand-washing practices by healthcare workers result in transmission of the diarrheal illness to themselves.

Outbreaks of diarrhea in long-term care facilities appear to be a common problem *(36,102,103)*. The risk for nursing home workers and posthospital healthcare workers can be appreciated by reviewing the medical literature on this topic. Norovirus, for example, is a common cause of gastroenteritis in long-term care facilities *(104,105)*. During an average outbreak, almost one-third of residents and one-fifth of staff members are infected *(106)*. Noroviruses also are a common cause of outbreaks of acute gastroenteritis on cruise ships; poor cleaning practices in the restrooms have been a factor in such outbreaks *(107)*. Restroom and hand hygiene practices are likely to be important in long-term facilities as well. One nursing home report *(108)* described an outbreak of *Giardia lamblia* that originated with an infected meal and then progressed by fecal–oral contamination and eventually affected 35 residents and 38 employees of the facility. Other bacterial pathogens have caused serious gastroenteritis outbreaks in the nursing home setting. For example, *Escherichia coli* 0157:H7 caused a period of enteritis exceeding 18 days in 33% of nursing home residents and 13% of staff members *(109)*. HIV-infected patients are recognized as commonly having diarrhea caused by enteric viruses *(110)*. Finally, *Clostridium difficile* is now recognized as one of the most common causes of healthcare-associated infections in long-term care facilities *(111,112)*. This, in part, is due to the emergence of a new, more virulent strain of *C. difficile (113)*. Clearly, the problem of fecal–oral transmission in posthospital healthcare workers is important.

Healthcare workers who are at risk for outbreaks spread by fecal–oral contamination must practice good hand-washing techniques themselves and reinforce the importance of hand washing for everyone within the facility, including healthcare workers, competent patients and residents, and visiting friends and family members *(114)*. In addition, supplies of soap, towels, and gloves must be adequate throughout the facility. If hand washing is difficult to do, the substitution of a waterless alcohol hand rub containing emollients is recommended *(115,116)* except for situations in which *C. difficile* is the suspected pathogen *(117)*. Soap and water is superior to alcohol hand rub and antiseptic wipes for removal of *C. difficile (117)*. The use of gloves must include changing gloves before going from one patient to another and washing hands each time a pair of gloves is removed. This is because many pathogens can stick to the latex gloves after contamination, and adherence persists despite washing the gloves with soap, chlorhexidine, or isopropyl alcohol *(118)*.

Finally, although the concept of interrupting or preventing outbreaks of infections with hand washing began with Semmelweis in 1847 *(119)* and is still considered necessary, the role of hand washing remains problematic even today *(120)*. Moreover, compliance with hand-washing recommendations has been poor *(121–123)*, leading to the use of alcoholic preparations that require no water *(115,116,124)*. The subject of hand washing and hand disinfection is extensively covered in Chapter 91. Hand washing is vital to interrupt the fecal–oral route of transmission of infection *(125,126)*.

KEY INFECTIOUS PATHOGENS OF CONCERN FOR POSTHOSPITAL HEALTHCARE WORKERS

A diverse group of specific pathogens are involved in healthcare-associated infections. These are discussed in detail in Section V of this book. Management, evaluation, and training for healthcare workers exposed to healthcare-associated pathogens and to other highly infectious pathogens are important topics, and guidelines for this have been published *(127–129)*. Some infectious pathogens are of minimal risk for occupationally acquired infections in posthospital healthcare workers (e.g., coagulase-negative staphylococci). On the other hand, a number of infectious pathogens may or may not be associated with healthcare-associated infections *per se* but are of particular concern to posthospital healthcare workers such as prosectors and morticians. Examples of these pathogens include HIV-1, rabies virus, and human prion agents. These and other

agents of particular concern to posthospital healthcare workers are briefly discussed in this section.

Human Immunodeficiency Virus

HIV-1, as already mentioned, is responsible for altering the approach to prevention of occupational exposure to infectious agents in the healthcare workplace *(130)*. Mechanisms for transmission of HIV-1 to posthospital healthcare workers include direct contact (e.g., splashing mucosal surfaces) and inoculation. To date, there is no evidence for airborne transmission or fecal–oral transmission. Obviously, the posthospital healthcare workers at risk include all those involved with blood and body fluids of premortem or postmortem AIDS victims and the trash haulers and landfill operators who may be exposed to improperly disposed needles. The key to prevention of HIV-1 infections in these persons is to prevent exposure. A number of these preventive measures were discussed previously in this chapter.

Additional measures include decontaminating any spills of blood or body fluids in the work area with 5% sodium hypochlorite. All instruments used for AIDS patient care should be soaked in disinfectant for 30 minutes before routine washing. HIV-1 is inactivated by a wide range of disinfectants *(131,132)*, including 50% ethanol, 3% hydrogen peroxide, phenolic compounds (e.g., Lysol), iodophor compounds (e.g., Betadine), and sodium hypochlorite (household bleach) in a freshly prepared 1:10 dilution in water (final concentration: 0.5%). Because of their corrosive action, soaking instruments in bleach solutions should be limited to 30 minutes. Instruments using electronic devices that are an integral part of the equipment are more difficult to disinfect *(133)*. Fortunately, studies have shown that HIV-1 is reliably eliminated by routine disinfection for such electronic instruments *(134)*. In addition, there are now guidelines for disinfection practices for semicritical items *(135)* (see Chapter 80).

Disposable needles must be used and disposed of properly. These needles should not be purposely bent, clipped, recapped, or otherwise manipulated by hand. A puncture-resistant container for sharp instruments should be within easy reach and must be used. Needles and syringes should be dropped into this container after use.

The risk for acquiring HIV-1 infection from an occupational exposure has been studied extensively in numerous prospective studies. These studies consistently have documented a comparatively low rate of infection per percutaneous exposure. When results of these studies are combined, the magnitude of risk for HIV-1 infection appears to be 0.32% per exposure (136). This means that, in general, one might expect between three and four occupational infections for every 1,000 parenteral exposures to blood from HIV-1–infected patients. The risk may be higher or lower, depending on the severity of injury. For example, if a large volume of blood is injected via a needlestick injury, the risk is considered higher than with a low volume. The risk for HIV-1 infection after a mucous membrane exposure is believed to be lower but is not zero.

A retrospective case control study *(71)* to identify risk factors for HIV seroconversion among healthcare workers after a percutaneous exposure to HIV-infected blood found that workers were more likely to become infected if they were exposed to a larger amount of blood (i.e., presence of visible blood on the device before injury, needle had been placed directly into the patient's vein or artery, or deep injury). Increased rates of transmission were also noted from terminally ill patients with AIDS that has been attributed to an increased titer of HIV in the blood of these patients.

If a posthospital healthcare worker is exposed to HIV-1, a number of issues must be addressed (136,*137,138*). The first is immediate and aggressive first aid. This may not eliminate the risk for HIV-1 infection after exposure but is probably of some help in reducing the healthcare worker's postinjury emotional and psychologic stress. Current recommendations for first-aid measures after exposure to HIV-1 include vigorous scrubbing of parenteral injury sites for 10 minutes with 10% povidone-iodine solution. Milking the wound site to promote bleeding is encouraged. Exposure of mucous membranes to HIV-1 should be followed by irrigation of these membranes with normal saline for 15 minutes. Immediately after completion of these first-aid measures, the employee should report the occupational exposure formally to appropriate persons. These include the responsible supervisor and medical personnel (e.g., occupational medical service, if available; emergency room if not). The safety officer and quality assurance personnel, if applicable, may be informed as well. The healthcare worker should be advised, however, that discussing the exposure widely with coworkers may prove to be a problem if the exposure does result in infection.

When appropriate medical personnel are notified, they should evaluate the injury, review and repeat first-aid measures, and initiate medical and psychologic therapy. The postinjury evaluation should include the route of exposure, the source (i.e., specific blood or body fluid involved), the likely volume of inoculum, the condition of the source patient (i.e., the stage of HIV-1 infection and history of any antiretroviral therapy), the amount of time (if any) between the removal of a needle (or other sharp instrument) and the penetration of the exposed worker, the extent of injury, the type and promptness of first-aid measures, and the health status and anxiety level of the injured healthcare worker. The worker's hepatitis B and hepatitis C infection status should be determined, because occupational hepatitis is also a potential problem *(139,140)*. Postexposure management for occupational exposure to hepatitis B and C virus is discussed in each respective section.

All parenteral injuries should be treated equally with identical initial postinjury triage and management for all reported injuries. Such identical triage and initial management tactics allow for the potential lack of a precise occupational exposure history from an anxious healthcare worker, serve to reassure the injured worker, and place the institution in a clear position of healthcare worker advocacy.

Because of the common and often extreme emotional reaction of exposed healthcare workers, initial guidance about relative risk may not be comprehended at the initial encounter and should be reviewed again at later counseling sessions. It is important that several such counseling sessions are scheduled soon after the exposure. Counseling should include relevant estimates of the risk for infection associated with the type of exposure experienced by the healthcare worker. Most exposed workers

find the relatively low 1/360 to 1/500 risk associated with parenteral exposure to HIV-1 to be somewhat reassuring. However, the counselor must explain that these figures represent an average risk and that the worker's specific injury may be associated with a higher or lower risk for infection. Counseling initially should address the rationale for considering antiretroviral prophylaxis. This must be done quickly, because prophylaxis should be initiated as soon as possible after the exposure. Counseling must include a plan for follow-up to include such measures as serologic testing and additional counseling. In addition, counseling should include the possibility that the exposure may result in infection, and precautions that may avoid transmission to others should be discussed. Finally, counseling should provide emotional support for the worker and should address all questions related to the exposure. This support may need to include other members of the worker's family. It is useful to provide a standard written summary for the counseling and advice provided so that lack of retention of the information because of the emotional state of the worker does not cause a problem.

A major issue with occupational exposure to HIV-1 has been whether or not to offer chemoprophylaxis. Part of the reason for this problem was that initially it was unknown whether ZVD could prevent HIV infection if it was administered before and/or during exposure. An animal study used infant rhesus macaques to investigate the efficacy of ZVD prophylaxis in preventing simian immunodeficiency virus (SIV) infection after a low dose of SIV *(141)*. In this study, ZVD prophylaxis given 2 hours before the SIV dose effectively prevented infection. Clinical experience with ZVD prophylaxis *(71)* has revealed that such prophylaxis is useful. Currently, postexposure prophylaxis with multiple antiretroviral agents is recommended (*72*,73,*74*,135). This postexposure prophylaxis should be initiated within the first 2 hours but could be instituted as late as 1 to 2 weeks after HIV exposure in high-risk exposures. ZVD should be considered for all regimens because of sufficient data to support its use in this setting. In addition, lamivudine should be added to ZDV therapy for increased antiretroviral activity and activity against ZVD-resistant strains. Finally, a protease inhibitor such as indinavir should be added for high-risk exposure or if ZVD-resistant strains are likely. The latest CDC guidelines for prophylaxis *(74)* should be obtained and reviewed; these are constantly being updated.

Most medical centers offer antiretroviral postexposure chemoprophylaxis to healthcare workers who sustain parenteral or mucous membrane occupational exposures to HIV-1, provided these institutions are able to provide emergency evaluation, treatment, and consultation 24 hours a day, 7 days a week (see Chapter 74). Clearly, it is much more difficult to offer such therapy to many posthospital healthcare workers. Such workers may want to participate, if possible, in an ongoing program at a local medical center.

Counseling is an extremely important aspect of postexposure care of the employee yet can be extremely difficult to provide to most posthospital healthcare workers. Such counseling can be complex, labor intensive, and time consuming. Because guidelines for counseling have been established *(138)* and are used at many medical centers, such centers may be able to provide this kind of counseling to posthospital healthcare workers on a contractual basis. Appropriate follow-up is needed and can also be supplied by the counseling service. (For a more thorough review of this topic, see Chapter 74.)

Hepatitis B Virus

HBV is the etiologic agent causing a form of acute hepatitis that characteristically has a long incubation period (40–120 days) after the initial contact with the infectious virion *(142)*. This form of hepatitis was first recognized in 1833 after administration of smallpox vaccine that contained human lymphatic fluids. It was not until the 1940s and 1950s that the percutaneous transfer of material containing human serum was appreciated as an important route of transmission *(143)*. Unfortunately, the appreciation of this route resulted in the name "serum jaundice" or "serum hepatitis" as opposed to the shorter incubation variety (i.e., that caused by hepatitis A virus [HAV]), which was called "infectious hepatitis." Although the name serum jaundice accurately describes the first recognized route, it implies that this is the only route. That is not the case with HBV, because it has become clear in recent years that HBV is most commonly spread by routes that do not involve direct percutaneous transfer *(144)*. Examples of these routes include sexual contact, transmission from mothers to their newborn infants, and contact with saliva *(145,146)*.

HBV is a well-recognized occupational hazard in the healthcare worker *(81–87,146)*. As with HIV, the major routes involving healthcare workers are percutaneous transfer and exposure of mucosal tissues and open sores to blood or body fluids containing the virus. As already mentioned, the prevalence of HBV antibody in physicians such as pathologists and surgeons approaches 30% *(83)*. Overall, healthcare workers who frequently encounter blood or blood products have an intermediate risk for HBV infections; approximately 1% to 2% of these workers are hepatitis B surface antigen (HBsAg)-positive, whereas 15% to 30% of workers have other markers, such as anti-HBs and antibody to hepatitis B core antigen (anti-HBc).

For healthcare workers, the most effective way to deal with the threat of hepatitis B is by preexposure immunization with hepatitis B vaccine *(89,90,147)*. There are several types of vaccines available *(89)*: the first, a plasma-derived vaccine (Heptavax-B), was licensed in 1981; the second, a recombinant vaccine (Recombivax-HB), was licensed in 1986. Subsequently, a second recombinant vaccine (Engerix-B, SmithKline Beecham) was licensed. Prospective, double-blind, placebo-controlled trials have shown >90% protection *(89,148)*. Those few individuals who later became infected with HBV have been among the vaccine recipients who failed to convert. The presence of anti-HBs antibody in the serum of healthcare workers after a course of three vaccinations with hepatitis B vaccine can be detected by serologic testing, and the occasional failure of vaccination can be identified. Healthcare workers who do not respond to or do not complete the primary vaccination series should be revaccinated with a second three-dose vaccine series or evaluated to determine whether they are HBsAg seropositive *(90)*. Revaccinated healthcare workers should be tested for anti-HBs at the completion of the second series. Vaccine-induced antibodies decline gradually with time, and as many as

60% of those who initially respond to vaccination will lose detectable anti-HBs by 8 years *(89)*.

Healthcare workers should be vaccinated against hepatitis B not only to protect their own health but also to prevent spread of hepatitis B infection to patients *(149)* or their families if healthcare workers become infected. Despite the availability of vaccines for over a decade, with vaccination available for free in many cases, and the cogent reasons for such vaccination, there are still healthcare workers involved in posthospital care who have not been vaccinated. The worry of possible transmission of AIDS in the plasma-derived vaccine has been shown to be groundless *(150)*. The ability of the HBV vaccine to protect healthcare workers is clearly documented *(89)*. There is no reason whatsoever for healthcare workers not to receive vaccination against HBV, and all should do so *(90)*.

For those workers who are not vaccinated and who are potentially exposed by accidental needlestick injury, mucosal splash with body fluids, or other such incident, a plan similar to that outlined for HIV is useful. In addition, postexposure prophylaxis of hepatitis B with hepatitis B vaccine and hepatitis B immune globulin is useful and should be undertaken (151). (For additional details, see Chapters 73 and 75.)

Other Types of Viral Hepatitis

The ability to serologically diagnose acute viral hepatitis caused by infection with HAV or HBV has led to the recognition of other viral hepatitis agents that are predominantly transmitted either by the percutaneous (blood) or the fecal–oral routes. These agents are grouped as non-A, non-B hepatitis agents. The first of these described was the hepatitis delta virus (HDV), which is made up of a single-stranded RNA (1,700 nucleotides) surrounded by a protein coat *(152)*. This protein coat is encoded by the delta virus genome and has an outer membranous protein envelope consisting of HBsAg encoded by the HBV. This HBsAg-containing envelope allows the delta virus to attach to hepatic cells. The delta virus is then infectious, provided that the new host has an active hepatitis B infection, because the delta virus coinfects with and requires the function of active HBV for its replication. The delta virus can infect a person simultaneously along with hepatitis B or superinfect a person who is already infected with hepatitis B. The duration of infection caused by the HDV, of course, is determined by the duration of and cannot outlast the hepatitis B infection. HDV thus also should be screened for in any situations involving potential transmission of hepatitis B infection.

The molecular cloning of a parenterally transmitted virus, referred to as hepatitis C virus (HCV), has been described *(153)* and is the recognized cause of most non-A, non-B hepatitis in the developed world. Because of its blood-borne route of transmission and its prevalence, this type of hepatitis is of concern to healthcare workers and is discussed separately.

A second form of non-A, non-B hepatitis is epidemiologically distinct, is transmitted by the fecal–oral route, and causes large epidemics in third-world countries. Additional work *(154)* suggests that a single virus is responsible for most of this form of hepatitis seen worldwide. This virus is hepatitis E virus *(155)* and, like HAV, is of somewhat less concern to the healthcare worker, because this virus is transmitted mainly by the fecal–oral route *(155,156)*.

Hepatitis C

HCV is of particular concern to healthcare workers, because its routes of transmission are similar to those of hepatitis B and because of the potential long-term untoward effects. In fact, one of the most disturbing features of HCV to healthcare workers exposed to this agent is the fact that this viral infection of the liver has a propensity to progress to chronic hepatitis with biochemical evidence of chronic hepatitis *(157)*. In addition, long-term follow-up studies have shown that 20% to 25% of patients ultimately develop cirrhosis of the liver *(158)*. HCV is currently considered one of the major causes of cirrhosis in the United States and ranks as one of the most common reasons for liver transplantation in adults. Multiple reports have shown that healthcare workers are at risk for HCV infection *(159–162)*.

Although HCV was not cultured until 2005 *(163,164)*, the previous development of an assay to detect antibody against a recombinant polypeptide of HCV had allowed investigators to pursue the epidemiologic study of this infection *(158,165)*. Confirmatory HCV testing has become commercially available and includes the Abbott MATRIX-HCV immunoblot assay and the Ortho-Chiron recombinant immunoblot assay. However, the interpretation of these anti-HCV assay results is limited by several factors, including lack of detection in approximately 5% of infected patients; inability to distinguish between acute, chronic, and past infections; prolonged interval between the onset of acute illness with HCV and seroconversion; and false-positive rates as high as 50% in areas with low prevalence of HCV infection *(165)*.

Despite these remarkable advances, the epidemiology of this infection in healthcare workers is not yet totally clear. What is now known is that transmission of HCV by blood products has been unequivocally demonstrated. Hepatitis C is, in fact, the most common cause of post-transfusion hepatitis *(158)*. Transmission of HCV by organ transplantation has also been documented *(166)*. In addition, this form of hepatitis has been shown to have sexual, vertical, and intrafamilial spread *(158)*.

Several case reports have demonstrated transmission of HCV infection from anti-HCV–seropositive patients to healthcare workers as a result of accidental needlestick injury or lacerations with sharp instruments *(152,165)*. The rate of anti-HCV seroconversion averaged 1.8%, whereas studies using HCV detection by PCR assay revealed a 10% rate of transmission *(154,157,162)*.

High-risk source patients for HCV infection clearly would include parenteral drug abusers, hemophilia patients, dialysis patients, multiply transfused patients, and patients with unexplained acute or chronic liver disease or enzyme elevation. Recommendations for follow-up of healthcare workers after occupational exposure to HCV now exist *(167,168)*, and regulations for the prevention of occupationally acquired HCV have been established *(13)*. Unfortunately, effective postexposure prophylaxis for HCV has not yet been determined (151). However, combination therapy of chronic hepatitis C with peginterferon-alpha-2a and oral ribavirin now appears to be a valuable first-line treatment option *(169,170)*. This combination may in time

prove useful for postexposure prophylaxis for HCV. In the meantime, medical centers should use the same general approach for HCV as that used for HIV and HBV. This approach should also be applied to posthospital healthcare workers. Readers wishing more information are referred to Chapter 73.

Mycobacterium Tuberculosis After a steady decline in the incidence of tuberculosis from the mid-1950s to the mid-1980s, tuberculosis again become a major health problem in the United States in the 1990s because of an increasing incidence and a similar increase in the numbers of multidrug-resistant and extensively drug-resistant strains *(15,16,171–175)*. The reasons for this resurgence are complex and include the AIDS epidemic, increasing numbers of homeless persons, increased migration from countries with a high prevalence of tuberculosis, increased crowding in housing among the poor, increased numbers of residents in long-term care facilities, decreased compliance in tuberculosis therapeutic regimens, atypical tuberculosis in AIDS patients, delayed recognition of tuberculosis, delayed recognition of multidrug-resistant and extensively drug-resistant isolates, and inadequate hospital facilities for treating patients with tuberculosis *(55–57,175–179)*. Fortunately, the response to this resurgence of tuberculosis after a sluggish start has become vigorous in the first decade of the 21st century *(15,180–182)*. Factors that have reversed this resurgence are new diagnostic methods for the detection of *M. tuberculosis (183)*, the use of directly observed therapy *(184,185)*, a four-drug/2-month "intensive phase" for treatment of active tuberculosis *(185)*, increased duration (at least 18 months) for treatment of multidrug-resistant tuberculosis *(186)*, interferon-gamma release assays for detection of active and latent tuberculosis *(187,188)*, increased collaboration and convergence between programs to control HIV and tuberculosis *(189)*, and development of new treatment regimens for the therapy of tuberculosis *(190)*.

The risk of acquiring tuberculosis by healthcare workers has increased *(60–67,179,191–197)*. The healthcare-associated transmission of tuberculosis has even been reported from patients with draining lesions *(198,199)*. Posthospital healthcare workers, like all others, are at greater risk for tuberculosis, as shown by outbreaks in nursing homes *(36)* and autopsy suites *(62,67)*.

Measures to prevent the spread of tuberculosis in posthospital healthcare workers are identical to those used to prevent the spread in hospitals and include infection control measures for source control and engineering controls (*17,18*,19,20,*27–29,46,55–57,66,175,179,191–197,200–202*,203,*204*). Infection control measures should be standardized based on guidelines from the CDC *(17)* and documented in an appropriate procedure manual. Such control measures include rapidly identifying and isolating patients with presumptive tuberculosis, having patients cover their mouths when coughing, using masks, and initiating antituberculosis therapy as soon as the diagnosis is established. Engineering controls include rapid air exchange, negative pressure ventilation with air exhausted to the outside, high-efficiency particulate air (HEPA) filters, and ultraviolet lighting.

Many healthcare-associated outbreaks of tuberculosis have been related to lack of adherence to proper infection control measures for tuberculosis and/or to inadequate functioning of isolation rooms *(60–62,67,179,191–197,200,205–207*). If hospitals have such problems, facilities in which posthospital healthcare workers are employed, such as nursing homes or patient homes, can hardly be expected to have adequate isolation rooms.

Although establishing and maintaining effective isolation rooms is necessary for preventing transmission of tuberculosis, such rooms alone do not offer sufficient protection for healthcare workers who take care of patients. This is because such persons who are physically close to patients with active tuberculosis will be exposed to infectious aerosols before ventilation can reduce the aerosol concentration significantly. Thus, healthcare workers who care for patients should wear appropriate respirators. The definition of an appropriate respirator currently is debated. The CDC *(17)* defines an appropriate respirator as a "particulate respirator," which is the same as what the NIOSH calls a "disposable dust/mist-filter respirator." This type of respirator excludes particles 2 μm in diameter. NIOSH instead recommends a fume filter that uses HEPA-filter media and excludes particles 0.6 to 1 μm in size (*18*,203). Finally, all types of air-purifying respirators allow some inward leakage of droplet nuclei around the face seal. Particulate respirators permit 10% to 20% leakage, whereas a powered air-purifying respirator with qualitative or quantitative fit testing as recommended by NIOSH (203) for high-risk medical procedures such as bronchoscopy permit far less leakage (2%).

The CDC has released guidelines for preventing tuberculosis transmission in healthcare facilities *(17)*, and these should help clarify many of these issues. In addition, OSHA has issued guidelines *(18)* for enforcement of tuberculosis protection requirements as delineated in 29 CFR 1910. Key elements of these tuberculosis protection requirements include the following:

1. Healthcare workers who enter rooms occupied by patients with suspected or known infectious tuberculosis or who perform high -risk procedures (e.g., bronchoscopy) on such individuals must use NIOSH-approved fume (HEPA) respirators. In addition, a complete respiratory protection program, including qualitative (irritant fume) or quantitative fit testing of respirators, must be in place.
2. Records of employee exposure to tuberculosis, of tuberculosis skin testing, and of medical evaluations and treatment for tuberculosis are subject to OSHA record-keeping rules. Any positive tuberculosis skin test in an employee (other than preemployment) would be presumed to be occupational and should be recorded on the OSHA 200 log as would any clinical infection with tuberculosis.
3. Medical management of any clinical manifestations of tuberculosis, including positive skin tests, is the responsibility of the employer. In addition, employers are expected to establish tuberculin skin testing programs for the early identification of personnel with tuberculosis infection. Finally, like the blood-borne pathogen standard, employers will be expected to have yearly training/educational programs for tuberculosis.

This clarification of OSHA regulations (*18*,203) is an important step. Employers of healthcare workers, including

posthospital healthcare workers, have access to additional information on control of tuberculosis *(204–207)*, including the use of screening methods *(208)* and vaccination *(209)*. Readers wishing additional information on tuberculosis should read Chapter 38, whereas Chapter 84 addresses the design and maintenance of hospital ventilation systems.

Methicillin-Resistant *Staphylococcus aureus*

Infections caused by *Staphylococcus aureus* continue to be an important clinical problem *(210)*. The emergence of antimicrobial resistance has been a consistent characteristic of this pathogen, with resistance generally following the widespread use of a particular antimicrobial agent *(211)*. This was seen for penicillin in the 1940s, erythromycin in the 1950s, methicillin in the 1960s, ciprofloxacin in the 1980s, and vancomycin in the 21st century. Methicillin-resistant *S. aureus* (MRSA) was first seen in the 1960s *(212)*, although the term *methicillin resistance* is somewhat misleading, because these isolates are resistant to many other antimicrobial agents such as aminoglycosides, clindamycin, and ciprofloxacin *(211)*. This multidrug resistance makes therapy and/or eradication very difficult. Moreover, resistance has raised the level of concern in healthcare workers who frequently deal with healthcare-associated staphylococcal infections and worry that they may become colonized and subsequently become infected themselves or transmit this pathogen to their patients or family *(213)*. Since the 1960s, MRSA has spread worldwide *(214)* and today is commonly found in hospitals, in long-term care facilities, and in the community *(215–217)*. The isolation of community-acquired MRSA (CA-MRSA) in children with no identified predisposing risk *(217)* has turned out to represent a genetic variant of MRSA that has a different epidemiology as well as additional virulence factors *(218–220)*. Infections caused by these strains are more invasive and serious *(220–222)*. Moreover, these CA-MRSA isolates are now recognized as causes of healthcare-associated infections as well as community-acquired infections (*223*,224). Finally, a report of vancomycin-resistant *S. aureus* containing the *vanA* resistance gene *(225)* is also very worrisome, because vancomycin resistance in MRSA strains will make therapy of staphylococcal infections more difficult.

Colonization of healthcare workers by MRSA is common *(226,227)*. Although the carriage on the hands may only be transient, *S. aureus* (susceptible strains, MRSA, as well as CA-MRSA) adheres well to human nasal epithelial cells *(228)*. Thus, healthcare workers may develop nasal colonization with MRSA, which may then be a significant risk factor for infection by spread of the colonizing strain *(229–232)*. Because of Standard Precautions, many healthcare workers now routinely wear gloves when taking care of patients. Unfortunately, some wear one pair of gloves while taking care of several patients. Hand washing sometimes is done between patients without removing the gloves. Staphylococci adhere well to gloves, and washing while wearing gloves facilitates transfer of *S. aureus* through the glove to the hand *(118)*. Obviously, hands should be washed between patients with an antimicrobial soap *(233)* after gloves are removed. Finally, the transfer of MRSA from inanimate objects to the hands of healthcare workers may be a real problem, as suggested by a number of reports *(233,234)*.

Although this possible mechanism remains controversial *(235)*, there are clearly instances wherein inanimate objects can harbor staphylococci or perhaps other pathogens. Perhaps wearing gloves facilitates the transfer of the staphylococci from the inanimate object to the hands of a healthcare worker and, if improper hand-washing techniques are used, from the hands of a healthcare worker to a patient. Bedrails are now thought to be an important factor in such transmission and may deposit microorganisms on the clothing of healthcare workers as they lean on these rails while caring for a patient. The use of gowns and gloves for routine care of patients with known colonization by multidrug-resistant microorganisms has been recommended.

Healthcare workers have noted the increase in healthcare-associated infections caused by MRSA and CA-MRSA and are concerned that they may become colonized or infected. Such concern about infection is valid because a number of reports have documented these kinds of infections in healthcare personnel *(236–239)*. The frequency of nasal carriage among healthcare workers ranges from 20% to 90%, but fewer than 10% of healthy nasal carriers disperse the microorganisms into the air *(240)*. However, nasal carriers with upper respiratory symptoms can disseminate the microorganisms into the air more effectively. It should be somewhat comforting for healthcare workers to understand that they alone can prevent such colonization and infection with MRSA and CA-MRSA by proper hand-washing techniques. These techniques are covered in detail in Chapter 91. Additional information on *S. aureus* and on MRSA is found in Chapters 28 and 29.

Group A Streptococcus

Group A streptococcus (*Streptococcus pyogenes*) is one of the most common and ubiquitous of human pathogens and causes an impressive variety of infections. These include acute pharyngitis, impetigo, sinusitis, otitis, peritonsillar and retropharyngeal abscess, pneumonia, scarlet fever, toxic shock syndrome, erysipelas, cellulitis, lymphangitis, puerperal sepsis, vaginitis, myositis, gangrene, necrotizing fasciitis, septic arthritis, suppurative thrombophlebitis, bacteremia, endocarditis, and osteomyelitis. This pathogen is also known for its association with two nonsuppurative sequelae, acute rheumatic fever and acute glomerulonephritis, which are related to specific immune responses by the host. It is no wonder that healthcare workers are concerned about this microorganism.

Although *S. pyogenes* is not generally viewed as a healthcare-associated pathogen, outbreaks have long been recognized in hospitals and nursing homes *(241–245)*. There has been a marked increase in the incidence of such invasive group A streptococcus outbreaks in long-term care facilities in the past decade *(246–249)*, which has resulted in guidelines for infection control measures for these outbreaks *(250)*. Clearly, healthcare workers are at risk for this infection. Because *S. pyogenes* is such a ubiquitous pathogen, it is sometimes difficult to determine if a healthcare worker has a group A streptococcal infection resulting from work-related acquisition. However, a number of streptococcal infections in healthcare workers have been determined as having been caused by work-related acquisition (*251–253*,254). One report describes

the healthcare-associated transmission of *S. pyogenes* from a single source patient to 24 healthcare workers *(251)*. Another report describes food-borne streptococcal pharyngitis, which has been reported in a hospital pediatric clinic after a potluck luncheon *(255)*. Healthcare workers with pharyngitis or other types of suspected streptococcal infections are at risk for spreading this pathogen *(256)*. It is for this reason that restriction from patient care activities and food handling is indicated for healthcare workers with group A streptococcal infections until 24 hours after they have received appropriate antimicrobial therapy. Unfortunately, asymptomatic carriage of *S. pyogenes* by healthcare workers also can result in healthcare-associated outbreaks *(257,258)*.

S. pyogenes is spread by respiratory secretions. This mechanism of transmission is facilitated by the ability of these streptococci to adhere to human epithelial cells *(259)* via lipoteichoic acid *(260)*, which is present at the streptococcal cell wall and adheres to surface fibronectin on the surface of oral epithelial-cell membranes *(261)*. Heavily encapsulated strains of *S. pyogenes* seem to be more readily transmitted from person to person than those with minimal hyaluronate capsules *(262)*. This may be due to initial attachment of the capsule to mucus. Once attached to human oral mucosal tissue, the group A streptococci may simply become colonizers of this tissue or may cause invasive streptococcal infections. Throat cultures of approximately 20% of persons with pharyngitis are positive for *S. pyogenes*. Unfortunately, if a control group without pharyngitis is also cultured for *S. pyogenes*, the cultures of 20% of this group are also positive *(263)*. It can be very difficult to differentiate active streptococcal pharyngitis from the carrier state in a symptomatic person *(264)*. The antistreptolysin O titer and other similar antibody titers such as antihyaluronidase and antideoxyribonuclease (DNase) B are useful, because these antibody titers become elevated with active infection. These are obtained as a single serologic test referred to as the "streptozyme test."

In addition to causing acute pharyngitis, group A streptococci are also recognized for their propensity to cause skin infections. This is not unexpected when the pathogenesis of these skin infections is understood *(265–267)*. Fibronectin, the attachment site on mucosal epithelial cells, is also found in other tissues such as blood vessels, in which it stabilizes cell-to-cell and cell-to-substrate attachments to endothelial cells *(268)*. Damage to blood vessels and their endothelial lining such as caused by an abrasion or any other such skin surface wound will expose the fibronectin in the endothelial lining and offer an attachment site for *S. pyogenes*. With 20% of the population carrying group A streptococci in their nasopharynx, it is no wonder that occasional injuries to the skin become infected by this pathogen.

S. pyogenes remains susceptible to β-lactam agents and is relatively easy to treat. If it were not for the sequelae of acute rheumatic fever, acute glomerulonephritis, and the superantigen-mediated toxic shock-like syndrome *(269)*, these infections would not cause as much concern. Concern by healthcare workers has increased, because acute rheumatic fever, after declining for many years *(270)*, has reemerged and remains a problem *(271–273)*. This reemergence has been associated with a concomitant increase in the rate of isolation of very mucoid well-recognized rheumatogenic serotypes (e.g., types 1, 3, 5, 6, and 18). Healthcare workers are also concerned because of the risk for toxic shock–like syndrome *(269)* as well as necrotizing fasciitis *(274)*.

The sequelae of acute rheumatic fever and acute glomerulonephritis are now thought to be related to a host immune response to M protein. This protein is a filamentous molecule consisting of two protein chains in a coiled configuration extending about 60 nm above the surface of the streptococcus *(275)*. The M protein is antigenic and can be studied using serologic methodology. The M serotype appears to be one marker of rheumatogenicity, and those M serotypes most strongly associated with acute rheumatic fever and postpharyngeal and postpyodermal acute glomerulonephritis appear to be distinct *(276)*. Indeed, purification of M protein combined with genetic analysis demonstrated distinct structural differences between the M proteins of streptococci associated with acute rheumatic fever and those known to cause acute glomerulonephritis *(277)*. Of clinical interest is the fact that the acute rheumatogenic sequelae can be prevented by timely treatment of the streptococcal infection, whereas the glomerulonephritic sequelae are not influenced by antimicrobial therapy.

From the viewpoint of prevention of streptococcal infection and sequelae in posthospital healthcare workers, it does not make sense to be overly concerned about a pathogen that can be isolated from 20% of the population in general. However, it would seem prudent to exercise some precautions when taking care of a patient with known group A streptococcal infection. Precautions taken for wound infections with a multiresistant pathogen such as MRSA (to include gloves and gown) would appear appropriate. This is because group A streptococci have been transmitted from infected patients to healthcare workers who have had contact with infectious secretions *(253,278)*, and these infected workers have subsequently acquired a variety of group A streptococcal illnesses. Equally important is the fact that healthcare workers who have become carriers of group A streptococcus have been linked to sporadic outbreaks of streptococcal infections *(257,279–281,281a)*. Finally, the therapy of group A streptococcal infection has not progressed as rapidly as has the understanding of the molecular pathogenesis *(282)*. However, intravenous immunoglobulin promises to be useful for superantigen-mediated aspects (toxic shock and necrotizing fasciitis) of these infections *(269,283)*. (See Chapter 32 for additional information on group A streptococci.)

Rabies Virus

The name rabies comes from Latin and means "rage" or "madness." Rabies has been the object of human fear ever since the disease was first recognized in antiquity *(283–286)*. Cases of human rabies have increased in the United States in the past decade; many of these are bat-associated cryptic cases *(287)*. In addition, rabies virus was inadvertently transmitted to a lung transplant recipient through donor lungs *(288)*. Needless to say, concerns about the possible transmission of rabies to healthcare workers are not at all surprising. This concern most often involves hospitalized patients with suspected or proven

rabies *(288,289)* and hospital healthcare workers. When patients with rabies die, similar concerns are voiced by prosectors and funeral home employees. Moreover, these posthospital healthcare workers may deal with a death by unknown causes in which the etiologic role of rabies is not recognized until long after the autopsy has been completed *(287,290,291)*.

These concerns, although not supported by actual case reports in which healthcare workers have become infected by rabies after direct exposure to an infected patient, are based on some data that clearly allow for the possibility of such transmission. Indeed, rabies virus has been detected in human tracheal secretions, saliva, nasal swabs, and human tissue *(292)*, and airborne transmission in a laboratory worker has been described *(293)*. The virus has never been detected in blood, urine, or feces.

As with any potentially transmissible infection, it is useful for the healthcare worker to understand the pathogenesis of rabies *(294,295)*. The rabies virus is present in high titers in infected animal's saliva and is introduced during a bite to the muscle tissue of another animal. The virus may attach to and enter peripheral nerve cells immediately if a large inoculum is introduced by the bite such that the virus comes into direct contact with these nerves. Otherwise, the inoculated rabies virus attaches to the plasma membrane of human cells via a glycoprotein present in spikelike projections in the outer layer *(296)*. The binding sites on human cells include the nicotinic acetylcholine receptor *(295,297,298)*. The rabies virus is thought to be amplified by replication in skeletal-muscle cells near the site of inoculation until the concentration of virus is high enough to reach and attach to unmyelinated sensory and motor terminals *(299)*. Once attached to the nerve cells, rabies virus readily enters the cell and then is able to travel through nerve cells, from one to the next via the endplates, until it reaches the central nervous system *(295)*. Once the virus has entered the nerve cells, it is sequestered from the immune system, and immunization from then on will be ineffective. Once the rabies virus reaches the spinal cord via retrograde axoplasmic flow at 8 to 20 μm/day, the first symptoms of the infection—pain or paresthesia at the wound site—may occur *(300)*. This is followed by rapidly progressive encephalitis as the virus first disseminates through the central nervous system. The virus next spreads throughout the body along the peripheral nerves. On arrival via peripheral nerves to the salivary glands, the rabies virus is shed in the saliva.

It is also useful to review the epidemiology of rabies *(284,285,301)*. Human rabies is uncommon in the United States, primarily because of canine rabies–control programs *(302)*; dogs account for <5% of the cases in animals. Moreover, ready access to improved human rabies biologicals (human rabies immune globulin and rabies vaccine) has been responsible, in part, for preventing rabies in those persons who come in contact with potentially rabid animals such as bats (bat rabies is enzootic in the United States, with cases reported from all of the 48 contiguous states), raccoons (predominant in the southeast and the northeast), foxes (predominant in upper New York State and upper Vermont and in parts of Arizona and Texas), skunks (predominant in California and the south-central and north-central states), and coyotes (predominant in the Texas panhandle) *(302)*.

Of particular interest to IPs are the reports of postexposure prophylaxis in healthcare workers and other patient contacts exposed to rabies virus–infected patients. In one report of postexposure prophylaxis in healthcare workers and other patient contacts exposed to a rabies virus–infected lung transplant recipient *(288)*, 131 individuals received postexposure prophylaxis. In another more extensive review of 14 patients with rabies treated in US hospitals, 576 contacts of the patients received postexposure prophylaxis *(303)*. Seventy percent of those who received postexposure prophylaxis were medical personnel, most of whom were nurses and respiratory therapists, who would have the greatest contact with saliva. Another example is that of an 11-year-old girl in New York State who died of unknown meningoencephalitis and was later found to have died of rabies when routine histopathologic slides of brain tissue were reviewed approximately 2 to 3 weeks after death. When the diagnosis was made, rabies postexposure prophylaxis was administered to 55 persons, including 8 family members, 3 friends, 35 healthcare workers, 5 members of the autopsy team, 3 transport personnel, and 1 mortician *(304)*. Thus, 9 of 55 were posthospital healthcare workers.

It becomes clear that a rapid antemortem diagnosis of rabies is important. The importance of early suspicion of rabies is not that the course or prognosis of rabies can be altered but that measures to reduce the number of persons potentially exposed to the rabies virus during patient care can be reduced, and those persons who are candidates for postexposure prophylaxis can be more easily identified. Rabies should be considered in the differential diagnosis of any acute progressive encephalitis of unknown etiology. Other clinical manifestations suggestive of rabies include paresthesia at an injury site, hydrophobia (patients withdraw when offered a drink and have difficulty swallowing oral secretions; strep throat is often blamed for these symptoms), and copious salivation. Once rabies is considered in the differential diagnosis, it is possible to make an antemortem diagnosis of human rabies by sending cerebrospinal fluid (CSF), serum, saliva, and a biopsy of nuchal skin or of brain tissue to the state laboratory or CDC. Tests for antibodies in the CSF and serum, PCR and/or cultures for rabies virus in the CSF and saliva, and fluorescent antibody tests for tissue inclusion bodies can be diagnostic.

Appropriate infection control measures are also indicated whenever a patient is suspected of being infected with rabies *(305)*. Wearing gloves, gowns, masks, and goggles is indicated for healthcare workers caring for possible rabies patients or for posthospital healthcare workers participating in an autopsy, involved in transportation of the patient, or involved as a mortician. In addition, respiratory precautions (as done with active pulmonary tuberculosis) should be followed, because transmission of rabies through inhalation of virus has been reported *(293)*. Finally, inoculation of some body fluids (such as saliva or tracheal secretions but not blood) could transmit rabies and should be avoided, whenever possible, with preventive measures such as those used for AIDS patients.

Preexposure and postexposure rabies prophylaxis for healthcare workers has not been satisfactorily delineated to date, and decisions regarding postexposure prophylaxis

should be made on a case-by-case basis after discussion with public health authorities (*90*,306). The lack of such guidelines for who should or should not receive prophylaxis most often results in overuse of this preventive measure because of the high level of anxiety associated with rabies *(303)*. Fortunately, guidelines for preexposure and postexposure rabies prophylaxis have been published (*90*,306).

When rabies prophylaxis has been decided on as a preventive measure, there are clear guidelines as to how to do this (*90*,306). The initial step in prevention of rabies in healthcare workers is to provide local wound treatment if the exposure involved a wound (e.g., a leak of respiratory or salivary fluid through a latex glove to an open wound). This treatment is similar to that used for HIV exposure via an open cut or wound and consists of immediate and thorough washing with soap and water or other antiseptic preparation for hand washing. Human rabies immune globulin and rabies vaccine should be used for exposures that do not involve bites and bites and cuts if the risk is high (e.g., a confirmed case and a respiratory therapist who cared for this patient). Ideally, treatment with both should be initiated for high-risk healthcare personnel. For low-risk persons, treatment can be delayed for up to 48 hours, pending the results of laboratory tests. The usual interval between exposure and prophylactic treatment for rabies in the United States is 5 days *(303)*, which suggests that delays do not seriously compromise successful prophylaxis. Remember, however, that the pathogenesis involves a race between the immunoglobulins and attachment and penetration of the rabies virus to nerve cells. Thus, it would be predicted that longer delays and/or higher inoculum would occasionally result in prophylaxis failures, which have been reported *(307,308)*.

Prophylaxis consists of both the human rabies immune globulin and the vaccine. The human rabies immune globulin should be given in a dose of 20 IU/kg, with one-half of this dose injected into the wound area and one-half given intramuscularly in the gluteal area (*90*,306). Two rabies vaccines are currently available: human diploid-cell rabies vaccine (HDCV: Imovax Rabies) and rabies vaccine absorbed (RVA), which are considered equivalent in terms of safety and efficacy. There are two approved schedules for rabies prophylaxis in the United States. The first is a postexposure schedule in which 1.0 mL of HDCV or RVA is given intramuscularly in the deltoid area on days 0, 3, 7, 14, and 28. The preexposure schedule is most often given to persons such as veterinarians and other animal handlers and consists of 1.0 mL of HDCV or RVA intramuscularly in the deltoid area on days 0, 7, and 21 or 28 or 0.1 mL of HDCV intradermally in the skin over the deltoid area on days 0, 7, and 21 or 28. Boosters may be needed if there is continuing risk. Although vaccination is quite effective, it is not 100% effective *(307,308)* (see also Chapter 47).

Transmissible Spongiform Encephalopathies Agent

The transmissible spongiform encephalopathies are fatal degenerative diseases of the central nervous system in humans and animals and are caused by prions *(309,310)*. They may be sporadic, infectious, or inherited in origin and are caused by abnormally configured (i.e., misfolded) host-encoded cell-surface glycoproteins (i.e., prion proteins) that accumulate in the central nervous system. Human prion diseases include Creutzfeldt–Jakob disease (CJD), variant Creutzfeldt–Jakob disease (vCJD), Gerstmann–Straussler–Scheinker (GSS) Syndrome, Fatal Familial Insomnia (FFI), and Kuru *(310,311)*. Although quite rare, CJD and other prion diseases are considered risks for healthcare workers (*312,313*,314,*315–317*). Because this progressive and relentless neurologic disease has a 100% mortality rate, it is not surprising that healthcare workers are aware of this rare disease and are concerned about the risk for transmission.

As mentioned, CJD is one of four recognized forms of spongiform encephalopathies in humans. The other three are kuru, GSS syndrome, and FFI syndrome. There are also animal forms of spongiform encephalopathies; these include scrapie in sheep and goats, bovine spongiform encephalopathy in cattle and dairy cows, chronic wasting disease in deer and elk, and transmissible mink encephalopathy. The bovine spongiform encephalopathy has been termed "mad cow disease" by the lay press. These spongiform encephalopathies are caused by novel infectious pathogens called prions, which means *pro*teinaceous *in*fectious particles. In brain tissue, prions produce a characteristic neuropathic spongiform change. Infected brains demonstrate an amyloid protein that can transmit an identical spongiform disease to experimentally inoculated animals *(310)*. Because prions resist inactivation by procedures and agents that modify nucleic acids and appear to consist only of an amyloid protein *(318)*, they are now considered an abnormal derivative of normal protein that results in infectious amyloidosis. Thus, it appears that an abnormal protein seed molecule is able to serve as a template for the alteration of other normal precursor protein molecules that are being produced in the cell. The precursor protein of these various spongiform encephalopathies is a membrane-anchored glycoprotein that is found in most organs and cell types, including neurons. The exact biologic role of the protein is unknown. Mutation of the coding gene for this precursor protein has been associated with inherited spongiform encephalopathies. This precursor protein coded by the mutated gene then acts as a template to normal precursor protein and alters these proteins such that they aggregate as insoluble amyloid fibrils. The mutation of this gene can be transmitted to offspring, and about 10% of cases of CJD have been recognized as familial. Familial prion disease causing CJD appears to be an autosomal dominant disorder, like Huntington's disease. When the mutated gene is introduced in genetic material of transgenic mice, spontaneous central nervous system degeneration occurs and is characterized by clinical signs indistinguishable from experimental murine scrapie. Moreover, neuropathy consisting of spongiform morphology and astrocytic gliosis is identical in both. The genetic disease caused by this mutation can become contagious if the altered protein itself is transmitted from an infected host to a normal host. This has been seen in experimental animal inoculation and with iatrogenic inoculation of humans by contaminated neurosurgical instruments, corneal and dura mater grafts, and pituitary hormone extracts. This abnormal protein then acts as a seed molecule to produce template-induced polymerization of normal proteins in the newly infected host.

From an infection control standpoint, the risk of transmission of CJD in healthcare personnel is limited to inoculation with infected central nervous system material (314,*319,320*). Clearly, patients known or suspected of having CJD become a potential problem in this regard if neurosurgical or autopsy procedures are performed. The precautions taken to prevent the transmission of HIV would be similar, the goal being to reduce the chance of inoculation injury. The World Health Organization has developed infection control guidelines for transmissible spongiform encephalopathies *(312)*. Moreover, a detailed description of precautions has been developed by the American Neurological Association and is available for those who wish more details *(313)*. The Centers for Disease Control (CDC) has also addressed infection control issues involving prions (314). Finally, comprehensive recommendations for disinfection and sterilization of medical devices contaminated by the Creutzfeldt–Jakob agent have been published (321) (see also Chapters 47 and 80).

SECTION XI
Disinfection and Sterilization

CHAPTER 80

Selection and Use of Disinfectants in Healthcare

William A. Rutala and David J. Weber

Each year in the United States there are 46 million procedures performed on hospital inpatients and an estimated 53.3 million surgical and nonsurgical procedures performed during ambulatory surgery visits *(1,2)*. For example, there are at least 10 million gastrointestinal endoscopies per year *(3)*. Each of these procedures involves contact by a medical device or a surgical instrument with a patient's sterile tissue or mucous membranes. A major risk of all such procedures is the introduction of infection. Failure to properly disinfect or sterilize equipment carries not only the risk associated with breach of the host barriers but also the additional risk of person-to-person transmission (e.g., hepatitis B virus) and transmission of environmental pathogens (e.g., *Pseudomonas aeruginosa*).

Achieving disinfection and sterilization through the use of disinfectants and sterilization practices is essential for ensuring that medical and surgical instruments do not transmit infectious pathogens to patients. Because it is unnecessary to sterilize all patient-care items, healthcare policies must identify whether cleaning, disinfection, or sterilization is indicated based primarily on the items' intended use.

Multiple studies in many countries have documented lack of compliance with established guidelines for disinfection and sterilization *(4,5)*. Failure to comply with scientifically based guidelines has led to numerous outbreaks *(5–9)*. In this chapter, which is an update of previous chapters (10,11,*12*,13–16), a pragmatic approach to the judicious selection and proper use of disinfection processes is presented. This is based on well-designed studies assessing the efficacy (via laboratory investigations) and effectiveness (via clinical studies) of disinfection and sterilization procedures.

DEFINITION OF TERMS

Sterilization is the complete elimination or destruction of all forms of microbial life and is accomplished in healthcare facilities by either physical or chemical processes. Steam under pressure, dry heat, ethylene oxide (ETO) gas, hydrogen peroxide gas plasma, ozone, hydrogen peroxide vapor, and liquid chemicals are the principal sterilizing agents used in healthcare facilities. Sterilization is intended to convey an absolute meaning, not a relative one.

Unfortunately, some health professionals as well as the technical and commercial literature refer to "disinfection" as "sterilization" and items as "partially sterile." When chemicals are used for the purpose of destroying all forms of microbiological life, including fungal and bacterial spores, they may be called *chemical sterilants*. These same germicides used for shorter exposure periods may also be part of the disinfection process (i.e., high-level disinfection).

Disinfection describes a process that eliminates many or all pathogenic microorganisms on inanimate objects, with the exception of bacterial spores. Disinfection is usually accomplished by the use of liquid chemicals or wet pasteurization in healthcare settings. The efficacy of disinfection is affected by a number of factors, each of which may nullify or limit the efficacy of the process. Some of the factors that affect both disinfection and sterilization efficacy are the prior cleaning of the object; the organic and inorganic load present; the type and level of microbial contamination; the concentration of and exposure time to the germicide; the nature of the object (e.g., crevices, hinges,

and lumens); the presence of biofilms; the temperature and pH of the disinfection process; and, in some cases, the relative humidity of the sterilization process (e.g., with ETO).

By definition then, disinfection differs from sterilization by its lack of sporicidal property, but this is an oversimplification. A few disinfectants will kill spores with prolonged exposure times (e.g., 3–12 hours) and are called *chemical sterilants*. At similar concentrations but with shorter exposure periods (e.g., 20 minutes for 2% glutaraldehyde), these same disinfectants will kill all microorganisms with the exception of large numbers of bacterial spores and are called *high-level disinfectants*. *Low-level disinfectants* may kill most vegetative bacteria, some fungi, and some viruses in a practical period of time (≤10 minutes), whereas *intermediate-level disinfectants* may be cidal for mycobacteria, vegetative bacteria, most viruses, and most fungi but do not necessarily kill bacterial spores. The germicides differ markedly among themselves primarily in their antimicrobial spectrum and rapidity of action. Table 80-1 is discussed later and consulted in this context.

Cleaning, on the other hand, is the removal of visible soil (e.g., organic and inorganic material) from objects and surfaces, and it normally is accomplished by manual or mechanical means using water with detergents or enzymatic products *(17)*. Thorough cleaning is essential before high-level disinfection and sterilization since inorganic and organic materials that remain on the surfaces of instruments interfere with the effectiveness of these processes. Also, if the soiled materials become dried or baked onto the instruments, the removal process becomes more difficult and the disinfection or sterilization process less effective or ineffective. Surgical instruments should be presoaked or rinsed to prevent drying of blood and to soften or remove blood from the instruments. *Decontamination* is a procedure that removes pathogenic microorganisms from objects so they are safe to handle, use, or discard.

[a]See text for discussion of hydrotherapy.
[b]The longer the exposure to a disinfectant, the more likely it is that all microorganisms will be eliminated. Ten-minute exposure is not adequate to disinfect many objects, especially those that are difficult to clean because they have narrow channels or other areas that can harbor organic material and bacteria. Twenty-minute exposure at 20°C is the minimum time needed to reliably kill *M. tuberculosis* and nontuberculous mycobacteria with a 2% glutaraldehyde. With the exception of >2% glutaraldehydes, follow the FDA-cleared high-level disinfection claim. Some high-level disinfectants have a reduced exposure time (e.g., ortho-phthalaldehyde at 12 min at 20°C) because of their rapid activity against mycobacteria or reduced exposure time due to increased mycobactericidal activity at elevated temperature (e.g., 2.5% glutaraldehyde at 5 min at 35°C, 0.55% OPA at 5 min at 25°C in automated endoscope reprocessor).
[c]Tubing must be completely filled for high-level disinfection and liquid chemical sterilization; care must be taken to avoid entrapment of air bubbles during immersion.
[d]By law, all applicable label instructions on EPA-registered products must be followed. If the user selects exposure conditions that differ from those on the EPA-registered products label, the user assumes liability from any injuries resulting from off-label use and is potentially subject to enforcement action under FIFRA.
[e]Material compatibility should be investigated when appropriate.
[f]A concentration of 1,000 ppm available chlorine should be considered where cultures or concentrated preparations of microorganisms have spilled (5.25% to 6.15% household bleach diluted 1:50 provides >1,000 ppm available chlorine). This solution may corrode some surfaces.
[g]Pasteurization (washer-disinfector) of respiratory therapy or anesthesia equipment is a recognized alternative to high-level disinfection. Some data challenge the efficacy of some pasteurization units.
[h]Thermostability should be investigated when appropriate.
[i]Do not mix rectal and oral thermometers at any stage of handling or processing.
The selection and use of disinfectants in the health-care field is dynamics, and products may become available that are not in existence when this chapter was written. As newer disinfectants become available, persons or committees responsible for selecting disinfectants and sterilization processes should be guided by products cleared by the FDA and the EPA as well as information in the scientific literature.
A, Heat sterilization, including steam or hot air (see manufacturer's recommendations, steam sterilization processing time from 3 to 30 min).
B, Ethylene oxide gas (see manufacturer's recommendations, generally 1–6 h processing time plus aeration time of 8–12 h at 50–60°C).
C, Hydrogen peroxide gas plasma (see manufacturer's recommendations for internal diameter and length restrictions, processing time between 28 and 72 min), ozone, and hydrogen peroxide vapor (see manufacturer's recommendations for internal diameter and length restrictions).
D, Glutaraldehyde-based formulations (≥2% glutaraldehyde, caution should be exercised with all glutaraldehyde formulations when further in-use dilution is anticipated); glutaraldehyde (1.12%) with 1.93% phenol/phenate; glutaraldehyde (3.4%) with 26% isopropanol. One glutaraldehyde-based product has a high-level disinfection claim of 5 min at 35°C.
E, Ortho-phthalaldehyde (OPA) ≥0.55%
F, Hydrogen peroxide 7.5% (will corrode copper, zinc, and brass) and 2.0% accelerated hydrogen peroxide.
G, Peracetic acid, concentration variable but 0.2% or greater is sporicidal. Peracetic acid immersion system operates at 50–56°C. This liquid chemical sterilant processing system should be used only for processing heat-sensitive semicritical and critical devices that are compatible with the sterilant and processing system and cannot be sterilized by other fully validated terminal sterilization methods for the device.
H, Hydrogen peroxide (7.35%) plus 0.23% peracetic acid; hydrogen peroxide 8.3% plus peracetic acid 7.0%; hydrogen peroxide 1% plus peracetic acid 0.08% (will corrode metal instruments).
I, Wet pasteurization at 70°C for 30 min with detergent cleaning.
J, Hypochlorite, single use chlorine generated on-site by electrolyzing saline containing >650–675 active free chlorine; (will corrode metal instruments).
K, Ethyl or isopropyl alcohol (70–90%).
L, Sodium hypochlorite (5.25–6.15% household bleach diluted 1:500 provides >100 ppm available chlorine).
M, Phenolic germicidal detergent solution (follow product label for use-dilution).
N, Lodophor germicidal detergent solution (follow product label for use-dilution).
O, Quaternary ammonium germicidal detergent solution (follow product label for use-dilution).
P, Accelerated hydrogen peroxide 0.5% (follow product label).
MR, Manufacturer's recommendations.
NA, Not applicable.

Terms with a suffix "cide" or "cidal" for killing action also are commonly used. For example, a germicide is an agent that can kill microorganisms, particularly pathogenic microorganisms ("germs"). The term *germicide* includes both antiseptics and disinfectants. *Antiseptics* are germicides applied to living tissue and skin, whereas *disinfectants* are antimicrobials applied only to inanimate objects. In general, antiseptics are only used on the skin and not for surface disinfection, and disinfectants are rarely used for skin antisepsis, because they may cause injury to skin and other tissues. Other words with the suffix "cide" (e.g., virucide, fungicide, bactericide, sporicide, and tuberculocide) can kill the type of microorganism identified by the prefix. For example, a bactericide is an agent that kills bacteria *(18–23)*.

A RATIONAL APPROACH TO DISINFECTION AND STERILIZATION

Over 40 years ago, Earle H. Spaulding *(19)* devised a rational approach to disinfection and sterilization of patient-care items or equipment. This classification scheme is so clear and logical that it has been retained, refined, and successfully used by infection preventionists and others when planning methods for disinfection or sterilization (10,11,*18,20,22,24,25*). Spaulding believed that the nature of disinfection could be understood more readily if instruments and items for patient care were divided into three categories based on the degree of risk of infection involved in the use of the items. The three categories he described were critical, semicritical, and noncritical.

Critical Items

Critical items are so called because of the high risk of infection if such an item is contaminated with any microorganism, including bacterial spores. Thus, it is critical that objects that enter sterile tissue or the vascular system be sterile, because any microbial contamination could result in disease transmission. This category includes surgical instruments, cardiac and urinary catheters, implants, and ultrasound probes used in sterile body cavities. Most of the items in this category should be purchased as sterile or be sterilized by steam sterilization if possible. If heat-sensitive, the object may be treated with ETO, hydrogen peroxide gas plasma, ozone, hydrogen peroxide vapor, or by liquid chemical sterilants if other methods are unsuitable. Table 80-1 lists several germicides categorized as chemical sterilants. These include ≥2.4% glutaraldehyde-based formulations; hypochlorous acid/hypochlorite 650 to 675 ppm free chlorine (or 400–450 ppm free chlorine at 30°C); 1.12% glutaraldehyde with 1.93% phenol/phenate; 3.4% glutaraldehyde with 26% isopropanol *(26)*; 7.5% hydrogen peroxide; 7.35% hydrogen peroxide with 0.23% peracetic acid; 8.3% hydrogen peroxide with 7.0% peracetic acid; 0.2% peracetic acid; ≥0.55% ortho-phthalaldehyde; 2.0% accelerated hydrogen peroxide; and 1.0% hydrogen peroxide with 0.08% peracetic acid *(27)*. Liquid chemical sterilants can be relied upon to produce sterility only if cleaning, to eliminate organic and inorganic material, precedes treatment and if proper guidelines as to concentration, contact time, temperature, and pH are met.

Semicritical Items

Semicritical items are those that come in contact with mucous membranes or nonintact skin. Respiratory therapy and anesthesia equipment, gastrointestinal endoscopes, bronchoscopes, laryngoscope blades, esophageal manometry probes, endocavitary probes, anorectal manometry catheters, infrared coagulation probes, cystoscopes *(28)*, and diaphragm fitting rings are included in this category. These medical devices should be free of all microorganisms, although small numbers of bacterial spores may be present. Intact mucous membranes, such as those of the lungs or the gastrointestinal tract, generally are resistant to infection by common bacterial spores but susceptible to other microorganisms such as bacteria, mycobacteria, and viruses. Semicritical items minimally require high-level disinfection using chemical disinfectants. Glutaraldehyde, hydrogen peroxide, ortho-phthalaldehyde, and peracetic acid with or without hydrogen peroxide are cleared by the Food and Drug Administration (FDA) and are dependable high-level disinfectants provided the factors influencing germicidal procedures are met (Table 80-1) *(27)*. When a disinfectant is selected for use with certain patient-care items, the chemical compatibility after extended use with the items to be disinfected also must be considered.

The complete elimination of all microorganisms in or on an instrument with the exception of small numbers of bacterial spores is the traditional definition of high-level disinfection. FDA's definition of high-level disinfection is a sterilant used for a shorter contact time to achieve a 6-$\log_{10}$ kill of an appropriate mycobacterium species. Cleaning followed by high-level disinfection should eliminate sufficient pathogens to prevent transmission of infection *(29,30)*.

Laparoscopes and arthroscopes entering sterile tissue should be sterilized between patients. As with flexible endoscopes, these devices may be difficult to clean and sterilize due to intricate device design (e.g., long narrow lumens, hinges). Meticulous cleaning must precede any sterilization process. Newer models of these instruments can withstand steam sterilization.

Semicritical items should be rinsed with sterile water after high-level disinfection to prevent their contamination with microorganisms that may be present in tapwater, such as nontuberculous mycobacteria *(9,31)*, *Legionella (32,33)*, or gram-negative bacilli such as *Pseudomonas (22,24,34–36)*. In circumstances where rinsing with sterile water rinse is not feasible, a tapwater or filtered water (0.2-μm filter) rinse should be followed by an alcohol rinse and forced air drying (11,36–39). Forced air drying markedly reduces bacterial contamination of stored endoscopes, most likely by removing the wet environment favorable for bacterial growth *(37)*. After rinsing, items should be dried and stored (e.g., packaged) in a manner that protects them from recontamination.

Some items that may come in contact with nonintact skin for a brief period of time (i.e., hydrotherapy tanks, bed side rails) are usually considered noncritical surfaces and are disinfected with low- or intermediate-level disinfectants (i.e., phenolic, iodophor, alcohol, chlorine) *(40)*. Since hydrotherapy tanks have been associated with spread of infection, some facilities have chosen to disinfect them with recommended levels of chlorine *(40)*.

Noncritical Items

Noncritical items are those that come in contact with intact skin but not mucous membranes. Intact skin acts as an effective barrier to most microorganisms; therefore, the sterility of items coming in contact with intact skin is "not critical." Examples of noncritical items are bedpans, blood pressure cuffs, crutches, bed rails, bedside tables, patient furniture, and floors. The five most commonly touched items in the patient environment have been quantitatively shown to be bed rails, bed surface, supply cart, overbed table, and IV pump *(41)*. In contrast to critical and some semicritical items, most noncritical reusable items may be decontaminated where they are used and do not need to be transported to a central processing area. There is virtually no documented risk of transmitting infectious agents to patients via noncritical items *(35)* when they are used as noncritical items and do not contact nonintact skin and/or mucous membranes. However, these items (e.g., bedside tables, bed rails) could potentially contribute to secondary transmission by contaminating hands of healthcare workers or by contact with medical equipment that will subsequently come in contact with patients *(18,42–45)*. Table 80-1 lists several low-level disinfectants that may be used for noncritical items. The exposure time listed in Table 80-1 is equal to or >1 minute. Most Environmental Protection Agency (EPA)–registered disinfectants have a 10-minute label claim. However, multiple investigators have demonstrated the effectiveness of these disinfectants against vegetative bacteria (e.g., *Listeria*, *Escherichia coli*, *Salmonella*, vancomycin-resistant enterococci [VRE], methicillin-resistant *Staphylococcus aureus* [MRSA]), yeasts (e.g., *Candida*), mycobacteria (e.g., *Mycobacterium tuberculosis*), and viruses (e.g. poliovirus) at exposure times of <60 seconds *(42–57)*. Thus, it is acceptable to disinfect noncritical medical equipment (e.g., blood pressure cuff) and noncritical surfaces (e.g., bedside table) with an EPA-registered disinfectant or disinfectant/detergent at the proper use dilution and a contact time of at least 1 minute *(58)*. Since the typical drying time for a germicide on a surface is 1 to 3 minutes (unless the product contains alcohol [e.g., a 60–70% alcohol will dry in about 30 seconds])(N. Omidbakhsh, written communication), one application of the germicide on all surfaces to be disinfected is recommended.

Mops (microfiber and cotton-string), reusable cleaning cloths, and disposable wipes are regularly used to achieve low-level disinfection *(59,60)*. Microfiber mops have demonstrated superior microbial removal compared with cotton string mops when used with detergent cleaner (95% vs. 68%, respectively). Use of a disinfectant did significantly improve microbial removal when a cotton string mop was used (95% vs. 95%, respectively) *(60)*. Mops (especially cotton-string mops) are commonly not kept adequately cleaned and disinfected, and if the water-disinfectant mixture is not changed regularly (e.g., after every three to four rooms, no longer than 60-minute intervals), the mopping procedure may actually spread heavy microbial contamination throughout the healthcare facility *(61)*. In one study, standard laundering provided acceptable decontamination of heavily contaminated mopheads, but chemical disinfection with a phenolic was less effective *(61)*. The frequent laundering of cotton-string mops (e.g., daily) is, therefore, recommended.

Hospital cleanliness continues to attract patient attention and in the United States it is still primarily assessed via visual appearance, which is not a reliable indicator of surface cleanliness *(62)*. Three other methods have been offered for monitoring patient room hygiene and they include adenosine triphosphate (ATP) bioluminescence *(63,64)*; fluorescent markers (65,*66*); and microbiologic sampling *(64)*. Studies have demonstrated suboptimal cleaning was documented by aerobic colony counts as well as the use of the ATP bioluminescence and fluorescent markers.

FACTORS AFFECTING THE EFFICACY OF DISINFECTION AND STERILIZATION

The activity of germicides against microorganisms depends on a number of factors, some of which are intrinsic qualities of the microorganism, while others depend on the chemical and external physical environment. An awareness of these factors should lead to a better utilization of disinfection and sterilization processes; thus, they will be briefly reviewed. More extensive consideration of these and other factors may be found in the references for this section *(18,19,21,67–69)*.

Number and Location of Microorganisms

All other conditions remaining constant, the larger the number of microbes present, the longer it takes for a germicide to destroy all of them. This relationship was illustrated by Spaulding when he employed identical test conditions and demonstrated that it took 30 minutes to kill 10 *Bacillus atrophaeus* (formerly *B. subtilis*) spores but 3 hours to kill 100,000 *B. atrophaeus* spores. This reinforces the need for scrupulous cleaning of medical instruments before disinfection and sterilization. Reducing the number of microorganisms that must be inactivated through meticulous cleaning increases the margin of safety when the germicide is used according to the labeling and shortens the exposure time required to kill the entire microbial load. Researchers have also shown that aggregated or clumped cells are more difficult to inactivate than monodispersed cells *(70)*.

The location of microorganisms also must be considered when assessing factors affecting the efficacy of germicides. Medical instruments with multiple pieces must be disassembled and equipment such as endoscopes that have crevices, joints, and channels are more difficult to disinfect than flat-surface equipment because it is more difficult to penetrate all parts of the equipment with a disinfectant. Only surfaces in direct contact with the germicide will be disinfected, so there must be no air pockets and the equipment must be completely immersed for the entire exposure period. Manufacturers should be encouraged to produce equipment that is engineered, so cleaning and disinfection may be accomplished with ease.

Innate Resistance of Microorganisms

Microorganisms vary greatly in their resistance to chemical germicides and sterilization processes (Fig. 80-1) *(71)*. Intrinsic resistance mechanisms in microorganisms to disinfectants vary. For example, spores are resistant to disinfectants because the spore coat and cortex act as a barrier,

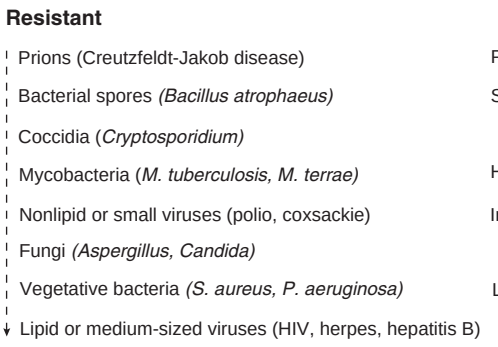

FIGURE 80-1 Decreasing order of resistance of microorganisms to disinfection and sterilization and the level of disinfection or sterilization. (Data from Favero MS, Bond WW. Chemical disinfection of medical and surgical materials. In: Block SS, ed. *Disinfection, sterilization, and preservation*. Philadelphia, PA: Lippincott Williams & Wilkins, 2001:881–917; Russell AD. Bacterial resistance to disinfectants: present knowledge and future problems. *J Hosp Infect* 1998;43:S57–S68.)

mycobacteria have a waxy cell wall that prevents disinfectant entry, and gram-negative bacteria possess an outer membrane that acts as a barrier to the uptake of disinfectants *(71–74)*. Implicit in all disinfection strategies is the consideration that the most resistant microbial subpopulation controls the sterilization or disinfection time. That is, in order to destroy the most resistant types of microorganisms-bacterial spores, the user needs to employ exposure times and a concentration of germicide needed to achieve complete destruction. With the exception of prions, bacterial spores possess the highest innate resistance to chemical germicides, followed by coccidia (e.g., *Cryptosporidium*), mycobacteria (e.g., *M. tuberculosis*), nonlipid or small viruses (e.g., poliovirus and coxsackievirus), fungi (e.g., *Aspergillus* and *Candida*), vegetative bacteria (e.g., *Staphylococcus* and *Pseudomonas*), and lipid or medium-size viruses (e.g., herpes, and HIV). The germicidal resistance exhibited by the gram-positive and gram-negative bacteria is similar with some exceptions (e.g., *Pseudomonas aeruginosa*, which shows greater resistance to some disinfectants) *(75–77)*. *P. aeruginosa* have also been shown to be significantly more resistant to a variety of disinfectants in their "naturally occurring" state as compared to cells subcultured on laboratory media *(75,78)*. *Rickettsiae*, *Chlamydiae*, and mycoplasma cannot be placed in this scale of relative resistance because information on the efficacy of germicides against these agents is limited *(79)*. Since these microorganisms contain lipid and are similar in structure and composition to other bacteria, it might be predicted that they would be inactivated by the same germicides that destroy lipid viruses and vegetative bacteria. A known exception to this supposition is *Coxiella burnetii*, which has demonstrated resistance to disinfectants *(80)*.

Concentration and Potency of Disinfectants

With other variables constant, and with one exception (i.e., iodophors), the more concentrated the disinfectant, the greater its efficacy and the shorter the time necessary to achieve microbial kill. Generally not recognized, however, is that all disinfectants are not similarly affected by concentration adjustments. For example, quaternary ammonium compounds and phenol have a concentration exponent of 1 and 6, respectively; thus, halving the concentration of a quaternary ammonium compound requires a doubling of its disinfecting time, but halving the concentration of a phenol solution requires a 64-fold (i.e., 2^6) increase in its disinfecting time *(69,81,82)*.

Quality control is indispensable for automated disinfectant dilution systems. While these systems are economical, efficient and promote a safer workplace, compared to manual dilution methods, failure to provide the required concentration of the disinfectant has been reported. Disinfectants must be used in the dilution specified by the manufacturer for optimal decontamination and attention must be given to quality control and preventive maintenance of automated disinfectant dilution systems as they regularly fail *(83)*.

It is also important to consider the length of the disinfection time, which is dependent upon the potency of the germicide. This was illustrated by Spaulding who demonstrated using the mucin-loop test that 70% isopropyl alcohol destroyed 10^4 *M. tuberculosis* in 5 minutes, whereas a simultaneous test with 3% phenolic required 2 to 3 hours to achieve the same level of microbial kill *(19)*.

Physical and Chemical Factors

Several physical and chemical factors also influence disinfectant procedures: temperature, pH, relative humidity, and water hardness. For example, the activity of most disinfectants increases as the temperature increases, but there are exceptions. Further, too great an increase in temperature will cause the disinfectant to degrade, weaken its germicidal activity, and may produce a potential health hazard.

An increase in pH improves the antimicrobial activity of some disinfectants (e.g., glutaraldehyde, quaternary ammonium compounds) but decreases the antimicrobial activity of others (e.g., phenols, hypochlorites, and iodine). The pH influences the antimicrobial activity by altering the disinfectant molecule or the cell surface *(69)*.

Relative humidity is the single most important factor influencing the activity of gaseous disinfectants/sterilants such as ETO, chlorine dioxide, and formaldehyde.

Water hardness (i.e., high concentration of divalent cations) reduces the rate of kill of certain disinfectants. This occurs because divalent cations (e.g., magnesium, calcium) in the hard water interact with the disinfectant to form insoluble precipitates *(18,84)*.

Organic and Inorganic Matter

Organic matter in the form of serum, blood, pus, fecal, or lubricant material may interfere with the antimicrobial activity of disinfectants in at least two ways. Most commonly, the interference occurs by a chemical reaction between the germicide and the organic matter resulting in a complex that is less germicidal or nongermicidal, leaving less of the active germicide available for attacking microorganisms. Chlorine and iodine disinfectants, in particular, are prone to such interaction. Alternatively, organic material may protect microorganisms from attack by acting as a physical barrier *(85)*.

The effects of inorganic contaminants on the sterilization process were studied in the 1950s and 1960s *(86,87)*. These studies and other studies show the protection of microorganisms to all sterilization processes is due to

occlusion in salt crystals *(88,89)*. This further emphasizes the importance of meticulous cleaning of medical devices before any sterilization or disinfection procedure since both organic and inorganic soils are easily removed by washing *(88)*.

Duration of Exposure

Items must be exposed to the germicide for the appropriate minimum contact time. Multiple investigators have demonstrated the effectiveness of low-level disinfectants against vegetative bacteria (e.g., *Listeria*, *Escherichia coli*, *Salmonella*, vancomycin-resistant Enterococci [VRE], methicillin-resistant *Staphylococcus aureus* [MRSA]), yeasts (e.g., *Candida*), mycobacteria (e.g., *M. tuberculosis*), and viruses (e.g. poliovirus) at exposure times of 30 to 60 seconds *(42–57,90–95)*. By law, all applicable label instructions on EPA-registered products must be followed. If the user selects exposure conditions that differ from those on the EPA-registered products label, the user assumes liability for any injuries resulting from off-label use and is potentially subject to enforcement action under FIFRA. While we are unaware of an EPA enforcement action against healthcare facilities for "off label" use of a surface disinfectant, there have been citations reported from The Joint Commission and the Center for Medicare and Medicaid Services (CMS).

All lumens and channels of endoscopic instruments must come in contact with the disinfectant. Air pockets will interfere with the disinfection process and items that float on the disinfectant will not be disinfected. The disinfectant must be introduced reliably into the internal channels of the device. The exact times for disinfecting medical items are somewhat elusive because of the effect of the aforementioned factors on disinfection efficacy. Contact times that have proved reliable are presented in Table 80-1, but, in general, the longer contact times are more effective than shorter ones.

Biofilms

Microorganisms may be protected from disinfectants due to the production of thick masses of cells *(96)* and extracellular materials or biofilms *(97–104)*. Biofilms are microbial masses attached to surfaces that are immersed in liquids. Once these masses are formed, microbes may be resistant to the disinfectants by multiple mechanisms including higher resistance of older biofilms, genotypic variation of the bacteria, microbial production of neutralizing enzymes, and physiologic gradients within the biofilm (e.g., pH). Bacteria within biofilms are up to 1,000 times more resistant to antimicrobials than the same bacteria in suspension *(105)*. Although new decontamination methods *(106)* are being investigated for removal of biofilms, chlorine and monochloramines are effective for inactivation of biofilm bacteria *(99,107)*. Investigators have hypothesized that the glycocalyx-like cellular masses on the interior walls of polyvinyl chloride pipe would protect embedded microorganisms from some disinfectants and serve as a reservoir for continuous contamination *(97,98,108)*. Biofilms have been found in whirlpools *(109)*, dental unit waterlines *(110)*, and numerous medical devices (e.g., contact lenses, pacemakers, hemodialysis systems, urinary catheters, central venous catheters, endoscopes) *(102,105,107,111)*. Their presence may have serious implications for immunocompromised patients and patients with indwelling medical devices. Some enzymes *(105,112,113)* and detergents *(105,114)* can be used for the degradation of biofilms or reduction in viable bacterial numbers, but no products are registered by the EPA or cleared by the FDA for this purpose. One study evaluating the clearance effect of enzymatic and nonenzymatic detergents against *E. coli* biofilms on the inner surface of gastroscopes found that both nonenzymatic detergents and high-speed lavage (250 mL/min) are important in temporal formed biofilm elimination *(115)*.

In general, the available data suggest that reusable medical devices (e.g., flexible endoscopes) that are properly cleaned, disinfected, rinsed, and dried pose little risk for biofilm development. However, biofilms can develop inside channels if established protocols are not met, and these biofilms can be difficult to remove *(104)*.

CLEANING

Cleaning is the removal of foreign material (e.g., soil and organic material) from objects, and it is normally accomplished using water with detergents or enzymatic products. Thorough cleaning is required before high-level disinfection and sterilization since inorganic and organic materials that remain on the surfaces of instruments interfere with the effectiveness of these processes. Also, if the soiled materials become dried or baked onto the instruments, the removal process becomes more difficult and the disinfection or sterilization process less effective or ineffective. Surgical instruments should be presoaked or rinsed to prevent drying of blood and to soften or remove blood from the instruments.

Cleaning is done manually when the use area does not have a mechanical unit (e.g., ultrasonic cleaner, or washer-disinfector), or for fragile or difficult-to-clean instruments. If cleaning is done manually, the two essential components are friction and fluidics. Using friction (e.g., rubbing/scrubbing the soiled area with a brush) is an old and dependable method. Fluidics (i.e., fluids under pressure) is used to remove soil and debris from internal channels after brushing and when the design does not allow the passage of a brush through a channel *(116)*. When using a washer-disinfector, care should be taken as to the method of loading instruments. Hinged instruments should be opened fully to allow adequate contact with the detergent solution. The stacking of instruments in washers should be avoided. Instruments should be disassembled as much as possible.

The most common types of mechanical or automatic cleaners include ultrasonic cleaners, washer-decontaminators, washer-disinfectors, and washer-sterilizers. Ultrasonic cleaning removes soil by a process called *cavitation and implosion* in which waves of acoustic energy are propagated in aqueous solutions to disrupt the bonds that hold particulate matter to surfaces. Bacterial contamination may be present in used ultrasonic cleaning solutions (and other used detergent solutions) as these solutions generally do not make antibacterial label claims *(117)*. While ultrasound alone does not cause significant inactivation of bacteria, sonication can act synergistically to increase the cidal efficacy of a disinfectant *(118)*. Users of ultrasonic cleaners should be aware that the cleaning fluid could

result in endotoxin contamination of surgical instruments that could cause severe inflammatory reactions *(119)*. Washer-sterilizers are modified steam sterilizers that clean by filling the chamber with water and detergent through which steam is passed to provide agitation. Instruments are subsequently rinsed and subjected to a short steam sterilization cycle. Another washer-sterilizer employs rotating spray arms for a wash cycle followed by a steam sterilization cycle at 285°F *(120,121)*. Washer-decontaminators/disinfectors act like a dishwasher that uses a combination of water circulation and detergents to remove soil. These units sometimes have a cycle that subjects the instruments to a heat process (e.g., 93°C for 10 minutes) *(122)*. Washer-disinfectors are generally computer-controlled units for cleaning, disinfecting, and drying solid and hollow surgical and medical equipment. In one study, cleaning (measured as 5- to 6-$\log_{10}$ reduction) was achieved on surfaces that were adequately in contact with the water flow in the machine *(123)*. Detailed information on cleaning and preparation of supplies for terminal sterilization is provided by professional organizations *(124,125)* and books *(126)*. Studies have shown that manual and mechanical cleaning of endoscopes achieves approximately a 4-$\log_{10}$ reduction of contaminating microorganisms *(127–130)*. Thus, cleaning alone is very effective in reducing the number of microorganisms present on contaminated equipment. Quantitative analysis of residual protein contamination of reprocessed surgical instruments has been done, and median levels of residual protein contamination per instrument for five trays were 267, 260, 163, 456, and 756 μg *(131)*. In another study, the median amount of protein from reprocessed surgical instruments from different hospitals ranged from 8 to 91 μg *(132)*. When manual methods are compared to automated methods for cleaning reusable accessory devices used for minimally invasive surgical procedures, the automated method was more efficient for cleaning biopsy forceps and ported and nonported laparoscopic devices and achieved a >99% reduction in soil parameters (i.e., protein, carbohydrate, hemoglobin) in the ported and nonported laparoscopic devices *(133,134)*.

The best choice for instrument cleaning is neutral or near-neutral pH detergent solutions, as these solutions generally provide the best material compatibility profile and good soil removal. Enzymes, usually proteases, are sometimes added to neutral pH solutions to assist in the removal of organic material. Enzymes in these formulations attack proteins that make up a large portion of common soil (e.g., blood, pus). Cleaning solution also can contain lipases (enzymes active on fats) and amylases (enzymes active on starches). Enzymatic cleaners are not disinfectants and proteinaceous enzymes may be inactivated by germicides. Like all chemicals, enzymes must be rinsed from the equipment or adverse reactions (e.g., fever, residual amounts of high-level disinfectants, proteinaceous residue) could result *(135,136)*. Enzyme solutions should be used in accordance with manufacturer's instructions, which includes proper dilution of the enzymatic detergent for the amount of time specified on the label *(136)*. Detergent enzymes may be associated with asthma or other allergic effects in users. Neutral pH detergent solutions that contain enzymes are compatible with metals and other materials used in medical instruments and are the best choice for cleaning delicate medical instruments, especially flexible endoscopes *(129)*. Alkaline-based cleaning agents are used for processing medical devices as they dissolve protein and fat residues efficiently; *(137)* however, they may be corrosive *(129)*. Some data demonstrate that enzymatic cleaners are more effective cleaners than neutral detergents *(138,139)* in removing microorganisms from surfaces, but two more recent studies found no difference in cleaning efficiency between enzymatic- and alkaline-based cleaners *(112,137)*. A new nonenzyme, hydrogen peroxide–based formulation (not FDA-cleared), was as effective as enzymatic cleaners in removing protein, blood, carbohydrate, and endotoxin from surface test carriers *(140)*. In addition, this product was able to effect a 5-$\log_{10}$ reduction in microbial loads with a 3-minute exposure at room temperature *(140)*. Although the effectiveness of high-level disinfection and sterilization mandates effective cleaning, there are no "real-time" tests that can be employed in a clinical setting to verify cleaning. If such tests were commercially available, they could be used to ensure that an adequate level of cleaning has been done *(141–144)*. The only way to ensure adequate cleaning is to conduct a reprocessing verification test (e.g., microbiologic sampling), but this is not routinely recommended *(145)*. Validation of the cleaning processes in a laboratory-testing program is possible by microorganism detection, chemical detection for organic contaminants, radionuclide tagging, and chemical detection for specific ions *(88,143)*. In the past few years, data have been published describing the use of an artificial soil, protein, endotoxin, X-ray contrast medium, or blood to verify the manual or automated cleaning process *(123,146–151)* and adenosine triphosphate bioluminescence and microbiologic sampling to evaluate the effectiveness of cleaning *(152)*. Minimally, all instruments should be individually inspected and be visibly clean.

DISINFECTANTS USED IN HEALTHCARE

A great number of disinfectants are used alone or in combinations (e.g., hydrogen peroxide and peracetic acid) in the healthcare setting. These include alcohols, chlorine and chlorine compounds, formaldehyde, glutaraldehyde, orthophthalaldehyde, hydrogen peroxide, iodophors, peracetic acid, phenolics, and quaternary ammonium compounds. The properties of an ideal disinfectant are described in Table 80-2. With some exceptions (e.g., ethanol or bleach), commercial formulations based on these chemicals are considered unique products and must be registered with the EPA or cleared by the FDA. In most instances, a given product is designed for a specific purpose and is to be used in a certain manner. Therefore, the label should be read carefully to ensure that the right product is selected for the intended use and applied in an efficient manner. Additionally, caution must be exercised to avoid hazards with using cleaners and disinfectants on electronic medical equipment. Problems associated with inappropriate use of liquids on electronic medical equipment have included equipment fires, equipment malfunctions, and healthcare worker burns *(153)*.

Disinfectants are not interchangeable and an overview of the performance characteristics of each is provided below, so the user has sufficient information to select an

TABLE 80-2

Properties of an Ideal Disinfectant

Broad spectrum: should have a wide antimicrobial spectrum
Fast acting: should produce a rapid kill
Not affected by environmental factors: should be active in the presence of organic matter (e.g., blood, sputum, feces) and compatible with soaps, detergents, and other chemicals encountered in use
Nontoxic: should not be harmful to the user or patient
Surface compatibility: should not corrode instruments and metallic surfaces and should not cause the deterioration of cloth, rubber, plastics, and other materials
Residual effect on treated surfaces: should leave an antimicrobial film on the treated surface
Easy to use with clear label directions
Odorless: should have a pleasant odor or no odor to facilitate its routine use
Economical: should not be prohibitively high in cost
Solubility: should be soluble in water
Stability: should be stable in concentrate and use-dilution
Cleaner: should have good cleaning properties
Environmentally friendly: should not damage the environment on disposal

(Modified from Molinari JA, Gleason MJ, Cottone JA, Barrett ED. Comparison of dental surface disinfectants. *Gen. Dent.* 1987;35: 171–175.)

appropriate disinfectant for any medical item and use it in the most efficient way. It should be recognized that excessive costs may be attributed to incorrect concentrations and inappropriate disinfectants. Finally, occupational diseases among cleaning personnel have been associated with the use of several disinfectants such as formaldehyde and glutaraldehyde, and precautions (e.g., gloves, proper ventilation) should be used to minimize exposure *(154)*. Asthma and reactive airway disease may occur in sensitized individuals exposed to any airborne chemical including germicides. Clinically important asthma may occur at levels below ceiling levels regulated by Occupational Safety and Health Administration (OSHA) or recommended by NIOSH. The preferred method of control is to eliminate aerosolization of the chemical (via engineering controls, or substitution) or relocate the worker.

Chemical Disinfectants

Alcohol In the healthcare setting, "alcohol" refers to two water-soluble chemical compounds whose germicidal characteristics are generally underrated: ethyl alcohol and isopropyl alcohol *(155)*. These alcohols are rapidly bactericidal rather than bacteriostatic against vegetative forms of bacteria; they also are tuberculocidal, fungicidal, and virucidal (enveloped viruses but poor activity against some nonenveloped viruses such as parvovirus) *(156)* but do not destroy bacterial spores. Their cidal activity drops sharply when diluted below 50% concentration and the optimum bactericidal concentration is in the range of 60–90% solutions in water (volume/volume) *(157,158)*.

Alcohols are not recommended for sterilizing medical and surgical materials principally because of their lack of sporicidal action and their inability to penetrate protein-rich materials. Fatal postoperative wound infections with *Clostridium* have occurred when alcohols were used to sterilize surgical instruments contaminated with bacterial spores *(159)*. Alcohols have been used effectively to disinfect oral and rectal thermometers, hospital pagers, scissors, CPR manikins, external surfaces of equipment (e.g., ventilator), computer keyboards *(60)*, touch pads, and stethoscopes *(12)*. Alcohol towelettes have been used for years to disinfect small surfaces such as rubber stoppers of multiple-dose medication vials or vaccine bottles.

Alcohols are flammable and consequently must be stored in a cool, well-ventilated area. They also evaporate rapidly and this makes extended exposure time difficult to achieve unless the items are immersed.

Chlorine and Chlorine Compounds Hypochlorites are the most widely used of the chlorine disinfectants and are available in a liquid (e.g., sodium hypochlorite) or solid (e.g., calcium hypochlorite) form. The most prevalent chlorine products in the United States are aqueous solutions of 5.25% to 6.15% sodium hypochlorite, which usually are called *household bleach*. A chlorine-containing product is currently registered by the EPA to kill *C. difficile* spores. They have a broad spectrum of antimicrobial activity (i.e., bactericidal, virucidal, fungicidal, mycobactericidal, sporicidal), do not leave toxic residues, are unaffected by water hardness, are inexpensive and fast acting *(160)*, remove dried or fixed microorganisms and biofilms from surfaces *(138)*, and have a low incidence of serious toxicity *(161,162)*. Sodium hypochlorite at the concentration used in domestic bleach (5.25–6.15%) may produce ocular irritation or oropharygeal, esophageal, and gastric burns *(154,163,164)*. Other disadvantages of hypochlorites include corrosiveness to metals in high concentrations (>500 ppm), inactivation by organic matter, discoloring or "bleaching" of fabrics, release of toxic chlorine gas when mixed with ammonia or acid (e.g., household cleaning agents) *(165)*, and relative stability *(166)*.

Reports have examined the microbicidal activity of a new disinfectant, "superoxidized water." The concept of electrolyzing saline to create a disinfectant or antiseptics is appealing as the basic materials of saline and electricity are cheap and the end product (i.e., water) is not damaging to the environment. The main products of this water are hypochlorous acid (HOCl) and hypochlorite (OCl^-), which constitute free available chlorine. This is also known as *electrolyzed water* and as with any germicide, the antimicrobial activity of superoxidized water is strongly affected by the concentration of the active ingredient (available free chlorine) *(167)*. The free available chlorine concentrations of different superoxidized solutions reported in the literature range from 7 to 180 ppm *(167)*. Data have shown that freshly generated superoxidized water, Sterilox®, is rapidly effective (<2 minutes) in achieving a 5-$\log_{10}$ reduction of pathogenic microorganisms (i.e., *M. tuberculosis*, *M. chelonae*, poliovirus, HIV, MRSA, *E. coli, Candida albicans*, *Enterococcus faecalis, Pseudomonas aeruginosa*) in the absence of organic loading. However, the biocidal activity of this disinfectant was substantially reduced in the presence of organic material (5% horse serum) *(168,169)*.

Hypochlorites are widely used in healthcare facilities in a variety of settings *(160)*. Inorganic chlorine solution is used for disinfecting tonometer heads *(170)* and for spot disinfection of counter tops and floors. A 1:10 to 1:100 dilution of 5.25–6.15% sodium hypochlorite (i.e., household bleach) *(171–174)* or an EPA-registered tuberculocidal disinfectant *(22)* has been recommended for decontaminating blood spills. For small spills of blood (i.e., drops of blood) on noncritical surfaces, the area can be disinfected with a 1:100 dilution of 5.25–6.15% sodium hypochlorite or an EPA-registered tuberculocidal disinfectant. Because hypochlorites and other germicides are substantially inactivated in the presence of blood *(54,175)*, large spills of blood require that the surface be cleaned before an EPA-registered disinfectant or a 1:10 (final concentration) solution of household bleach is applied. If there is a possibility of a sharps injury, there should be an initial decontamination *(154,176)*, followed by cleaning and terminal disinfection (1:10 final concentration) *(54)*. Extreme care should always be employed to prevent percutaneous injury. At least 500 ppm available chlorine for 10 minutes is recommended for decontamination of cardiopulmonary resuscitation training manikins. Other uses in healthcare include as an irrigating agent in endodontic treatment and for disinfecting laundry, dental appliances, hydrotherapy tanks *(40)*, regulated medical waste before disposal *(160)*, applanation tonometers, *(177)* and the water distribution system in hemodialysis centers and hemodialysis machines *(12)*. Disinfection with a 1:10 dilution of concentrated sodium hypochlorite (i.e., bleach) has been shown to be effective in reducing environmental contamination in patient rooms and in reducing *C. difficile* infection rates in hospital units where there is a high endemic *C. difficile* infection rate or in an outbreak setting (11*,178,179*). Recently, Hacek and colleagues reported that the use of bleach (1:10 dilution) in the rooms of all patients with CDI at terminal room cleaning made a sustained, significant impact on reducing the rate of healthcare-associated CDI in a healthcare system *(180)*.

Chlorine has long been favored as the preferred disinfectant in water treatment. Hyperchlorination of a *Legionella*-contaminated hospital water system *(40)* resulted in a dramatic decrease (30% to 1.5%) in the isolation of *L. pneumophila* from water outlets and a cessation of healthcare-associated Legionnaires' disease in the affected unit *(181,182)*. Chloramine T and hypochlorites have been used in disinfecting hydrotherapy equipment *(12)*.

Hypochlorite solutions in tapwater at a pH > 8 stored at room temperature (23°C) in closed, opaque plastic containers may lose up to 40–50% of their free available chlorine level over a period of 1 month. Thus, if a user wished to have a solution containing 500 ppm of available chlorine at day 30, a solution containing 1,000 ppm of chlorine should be prepared at time 0. There is no decomposition of sodium hypochlorite solution after 30 days when stored in a closed brown bottle *(166)*.

Glutaraldehyde Glutaraldehyde is a saturated dialdehyde that has gained wide acceptance as a high-level disinfectant and chemical sterilant *(183)*. Aqueous solutions of glutaraldehyde are acidic and generally in this state are not sporicidal. Only when the solution is "activated" (made alkaline) by use of alkalinizing agents to pH 7.5 to 8.5 does the solution become sporicidal. Once "activated," these solutions have a shelf-life of minimally 14 days because of the polymerization of the glutaraldehyde molecules at alkaline pH levels. This polymerization blocks the active sites (aldehyde groups) of the glutaraldehyde molecules that are responsible for its biocidal activity.

Novel glutaraldehyde formulations (e.g., glutaraldehyde-phenol-sodium phenate, potentiated acid glutaraldehyde, stabilized alkaline glutaraldehyde) produced in the past 40 years have overcome the problem of rapid loss of activity (e.g., use- life: 28 to 30 days) while generally maintaining excellent microbicidal activity *(12,184,185)*. However, it should be recognized that antimicrobial activity is dependent not only on age but also on use conditions such as dilution and organic stress. The use of glutaraldehyde-based solutions in healthcare facilities is common because of their advantages that include excellent biocidal properties; activity in the presence of organic matter (20% bovine serum); and noncorrosive action to endoscopic equipment, thermometers, rubber, or plastic equipment. The advantages, disadvantages, and characteristics of glutaraldehyde are listed in Table 80-3.

The *in vitro* inactivation of microorganisms by glutaraldehydes has been extensively investigated and reviewed *(186)*. Several investigators showed that ≥2% aqueous solutions of glutaraldehyde, buffered to pH 7.5 to 8.5 with sodium bicarbonate, were effective in killing vegetative bacteria in <2 minutes; *M. tuberculosis*, fungi, and viruses in <10 minutes; and spores of *Bacillus* and *Clostridium* species in 3 hours *(186,187)*. Spores of *Clostridium difficile* are more rapidly killed by 2% glutaraldehyde than are spores of other species of *Clostridium* and *Bacillus (188,189)*, this includes the hypervirulent binary toxin stains of *C. difficile* spores (WA Rutala, Unpublished Results, October 2009). There have been reports of microorganisms with relative resistance to glutaraldehyde, including some mycobacteria (*Mycobacterium chelonae*, *M. avium-intracellulare, M. xenopi*) *(190,191)*, *Methylobacterium mesophilicum (192)*, *Trichosporon*, fungal ascospores (e.g., *Microascus cinereus*, *Cheatomium globosum*), and *Cryptosporidium (193)*. *M. chelonae* persisted in a 0.2% glutaraldehyde solution used to store porcine prosthetic heart valves *(194)* and a large outbreak of *M. massiliense* infections in Brazil after videolaparoscopy equipment, used for different elective cosmetic procedures (e.g., liposuction), was highly tolerant to 2% glutaraldehyde *(195)* Porins may have a role in the resistance of mycobacteria to glutaraldehyde and OPA *(196)*.

Dilution of glutaraldehyde during use commonly occurs and studies show a glutaraldehyde concentration decline after a few days of use in an automatic endoscope washer *(197)*. This occurs because instruments are not thoroughly dried and water is carried in with the instrument, which increases the solution's volume and dilutes its effective concentration. This emphasizes the need to ensure that semicritical equipment is disinfected with an acceptable concentration of glutaraldehyde. Data suggest that 1.0% to 1.5% glutaraldehyde is the minimum effective concentration for >2% glutaraldehyde solutions when used as a high-level disinfectant *(197–199)*. Chemical test strips or liquid chemical monitors are available for determining whether an effective concentration of glutaraldehyde is present despite repeated use and dilution. The frequency of testing should be based on how frequently the solutions are used (e.g., used daily, test daily; used weekly, test before

TABLE 80-3

Summary of Advantages and Disadvantages of Chemical Agents Used as Chemical Sterilants[a] or as High-Level Disinfectants

Sterilization Method	*Advantages*	*Disadvantages*
Peracetic acid plus hydrogen peroxide	• No activation required • Odor or irritation not significant	• Materials compatibility concerns (lead, brass, copper, zinc) both cosmetic and functional • Limited clinical experience • Potential for eye and skin damage
Glutaraldehyde	• Numerous use studies published • Relatively inexpensive • Excellent materials compatibility	• Respiratory irritation from glutaraldehyde vapor • Pungent and irritating odor • Relatively slow mycobactericidal activity • Coagulates blood and fixes tissue to surfaces • Allergic contact dermatitis • Glutaraldehyde vapor monitoring recommended
Hydrogen peroxide	• No activation required • May enhance removal of organic matter and microorganisms • No disposal issues • No odor or irritation issues • Does not coagulate blood or fix tissues to surfaces • Inactivates Cryptosporidium • Use studies published	• Material compatibility concerns (brass, zinc, copper, and nickel/silver plating) both cosmetic and functional • Serious eye damage with contact
Ortho-phthalaldehyde	• Fast acting high-level disinfectant • No activation required • Odor not significant • Excellent materials compatibility claimed • Does not coagulate blood or fix tissues to surfaces claimed • Does not require special venting or air monitoring	• Stains skin, mucous membranes, clothing, and environmental surfaces • Repeated exposure may result in hypersensitivity in some patients with bladder cancer • More expensive than glutaraldehyde • Eye irritation with contact • Slow sporicidal activity
Peracetic acid	• Rapid sterilization cycle time (30–45 min) • Low-temperature (50–55°C) liquid immersion sterilization • Environment-friendly byproducts (acetic acid, O_2, H_2O) • Fully automated • Single-use system eliminates need for concentration testing • Standardized cycle • May enhance removal of organic material and endotoxin • No adverse health effects to operators under normal operating conditions • Compatible with many materials and instruments • Sterilant flows through scope facilitating salt, protein, and microbe removal • Rapidly sporicidal • Provides procedure standardization (constant dilution, perfusion of channel, temperatures, exposure)	• Potential material incompatibility (e.g., aluminum anodized coating becomes dull, ureteroscopes) • Used for immersible instruments only • Biological indicator may not be suitable for routine monitoring • One scope or a small number of instruments can be processed in a cycle • More expensive (endoscope repairs, operating costs, purchase costs) than high-level disinfection • Serious eye and skin damage (concentrated solution) with contact • Point-of-use system, no sterile storage
Accelerated hydrogen peroxide (2.0%); high-level disinfectant	• No activation required • No odor • Nonstaining • No special venting requirements • Manual or automated applications • 12-mo shelf life, 14-d reuse • 8 min at 20°C high-level disinfectant claim	• Material compatibility concerns due to limited clinical experience • Antimicrobial claims not independently verified • Organic material resistance concerns due to limited data

[a]All products effective in presence of organic soil, relatively easy to use, and have a broad spectrum of antimicrobial activity (bacteria, fungi, viruses, bacterial spores, and mycobacteria). The above characteristics are documented in the literature; contact the manufacturer of the instrument and sterilant for additional information. All products listed above are FDA-cleared as chemical sterilants except OPA, which is an FDA-cleared high-level disinfectant. (Modified from Rutala WA, Weber DJ. Disinfection of endoscopes: review of new chemical sterilants used for high-level disinfection. *Infect Control Hosp Epidemiol* 1999;20:69–76.)

use; used 30 times per day, test each tenth use), but the strips should not be used to extend the use life beyond the expiration date. Data suggest the chemicals in the test strip deteriorate with time *(200)*, and a manufacturer's expiration date should be placed on the bottles. The bottle of test strips should be dated when opened and used for the period of time indicated on the bottle (e.g., 120 days). The results of test strip monitoring should be documented. The glutaraldehyde test kits have been preliminarily evaluated for accuracy and range *(200)*, but the reliability has been questioned *(201)*. The concentration should be considered unacceptable or unsafe when the test indicates a dilution below the product's minimum effective concentration or MEC (generally to 1.0 to 1.5% glutaraldehyde or lower) by the indicator not changing color.

Glutaraldehyde is used most commonly as a high-level disinfectant for medical equipment such as endoscopes *(176)*, spirometry tubing, dialyzers, transducers, anesthesia and respiratory therapy equipment, hemodialysis proportioning and dialysate delivery systems, and reuse of laparoscopic disposable plastic trocars *(12)*. Glutaraldehyde is noncorrosive to metal and does not damage lensed instruments, rubber or plastics. The FDA-cleared labels for high-level disinfection with >2% glutaraldehyde at 25°C range from 20 to 90 minutes depending upon the product. However, multiple scientific studies and professional organizations support the efficacy of >2% glutaraldehyde for 20 minutes at 20°C (11,*22,39*). Minimally, follow this latter recommendation. Glutaraldehyde should not be used for cleaning noncritical surfaces as it is too toxic and expensive.

Chemical colitis (presents clinically with severe abdominal pain, bloody and mucoid diarrhea, rectal bleeding, and tenesmus 48–72 hours after colonoscopy) believed due to glutaraldehyde exposure from residual disinfecting solution in the endoscope solution channels has been reported and is preventable by careful endoscope rinsing *(154)*. One study found that residual glutaraldehyde levels were higher and more variable after manual disinfection (<0.2–159.5 mg/L) than after automatic disinfection (0.2–6.3 mg/L) *(202)*. Similarly, keratopathy and corneal decompensation were caused by ophthalmic instruments that were inadequately rinsed after soaking in 2% glutaraldehyde *(203)*.

Glutaraldehyde exposure should be monitored to ensure a safe work environment. In the absence of an OSHA PEL, if the glutaraldehyde level is higher than the ACGIH ceiling limit of 0.05 ppm, it would be prudent to take corrective action and repeat monitoring *(204)*.

Hydrogen Peroxide The literature contains several accounts of the properties, germicidal effectiveness, and potential uses for stabilized hydrogen peroxide in the healthcare setting. Published reports ascribing good germicidal activity to hydrogen peroxide have been published and attest to its bactericidal, virucidal, sporicidal, and fungicidal properties *(205–208)*. The advantages, disadvantages, and characteristics of hydrogen peroxide are listed in Table 80-3. As with other chemical sterilants, dilution of the hydrogen peroxide must be monitored by regularly testing the minimum effective concentration (i.e., 7.5 to 6.0%). Compatibility testing by Olympus America of the 7.5% hydrogen peroxide found both cosmetic changes (e.g., discoloration of black anodized metal finishes) *(176)* and functional changes with the tested endoscopes (Olympus, October 15, 1999, written communication).

Commercially available 3% hydrogen peroxide is a stable and effective disinfectant when used on inanimate surfaces. It has been used in concentrations from 3 to 6% for the disinfection of soft contact lenses (e.g., 3% for 2–3 hours) *(205,209)*, tonometer biprisms, ventilators, fabrics *(210)*, and endoscopes *(128)*. Hydrogen peroxide was effective in spot disinfecting fabrics in patients' rooms *(210)*. Corneal damage from a hydrogen peroxide–soaked tonometer tip that was not properly rinsed has been reported *(211)*.

An accelerated hydrogen peroxide–based technology has been recently introduced into healthcare for disinfection of noncritical environmental surfaces and patient equipment *(212)*, and high-level disinfection of semicritical equipment such as endoscopes *(213)*. Accelerated hydrogen peroxide contains very low levels of anionic and nonionic surfactants that act with hydrogen peroxide to produce microbicidal activity. These ingredients are considered safe for humans and benign for the environment. It is prepared and marketed in several concentrations from 0.5% to 7%. The lower concentrations (0.5%) are designed for the disinfection of hard surfaces, while the higher concentrations (2%) are recommended for use as high-level disinfectants. A 0.5% accelerated hydrogen peroxide demonstrated bactericidal and virucidal activity in 1 minute and mycobactericidal and fungicidal activity in 5 minutes *(212)*. It is more costly than other low-level disinfectants such as quaternary ammonium compounds. The product is claimed to have an excellent antimicrobial performance and a favorable safety profile. Another hydrogen peroxide–based technology has also been used for equipment cleaning *(140)*.

As mentioned, a high-level disinfectant based on AHP (2.0%) is available for heat-sensitive semicritical medical devices including manual and automatic reprocessing of flexible endoscopes. It is odorless, nonstaining, ready to use, and has a 12-month shelf life and a 14-day reuse life. This product has demonstrated sporicidal activity, with a reduction in viability titer of >6-$\log_{10}$ in 6 hours at 20°C, but also mycobactericidal, fungicidal, and virucidal activity with a contact time of 8 minutes. It is reported to be a relatively mild solution for end users and is considered to be compatible with flexible endoscopes. It is slightly irritating to skin and mildly irritating to eyes according to accepted standard test methods (same as 3% topical hydrogen peroxide) *(213)*. AHP (7%) can be reused for several days and retain its broad-spectrum antimicrobial activity *(214)*.

Iodophors Iodine solutions or tinctures have long been used by health professionals, primarily as antiseptics on skin or tissue. The FDA has not cleared any liquid chemical sterilant/high-level disinfectants with iodophors as the main active ingredient. However, iodophors have been used both as antiseptics and disinfectants. An iodophor is a combination of iodine and a solubilizing agent or carrier; the resulting complex provides a sustained-release reservoir of iodine and releases small amounts of free iodine in aqueous solution. The best known and most widely used iodophor is povidone-iodine, a compound of polyvinylpyrrolidone with iodine. This product and other iodophors retain the germicidal efficacy of iodine but, unlike iodine, are generally nonstaining and are relatively free of toxicity and irritancy *(215)*.

There are several reports that documented intrinsic microbial contamination of antiseptic formulations of povidone-iodine and poloxamer-iodine *(216,217)*. It was found that "free" iodine (I_2) contributes to the bactericidal activity of iodophors, and dilutions of iodophors demonstrate more rapid bactericidal action than does a full-strength povidone-iodine solution. Therefore, iodophors must be diluted according to the manufacturers' directions to achieve antimicrobial activity.

Published reports on the *in vitro* antimicrobial efficacy of iodophors demonstrate that iodophors are bactericidal, mycobactericidal, and virucidal but may require prolonged contact times to kill certain fungi and bacterial spores *(19,218–221)*.

Besides their use as an antiseptic, iodophors have been used for the disinfection of blood culture bottles and medical equipment such as hydrotherapy tanks and thermometers. Antiseptic iodophors are not suitable for use as hard-surface disinfectants because of concentration differences. Iodophors formulated as antiseptics contain less free iodine than those formulated as disinfectants *(222)*. Iodine or iodine-based antiseptics should not be used on silicone catheters as the silicone tubing may be adversely affected *(223)*.

Ortho-phthalaldehyde (OPA) Ortho-phthalaldehyde is a high-level disinfectant that received FDA clearance in October 1999. It contains at least 0.55% OPA and it has supplanted glutaraldehyde as the most commonly used high-level disinfectant in the United States. OPA solution is a clear, pale-blue liquid with a pH of 7.5. The advantages, disadvantages, and characteristics of OPA are listed in Table 80-3.

Studies have demonstrated excellent microbicidal activity in *in vitro* studies *(12,176,193,224–229)* including superior mycobactericidal activity (5-$\log_{10}$ reduction in 5 minutes) compared to glutaraldehyde. Walsh and colleagues also found OPA effective (>5-$\log_{10}$ reduction) against a wide range of microorganisms, including glutaraldehyde-resistant mycobacteria and *Bacillus atrophaeus* spores *(227)*.

OPA has several potential advantages compared to glutaraldehyde. It has excellent stability over a wide pH range (pH 3–9), is not a known irritant to the eyes and nasal passages, does not require exposure monitoring, has a barely perceptible odor, and requires no activation. OPA, like glutaraldehyde, has excellent material compatibility. A potential disadvantage of OPA is that it stains proteins gray (including unprotected skin) and thus must be handled with caution *(176)*. However, skin staining would indicate improper handling that requires additional training and/or personal protective equipment (PPE) (gloves, eye and mouth protection, fluid-resistant gowns). OPA residues remaining on inadequately water-rinsed transesophageal echocardiogram probes may leave stains of the patient's mouth. Meticulous cleaning, using the correct OPA exposure time (e.g., 12 minutes in the United States; 5 minutes at 25°C in an AER), and copious rinsing of the probe with water should eliminate this problem. Since OPA has been associated with several episodes of anaphylaxis following cystoscopy *(230)*, the manufacturer has modified its instructions for use of OPA and contraindicates the use of OPA as a disinfectant for reprocessing all urological instrumentation for patients with a history of bladder cancer. PPE should be worn when handling contaminated instruments, equipment, and chemicals *(225)*. In addition, equipment must be thoroughly rinsed to prevent discoloration of a patient's skin or mucous membrane. The minimum effective concentration of OPA is 0.3% and that concentration is monitored by test strips designed specifically for the OPA solution. OPA exposure level monitoring found that the concentration during the disinfection process was significantly higher in the manual group (median: 1.43 ppb) than in the automatic group (median: 0.35 ppb). These findings corroborate other findings that show that it is desirable to introduce automatic endoscope reprocessors to decrease disinfectant exposure levels among scope reprocessing technicians *(231)*.

Peracetic Acid Peracetic, or peroxyacetic acid, is characterized by a very rapid action against all microorganisms. Special advantages of peracetic acid are its lack of harmful decomposition products (i.e., acetic acid, water, oxygen, hydrogen peroxide), it enhances removal of organic material *(232)* and leaves no residue. It remains effective in the presence of organic matter and is sporicidal even at low temperatures. Peracetic acid can corrode copper, brass, bronze, plain steel, and galvanized iron, but these effects can be reduced by additives and pH modifications. The advantages, disadvantages, and characteristics of peracetic acid are listed in Table 80-3.

Peracetic acid will inactivate gram-positive and gram-negative bacteria, fungi, and yeasts in <5 minutes at <100 ppm. In the presence of organic matter, 200 to 500 ppm is required. For viruses, the dosage range is wide (12–2,250 ppm), with poliovirus inactivated in yeast extract in 15 minutes with 1,500 to 2,250 ppm. An automated machine using peracetic acid to reprocess heat-sensitive devices such as endoscopes and their accessories is used in the United States *(233,234)*. In this system, a 35% concentration of peracetic acid is diluted to 0.2% with filtered water at a temperature of 50°C. Since the rinse water is tapwater that has been filtered and exposed to ultraviolet rays, it is not sterile. Therefore, the final processed devices are not sterile (FDA, April 6, 2010). Simulated-use trials have demonstrated excellent microbicidal activity *(234–238)*, and three clinical trials have demonstrated both excellent microbial killing and no clinical failures leading to infection *(239–241)*. Three clusters of infection using the peracetic acid automated endoscope reprocessor were linked to inadequately processed bronchoscopes when inappropriate channel connectors were used with the system *(242,243)*. These clusters highlight the importance of training, proper model-specific endoscope connector systems, and quality control procedures to ensure compliance with endoscope manufacturer's recommendations and professional organization guidelines. A high-level disinfectant available in the United Kingdom contains 0.35% peracetic acid. Although this product is rapidly effective against a broad range of microorganisms *(244,245)*, it tarnishes the metal of endoscopes and is unstable, resulting in only a 24-hour use life *(245)*.

Peracetic Acid with Hydrogen Peroxide Three chemical sterilants are FDA-cleared that contain peracetic acid plus hydrogen peroxide (0.08% peracetic acid plus 1.0% hydrogen peroxide, 0.23% peracetic acid plus 7.35% hydrogen peroxide, and 8.3% hydrogen peroxide plus 7.0% peracetic acid).

The advantages, disadvantages, and characteristics of peracetic acid with hydrogen peroxide are listed in Table 80-3.

The bactericidal properties of peracetic acid plus hydrogen peroxide have been demonstrated *(246)*. Manufacturer's data demonstrated that this combination of peracetic acid plus hydrogen peroxide inactivated all microorganisms with the exception of bacterial spores within 20 minutes. The 0.08% peracetic acid plus 1.0% hydrogen peroxide product was effective in inactivating a glutaraldehyde-resistant mycobacteria *(247)*.

The combination of peracetic acid and hydrogen peroxide has been used for disinfecting hemodialyzers *(248)*. The percentage of dialysis centers using a peracetic acid with hydrogen peroxide–based disinfectant for reprocessing dialyzers increased from 5% in 1983 to 62% in 2001 *(249)*.

Phenolics Phenol has occupied a prominent place in the field of hospital disinfection since its initial use as a germicide by Lister in his pioneering work on antiseptic surgery. In the past 40 years, however, work has been concentrated upon the numerous phenol derivatives or phenolics and their antimicrobial properties. Phenol derivatives originate when a functional group (e.g., alkyl, phenyl, benzyl, halogen) replaces one of the hydrogen atoms on the aromatic ring. Two phenol derivatives commonly found as constituents of hospital disinfectants are ortho-phenylphenol and ortho-benzyl-para-chlorophenol.

Published reports on the antimicrobial efficacy of commonly used phenolics showed that they were bactericidal, fungicidal, virucidal, and tuberculocidal *(12,19,53,76,218, 250–253)*.

Many phenolic germicides are EPA-registered as disinfectants for use on environmental surfaces (e.g., bedside tables, bedrails, laboratory surfaces) and noncritical medical devices. Phenolics are not FDA-cleared as high-level disinfectants for use with semicritical items but could be used to preclean or decontaminate critical and semicritical devices prior to terminal sterilization or high-level disinfection.

The use of phenolics in nurseries has been questioned because of the occurrence of hyperbilirubinemia in infants placed in bassinets where phenolic detergents were used *(254)*. In addition, Doan and coworkers demonstrated bilirubin level increases in phenolic-exposed infants compared to nonphenolic-exposed infants when the phenolic was prepared according to the manufacturers' recommended dilution *(255)*. If phenolics are used to clean nursery floors, they must be diluted according to the recommendation on the product label. Phenolics (and other disinfectants) should not be used to clean infant bassinets and incubators while occupied. If phenolics are used to terminally clean infant bassinets and incubators, the surfaces should be rinsed thoroughly with water and dried before the infant bassinets and incubators are reused *(22)*.

Quaternary Ammonium Compounds The quaternary ammonium compounds are widely used as surface disinfectants. There have been some reports of healthcare-associated infections associated with contaminated quaternary ammonium compounds used to disinfect patient-care supplies or equipment such as cystoscopes or cardiac catheters *(256,257)*. As with several other disinfectants (e.g., phenolics, iodophors), gram-negative bacteria have been found to survive or grow in them (258).

Results from manufacturers' data sheets and from published scientific literature indicate that the quaternaries sold as hospital disinfectants are generally fungicidal, bactericidal, and virucidal against lipophilic (enveloped) viruses; they are not sporicidal and generally not tuberculocidal or virucidal against hydrophilic (nonenveloped) viruses *(19,49,50,52,53,92,218,259,260)*. Best et al. and Rutala et al. demonstrated the poor mycobactericidal activities of quaternary ammonium compounds *(49,218)*.

The quaternaries are commonly used in ordinary environmental sanitation of noncritical surfaces such as floors, furniture, and walls. They have demonstrated sustained antimicrobial activity against VRE for 48 hours *(59)*. EPA-registered quaternary ammonium compounds are appropriate to use when disinfecting medical equipment that come into contact with intact skin (e.g., blood pressure cuffs).

Pasteurization

Pasteurization is not a sterilization process; its purpose is to destroy all pathogenic microorganisms with the exception of bacterial spores. The time-temperature relation for hot-water pasteurization is generally >70°C (158°F) for 30 minutes. The water temperature and time should be monitored as part of a quality assurance program *(261)*. Pasteurization of respiratory therapy *(262,263)* and anesthesia equipment *(264)* is a recognized alternative to chemical disinfection.

Ultraviolet Light

Ultraviolet light (UV) has been recognized as an effective method for killing microorganisms. It has been suggested for use in healthcare for several purposes to include air disinfection, room decontamination (see section Room Decontamination below), surface disinfection, biofilm disinfection *(265)*, and ultrasound probe disinfection *(266)*. Contaminated ultrasound probes can potentially transmit pathogens. When the probe is only in contact with the patient's skin, there is a low risk of infection and low-level disinfection is recommended; however, a higher level of disinfection is recommended when the probe contacts mucous membranes or nonintact skin. An evaluation of a new disinfection procedure for ultrasound probes using ultraviolet light demonstrated the median microbial reduction for UV was 100%, 87.5% for antiseptic wiping, and 88% for dry wiping *(266)*.

Surface disinfection with ultraviolet light (100–280 nm) has been evaluated with three hospital-related surfaces, namely, aluminum (bed railings), stainless steel (operating tables), and scrubs (laboratory coats). *Acinetobacter baumannii* were inoculated on small coupons (10^3 or 10^5/coupon) and exposed to 90 Joule/m^2. This exposure was effective in the inactivation of *Acinetobacter* from the metal coupon surfaces but ineffective in the decontamination of scrubs *(267)*.

REPROCESSING SEMICRITICAL ITEMS

Semicritical items represent the greatest risk of disease transmission as far more healthcare associated infections have been caused by semicritical items than critical or noncritical items (11). There is virtually no documented

risk of transmitting infectious agents to patients via noncritical items *(35)* when they are used as noncritical items and do not contact nonintact skin and/or mucous membranes. Critical items have a high risk of infection if such an item is contaminated with any microorganism; however, sterilization cycles that are designed for hospitals are usually based on the overkill approach. The time required for a 6-$\log_{10}$ reduction of highly resistant spores by the process is considered a half-cycle, and the full-cycle exposure time is the time for the half cycle doubled. Thus, a sterilization process can achieve a 12-$\log_{10}$ reduction of highly resistant spores while medical/surgical devices are contaminated with low numbers of microorganisms (85% of instruments <100 bacteria) after use in surgery *(268)*. This results in a huge margin of safety and a sterility assurance level of 10^{-6}, which means there is <1 chance in 1 million that a contaminant will survive on a medical product after the sterilization process. In contrast, semicritical items (e.g., gastrointestinal endoscopes), by virtue of the body cavities they enter, may be contaminated with a 1 billion bacteria *(269)*. A further complication is that many of these devices are constructed in a way that is very difficult to properly clean them (e.g., long, narrow lumens) before the high-level disinfection procedure. Thus, the result is a device with a sterility assurance level of 10^{0} to 10^{-3}, which means there is a greater chance that a contaminant will survive on a medical device after the high-level disinfection procedure than after sterilization (i.e., >1 in 1,000 chance that a contaminant will survive) *(270)*. Thus, reprocessing semicritical items has a narrower margin of safety, and any deviation from the reprocessing protocol can lead to the survival of microorganisms and an increased risk of infection.

Reprocessing of Endoscopes

Physicians use endoscopes to diagnose and treat numerous medical disorders. While endoscopes represent a valuable diagnostic and therapeutic tool in modern medicine and the incidence of infection associated with use has been reported as very low (about 1 in 1.8 million procedures) *(271)*, more healthcare-associated outbreaks have been linked to contaminated endoscopes than to any other medical device *(5–7,272,273)*. In order to prevent the spread of healthcare-associated infections, all heat-sensitive endoscopes (e.g., gastrointestinal endoscopes, bronchoscopes, nasopharygoscopes) must be properly cleaned and at a minimum subjected to high-level disinfection following each use. High-level disinfection can be expected to destroy all microorganisms although when high numbers of bacterial spores are present, a few spores may survive.

Flexible endoscopes, by virtue of the types of body cavities they enter, acquire high levels of microbial contamination (bioburden) during each use *(274)*. For example, the bioburden found on flexible gastrointestinal endoscopes following use has ranged from 10^{5} colony-forming units (CFU)/mL to 10^{10} CFU/mL, with the highest levels being found in the suction channels *(228,274–276)*. The average load on bronchoscopes before cleaning was 6.4×10^{4} CFU/mL. Cleaning reduces the level of microbial contamination by 4- to 6-$\log_{10}$. *(130,277)*. Using HIV-contaminated endoscopes, several investigators have shown that cleaning completely eliminates the microbial contamination on the scopes *(127,278)*. Similarly, other investigators found that ETO sterilization or high-level disinfection (soaking in 2% glutaraldehyde for 20 minutes) was effective only when the device was first properly cleaned *(279)*.

FDA maintains a list of cleared liquid chemical sterilants/high-level disinfectants that can be used to reprocess heat-sensitive medical devices, such as flexible endoscopes. Users can access and view the list at http://www.fda.gov/cdrh/ode/germlab.html *(27)*. At this time, the FDA-cleared and marketed formulations include ≥2.4% glutaraldehyde, 0.55% ortho-phthalaldehyde (OPA), 1.12% glutaraldehyde with 1.93% phenol/phenate, 7.35% hydrogen peroxide with 0.23% peracetic acid, 1.0% hydrogen peroxide with 0.08% peracetic acid, hypochlorite and hypochlorous acid system (650–675 ppm free available chlorine), 2.0% accelerated hydrogen peroxide, 3.4% glutaraldehyde with 26% isopropanol, 8.3% hydrogen peroxide with 7.0% peracetic acid, and 7.5% hydrogen peroxide *(27)*. These products have excellent antimicrobial activity; however, some oxidizing chemicals (e.g., 7.5% hydrogen peroxide, and 1.0% hydrogen peroxide with 0.08% peracetic acid) have been reported to cause cosmetic and functional damage to endoscopes *(176)*. Users should check with device manufacturers for information on germicide compatibility with their device. If the germicide is FDA-cleared, then it is safe when used according to the label directions; however, professionals should review the scientific literature as new data may become available regarding human safety or materials compatibility. ETO sterilization of flexible endoscopes is infrequent because it requires a lengthy processing and aeration time (e.g., 12–15 hours) and is a potential hazard to staff and patients. Three products that are commonly used for reprocessing endoscopes in the United States are ortho-phthalaldehyde; glutaraldehyde; and an automated, liquid chemical sterilant processing system that uses peracetic acid *(183)*. Ortho-phthalaldehyde has replaced glutaraldehyde in many healthcare facilities as it possesses several potential advantages compared to glutaraldehyde: no known irritation to the eyes and nasal passages, does not require activation or exposure monitoring, and has a 12-minute high-level disinfection claim in the United States *(176)*. Disinfectants that are not FDA-cleared and should not be used for reprocessing endoscopes include iodophors, alcohols, quaternary ammonium compounds, and phenolics. These solutions may still be in use outside the United States, but their use should be strongly discouraged because of lack of proven efficacy against all microorganisms or materials incompatibility.

The FDA's clearance of the contact conditions listed on germicide labeling is based on the manufacturer's test results. They conduct the testing under worst-case conditions for germicide formulation (i.e., minimum recommended concentration of the active ingredient) and include organic soil. Typically, manufacturers use 5% serum as the organic soil and hard water as examples of organic and inorganic challenges. The soil is used to represent the organic loading to which the device is exposed during actual use and that would remain on the device in the absence of cleaning. This method assures that the contact conditions provides complete elimination of the test mycobacteria (e.g., 10^{5} to 10^{6} *Mycobacteria tuberculosis* in organic soil and dried on a scope) if inoculated in the most difficult areas for the disinfectant to penetrate and contact in the absence

of cleaning, and thus, provides a margin of safety *(280)*. For 2.4% glutaraldehyde that requires a 45-minute immersion at 25°C to achieve high-level disinfection (i.e., 100% kill of *Mycobacterium tuberculosis*), FDA itself does not conduct testing, but relies solely on the disinfectant manufacturer's data. Users can find the contact conditions for cleared high-level disinfectants/chemical sterilants at http://www.fda.gov/cdrh/ode/germlab.html. It is important to note that data suggest that *M. tuberculosis* levels can be reduced by at least 8-$\log_{10}$ with cleaning (4-$\log_{10}$) *(130,275,276,281)* followed by chemical disinfection for 20 minutes at 20°C (4- to 6-$\log_{10}$) *(130,282–284)*. Based on these data, APIC *(285)*, the Society of Gastroenterology Nurses and Associates (SGNA) *(36,286–288)* the ASGE *(3)*, American College of Chest Physicians *(273)*, and a multisociety guideline *(39)* recommend alternative contact conditions with 2% glutaraldehyde to achieve high-level disinfection based on articles in the literature (e.g., that equipment be immersed in 2% glutaraldehyde at 20°C for at least 20 minutes for high-level disinfection) *(3,25,51,130,282,288–294)*. It is FDA's position that if the user chooses to use alternative contact conditions, they assume liability. In the absence of several well-designed experimental scientific studies regarding alternative exposure times of high-level disinfectants, the manufacturers' recommendations to achieve high-level disinfection should be followed. Currently, such data are available only for 2% glutaraldehyde solutions.

Dilution of glutaraldehyde during use commonly occurs and studies show a glutaraldehyde concentration decline after a few days of use in an automatic endoscope washer *(197,295)*. This occurs because instruments are not thoroughly dried and water is carried in with the instrument, which increases the solution's volume and dilutes its effective concentration *(296)*. This emphasizes the need to ensure that semicritical equipment is disinfected with an acceptable concentration of glutaraldehyde. Data suggest that 1.0% to 1.5% glutaraldehyde is the minimum effective concentration for >2% glutaraldehyde solutions when used as a high-level disinfectant *(197–199,297)*. Chemical test strips or liquid chemical monitors *(296,298)* are available for determining whether an effective concentration of glutaraldehyde is present despite repeated use and dilution. The frequency of testing should be based on how frequently the solutions are used (e.g., used daily, test daily; used weekly, test before use; used 30 times per day, test each tenth use), but the strips should not be used to extend the use life beyond the expiration date. Data suggest the chemicals in the test strip deteriorate with time *(200)*, and a manufacturer's expiration date should be placed on the bottles. The bottle of test strips should be dated when opened and used for the period of time indicated on the bottle (e.g., 120 days). The results of test strip monitoring should be documented. The glutaraldehyde test kits have been preliminarily evaluated for accuracy and range *(200)*, but the reliability has been questioned *(201)*. Manufacturers of some, but not all, chemical test strips, for ensuring the minimum effective concentration of the high-level disinfectant is present, recommend the use of quality control procedures to ensure the strips perform properly. If the manufacturer of the chemical test strip recommends a quality control procedure, comply with the manufacturer's recommendations. The concentration should be considered unacceptable or unsafe when the test indicates a dilution below the product's minimum effective concentration or MEC (generally to 1.0 to 1.5% glutaraldehyde or lower) by the indicator not changing color.

Flexible endoscopes are particularly difficult to disinfect *(299)* and easy to damage because of their intricate design and delicate materials *(300)*. Meticulous cleaning must precede any sterilization or high-level disinfection of these instruments. Failure to perform good cleaning may result in a sterilization or disinfection failure, and outbreaks of infection may occur. Several studies have demonstrated the importance of cleaning in experimental studies with the duck hepatitis B virus *(279,301)*, HIV *(302)*, and *Helicobacter pylori (303)*.

Examining healthcare-associated infections related only to endoscopes through July 1992, Spach found that 281 infections were transmitted by gastrointestinal endoscopy and 96 were transmitted by bronchoscopy. The clinical spectrum ranged from asymptomatic colonization to death. *Salmonella* species and *P. aeruginosa* repeatedly were identified as causative agents of infections transmitted by gastrointestinal endoscopy, and *M. tuberculosis* (TB), atypical mycobacteria, and *P. aeruginosa* were the most common causes of infections transmitted by bronchoscopy *(273)*. Major reasons for transmission were inadequate cleaning, improper selection of a disinfecting agent, failure to follow recommended cleaning and disinfection procedures *(5,7,35,272)*, damaged endoscopes *(304)* and flaws in endoscope design *(305,306)*, or automated endoscope reprocessors *(6,272)*. Failure to follow established guidelines has continued to lead to infections associated with gastrointestinal endoscopes *(7)* and bronchoscopes *(6,273)*. Potential device-associated problems should be reported to the FDA's Center for Devices and Radiologic Health. One multistate investigation found that 23.9% of the bacterial cultures from the internal channels of 71 gastrointestinal endoscopes grew ≥100,000 colonies of bacteria after completion of all disinfection/sterilization procedures (9 of 25 facilities were using a product that has been removed from the marketplace [6 facilities using 1:16 glutaraldehyde phenate], is not FDA-cleared as a high-level disinfectant [an iodophor] or no disinfecting agent) and before use on the next patient *(307)*. It should be acknowledged that the incidence of postendoscopic procedure infections resulting from an improperly processed endoscope has not been rigorously assessed.

Recommendations for the cleaning and disinfection of endoscopic equipment have been published and should be strictly followed *(3,36,39,273,285–288,308–311)*. Unfortunately, audits have shown that personnel do not consistently adhere to guidelines on reprocessing *(312–314)*, and outbreaks of infection continue to occur *(306,315–317)*. In order to ensure that reprocessing personnel are properly trained, there should be initial and annual competency testing for each individual who reprocesses endoscopic instruments *(36,243)*.

In general, endoscope disinfection involves five steps after leak testing: (1) clean—mechanically clean internal and external surfaces, including brushing internal channels and flushing each internal channel with water and a detergent or enzymatic cleaners (leak testing is recommended for endoscopes before immersion); (2) disinfect—immerse endoscope in high-level disinfectant (or chemical sterilant)

and perfuse (eliminates air pockets and ensures contact of the germicide with the internal channels) disinfectant into all accessible channels such as the suction/biopsy channel and air/water channel and expose for a time recommended for specific products; (3) rinse—rinse the endoscope and all channels with sterile water, filtered water (commonly used with AERs) or tapwater (i.e., high-quality potable water that meets federal clean water standards at the point of use); (4) dry—rinse the insertion tube and inner channels with alcohol and dry with forced air after disinfection and before storage; and (5) store—store the endoscope in a way that prevents recontamination and promotes drying (e.g., hung vertically). Drying the endoscope (steps 3 and 4) is essential to greatly reduce the chance of recontamination of the endoscope by microorganisms that may be present in the rinse water *(39,318)*. Because tapwater may contain low levels of microorganisms *(319)*, some have suggested that only sterile water (which may be prohibitively expensive) *(320)* or AER-filtered water be used. The suggestion to use only sterile water or filtered water is not consistent with published guidelines that allow tapwater with an alcohol rinse and forced air drying *(3,36,285,288)* or the scientific literature *(37,283)*. In addition, there has been no evidence of disease transmission when tapwater followed by an alcohol rinse and forced air drying has been used. AERs produce filtered water via passage through a bacterial filter (e.g., 0.2 μm). In addition to the endoscope reprocessing steps, a protocol should be developed that assures the user knows whether an endoscope has been appropriately cleaned and disinfected (e.g., using a room or cabinet for processed endoscopes only) or has not been reprocessed. Confusion can result when users leave endoscopes on movable carts, and it is unclear whether the endoscope has been processed or not. While one guideline has recommended that an endoscope (e.g., a duodenoscope) should be reprocessed immediately before its use *(310)*, other guidelines do not require this activity *(3,36,287,288)* and with the exception of the Association of periOperative Registered Nurses (AORN), professional organizations do not recommend that reprocessing be repeated so long as the original processing is done correctly. Based on studies that have assessed the microbiological stability of endoscopes after high-level disinfection, it appears that reprocessing after storage for a week or 2 weeks is unnecessary *(321–323)*. As part of a quality assurance program, healthcare facility personnel may consider random bacterial surveillance cultures of processed endoscopes to ensure high-level disinfection or sterilization *(6,324–327)*, although some investigators have suggested it is too time consuming and costly and process controls are preferable *(328)*. Reprocessed endoscopes should be free of microbial pathogens except for small numbers of relatively avirulent microbes that represent exogenous environmental contamination (e.g., coagulase-negative *Staphylococcus*, *Bacillus* species, diphtheroids). It has also been suggested that the final rinse water used during endoscope reprocessing be microbiologically cultured at least monthly *(329)*. The microbiologic standard that should be met has not been set and the value of routine endoscope cultures has not been shown *(330)*. In addition, neither the routine culture of reprocessed endoscopes nor the final rinse water has been validated by correlating viable counts on an endoscope to infection following an endoscopic procedure. If culturing of reprocessed endoscopes were done, sampling the endoscope would assess water quality as well as other important steps (e.g., disinfectant effectiveness, exposure time, cleaning) in the reprocessing procedure. A number of methods for sampling endoscopes and water have been described *(40,322,325,331–334)*. Novel approaches (e.g., ATP) to evaluate the effectiveness of endoscope cleaning *(150,152)* or endoscope reprocessing *(335)* have also been evaluated, but there is no accepted method for assessing the outcome of endoscope reprocessing.

The carrying case used to transport clean and reprocessed endoscopes outside of the healthcare environment should not be used to store an endoscope or to transport the instrument within the healthcare facility. A contaminated endoscope should never be placed in the carrying case as the case can also become contaminated. When the endoscope is removed from the case and properly reprocessed and put back in the case, the endoscope can become recontaminated by the case. If the carrying case becomes contaminated, it should be discarded (Olympus America, June 2002, written communication).

Infection preventionists should ensure that institutional policies are consistent with national guidelines and conduct infection control rounds periodically (e.g., at least annually) in areas where endoscopes are reprocessed to make certain there is compliance with policy. Breaches in policy should be documented and corrective action instituted. Some studies suggest the assurance of quality for endoscopic use could be achieved through process control (e.g., minimum effective concentration, training) as opposed to product control (i.e., microbiological monitoring) *(328)*. In incidents in which endoscopes were not exposed to a high-level disinfection process, all patients were assessed for possible acquisition of human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV). A 14-step method for managing a failure incident associated with high-level disinfection or sterilization has been described *(336)*. The possible transmission of bloodborne pathogens and other infectious agents highlights the importance of rigorous infection control *(337,338)*.

Automated Endoscope Reprocessors Automated endoscope reprocessors (AER) offer several advantages compared to manual reprocessing: they automate and standardize several important reprocessing steps; *(339–341)* reduce the likelihood that an essential reprocessing step will be skipped; reduce personnel exposure to high-level disinfectants or chemical sterilants; provide significant microbial reduction *(342)* and filtered tap water; and remove established biofilms and retards biofilm generation *(343)*. Disadvantages associated with some AERs include: generally does not eliminate cleaning; failure and outbreaks have been linked to poorly designed reprocessors; and does not monitor high-level disinfectant concentration. Failure of AERs has been linked to outbreaks of infections *(344)* or colonization *(6,345)*, and the AER water filtration system may not be able to reliably provide "sterile" or bacteria-free rinse water *(346,347)*. It is critical that correct connectors between the AER and the device are established to ensure complete flow of disinfectants and rinse water *(6,348)*. In addition, some

endoscopes such as the duodenoscopes (e.g., endoscopic retrograde cholangiopancreatography [ERCP]) contain features (e.g., elevator-wire channel) that require a flushing pressure that is not achieved by some AERs and must be reprocessed manually using a 2- to 5-mL syringe. There is a need for further development and redesign of AERs *(6,349)* and endoscopes *(300,350)* so that they do not represent a potential source of infectious agents. The potential for transmission of infection during endoscopy remains a concern for healthcare workers and patients (11).

A variety of capabilities has been incorporated into the available AERs, and these capabilities have been recently summarized *(351)*. All models have disinfection and rinsing cycles, and some have detergent cleaning, alcohol flush, and/or extended forced-air-drying cycles. Additional features may include variable cycle times; printed documentation of the process; low-intensity ultrasound waves; high-level disinfectant vapor recovery systems; heating to optimize the high-level disinfectants efficacy; a variable number of endoscopes processed per cycle; automated leak testing; automated detection of channel obstructions; and table top, floor standing and cart-mounted models *(351)*.

Not all reprocessors are compatible with all high-level disinfectants or with endoscopes from all manufacturers. Newer AERs should offer benefits over older models. One AER integrates cleaning and has achieved an FDA-cleared cleaning claim (Evo-Tech™). The users must continue to do the "bedside" cleaning (wipe external surfaces and flush each lumen with a detergent solution) and then place the scope directly (within one hour) into the Evo-Tech™ machine. This eliminates the labor-intensive manual cleaning. It also automatically detects leaks, alcohol is flushed through the channels prior to cycle completion to promote drying, and the AER integrates minimum effective concentration (MEC) monitoring. In addition, the printer provides complete monitoring of critical cycle parameters including MEC of the high-level disinfectant (ortho-phthalaldehyde), disinfection time, channel blockage detection, temperature, pressure, and time to ensure compliance throughout the process. Manufacturer's residual data for cleaning of the internal channels as well as external insertion tube surfaces were below the limit of <8.5 μg/cm^2. Another AER (Reliance) requires a minimal number of connections to the endoscope channels and uses a control boot (housing apparatus that creates pressure differentials to ensure connector-less fluid flow through all channels that are accessible through the endoscope's control handle channel ports). Data demonstrate that the soil and microbial removal effected by Reliance washing phase was equivalent to that achieved by optimal manual cleaning. For example, there was >99% reduction in protein and hemoglobin and both methods reduced the level of residual organic material to below 6.4 μg/cm^2 *(352)*.

Tonometers

Disinfection strategies for other semicritical items (e.g., applanation tonometers, rectal/vaginal probes, cryosurgical instruments, and diaphragm fitting rings) are highly variable. Currently, FDA requests that the device manufacturer include at least one validated cleaning and disinfection/sterilization protocol in the labeling for their device. As with all medications and devices, users should be familiar with the label instructions. One study revealed that no uniform technique was in use for disinfection of applanation tonometers, with disinfectant contact times varying from <15 sec to 20 minutes *(38)*. In view of the potential for transmission of viruses (e.g., herpes simplex virus [HSV], adenovirus 8, or HIV) *(353)* by tonometer tips, CDC has recommended *(354)* that the tonometer tips be wiped clean and disinfected for 5–10 minutes with either 3% hydrogen peroxide, 5,000 ppm chlorine, 70% ethyl alcohol, or 70% isopropyl alcohol. However, more recent data suggest that 3% hydrogen peroxide and 70% isopropyl alcohol are not effective against adenovirus capable of causing epidemic keratoconjunctivitis and similar viruses and should not be used for disinfecting applanation tonometers *(90,177,355)*. For this reason, the current CDC guideline recommends to wipe clean tonometer tips and then disinfect them by immersing for 5 to 10 minutes in either 5,000 ppm chlorine or 70% ethyl alcohol (11*,90,170,177,354,355*). Structural damage to Schiotz tonometers has been observed with a 1:10 sodium hypochlorite (5,000 ppm chlorine) and 3% hydrogen peroxide *(356)*. After disinfection, the tonometer should be thoroughly rinsed in tapwater and air dried before use.

Because a short and simple decontamination procedure is desirable in the clinical setting, swabbing the tonometer tip with a 70% isopropyl alcohol wipe is sometimes practiced *(357)*. Preliminary reports suggest that wiping the tonometer tip with an alcohol swab and then allowing the alcohol to evaporate may be an effective means of eliminating HSV, HIV, and adenovirus *(357–359)*. However, since these studies involved only a few replicates and were conducted in a controlled laboratory setting, further studies are needed before this technique can be recommended. In addition, two reports have found that disinfection of pneumotonometer tips between uses with a 70% isopropyl alcohol wipe contributed to outbreaks of epidemic keratoconjunctivitis caused by adenovirus type 8 *(360,361)*.

Endocavitary Probes

Vaginal probes are used in sonographic scanning. A vaginal probe and all endocavitary probes without a probe cover are semicritical devices as they have direct contact with mucous membranes (e.g., vagina, rectum, pharynx). While one could argue that the use of the probe cover changes the category, the CDC guideline proposes that a new condom/probe cover should be used to cover the probe for each patient, and since condoms/probe covers may fail *(362–365)*, high-level disinfection of the endocavitary probe also should be performed (11). The relevance of this recommendation is reinforced with the findings that sterile transvaginal ultrasound probe covers have a very high rate of perforations even before use (0%, 25%, and 65% perforations from three suppliers) *(365)*. After oocyte retrieval use, Hignett and Claman found a very high rate of perforations in used endovaginal probe covers from two suppliers (75% and 81%) i, while Amis and coworkers *(366)* and Milki and Fisch *(362)* demonstrated a lower rate of perforations after use of condoms (0.9% and 2.0%, respectively). Rooks and coworkers found that condoms were superior to commercially available probe covers for covering the ultrasound probe (1.7% for condoms versus 8.3% leakage for probe covers) *(367)*. These studies underscore the need for routine probe disinfection between examinations. Although most ultrasound manufacturers recommend the

use of 2% glutaraldehyde for high-level disinfection of contaminated transvaginal transducers, the use of this agent has been questioned *(368)* because it may shorten the life of the transducer and may have toxic effects on the gametes and embryos *(369)*. An alternative procedure for disinfecting the vaginal transducer has been offered by Garland and deCrespigny *(370)*. It involves the mechanical removal of the gel from the transducer, cleaning the transducer in soap and water, wiping the transducer with 70% alcohol or soaking it for 2 minutes in 500 ppm chlorine, and rinsing with tapwater and air drying. The effectiveness of this and other methods *(366)* has not been validated in either rigorous laboratory experiments or in clinical use. High-level disinfection with a product (e.g., hydrogen peroxide) that is not toxic to staff, patients, probes, and retrieved cells should be used until such time as the effectiveness of alternative procedures against microbes of importance at the cavitary site is demonstrated by well-designed experimental scientific studies. Other probes such as rectal, cryosurgical, and transesophageal probes/devices should also be subjected to high-level disinfection between patients.

Ultrasound probes may also be used during surgical procedures and have contact with sterile body sites. These probes may be covered with a sterile sheath to reduce the level of contamination on the probe and reduce the risk of infection. However, since the sheath does not provide complete protection of the probe, the probes should be sterilized between each patient use as with other critical items. If this is not possible, minimally high-level disinfect the probe and cover it with a sterile probe cover.

Some cryosurgical probes are not fully immersible. When reprocessing these probes, the tip of the probe should be immersed in a high-level disinfectant for the appropriate time (e.g., 20 minutes exposure with 2% glutaraldehyde) and any other portion of the probe that could have mucous membrane contact could be disinfected by immersion or wrapping (or wiping) with a cloth soaked in a high-level disinfectant in order to allow the recommended contact time. After disinfection, the probe should be rinsed with tapwater and dried before use. Healthcare facilities that use nonimmersible probes should replace them as soon as possible with fully immersible probes.

One study showed that the use of a high-quality, snugly fitting, sterile, disposable polyurethane sheath on a nasopharyngoscopes during a clinical examination, combined with enzymatic detergent cleaning and disinfection with 70% ethanol, can provide a reliably decontaminated, patient-ready instrument that eliminates the need for high-level disinfection of nasopharyngoscopes *(371)*. If other studies corroborate the integrity of the sterile polyurethane sheaths used in nasopharyngoscopy (or other procedures), this practice may be an option to high-level disinfection.

Thus, the CDC guideline states that even if probe covers have been used, clean and high-level disinfect other semicritical devices such as rectal probes, vaginal probes, and cryosurgical probes with a product that is not toxic to staff, patients, probes, and retrieved germ cells (if applicable). Use a high-level disinfectant at the FDA-cleared exposure time. When probe covers are available, use a probe cover or condom to reduce the level of microbial contamination. Do not use a lower category of disinfection or cease to follow the appropriate disinfectant recommendations when using probe covers because these sheaths and condoms may fail. Following high-level disinfection, rinse all items. Use sterile water, filtered water, or tapwater followed by an alcohol rinse for semicritical equipment that will have contact with the mucous membranes of the upper respiratory tract (e.g., nose, pharynx, esophagus) (11).

Prostate Biopsy Probes

Transrectal ultrasound (TRUS)–guided prostate biopsies are among the most common outpatient diagnostic procedures performed in urology practice to evaluate patients for prostate cancer after an elevated prostate-specific antigen level or abnormal digital rectal examination findings *(372)*. It involves obtaining multiple prostate tissue cores by passing a disposable biopsy needle through a needle guide under ultrasound guidance. All prostatic biopsy procedures likely result in contamination of the probe with blood or feces. During this procedure, the transducer assembly is generally covered with a barrier sheath *(373)*. Breaches in the reprocessing of prostate biopsy probes can pose a risk of disease transmission *(372,374)*.

Disinfection or sterilization of ultrasound transducer components is based on the function or use of each component. Since the biopsy needle penetrates sterile tissue for biopsy, it should be sterile. Ideally, the needle guide should be sterilized between patient uses. However, if this is not possible (i.e., clinic does not have a sterilizer as biopsy needles are likely purchased as single-use sterile devices), then high-level disinfection after disassembly and cleaning is acceptable as it has contact with mucous membranes but not sterile tissue. The FDA alert *(373)* and a CDC article *(372)* recommend that the needle guide be sterilized as the biopsy needle contacts the needle guide before it penetrates sterile tissue. This recommendation is inconsistent with current recommendation for the disinfection of endoscopes. It is currently recommended that gastrointestinal endoscopes be high-level disinfected minimally but that medical devices that pass through the endoscope and enter sterile tissue (biopsy forceps) be sterilized. There is no recommendation that the lumen or channel through which they pass should also be sterilized. One possible explanation for the inconsistency in this FDA recommendation is that the gastrointestinal endoscopes are high-level disinfected as there is no practical way to sterilize them, while the reusable needle guide for prostate probes can be sterilized (MJ Arduino, August 2006, written communication). While a barrier sheath is used on the transducer assembly during the biopsy procedure, the sheath is compromised by the penetration of the needle *(373)*. Although prostate probes and other endocavitary probes are often covered with a disposable sheath or condom *(373)*, such covers do not adequately protect the probe from microbial contamination due to leakage, (9%) *(375)* and thus the use of a cover does not alter the requirement for high-level disinfection minimally (11). FDA specifies the use of a sterile barrier sheath in their recommendation for reprocessing reusable ultrasound transducer assemblies *(373)*. It is appropriate to use a sterile barrier sheath when an ultrasound probe is entering a sterile body cavity, but when the probe is entering the rectum the need for a sterile barrier sheath is unclear.

All semicritical and critical medical devices must be thoroughly cleaned with enzymatic or nonenzymatic detergents before it is subjected to a high-level disinfection or

sterilization process., respectively. Brushes should be used, when possible, to effectively clean the transducer assemblies, especially the lumens. One investigation showed that the needle guide and prostate probe can be effectively disinfected with glutaraldehyde, but the needle guide must be disassembled from the transducer assembly *(376)*.

The FDA issued a Public Health Notification in June 2006 as a result of follow-up to the Department of Veterans Affairs (VA), Veterans Health Administration Patient Safety Alert related to a particular company's ultrasound transducer assemblies. During patient safety rounds, the lumen of a needle guide of an ultrasound transducer assembly was found to be soiled. The FDA guidance consisted of several steps (see http://www.fda.gov/MedicalDevices/Safety/AlertsandNotices/PublicHealthNotifications/ucm062086.htm for the complete method recommend by the FDA). We have evaluated the FDA steps and suggest some modifications (Table 80-4). Do not reuse items labeled for single use (e.g., single-use biopsy needles). Additional recommendations may be available in the operator's manuals or user guides. It is important that these recommendations be consistent with disinfection and sterilization guidelines/principles or that these recommendations have been validated by appropriate scientific studies. Do not use any disinfectant that can cause irreparable damage to the materials used to construct the probe. For example, if an alcohol rinse is not compatible with the probe, rinse with sterile water (not filtered water, or tap water) and do not rinse with alcohol. These recommendations could be adapted to all ultrasonic prostate probes to include those with an external needle guide attachment.

TABLE 80-4

Recommendations for Reprocessing Transrectal Ultrasound Prostate Biopsy Probes[a]

Cleaning
- Clean immediately after use
- Disassemble the transducer (remove needle guide from the probe)
- Brush clean (if possible) or flush each lumen and thoroughly clean all surfaces of reusable components with enzymatic or nonenzymatic detergent
- Rinse with tap water
- Dry with disposable cloth/towel or air dry
- Visibly inspect the entire device to ensure it is clean

High-Level Disinfection or Sterilization
- Steam sterilize all heat-stable reusable components
- Alternatively, high-level disinfect the probe and the needle guide separately following disassembly
- High-level disinfect all heat sensitive components (ensure disinfectant reaches all areas inside the lumens and the minimum effective concentration of the high-level disinfectant is monitored)
- Rinse with sterile water, filtered water, or tap water (FDA specifies sterile water for rinsing)
- If filtered water or tap water is used, follow with an alcohol rinse (not immersion of the probe in alcohol) to enhance drying (and no residual water is left for microbial growth)
- Dry the device
- Appropriately store the device to ensure the device is not recontaminated

[a]Users should be familiar with the manufacturer's recommendations for use and disinfection of the specific device used by the facility. (Modified from Rutala WA, Gergen MF, Weber DJ. Disinfection of a probe used in ultrasound-guided prostate biopsy. *Infect Control Hosp Epidemiol* 2007;28.)

Infrared Coagulation (IRC)

Infrared coagulation is a widely used method for treating hemorrhoids. The procedure involves applying infrared light to compress and seal hemorrhoid veins. The manufacturer of the device sells a sterile disposable sheath and states removing and soaking lightguides between procedures is no longer required. The manufacturer also states that the lightguide is damaged by immersion in a disinfectant as the lightguide is not sealed at the end and disinfectant gets between the quartz glass and the covering.

As mentioned, the CDC guideline recommends immersion for reprocessing endocavitary probes with covers because integrity of the cover is compromised. Since the lightguide cannot be immersed, we investigated an alternative procedure. This procedure involved wiping the probe for 2 minutes with a 1:10 bleach (5,000 ppm) and after that is completed, wipe the probe with sterile water and let the probe air dry. This procedure has been found effective in eliminating >6-$\log_{10}$ reduction (7.8×10^6) of *Mycobacterium terrae* and is used at our hospital for decontamination of the sheathed device after use *(377)*.

Laryngoscopes

Laryngoscopes are routinely used to view the vocal cords and larynx and for airway management. It typically consists of a blade that connects to a handle, which usually contains two batteries that powers the light source. Limited guidelines are available for reprocessing laryngoscope blades and handles, and hospital practices vary *(378,379)*. For example, some guidelines and hospitals low-level disinfect the handle as it does not have direct contact with a mucous membrane, and others recommend that the handle be high-level disinfected to prevent disease transmission. While blades have been linked to healthcare-associated infections, handles have not been directly linked to healthcare-associated infections (HAIs), but contamination with blood and other potentially infected materials during clinical use suggests its potential *(380)* and the blade and handle function together. When patient-ready handles were evaluated for blood or bacterial contamination, a high incidence of contamination was found *(380,381)*. For this reason, it is ideal that the blades and handles be high-level disinfe cted or sterilized even if a protective barrier or sheath is used during the procedure.

DISINFECTION OF SURFACES

Room Decontamination Units (Hydrogen Peroxide Vapor and Ultraviolet Light)

Surface disinfection of noncritical surfaces and equipment is normally performed by manually applying a liquid disinfectant to the surface with a cloth, wipe, or mop. Recent

studies have identified significant opportunities in hospitals to improve the cleaning of frequently touched objects in the patient's immediate environment (65*,382,383*). For example, of 20,646 standardized environmental surfaces (14 types of objects), only 9,910 (48%) were cleaned at terminal room cleaning (65). Epidemiologic studies have shown that patients admitted to rooms previously occupied by individuals infected or colonized with MRSA (384), VRE *(385)*, or *C. difficile (386)* are at significant risk of acquiring these microorganisms from contaminated environmental surfaces. These data have led to the development of room decontamination units that avoid the problems associated with the thoroughness of terminal cleaning activities in patient rooms.

Hydrogen peroxide vapor (HPV) has been used increasingly for the decontamination of biological safety cabinets and rooms in healthcare (387*,388–397*). These investigators found that HPV is a highly effective method for eradicating various pathogens (e.g., MRSA, *M. tuberculosis*, *Serratia*, *Clostridium difficile* spores, *Clostridium botulinum* spores) from rooms, furniture, and equipment. This room decontamination system has not only been found to be effective in eradicating pathogens from contaminated surfaces but has also been found to significantly reduced the incidence of *C. difficile* infection rates (387). Otter et al. *(398)* reported that the HPV decontamination required a mean time of 2 hours and 20 minutes, compared with 32 minutes for conventional cleaning. A summary of the advantages and disadvantages of hydrogen peroxide vapor for room decontamination is shown in Table 80-5.

Ultraviolet C light units have also been proposed for room decontamination. One unit (Tru-D) uses an array of UV sensors, which determines and targets shadowed areas to deliver a measured dose of UV energy that destroys microorganisms. This unit is fully automated, activated by a hand-held remote, and the room ventilation does not need to be modified. It uses UV-C (254 nm range) to decontaminate surfaces. It measures UV reflected from walls,

TABLE 80-5

Advantages and Disadvantages for Room Decontamination by Hydrogen Peroxide Vapor (HPV) and Ultraviolet C

Room Decontamination	*Advantages*	*Disadvantages*
HPV	• Efficacious (reliable biocidal activity) against wide range of pathogens (e.g., kills ~6 logs spores) • Surfaces and equipment decontaminated • Decrease incidence of disease (*C. difficile*) • Residue free and does not give rise to health and safety concerns (aeration units convert HPV into oxygen and water) • Uniform distribution in the room via an automated dispersal system • Useful for disinfecting complex equipment and furniture	• Contribution of the environment to disease transmission ~5% • Only done at terminal disinfection (not daily cleaning) • Rapid recontamination of the environment • All patients must be removed from the area • Decontamination takes ~3–5 h (bed turnover time: 72 min) • HVAC system must be disabled to prevent unwanted dilution of HPV during the exposure; room sealed with tape • Costs • Does not remove dust and stains that are important to patients/visitors • Sensitive parameters-HP concentration 280 ppm, temperature: 26–28°C, relative humidity: 48–57% • Long-term use exposure damage from microcondensation to sensitive electronics may occur? • Does not remove dust and stains
UVC	• Reliable biocidal activity against a wide range of pathogens (e.g., kills 3–4 logs vegetative bacteria) • Surfaces and equipment decontaminated • Room decontamination is rapid (~15 m) for vegetative bacteria • HVAC system does not need to be disabled • Room does not need to be sealed • It is residual free and does not give rise to health and safety concerns • No consumable products, so costs are capital equipment and staff time • Good distribution of UV energy via an automated monitoring system	• Do not know if use decreases the incidence of HAIs • Only done at terminal disinfection (i.e., not daily cleaning) • All patients and staff must be removed from the room/area • Capital equipment costs are substantial • Does not remove dust and stains • Sensitive use parameters (e.g., UV dose delivered)

(Modified from Rutala WA, Weber DJ. Disinfection and sterilization in healthcare facilities. In: Lautenbach E, Woeltje KF, Malani PN, eds. *Practical healthcare epidemiology*. Chicago, IL: University of Chicago Press, 2010:61–80.)

ceiling, floors, or other treated areas and calculated the operation time to deliver the programmed lethal dose for pathogens *(399)*. After UV dose is delivered, it will power down and an audible alarm will notify the operator. In one study, the effectiveness of UV-C radiation of MRSA, VRE, and MDR-*Acinetobacter* on surfaces was >99.9% within 15 minutes and 99.84% for C. difficile spores with 50 minutes. In rooms occupied by patients with MRSA, UV-C irradiation of <15 minutes reduced MRSA per surface site from 384 CFU to 19 CFU and reduced the number of positive samples for MRSA from 20.3% (81/400) to 0.5% (2/400) *(400)*.

OTHER DISINFECTION ISSUES

OSHA Bloodborne Pathogen Standard

In December 1991, the OSHA promulgated a standard entitled "Occupational Exposure to Bloodborne Pathogens" to eliminate or minimize occupational exposure to bloodborne pathogens *(401)*. One component of this requirement is that all equipment and environmental and working surfaces be cleaned and decontaminated with an appropriate disinfectant after contact with blood or other potentially infectious materials. While the OSHA standard does not specify the type of disinfectant or procedure, the OSHA original compliance document *(402)* suggested that a germicide must be tuberculocidal to kill the HBV (e.g., phenolic, chlorine). However, in February 1997, OSHA amended its policy and stated that EPA-registered disinfectants that are labeled as effective against HIV and HBV would be considered as appropriate disinfectants "…provided such surfaces have not become contaminated with agent(s) or volumes of or concentrations of agent(s) for which higher level disinfection is recommended." When bloodborne pathogens other than HBV or HIV are of concern, OSHA continues to require the use of EPA-registered tuberculocidal disinfectants or hypochlorite solution (diluted 1:10 or 1:100 with water) *(172,403)*. Recent studies demonstrate that, in the presence of large blood spills, a 1:10 final dilution of EPA-registered hypochlorite solution initially should be used to inactivate bloodborne viruses *(54,404)* to minimize risk of disease to the healthcare worker from percutaneous injury during the clean-up process.

Emerging Pathogens (*Cryptosporidium*, *Helicobacter pylori*, *Escherichia coli* O157:H7, Rotavirus, Human Papillomavirus, Norovirus, Severe Acute Respiratory Syndrome [SARS] Coronavirus, Avian Influenza Virus (H5N1), Novel Influenza H1N1, Hepatitis C Virus, Creutzfeldt-Jacob Disease (CJD), Antibiotic-resistant bacteria [VRE, MRSA])

Emerging pathogens are of growing concern to the general public and infection preventionists. Relevant pathogens include *Cryptosporidium parvum*, *Helicobacter pylori*, *E. coli* O157:H7, rotavirus, human papillomavirus, norovirus, SARS coronavirus, avian influenza virus, novel influenza H1N1, hepatitis C virus, CJD, multidrug-resistant bacteria such as MRSA. The susceptibility of each of these pathogens to chemical disinfectants/sterilants has been studied. With the exceptions discussed below, all of these emerging pathogens are susceptible to currently available chemical disinfectants/sterilants (11*,229,405*).

Cryptosporidium *Cryptosporidium* is resistant to chlorine at concentrations used in potable water. *C. parvum* is not completely inactivated by most disinfectants used in healthcare including ethyl alcohol *(193)*, glutaraldehyde *(193,406)*, 5.25% hypochlorite *(193)*, peracetic aci *(193)*, ortho-phthalaldehyde *(193)*, phenol *(193,406)*, povidone-iodine *(193,406)*, and quaternary ammonium compounds *(193)*. The only chemical disinfectants/sterilants able to inactivate greater than a 3-$\log_{10}$ reduction of *C. parvum* were 6% and 7.5% hydrogen peroxide *(193)*. Sterilization methods will fully inactivate *C. parvum*, including steam *(193)*, ETO, *(193,407)* and hydrogen peroxide gas plasma *(193)*. Although most disinfectants are ineffective against *C. parvum*, current cleaning and disinfection practices appear satisfactory to prevent healthcare-associated transmission. For example, endoscopes are unlikely to represent an important vehicle for the transmission of *C. parvum* because the results of bacterial studies indicate mechanical cleaning will remove approximately 10^4 microorganisms and drying rapidly results in loss of *C. parvum* viability (e.g., 30 minutes, 2.9-$\log_{10}$ decrease, and 60 minutes, 3.8-$\log_{10}$ decrease) *(193)*.

E. coli O157:H7 Chlorine at approximately 1 ppm has been found capable of eliminating approximately 4-$\log_{10}$ of *E. coli* O157:H7 within 1 minute in a suspension test *(95)*. Electrolyzed oxidizing water at 23°C was effective in 10 minutes in producing a 5-$\log_{10}$ decrease in *E. coli* O157:H7 inoculated onto kitchen cutting boards *(408)*. The following disinfectants eliminated >5-$\log_{10}$ of *E. coli* O157:H7 within 30 seconds: a quaternary ammonium compound, a phenolic, a hypochlorite (1:10 dilution of 5.25% bleach), and ethanol *(48)*.

Helicobacter pylori Data are available on the susceptibility of *H. pylori* to disinfectants. Using a suspension test, Akamatsu and colleagues assessed the effectiveness of a variety of disinfectants against nine strains of *H. pylori (93)*. Ethanol (80%) and glutaraldehyde (0.5%) killed all strains within 15 seconds; chlorhexidine gluconate (0.05%, 1.0%), benzalkonium chloride (0.025%, 0.1%), alkyldiaminoethylglycine hydrochloride (0.1%), povidone-iodine (0.1%), and sodium hypochlorite (150 ppm) killed all strains within 30 seconds. Both ethanol (80%) and glutaraldehyde (0.5%) retained similar bactericidal activity in the presence of organic matter, while the other disinfectants showed reduced bactericidal activity. In particular, the bactericidal activity of povidone-iodine (0.1%) and sodium hypochlorite (150 ppm) was markedly decreased in the presence of dried yeast solution with killing times increased to 5 to 10 minutes and 5 to 30 minutes, respectively. Disinfection of experimentally contaminated endoscopes using 2% glutaraldehyde (10, 20, 45 minutes exposure times) or the peracetic acid system (with and without active peracetic acid) has been demonstrated to be effective in eliminating *H. pylori (291)*. Epidemiologic investigations of patients who had undergone endoscopy with endoscopes mechanically washed and disinfected with 2.0% to 2.3% glutaraldehyde have revealed no evidence of person-to-person transmission of *H. pylori (303,409)*.

Rotavirus An outbreak of healthcare-associated rotavirus gastroenteritis on a pediatric unit has been reported *(410)*. Person-to-person via the hands of healthcare workers was proposed as the mechanism of transmission. Prolonged survival of rotavirus on environmental surfaces (90 minutes to more than 10 days at room temperature) and hands

(>4 hours) has been demonstrated. Rotavirus suspended in feces can survive for a longer period of time *(411,412)*. Vectors for this infection have included air, hands, fomites, water, and food *(412)*. Products with demonstrated efficacy (>3-$\log_{10}$ reduction in virus) against rotavirus within 1 minute include 95% ethanol, 70% isopropanol, some phenolics, 2% glutaraldehyde, 0.35% peracetic acid, and some quaternary ammonium compounds *(52,413–415)*. In a human challenge study, a disinfectant spray (0.1% ortho-phenylphenol and 79% ethanol), sodium hypochlorite (800 ppm free chlorine), and a phenol-based product (14.7% phenol diluted 1:256 in tapwater) when sprayed onto contaminated stainless steel disks were effective in interrupting the transfer of a human rotavirus from stainless steel disk to fingerpads of volunteers after an exposure time of 3 to 10 minutes. A quaternary ammonium product (7.05% quaternary ammonium compound diluted 1:128 in tapwater) and tapwater allowed transfer of virus *(47)*.

Human Papillomavirus Human papillomavirus (HPV) is an extremely common sexually acquired infection and is considered the cause of cervical cancer. While there are limited data regarding the inactivation of HPV by disinfectants because *in vitro* replication of complete virions has only been achieved recently, a pseudotype HPV-16 and a bovine papillomavirus were used in an infectivity assay to evaluate potential methods of disinfecting HPV-contaminated surfaces *(416)*. In this study, the bovine papillomavirus demonstrated substantial sensitivity to 70% ethanol, and all infectivity was eliminated for pseudotype HPV-16 virions. Studies with the bovine papillomavirus have shown a 99.9% inactivation with a 0.3% povidone-iodine solution *(417)*.

Pandemic Influenza The effect of chlorine on the H5N1 subtype of the avian influenza virus was evaluated. Free chlorine concentrations typically used in drinking water treatment (0.52 to 1.08 ppm) were sufficient to inactivate the virus by >3-$\log_{10}$ with an exposure time of 1 minute *(418)*. Common disinfectants (e.g., 70% ethanol, 70% propanol) and detergents were effective in inactivating influenza A virus H1N1 within 1 minute in surface and suspension tests *(57)*.

Norovirus More is known about the inactivation of norovirus (members of the family *Caliciviridae* and important causes of gastroenteritis in humans) even though they cannot easily be grown in tissue culture. Improper disinfection of environmental surfaces contaminated by the feces or vomitus of infected patients is believed to play a role in the spread of noroviruses in some settings *(419,420)*. Prolonged survival of a norovirus surrogate (i.e., feline calicivirus [FCV], a closely related cultivable virus) has been demonstrated (e.g., at room temperature, FCV in a dried state survived for between 18 and 21 days) *(260)*. Because of the limited ability to culture noroviruses, data are based on surrogates such as murine norovirus or feline calicivirus or an assessment for the presence of human norovirus genome by RT-PCR. Both methods have important drawbacks. The surrogate viruses may not mimic the susceptibililty of human noroviruses to germicides and the use of RT-PCR may detect nonviable norovirus (421).

Inactivation studies with FCV have shown the effectiveness of chlorine, glutaraldehyde, and iodine-based products, whereas the quaternary ammonium compound, detergent, and ethanol failed to inactivate the virus completely *(260)*. Sattar also evaluated the effectiveness of several disinfectants against the feline calicivirus and found that bleach diluted to 1,000 ppm of available chlorine reduced infectivity of FCV by 4.5 logs in 1 minute. Other effective (reduction factor of >4-$\log_{10}$ in virus) disinfectants included accelerated hydrogen peroxide-5,000 ppm (3 minutes); chlorine dioxide-1,000 ppm chlorine (1 minute); a mixture of four quaternary ammonium compounds-2,470 ppm (10 minutes); 79% ethanol with 0.1% quaternary ammonium compound (3 minutes); and 75% ethanol (10 minutes) *(422)*. Gehrke et al. *(423)* showed that 70% ethanol and 70% 1-propanol reduced FCV by a 3- to 4-$\log_{10}$ reduction in 30 seconds, and Whitehead and McCue showed >4-$\log_{10}$ reduction with 100 ppm chlorine in a 1-minute contact time *(424)*.

SARS or Severe Acute Respiratory Syndrome The CDC announced that a previously unrecognized human virus from the coronavirus family is the cause of a recently described syndrome of SARS or Severe Acute Respiratory Syndrome *(425)*. Two coronaviruses that are known to infect humans causes approximately one-third of common colds and may cause gastroenteritis. The virucidal efficacy of chemical germicides against coronavirus has been investigated. Sattar et al. *(355)* investigated the activity of several disinfectants against coronavirus 229E and found several disinfectants were effective after a 1-minute contact time including sodium hypochlorite (at a free chlorine concentration of 1,000 ppm and 5,000 ppm), 70% ethyl alcohol, and povidone-iodine (1% iodine). Saknimit et al. *(426)* showed that 70% ethanol, 50% isopropanol, 0.05% benzalkonium chloride, 50 ppm iodine in iodophor, 0.23% sodium chlorite, 1% cresol soap, and 0.7% formaldehyde inactivated >3 logs of two animal coronaviruses (mouse hepatitis virus, canine coronavirus) after a 10-minute exposure time. Sizun et al. *(427)* demonstrated the activity of povidone-iodine against human coronaviruses 229E and OC43. Since the SARS coronavirus is stable in feces and urine at room temperature for at least 1–2 days (World Health Organization, 2003; http://www.who.int/csr/sars/survival_2003_05_04/en/index.html), surfaces may be a possible source of contamination and lead to infection with the SARS coronavirus and should be disinfected. The antiviral action of common disinfectants (0.21% sodium hypochlorite, 0.23% pine oil, or 0.10% of a quaternary compound with 79% of ethanol) against murine hepatitis virus, a surrogate for SARS coronavirus, demonstrated a 3-$\log_{10}$ reduction or better in a 30-second contact time *(56)* Until more precise information is available, assume the environment in which SARS patients are housed is heavily contaminated and thoroughly disinfect the room and equipment daily and after the patient is discharged. Use EPA-registered disinfectants or 1:100 dilution of household bleach and water for surface disinfection and disinfection on noncritical patient-care equipment. High-level disinfection and sterilization of semicritical and critical medical devices, respectively, does not need to be altered for patients with known or suspected SARS.

Creutzfeldt Jakob Disease (CJD) The prions of CJD and other transmissible spongiform encephalopathies exhibit an unusual resistance to conventional chemical and physical decontamination methods. Because the CJD agent

is not readily inactivated by conventional disinfection and sterilization procedures and because of the invariably fatal outcome of CJD, the procedures for disinfection and sterilization of the CJD prion have been both cautious and controversial for many years. Recommendations for disinfection and sterilization of prion-contaminated medical devices are as follows (428). Instruments should be kept wet or damp until they are decontaminated, and they should be decontaminated as soon as possible after use. Dried films of tissue are more resistant to prion inactivation by steam sterilization compared to tissues that were kept moist. This may relate to the rapid heating that occurs in the film of dried material compared to the bulk of the sample, and the rapid fixation of the prion protein in the dried film *(429)*. It also appears that prions in the dried portions of the brain macerates are less efficiently inactivated than undisturbed tissue. For high-risk tissues (brain, spinal cord, and eyes), high-risk patients, and critical or semicritical medical devices, it is recommended to clean the device and sterilize by one of four methods, using steam sterilization as recommended in the scientific literature (428,*430*) (option 1 or 2) or using a combination of sodium hydroxide and autoclaving as recommended by the World Health Organization *(431)* (option 3 or 4):

1. Autoclave at 134°C for 18 minutes in a prevacuum sterilizer.
2. Autoclave at 132°C for 1 hour in a gravity displacement sterilizer.
3. Immerse in 1N NaOH [1N NaOH is a solution of 40 g NaOH in 1 L of water] for 1 hour; remove and rinse in water, then transfer to an open pan and autoclave [121°C gravity displacement or 134°C porous or prevacuum sterilizer] for 1 hour.
4. Immerse instruments in 1N NaOH for 1 hour and heat in a gravity displacement sterilizer at 121°C for 30 minutes. However, the combination of sodium hydroxide and steam sterilization may be deleterious to surgical instruments, sterilizers, as well as sterilizer operators who would be breathing vaporized chemicals unless engineering controls or use of PPE prevents exposure *(432)*.

The temperature should not exceed 134°C because under certain conditions the effectiveness of autoclaving actually declines as the temperature is increased (e.g., 136°C, 138°C) *(433)*. Prion-contaminated medical devices that are impossible or difficult to clean should be discarded. Flash sterilization should not be used for reprocessing. To minimize environmental contamination, noncritical environmental surfaces should be covered with plastic-backed paper and when contaminated with high-risk tissues the paper should be properly discarded. Environmental surfaces (noncritical) contaminated with high-risk tissues (e.g., laboratory surfaces) should be cleaned and then spot decontaminated with a 1:10 dilution of hypochlorite solutions (428).

To minimize the possibility of use of neurosurgical instruments that have been potentially contaminated during procedures performed on patients in whom CJD is later diagnosed, healthcare facilities should consider using the sterilization guidelines outlined above for neurosurgical instruments used during brain biopsy done on patients in whom a specific lesion has not been demonstrated (e.g., by magnetic resonance imaging or computerized tomography scans). Alternatively, neurosurgical instruments used in such patients could be disposable *(430)* or instruments quarantined until the pathology of the brain biopsy is reviewed and CJD excluded (428).

Multidrug-Resistant Microorganisms There are no data to show that antibiotic-resistant bacteria are less sensitive to the liquid chemical germicides than antibiotic-sensitive bacteria at currently used germicide contact conditions and concentrations *(434)*. Several studies have found antibiotic-resistant hospital strains of common healthcare-associated pathogens (i.e., *Enterococcus*, *P. aeruginosa*, *Klebsiella pneumoniae*, *E. coli*, *S. aureus*, and *S. epidermidis*) to be equally susceptible to disinfectants as antibiotic-sensitive strains *(48,435–437)*. The susceptibility of glycopeptide-intermediate *S. aureus* was similar to vancomycin-susceptible, methicillin-resistant *S. aureus (438)*. Based on these data, routine disinfection and housekeeping protocols do not need to be altered because of antibiotic resistance provided the disinfection method is effective *(439,440)*. A study that evaluated the efficacy of selected cleaning methods (e.g., QUAT-sprayed cloth, and QUAT-immersed cloth) for eliminating VRE found that currently used disinfection processes are likely highly effective in eliminating VRE. Despite the *in vitro* effectiveness of disinfectants, it is critical that the disinfectant have contact with the contaminated surface in order to remove and/or inactivate the pathogen *(439)*.

Disinfection of HBV-, HCV-, HIV- or Tuberculosis-Contaminated Devices

The CDC recommendation for high-level disinfection of HBV-, HCV-, HIV- or tuberculosis-contaminated devices is appropriate because experiments have demonstrated the effectiveness of high-level disinfectants to inactivate these and other pathogens that may contaminate semicritical devices *(53,94,172,218,278,293,302,404,441–457)*. Nonetheless, some healthcare facilities have modified their disinfection procedures when endoscopes are used with a patient known or suspected to be infected with HBV, HIV, or *M. tuberculosis (38,458)*. This is inconsistent with the concept of Standard Precautions that presumes that all patients are potentially infected with bloodborne pathogens *(172)*. Several studies have highlighted the inability to distinguish HBV- or HIV-infected patients from noninfected patients on clinical grounds *(459–461)*. It also is likely that mycobacterial infection will not be clinically apparent in many patients. In most instances, hospitals that altered their disinfection procedure used ETO sterilization on the endoscopic instruments because they believed this practice reduced the risk of infection *(38,458)*. ETO is not routinely used for endoscope sterilization because of the lengthy processing time. Endoscopes and other semicritical devices should be managed the same way whether or not the patient is known to be infected with HBV, HCV, HIV, or *M. tuberculosis*.

An evaluation of a manual disinfection procedure to eliminate HCV from experimentally contaminated endoscopes provided some evidence that cleaning and 2% glutaraldehyde for 20 minutes should prevent transmission *(455)*. Using experimentally contaminated hysteroscopes, Sartor and colleagues detected HCV by polymerase chain

reaction (PCR) in one (3%) of 34 samples following cleaning with a detergent, but no samples were positive following treatment with a 2% glutaraldehyde solution for 20 minutes *(292)*. Rey and colleagues demonstrated complete elimination of HCV (as detected by PCR) from endoscopes used on chronically infected patients following cleaning and disinfection for 3 to 5 minutes in glutaraldehyde *(290)*. Similarly, Chanzy and coworkers used PCR to demonstrate complete elimination of HCV following standard disinfection of experimentally contaminated endoscopes *(455)*, while Ishino and colleagues found that endoscopes used on patients who were positive for HCV antibody had no detectable HCV RNA after high-level disinfection *(462)*. The inhibitory activity of a phenolic and a chlorine compound on HCV showed that the phenolic inhibited the binding and replication of HCV, but the chlorine was ineffective, probably due to its low concentration and its neutralization in the presence of organic matter *(463)*. Recent experiments using cell-culture grown HCV showed 0.5% glutaraldehyde, 0.05% peracetic acid, and ethanol were able to completely inactivate HCV within 1 minute *(55)*.

Inactivation of Biothreat Agents

Recent publications have highlighted the concern about the potential for biological terrorism *(464,465)*. The CDC has categorized several agents as "high priority" because they can be easily disseminated or transmitted person-to-person, cause high mortality, and are likely to cause public panic and social disruption *(466)*. These agents include *Bacillus anthracis* (anthrax), *Yersinia pestis* (plague), variola major (smallpox), *Clostridium botulinum* toxin (botulism), *Francisella tularensis* (tularemia), filoviruses (Ebola hemorrhagic fever, Marburg hemorrhagic fever); and arenaviruses (Lassa [Lassa fever], Junin [Argentine hemorrhagic fever]), and related viruses *(466)*.

A few comments can be made regarding the role of sterilization and disinfection of potential agents of bioterrorism. First, the susceptibility of these agents to germicides *in vitro* is similar to other related pathogens. For example, variola is similar to vaccinia *(219)* and *B. anthracis* is similar to *B. atrophaeus* (formerly *B. subtilis*) *(467)*. Thus, one can extrapolate from the larger database available on the susceptibility of genetically similar microorganisms. Second, many of the potential bioterrorist agents are stable enough in the environment that contaminated environmental surfaces or fomites could lead to transmission of agents such as *B. anthracis*, *F. tularensis*, variola major, *C. botulinum* toxin, and *C. burnetii (468)*. Third, data suggest that current disinfection and sterilization practices are appropriate for the management of patient-care equipment and environmental surfaces when potentially contaminated patients are evaluated and/or admitted in a healthcare facility following exposure to a bioterrorist agent. For example, sodium hypochlorite may be used for surface disinfection (see http://www.epa.gov/pesticides/factsheets/chemicals/bleachfactsheet.htm). In instances where the healthcare facility is the site of a bioterrorist attack, environmental decontamination may require special decontamination procedures (e.g., chlorine dioxide gas for anthrax spores; see http://www.epa.gov/pesticides/factsheets/chemicals/chlorinedioxidefactsheet.htm). The effectiveness of sporicides to decontaminate rooms, buildings, and surfaces contaminated with biothreat agents is being investigated by the EPA and others *(469,470)*. These studies demonstrate that the effectiveness of sporicides varies based on many factors such as surface composition, exposure conditions, and method of application. For example, one study found that spraying or spreading chlorine dioxide resulted in only a 1-$\log_{10}$ reduction against *B. anthracis* (Sterne strain) because the chlorine dioxide gas was rapidly vaporized from the solutions compared to an 8-$\log_{10}$ reduction with aqueous chlorine dioxide in sealed tubes *(471)*. Use of disinfectants for decontamination following a bioterrorist attack requires crises exemption from the EPA (see http://www.epa.gov/opprd001/section18/). Of only theoretical concern is the possibility that a bioterrorist agent could be engineered to be less susceptible to disinfection and sterilization processes.

Toxicological, Environmental, and Occupational Concerns

Health hazards associated with the use of germicides in healthcare vary from mucous membrane irritation to death, with the latter involving accidental injection by mentally disturbed patients *(472)*. While variations exist in the degree of toxicity *(154,473–475)*, all disinfectants should be used with the proper safety precautions *(476)* and for the intended purpose only.

The key factors associated with assessing the health risk of a chemical exposure include the duration, intensity (i.e., how much chemical is involved), and route (e.g., skin, mucous membranes, and inhalation) of the exposure. Toxicity may be acute or chronic. Acute toxicity usually results from an accidental spill of a chemical substance. The exposure of personnel is sudden and often produces an emergency situation. Chronic toxicity results from repeated exposure to low levels of the chemical over a prolonged period. The responsibility for informing workers of the chemical hazards in the workplace and implementing control measures rests with the employer. The OSHA Hazard Communication Standard (29 CFR 1910.1200, 1915.99, 1917.28, 1918.90, 1926.59, and 1928.21) requires manufacturers and importers of hazardous chemicals to develop Material Safety Data Sheets (MSDSs) for each chemical or mixture of chemicals. Employers must have MSDSs readily available to employees who work with the products and thus may be exposed.

Exposure limits have been published for many chemicals used in healthcare to aid in providing a safe environment and are discussed in each section of this guideline as relevant. Only the exposure limits published by OSHA carry the legal force of regulations. OSHA publishes a limit as a time-weighted average (TWA), that is, the average concentration for a normal 8-hour work day and a 40-hour work week to which nearly all workers may be repeatedly exposed to a chemical without adverse health effects. For example, the permissible exposure limit (PEL) for ETO is 1.0 ppm, 8 hour TWA. The National Institute for Occupational Safety and Health (NIOSH) develops recommended exposure limits (RELs). RELs are occupational exposure limits recommended by NIOSH as being protective of worker health and safety over a working lifetime. This limit is frequently expressed as a 40-hour TWA exposure for up to 10 hours per day during a 40-per-hour work week. These exposure limits are designed for inhalation exposures.

Irritant and allergic affects may occur below the exposure limits, and skin contact may result in dermal effects or systemic absorption apart from inhalation. The current RELs can be accessed via the NIOSH webpage (www.cdc.gov/niosh). Guidelines on exposure limits are also provided by the American Conference of Governmental Industrial Hygienists (ACGIH) *(477)*. Additionally, information about workplace exposures and methods to reduce them (e.g., work practices, engineering controls, PPE) is available on the OSHA (www.osha.gov) and the NIOSH websites.

Some states have excluded the disposal of certain chemical germicides (e.g., glutaraldehyde, formaldehyde, and some phenols) or limited certain concentrations via the sewer system. These rules are intended to minimize environmental harm. If healthcare facilities exceed the maximum allowable concentration for a chemical (e.g., ≥5.0 mg/L), they have three options. First, they can switch to alternative products. For example, they can change from glutaraldehyde to another disinfectant for high-level disinfection or from phenolics to quaternary ammonium compounds for low-level disinfection. Second, the healthcare facility can collect the disinfectant and dispose of it as a hazardous chemical. Third, they can use a commercially available small-scale treatment method (e.g., neutralize glutaraldehyde with glycine).

The safe disposal of regulated chemicals is important throughout the medical community. In the case of disposal of large volumes of spent solutions, users may decide to neutralize the microbicidal activity prior to disposal (e.g., glutaraldehyde). This can be accomplished by reaction with chemicals such as sodium bisulfite *(478,479)* or glycine *(480)*.

European authors have suggested that disinfection by heat rather than chemicals should be used for instruments and ventilation therapy equipment. The concerns for chemical disinfection include the toxic side effects for the patient caused by chemical residues on the instrument or object; occupational exposure to toxic chemicals; and the danger of recontamination by rinsing the disinfectant with microbially contaminated tapwater *(481)*.

***Clostridium difficile*: Role of the Environment and Disinfection Prevention Strategies** *Clostridium difficile* is an enteric bacterial pathogen that causes an infection that results in a broad spectrum of disease ranging from mild diarrhea to life-threatening pseudomembraneous colitis. Although *C. difficile* infection (CDI) has been frequently encountered in hospitals and long-term care facilities for many years, the rates in the United States have tripled from 2000 to 2005, and disease morbidity and mortality have also increased *(178,482–484)*. This trend has been associated with the emergence of a new, highly virulent strain of *C. difficile* that produces greater quantities of toxins A and B and a separate binary toxin. To effectively manage this disease and keep informed of its changing epidemiology, optimal strategies in CDI surveillance, diagnosis, treatment, antibiotic control, and infection prevention are warranted *(485)*. This chapter only considers the role of the environment in transmission and the infection prevention strategies that prevent transmission.

The two major reservoirs of *C. difficile* in healthcare settings are humans, who are colonized or infected, and inanimate objects. Patients with symptomatic intestinal infection are thought to be major reservoir. The three mechanisms of transfer of *C. difficile* in the healthcare setting are: (a) direct transfer of *C. difficile* from a colonized or infected patient to the environment (e.g., rectal thermometer, commode, over-the-bed table) and contact by another patient and inoculation into the mouth (Fig. 80-2, section A); (b) direct transfer from a colonized or an infected patient to a healthcare worker via contact and transfer via hands to a noncolonized or noninfected patient (Fig. 80-2, section B); and (c) indirect transfer via healthcare worker contact (or any other person) with the contaminated environment and transfer to a noncolonized or noninfected patient (Fig. 80-2, section C) *(486)*. These modes of transmission can be prevented by infection prevention strategies such as Contact Precautions, hand hygiene with soap and water, and removing or inactivating the *C. difficile* spores from the inanimate environment (environmental surfaces or patient-care equipment).

Several factors facilitate the environmental route of transmission with *C. difficile*. First, *C. difficile* contaminates the environment of patients colonized or infected with *C. difficile*. Second, the *C. difficile* spore can survive in the hospital environment for up to 5 months *(487)*, whereas the vegetative bacteria die, due to desiccation, within 15 minutes in room air *(488)*. Vegetative *C. difficile* can remain viable on moist surfaces for up to 3 hours in room air. These data suggest that moist surfaces in hospitals (e.g., toilets, sinks, moist dressings) may provide a suitable environment for vegetative *C. difficile* to persist for several hours *(488)*. The spore is also more resistant to the effect of the gastric acids in the stomach *(489)*. Thus, the spore is the more likely bacterial form that is important in disease transmission that must be inactivated and/or removed by surface disinfection. Since the *C. difficile* spores are more likely involved in disease transmission than are vegetative bacteria, a claim based only on the vegetative bacteria would likely be potentially misleading and be incompletely effective in preventing disease transmission. Thus, the recent EPA letter preventing claims based on the inactivation of vegetative bacteria is both soundly based in science and judicious public health policy (F. Sanders, EPA, written communication, September 2008). Third, since spores are relatively resistant to inactivation by low-level disinfectants, a higher level of disinfection is needed to prevent an environmental mode of spread.

Transmission of *C. difficile* to a patient via transient hand carriage on healthcare workers' hands is thought to be the most likely mode of transmission (Fig. 80-2, sections B and C). Transient hand carriage can occur through patient or environmental contact. Fifty-nine percent of 35 healthcare workers had positive cultures for *C. difficile* from their hands after direct contact with a culture-positive patient *(490)*. *C. difficile* can be found at multiple sites of patients with CDI including groin, chest, abdomen, forearm, and hands and can be transferred to the care provider's hands *(491)*.

While healthcare workers are the most likely mode of transmission, the hands may become contaminated by either patient contact or contact with a contaminated environment or both. *C. difficile* contamination has been found in rooms of patients that are colonized or infected with

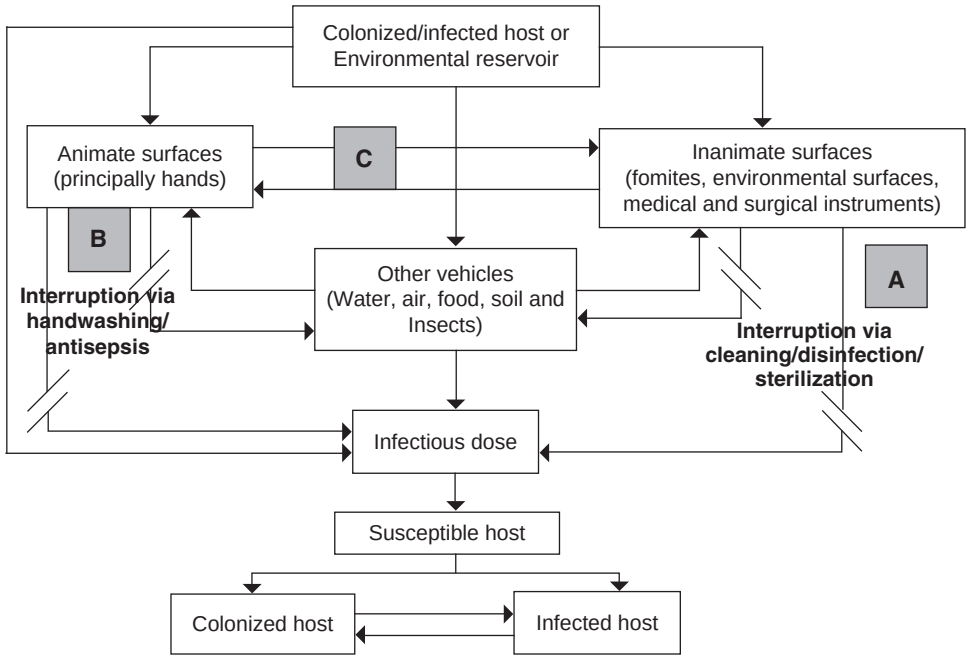

FIGURE 80-2 Transmission of *Clostridium difficile* via animate and inanimate surfaces. The three mechanisms of transfer of *C. difficile* in the healthcare setting are: (i) direct transfer of *C. difficile* from a colonized or an infected patient to the environment (e.g., rectal thermometer, commode, over-the-bed table) and contact by another patient and inoculation into the mouth (**section A**); (ii) direct transfer from a colonized or an infected patient to a healthcare worker via contact and transfer via hands to a noncolonized or noninfected patient (**section B**); and (iii) indirect transfer via healthcare worker contact with the contaminated environment and transfer to a noncolonized or noninfected patient (**section C**).

C. difficile, and the spores can persist on hard surfaces for months *(487)*. For example, *C. difficile* contamination has been found on 49% of sites in rooms occupied by patients with *C. difficile* infection and 29% of sites in rooms occupied by asymptomatic carriers *(490)*. Contamination of the environment and patient-care equipment occurs through fecal shedding or through the contaminated hands of the patient or healthcare workers *(489)*. There are several observations that demonstrate that contaminated environmental surfaces are important in the acquisition of *C. difficile* to include the incidence of CDI is significantly associated with the proportion of culture-positive environmental sites and epidemiological evidence that the use of sodium hypochlorite for environmental cleaning may significantly reduce the incidence of CDI. Data also demonstrate that the frequency of positive personnel hand cultures was strongly correlated with the density of environmental contamination *(492)*. For example, hand contamination was 0% when environmental contamination was 0–25%, 8% when environmental contamination was 25–50%, and 36% of the hand cultures positive when environmental contamination was >50% *(493)*. Additionally, the use of an effective antimicrobial (i.e., chlorine) significantly decreased environmental contamination in rooms of patients with *C. difficile*. For example, Eckstein observed nine of the rooms (90%) of patients with CDI had one or more positive cultures prior to cleaning with 1:10 dilution of bleach versus 2 (20%) after cleaning *(494)*. Kaatz et al. recovered *C. difficile* from 31% of the environmental samples. When the ward was disinfected with unbuffered hypochlorite (500 ppm available chlorine), surface contamination decreased to 21% of the initial levels and the CDI outbreak ended. Phosphate-buffered hypochlorite (1,600 ppm available chlorine) was even more effective in reducing environmental *C. difficile* levels, with a resultant 98% reduction in surface contamination *(495)*.

With increasing CDI rates, clearly there is a need for more effective infection prevention strategies. Strategies to prevent patient ingestion of spores consist of traditional infection prevention strategies that target the environment, hand hygiene, and barrier precautions such as Contact Precautions *(178)*. Two strategies have been shown to be effective at interrupting disease transmission during CDI clusters or epidemic periods: effective room decontamination by surface disinfection with sodium hypochlorite to minimize environmental contamination; and the use of effective barrier precautions (especially gloves) during patient contact to prevent transmission *(178)*.

Studies have shown that admission to a room previously occupied by a patient with MRSA (384), VRE *(385)*, or *C. difficile (386)* significantly increases the odds of acquiring the drug-resistant microorganisms. These studies demonstrate the importance of effective room disinfection or eliminating the pathogen from the environment. Pathogen survival of environmental surfaces or patient-care equipment may be attributable to ineffective products (i.e., disinfectants that don't kill the pathogen) or poor practices (i.e., all surfaces are not wiped or a poor technique that does not remove the pathogen) *(383)*.

Since *C. difficile* is shed in the feces, any surface or device that becomes contaminated by feces or hands can serve as a reservoir for *C. difficile* spores. The frequency of *C. difficile* contamination in patients' rooms may vary

from approximately 10% to >50% (387,*487,492–502*). The *C. difficile* spore load on environmental surfaces in healthcare facilities is low. To our knowledge, seven studies assessed the microbial load of *C. difficile* on environmental surfaces and most studies usually found <10 colonies of *C. difficile* on sampled surfaces found to be contaminated (387,*487,493–495,497,502*). Two studies reported more than 100 colonies; one reported a range of "1 to >200" and one study that sampled several sites with a sponge found 1,300 colonies. The heaviest contamination is found on floors but other sites frequently found contaminated are windowsills, commodes, toilets, call buttons, scales, blood pressure cuffs, toys, bathtubs, tables, light switches, phones, door handles, mops, electronic thermometers, and feeding tube equipment. These spores will remain in the environment for months unless physical removed or inactivated by disinfectants. Most low-level disinfectants used in healthcare (e.g., alcohol, quaternary ammonium compounds, phenolics) are not effective against *C. difficile* spores, while higher-level disinfectants kill the spores (e.g., glutaraldehyde, 5,000 ppm chlorine)(Unpublished data, WA Rutala, December 2008) *(179)*.

The importance of environmental contamination in disease transmission is emphasized by the epidemiological findings that disinfection with sodium hypochlorite (i.e., bleach) has been shown to be effective in reducing environmental contamination in patient rooms and in reducing CDI rates in hospital units where the rate of CDI is high (defined as >3 cases per 1,000 patient days). In an intervention study, the incidence of CDI for bone marrow transplant patients decreased significantly, from 8.6 to 3.3 cases per 1,000 patient days after the environmental disinfection was switched from a quaternary ammonium compound to 1:10 dilution of concentrated hypochlorite solution (i.e., bleach) in the rooms of patients with CDI *(498)*. When the protocol was reversed and a quaternary ammonium compound was reintroduced to those units, rates returned to the high baseline rate of 8.1 cases per 1,000-patient days. No reduction in CDI rates was seen among neurosurgical ICU and medicine patients for whom baseline rates were 3.0 and 1.3 cases per 1,000 patient days. Three other studies have also provided epidemiological data that demonstrates the effectiveness of chlorine disinfection in reducing *C. difficile* spores on environmental surfaces and reduces the incidence of *C. difficile*. *(492,495,503)*. For this reason, the use of bleach (1:10 dilution of concentrated bleach) is recommended by the Centers for Disease Control and Prevention during outbreaks of CDI (11). One application of bleach covering all surfaces to allow a sufficient wetness for ≥ 1 minute contact time is recommended. A dilution of bleach with water normally takes 1 to 3 minutes to dry. For sporadic CDI cases where there is no epidemic or recognized cross transmission of *C. difficile*, hospitals can use their regular EPA-registered disinfectant for disinfection of patient rooms. Recently, room disinfection by vaporized hydrogen peroxide has also been found to reduce *C. difficile* incidence rates (387).

In summary, environmental interventions are an important part of a comprehensive strategy in preventing transmission of *C. difficile* in a healthcare setting. The use of chlorine during hyperendemic and epidemic periods has been shown to reduce environmental contamination with *C. difficile* and to reduce the incidence of *C. difficile* infection rates. Interventions, such as chlorine, aimed at optimizing environmental disinfection are an important component of our infection prevention strategies.

Dental Instruments

Scientific articles and increased publicity about the potential for transmitting infectious agents in dentistry have focused attention on dental instruments as possible agents for pathogen transmission *(504,505)*. The American Dental Association recommends that surgical and other instruments that normally penetrate soft tissue or bone (e.g., extraction forceps, scalpel blades, bone chisels, periodontal scalers, and surgical burs) be classified as critical devices that should be sterilized after each use or discarded. Instruments that are not intended to penetrate oral soft tissues or bone (e.g., amalgam condensers, and air/water syringes) but may come in contact with oral tissues are classified as semicritical but are recommended to be sterilized after each use if the instruments are heat tolerant *(506,507)*. If a semicritical item is heat sensitive, it should, at a minimum, be processed with high-level disinfection *(507,508)*. Handpieces can be contaminated internally with patient material and should be heat sterilized after each patient. Handpieces that cannot be heat sterilized should not be used *(509)*. Methods of sterilization that may be used for critical or semicritical dental instruments and materials that are heat-stable include steam under pressure (autoclave), chemical (formaldehyde) vapor, and dry heat (e.g., 320°F for 2 hours). The steam sterilizer is the method most commonly used by dental professionals *(510)*. All 3 sterilization procedures can be damaging to some dental instruments, including steam-sterilized handpieces *(511)*. Heat-tolerant alternatives are available for most clinical dental applications and are preferred *(507)*.

CDC has divided noncritical surfaces in dental offices into clinical contact and housekeeping surfaces *(507)*. Clinical contact surfaces may be touched frequently with gloved hands during patient care or surfaces that may become contaminated with blood or other potentially infectious material and subsequently contact instruments, hands, gloves, or devices (e.g., light handles, switches, dental x-ray equipment, chair-side computers). Barrier protective coverings (e.g., clear plastic wraps) may be used for these surfaces particularly those that are difficult to clean (e.g., light handles, chair switches). The coverings should be changed when visibly soiled, when damaged, and on a routine basis (e.g., between patients). Disinfect protected surfaces at the end of the day or if contamination is evident. If not barrier-protected, these surfaces should be disinfected between patients with an intermediate-disinfectant (i.e., EPA-registered hospital disinfectant with tuberculocidal claim) or low-level disinfectant (i.e., EPA-registered hospital disinfectant with an HBV and HIV label claim) *(401,403,507)*.

Most housekeeping surfaces need to be cleaned only with a detergent and water or an EPA-registered hospital disinfectant, depending on the nature of the surface and the type and degree of contamination. When housekeeping surfaces are visibly contaminated by blood or body substances, however, prompt removal and surface disinfection is a sound infection control practice and required by OSHA *(401,507)*.

Several studies have demonstrated variability among dental practices while trying to meet these recommendations *(512,513)*. For example, 68% of respondents believed they were sterilizing their instruments but did not use appropriate chemical sterilants or exposure times and 49% of respondents did not challenge autoclaves with biological indicators *(512)*. Other investigators using biological indicators have found a high portion (15–65%) of positive spore tests after assessing the efficacy of sterilizers used in dental offices. In one study of Minnesota dental offices, operator error, rather than mechanical malfunction *(514)*, caused 87% of sterilization failures. Common factors in the improper use of sterilizers include chamber overload; low temperature setting; inadequate exposure time; failure to preheat the sterilizer; and interruption of the cycle.

Disinfection in the Hemodialysis Unit

Hemodialysis systems include hemodialysis machines, water supply, water treatment systems, and the distribution system. During hemodialysis, patients have acquired bloodborne viruses and pathogenic bacteria *(515–517)*. Cleaning and disinfection are important components of infection control in a hemodialysis center. Disinfectants used to reprocess hemodialyzers, hemodialysis machines, and water treatment systems are regulated by the EPA and the FDA.

Disinfection on noncritical surfaces (e.g., dialysis bed or chair, countertops, external surfaces of dialysis machines, and equipment [scissors, hemostats, clamps, blood pressure cuffs, stethoscopes]) should be done with an EPA-registered disinfectant unless the item is visibly contaminated with blood in which case a tuberculocidal agent (or a disinfectant with specific label claims for HBV and HIV) or a 1:100 dilution of a hypochlorite solution (500–600 ppm free chlorine) should be used *(516,518)*. This procedure accomplishes two goals, i.e., it removes soil on a regular basis and maintains an environment that is consistent with good patient care. Disinfection of hemodialyzers is accomplished with peracetic acid, formaldehyde, glutaraldehyde, heat pasteurization with citric acid, and chlorine-containing compounds *(519)*. Disinfection of hemodialysis systems is normally accomplished by chlorine-based disinfectants (e.g., sodium hypochlorite), aqueous formaldehyde, heat pasteurization, ozone, or peracetic acid *(520,521)*. All products must be used according to the manufacturers' recommendations. Some dialysis systems use hot-water disinfection for the control of microbial contamination.

At its high point, 82% of U.S. chronic hemodialysis centers were reprocessing (i.e., reuse) dialyzers for the same patient using high-level disinfection *(519)*. However, one of the large dialysis organizations has decided to phase out reuse, and as of 2002 the percentage of dialysis facilities reprocessing hemodialyzers had dropped to 63% *(522)*. The two commonly used disinfectants to reprocess dialyzers were peracetic acid and formaldehyde; 72% used peracetic acid and 20% used formaldehyde to disinfect hemodialyzers. Another 4% of the facilities either used glutaraldehyde or heat pasteurization in combination with citric acid *(522)*. Detailed infection control recommendations, to include disinfection and sterilization and the use of dedicated machines for HBsAg-positive patients, in the hemodialysis setting may be found in two reviews *(515,516)*. Recommended practices for the reuse of hemodialyzers have been published by the Association for the Advancement of Medical Instrumentation *(523)*.

Disinfection in Ambulatory Care, Home Care, and the Home

With the advent of managed healthcare, increasing numbers of patients are now being cared for in ambulatory care and in home settings. Many patients cared for in these settings may have communicable diseases, immunocompromising conditions, or invasive devices. Therefore, adequate disinfection in these settings is necessary to provide a safe patient environment. Since the ambulatory care setting (i.e., outpatient facilities) provides the same infection risk as the hospital, the Spaulding classification scheme described in this guideline should be followed (Table 80-1) *(22)*.

The home environment should be a much safer setting than hospitals or ambulatory care. Epidemics should not be a problem and cross infection should be rare. The healthcare provider is responsible for providing the responsible family member information on infection control procedures to follow in the home including hand hygiene, proper cleaning and disinfection of equipment, and safe storage of cleaned and disinfected devices. Among the products recommended for home disinfection of reusable objects are bleach, alcohol, and hydrogen peroxide. It has been recommended by APIC that reusable objects (e.g., tracheostomy tubes) that touch mucous membranes be disinfected by immersion in 70% isopropyl alcohol for 5 minutes, or 3% hydrogen peroxide for 30 minutes. Additionally, a 1:50 dilution of 5.25%–6.15% sodium hypochlorite (household bleach) for 5 minutes should be effective *(160,166,524)*. Noncritical items (e.g., blood pressure cuffs, crutches) can be cleaned with a detergent. Blood spills should be handled as per OSHA regulations as described in a previous section. In general, sterilization of critical items is not practical in homes but theoretically could be accomplished by chemical sterilants or boiling. Single-use disposable items can be used or reusable items sterilized in a hospital *(525,526)*.

Some environmental groups advocate "environmentally safe" products as alternatives to commercial germicides in the home-care setting. These alternatives (e.g., ammonia, baking soda, vinegar, Borax, liquid detergent) are not registered with the EPA and should not be used for disinfecting because they are ineffective against *S. aureus*. Borax, baking soda, and detergents are also ineffective against *Salmonella typhi* and *E. coli*; however, undiluted vinegar and ammonia are effective against *S. typhi* and *E.coli (48,527,528)*. Common commercial disinfectants designed for home use have also been found effective against selected antibiotic-resistant bacteria *(48)*.

Public concerns have been raised that the use of antimicrobials in the home may promote the development of antibiotic-resistant bacteria *(529,530)*. This issue is unresolved and needs to be considered further via scientific and clinical investigations. While the public health benefits resulting from the use of disinfectants in the home environment are unknown, it is known that many sites in the home kitchen and bathroom are microbially contaminated *(531)*, the use of hypochlorites results in a marked reduction of bacteria *(532)*, and good standards of hygiene (e.g., food hygiene, hand hygiene) may have an impact on reducing infections arising in the home *(533,534)*. It is also known from laboratory studies that many commercially prepared

household disinfectants are effective against common pathogens *(48)* and can interrupt surface-to-human transmission of pathogens *(44)*. The "targeted hygiene concept," which means identifying situations and areas (e.g., food preparation surfaces and bathroom) where there is a risk of transmission of pathogens, may be a reasonable way to identify when disinfection may be appropriate *(535)*.

Susceptibility of Antibiotic-Resistant Bacteria to Disinfectants

As with antibiotics, reduced susceptibility (or acquired "resistance") of bacteria to disinfectants can arise by either chromosomal gene mutation or the acquisition of genetic material in the form of plasmids or transposons *(71–74,533,536)*. When there is a change in bacterial susceptibility that renders an antibiotic ineffective against an infection previously treatable by that antibiotic, the bacteria are referred to as "resistant." In contrast, reduced susceptibility to disinfectants does not correlate with failure of the disinfectant because concentrations used in disinfection still greatly exceed the cidal level. Thus, the word "resistance" when applied to these changes is incorrect, and the preferred term is reduced susceptibility or increased tolerance *(71,537)*. Currently, there are no data to show that antibiotic-resistant bacteria are less sensitive to the liquid chemical germicides than antibiotic-sensitive bacteria at currently used germicide contact conditions and concentrations *(434)*.

MRSA and VRE are recognized as important healthcare-associated agents. It has been known for years that some antiseptics and disinfectants are, on the basis of minimum inhibitory concentrations (MICs), somewhat less inhibitory to *S. aureus* strains that contain a plasmid-carrying gene encoding resistance to the antibiotic gentamicin *(71)*. For example, Townsend et al. found that gentamicin resistance also encodes reduced susceptibility to propamidine, quaternary ammonium compounds, and ethidium bromide *(538)*, and Brumfitt and associates found MRSA strains less susceptible than methicillin-sensitive *S. aureus* (MSSA) strains to chlorhexidine, propamidine, and the quaternary ammonium compound cetrimide *(539)*. Al-Masaudi et al. found the MRSA and the MSSA strains to be equally sensitive to phenols and chlorhexidine, but MRSA strains were slightly more tolerant to quaternary ammonium compounds *(540)*. Studies have established the involvement of two gene families (*qac*CD [now referred to as *smr*] and *qac*AB) in providing protection against agents that are components of disinfectant formulations such as quaternary ammonium compounds. Tennant and coworkers propose that staphylococci evade destruction because the protein specified by the *qac*A determinant is a cytoplasmic-membrane-associated protein involved in an efflux system that actively reduces intracellular accumulation of toxicants such as quaternary ammonium compounds to intracellular targets *(541)*.

Other studies demonstrated that plasmid-mediated formaldehyde tolerance is transferable from *Serratia marcescens* to *E. coli (542)* and plasmid-mediated quaternary ammonium tolerance is transferable from *S. aureus* to *E. coli (543)*. Tolerance to mercury and silver is also plasmid borne *(71–74,536)*.

Since the concentrations of disinfectants used in practice are much higher than the MICs observed, even for the more tolerant strains, the clinical relevance of these observations is questionable. Several studies have found antibiotic-resistant hospital strains of common healthcare-associated pathogens (i.e., *Enterococcus, P. aeruginosa, Klebsiella pneumoniae, E. coli*, *S. aureus*, and *S. epidermidis*) to be equally susceptible to disinfectants as antibiotic-sensitive strains *(48,435–437)*. The susceptibility of glycopeptide-intermediate *S. aureus* was similar to vancomycin-susceptible, methicillin-resistant *S. aureus*. *(438)* Based on these data, routine disinfection and housekeeping protocols do not need to be altered because of antibiotic resistance provided the disinfection method is effective *(439,440)*. A study that evaluated the efficacy of selected cleaning methods (e.g., QUAT-sprayed cloth, and QUAT-immersed cloth) for eliminating VRE found that currently used disinfection processes are likely highly effective in eliminating VRE. However, surface disinfection must involve contact with all contaminated surfaces *(439)*.

Lastly, does the use of antiseptics or disinfectants facilitate the development of disinfectant-tolerant microorganisms? Based on current evidence and reviews *(529,530,536,537,544)*, the development of enhanced tolerance to disinfectants in response to disinfectant exposure can occur. However, it is not important in clinical terms since the level of tolerance is low and unlikely to compromise the effectiveness of disinfectants where much higher concentrations are used *(537,545)*.

The issue of whether low-level tolerance to germicides selects for antibiotic-resistant strains is unsettled but may depend on the mechanism by which tolerance is attained. For example, changes in the permeability barrier or efflux mechanisms may affect susceptibility to antibiotics and germicides, but specific changes to a target site may not. Some researchers have suggested that the use of disinfectants or antiseptics (e.g., triclosan) could facilitate the development of antibiotic-resistant microorganisms *(529,530,546)*. While there is evidence in laboratory studies of low-level resistance to triclosan, the concentrations of triclosan in these studies were low (generally <1 μg/mL) and dissimilar from the higher levels used in antimicrobial products (2,000–20,000 μg/mL) *(82,547)*. Thus, researchers can create laboratory-derived mutants that demonstrate reduced susceptibility to antiseptics or disinfectants. In some experiments, such bacteria have demonstrated reduced susceptibility to certain antibiotics *(530)*. There is no evidence that using antiseptics/disinfectants selects for antibiotic-resistant microorganisms in nature or that mutants survive in nature *(548)*. In addition, there are fundamental differences between the action of antibiotics and disinfectants. Antibiotics are selectively toxic and generally have a single target site in bacteria, thereby inhibiting a specific biosynthetic process. Germicides generally are considered to be nonspecific antimicrobials because of a multiplicity of toxic effect mechanisms or target sites and are broader spectrum in the types of microorganisms against which they are effective *(71,537)*.

The rotational use of disinfectants in some environments (e.g., pharmacy production units) has been recommended and practiced in an attempt to prevent the development of resistant microbes *(549,550)*. Currently, there appears to be rare case reports that appropriately used disinfectants have resulted in a clinical problem

arising from the selection or development of nonsusceptible microorganisms *(77)*.

Contact Times for Surface Disinfectants

An important issue concerning the use of disinfectants for noncritical surfaces in healthcare settings is that the contact time specified on the label of the product is often too long to be practically followed. The labels of most products registered by EPA for use against HBV, HIV, or *M. tuberculosis* (TB) specify a contact time of 10 minutes. The only way an institution can achieve a contact time of 10 minutes is to reapply the surface disinfectant 5–6 times to the surface as the typical dry time for a water-based disinfectant is 1.5–2 minutes and currently, healthcare facilities like UNC Health Care are achieving surface disinfection of noncritical patient-care items and environmental surfaces by one application of a disinfectant and requiring a >1 minute dry time. Long contact time, such as 10 minutes, are not practical for disinfection of environmental surfaces in a healthcare setting and requiring housekeeping staff to follow label directions for actions with no proven benefit to employee or patient safety may serve to reduce efforts proven to improve patient outcomes.

Multiple scientific papers have demonstrated significant microbial reduction with contact times of 30 to 60 seconds, and these studies are the basis for the CDC guideline of at least 1 minute for surface disinfection of noncritical surfaces *(42–50,52–57,90–95)*. Equally important as disinfectant contact time is the application of the disinfectant to the surface or the equipment to ensure that all contaminated surfaces and non-critical patient-care equipment are wiped as current studies demonstrate that only approximately 50% of high-risk objects are cleaned at terminal cleaning. Additionally, there are no data that demonstrate improved infection prevention by a 10-minute contact time versus a 1-minute contact time.

Currently, some EPA-registered disinfectants have contact times from 1 to 3 minutes and EPA will approve a shortened contact time for any product for which the manufacturers will submit confirmatory efficacy data. By law, all applicable label instructions on EPA-registered products must be followed, but we are not aware of an EPA enforcement action against healthcare facilities for "off label" use of a surface disinfectant although there have been citations reported from the Joint Commission and CMS.

Microbial Contamination of Disinfectants

Contaminated disinfectants and antiseptics have been occasional vehicles of healthcare-associated infections and pseudoepidemics for more than 50 years. A summary of the published reports describing contaminated disinfectants and antiseptic solutions leading to healthcare-associated infections has been published (258*,551*). Since this summary, additional reports have been published *(552–555)*. When examining the reports of disinfectants found contaminated with microorganisms, there are several noteworthy observations. Perhaps most importantly, high-level disinfectants/liquid chemical sterilants have not been associated with outbreaks due to intrinsic or extrinsic contamination. Another feature of these outbreaks has been that members of the genus *Pseudomonas* (e.g., *P. aeruginosa*) are the most frequent isolates from contaminated disinfectants, being the agents recovered from 80% of the contaminated products. Their ability to remain viable or grow in use-dilutions of disinfectants is unparalleled. This survival advantage for *Pseudomonas* is presumably due to their nutritional versatility, their unique outer membrane that constitutes an effective barrier to the passage of germicides, and/or efflux systems *(556)*. While the concentrated solutions of the disinfectants have not been demonstrated to be contaminated at the point of manufacture, Newman et al. found that an undiluted phenolic may be contaminated by a *Pseudomonas* sp. during use *(557)*. In most of the reports that describe illness associated with contaminated disinfectants, the product was used to disinfect patient-care equipment such as cystoscopes, cardiac catheters, and thermometers. The germicides used as disinfectants that were reported contaminated include chlorhexidine, quaternary ammonium compounds, phenolic, and pine oil.

The following control measures should be instituted to reduce the frequency of bacterial growth in disinfectants and the threat of serious healthcare-associated infections from the use of such contaminated products *(551)*. First, some disinfectants should not be diluted and those that are must be prepared correctly to achieve the manufacturer's recommended use-dilution. Second, infection preventionists must learn from the literature what inappropriate activities result in extrinsic contamination (i.e., at the point of use) of germicides and train users to prevent their recurrence. Common sources of extrinsic contamination of germicides in the reviewed literature are the water to make working dilutions, contaminated containers, and general contamination of the hospital areas where the germicides are prepared and/or used. Third, stock solutions of germicides must be stored as indicated on the product label. Currently, the EPA verifies manufacturers' efficacy claims against microorganisms. These measures should provide assurance that products that meet the EPA registration requirements are capable of achieving a certain level of antimicrobial activity when used as directed.

New Products and Issues in Disinfection

Several recent issues in disinfection that require comments will be briefly discussed. First, toxic anterior segment syndrome (TASS), which is an increasingly reported complication of cataract surgery. TASS is a sterile postoperative inflammatory reaction caused by a noninfectious substance that enters the anterior segment of the eye, resulting in toxic damage to intraocular tissues. The induction of TASS may be associated with specific products such as balanced salt solution, detergent (enzymatic and nonenzymatic) residues, bacterial endotoxins, preservatives, foreign matter, and residues from sterilization processing. Staff involved in reprocessing ocular instruments should be properly instructed in thoroughly cleaning and rinsing instruments prior to sterilization. Recommended practices related to reprocessing and preventing TASS are published by several professional organizations and government agencies (CDC, FDA, American Association of Medical Instrumentation, American Society of Cataract and Refractive Surgery, American Society of Ophthalmic Registered Nurses) *(558–563)*. Second, the use of bactericidal surface materials, such as copper and its alloys, might constitute a way to

minimize the spread of healthcare-associated pathogens. Effective inhibition of healthcare-associated pathogens by copper and alloys was best when the copper content was >55%. The use of copper-containing materials for surfaces in the hospital environment may be an adjunct for the prevention of HAIs and requires further evaluation *(564,565)*. Some strains of bacteria may be resistant to the toxic properties exerted by dry metallic copper surfaces *(566,567)*. Copper-based biocides have also been shown to have an antibacterial effect *(568)*. Third, antimicrobial coatings (e.g., polymer-encapsulated chlorine-dioxide-coated surfaces) continue to be investigated. One product provides a slow sustained release of gaseous chlorine dioxide at a rate sufficient to inhibit bacterial growth for 28 days. These investigations may offer a new direction for providing persistent microbicidal properties on surfaces *(569,570)*. Fourth, the use of atmospheric nonthermal plasma as a disinfectant for objects contaminated with bacteria such as MRSA also warrants further study *(571)*.

There are several issues that affect the reprocessing of semicritical items (items that touch mucous membranes) such as endoscopes, endocavitary probes, and laryngoscopes. First, there are new high-level disinfectants that include a 2% accelerated hydrogen peroxide *(213)*, an 8.3% hydrogen peroxide with 7.0% peracetic acid, and a 3.4% glutaraldehyde with 26% isopropanol *(572)*. Second, since breaches of high-level disinfection and sterilization guidelines are not uncommon, a 14-step protocol was developed to aid infection preventionists in the evaluation of potential disinfection and sterilization failures *(336)*. Third, prevention of disease transmission associated with laryngoscopes, prostate biopsy probes, and endoscopes requires adequate reprocessing of the device. Several recent papers review the recommendations for reprocessing semicritical medical devices that have been associated with disease transmission *(39,376,378,573)*.

Regarding the disinfection of noncritical items such as environmental surfaces, there are several noteworthy observations. First, and importantly, Carling and colleagues used an invisible fluorescent targeting method that assessed whether high-touch objects in a patient's room were cleaned as part of terminal disinfection procedure. They found that 50% of a standardized set of 14 objects were not cleaned at all. This information should be used to develop focused administrative and educational interventions that incorporate ongoing feedback to the environmental services staff to improve cleaning and disinfection practices *(383)*. For example, healthcare facilities may need to introduce the use of checklists or other tools (e.g., invisible fluorescent dyes) to ensure complete cleaning of all potentially contaminated surfaces. The inadequacy of terminal room disinfection likely explains why admission to a room previously occupied by an MRSA-positive patient or a VRE-positive patient significantly increased the odds of acquisition for MRSA and VRE (384). These observations highlight the importance of cleaning all surfaces and all accessible equipment each time cleaning is done in patient rooms. Second, healthcare facilities have started to use a microfiber mopping technique rather than a conventional, cotton string mop to clean floors. The microfiber system demonstrated superior microbial removal compared with cotton string mops when used with a detergent cleaner *(60)*. Third, an accelerated hydrogen peroxide product (0.5%) that claims virucidal, bactericidal, fungicidal, and tuberculocidal activity has been introduced into the United States for disinfection of noncritical environmental surfaces and equipment *(212)*. Fourth, a diverse group of pathogenic microorganisms were killed within 5 seconds by a steam disinfection system and therefore may represent a novel alternative to liquid chemical disinfectants *(574)*. Fourth, a new antimicrobial containing glucoprotamin (0.5%) as the active ingredient has proved to be very effective against bacterial clinical isolates in 1 minute *(575)*.

CONCLUSION

When properly used, disinfection and sterilization can ensure the safe use of invasive and noninvasive medical devices. The method of disinfection and sterilization depends on the intended use of the medical device: critical items (contact sterile tissue) must be sterilized prior to use; semicritical items (contact mucous membranes or nonintact skin) must be high-level disinfected; and noncritical items (contact intact skin) should receive low-level disinfection. Cleaning should always precede high-level disinfection and sterilization. Current disinfection and sterilization guidelines must be strictly followed.

Since semicritical equipment has been associated with reprocessing errors that result in patient lookback and patient notifications, it is essential that control measures be instituted to prevent patient exposures *(336)*. Before new equipment (especially semicritical equipment as the margin of safety is less than that for sterilization) *(270)* is used for patient care on more than one patient, reprocessing procedures for that equipment should be developed. Staff should receive training on the safe use and reprocessing of the equipment and be competency tested. Infection control rounds or audits should be conducted annually in all clinical areas that reprocess semicritical devices to ensure adherence to the reprocessing standards and policies. Results of infection control rounds should be provided to the unit managers and deficiencies in reprocessing should be corrected and the corrective measures documented to infection control within 2 weeks.

CHAPTER 81

Sterilization and Pasteurization in Healthcare Facilities

Lynne M. Sehulster and Walter W. Bond

Since ancient times, man has understood the importance of heat and water as purifying agents. One of the first references to purifying rituals using heat and water is found in the Old Testament, describing the cleaning procedures for warriors' blood-contaminated weapons and clothing after the battle:

> *"Purify every garment, everything made of leather, everything woven of goat's hair, and everything made of wood. Only the gold, the silver, the bronze, the iron, the lead, everything that can endure the fire, you shall put through the fire, and it shall be clean; and it shall be purified with the water of purification.[1] But all that cannot endure fire you shall put through water."*
>
> *Numbers 31:20, 22-23 (New King James Version)*

Although mankind held a vague concept that an unseen presence was associated with the spread of disease, scientific awareness and acceptance of the microbial world emerged in Europe beginning in 1677 with Anton van Leeuwenhoek's invention of the microscope. Over the next 300 years, the great names in microbiology and medicine (e.g., Lazzaro Spallanzani, Louis Pasteur, and Robert Koch) advanced our understanding of the microbial world, all of which instituted efforts in the civilized world to develop the means to control infectious diseases through environmental sanitation, personal hygiene, and processes to preserve and protect food and water. The canning industry was among the first to employ pressurized steam sterilization to inactivate spoilage microorganisms, thereby rendering containerized food products safe to eat even after long periods of storage. In fact, *Geobacillus stearothermophilus* (formerly *Bacillus stearothermophilus*), the source of the highly resistant bacterial endospores used today as the reference standard in the design and monitoring of steam autoclave cycles, is a common food spoilage microorganism.

The findings and conclusions in this chapter are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention. Any use of mention of trade names in this chapter is for identification purposes only and does not represent any endorsement by either the CDC or the U.S. Public Health Service.

[1]Also known as "water of separation"—a presumably alkaline infusion of select herbs and ritually prepared animal ashes.

It has been little more than 110 years since the development of formal procedures for the sterilization of instruments and medical devices, liquids, and other materials used in hospitals. At that time, there was a growing appreciation for the role of microorganisms in the transmission of infectious diseases and for the necessity of sterile materials in surgery and other hospital activities. Although infection prevention as we know it today was in its infancy, scientists both in hospitals and in the medical device industry began to sterilize instruments and materials used in patient treatments (1).

Historically, physical methods (e.g., steam under pressure in steam autoclaves, dry heat in sterilizing ovens) have played the predominant role for sterilizing devices, equipment, and supplies in hospitals and industry. Since the 1950s, however, the number of heat-sensitive devices that must be sterilized using low-temperature processes has increased. Those low-temperature sterilization processes available to hospitals may employ gases, gas plasmas, or liquid chemicals, whereas the medical device industry typically uses gas (ethylene oxide, ETO) or irradiation for terminal sterilization. Exposure of heat-sensitive materials to short-cycle substerilizing temperatures (e.g., pasteurization [60–75°C for 5–15 minutes]) is common in the food industry but of limited use in the medical arena in the United States.

The material in this chapter centers on a review of the general principles of sterilization and pasteurization as currently performed primarily in US healthcare facilities. Discussion of the sterilization methods used in industry (e.g., irradiation), as well as an in-depth review of the mathematical/engineering basis of sterilization, is beyond the scope of this chapter. The reader is referred to two excellent texts for more detailed information on these topics (*2,*3). This chapter also does not discuss the use of liquid chemicals for disinfection as this topic is thoroughly covered in Chapter 80. Furthermore, the day-to-day operations and maintenance of sterilizers and all the attendant processes, occupational safety, construction, regulations, and quality control aspects, are addressed in Chapter 70.

DEFINITIONS

Over the years, the terms "sterilization," "sterile," "decontamination," and "disinfection" have often been used

interchangeably, thereby leading to considerable confusion among healthcare personnel. For "sterile" and "sterilization," we view these, respectively, in the context of the *state* of sterility, as the *process* of sterilization and the *application* of sterilization. Any device or solution is considered to be sterile when it is completely free of all microorganisms, either living or inert (i.e., viruses, bacterial endospores, or fungal spores) (1). This *state* of sterility is the objective of the sterilization procedure, and viewed in this context, the definition is categorical and absolute (i.e., an item is either sterile or it is not). An interesting dilemma arises with fluids "sterilized" via filtration, using bacteriologic filters (nominal pore size of 0.2 μm) for this purpose. Such filtered liquids are often labeled as "sterile," but the pore size of the filters used is large enough to permit the passage of viruses or certain pleomorphic or cell wall–deficient gram-negative bacterial species (e.g., species of *Pseudomonas, Proteus, and Stenotrophomonas*), *Mycoplasma* spp., or *Mycobacterium* spp. (including *Mycobacterium tuberculosis* and waterborne nontuberculous mycobacteria) to the filtrate. Therefore, in the most practical sense of the term, such liquids do not meet the strict definition of "sterile" (4). This is especially true if the fluid being filtered has a potentially high microbial content (e.g., untreated, contaminated water or, not infrequently, water from the piping and tubing systems of treated public/institutional water supplies). An exception is noted for the end-stage filtration of "finished" liquids in the production of pharmaceutical and medical products that have been subjected to one or more rigorous prefiltration purification steps.

Sterilization is the use of a physical, chemical (liquid, gas, or plasma), or irradiation process to destroy all microorganisms including large numbers of highly resistant bacterial endospores. A *sterilization procedure,* on the other hand, cannot be categorically defined. Rather, the procedure is defined as a process, after which the probability of a microorganism surviving on an item is <1 in 1 million (10^{-6}). This is referred to as the *sterility assurance level* (SAL), and the attendant concepts are used by the medical device industry to design and monitor sterilization cycles for wide varieties and large quantities of medical devices.

The *application* of sterilization takes into account additional considerations (e.g., the Spaulding terminology used in the classification of materials subjected to various germicidal processes). Dr. E. H. Spaulding in 1972 *(5)* devised a classification scheme for reusable medical devices and instruments to determine the appropriate terminal reprocessing step for each of these items. Such medical devices and instruments were categorized as "critical," "semi-critical," or "noncritical" based on the manner in which they come into contact with patients and the corresponding risk of infection transmission during their use. *Critical* instruments or devices, the first category, are so called because of the substantial risk of infection if the item is contaminated with microorganisms at the time of use (i.e., with these instruments, sterility is *critical*). These are instruments or objects that are introduced directly into the human body, either into or in contact with the bloodstream or normally sterile areas of the body. Examples include needles, scalpels, transfer forceps, cardiac catheters, implants, and also the inner surface components of extracorporeal bloodflow devices, such as those of the heart–lung oxygenator and the blood side of artificial kidneys (hemodialyzers). These items must be meticulously cleaned, then sterilized by a validated sterilization process before use on the next patient, thereby minimizing the potential for disease transmission. Instruments or devices in the second category are classified as *semi-critical* in terms of the risk of infection, and examples are flexible gastrointestinal endoscopes, bronchoscopes, endotracheal and aspirator tubes, respiratory therapy equipment, and vaginal speculа. Although these items come in contract with mucous membranes, they do not ordinarily come into contact with the bloodstream or a sterile body site during normal use. Sterilization of many of these items, although desirable and cost-effective if they can withstand steam autoclaving, is not absolutely essential (i.e., according to Spaulding's classification, it is *semi-critical* that they be sterile at the time of use). At a minimum, semi-critical instruments or devices should be subjected to the comparatively potent heat or chemical treatment referred to as *high-level disinfection*—a process that is discussed in detail in Chapter 80. Instruments, devices, or surfaces that come into direct or indirect contact only with intact skin during routine use (e.g., backboards, blood pressure cuffs, and stethoscopes) have only minimal risk of disease transmission. The sterility of these surfaces and devices is *noncritical*. For some of these items and surfaces, washing with soap and water may be the only between-use process necessary. Medical equipment used routinely in patient care is typically cleaned and disinfected routinely, but care must be used to minimize damage to and malfunction of electronic medical equipment when using liquid cleaners and disinfectants. Cleaning and application of low- to intermediate-level disinfection for noncritical surfaces are defined and discussed in Chapter 80.

GENERAL FACTORS AFFECTING STERILIZATION PROCESSES

A significant consideration in assessing the effectiveness of a sterilization process is the overall *resistance* level of the target microbial population. Resistance can be categorized as *intrinsic* or *extrinsic. Intrinsic resistance* is the innate capacity of a particular microbial cell to resist a specific potentially lethal treatment. *Extrinsic resistance*, in contrast, describes the added challenge that inert organic matter and other extraneous materials or configurations (e.g., mated surfaces such as forceps' hinges) pose to a sterilizing process. Organic matter, soil, patient material, or charred matter can diminish the effectiveness of the sterilizing treatment. It follows that high numbers of the most highly resistant microorganisms and large amounts of organic matter present on a device or surface will contribute significantly to the overall resistance of the population to inactivation and therefore, both of these contaminants should be minimized prior to sterilization or any other terminal reprocessing. Meticulous cleaning of devices, instruments, and surfaces is therefore an enormously important first step that will ensure the overall success of the process.

Intrinsic Resistance

Microorganisms vary widely in their responses to physical and chemical stresses. Among the various categories of

microorganisms, the species that form bacterial endospores possess the highest level of intrinsic resistance to sterilization processes, and because of this, they are consistently used as standard challenge microorganisms when initially designing and engineering a sterilization cycle and also when monitoring in-use performance of sterilizer equipment in the healthcare setting. Intrinsic resistance stems from innate and specific biophysical and biochemical properties of the particular strain of the spore-forming bacterium. These properties can be affected by external factors such as pH and the ionic concentration of growth and sporulation media, all of which can have pronounced effects on spore resistance to heat. Endospores are more readily inactivated at low pH because pH can affect ionic adsorption to the spore surface, which in turn can affect heat stability *(6)*. In contrast, yeasts in low pH media can exhibit increased resistance to heat *(2)*. With respect to thermal resistance of bacterial endospores, Powell, in 1953, identified dipicolinic acid (DPA) (pyridine-2, 6-dicarboxylic acid) as closely associated with thermoresistance *(7)*. This chemical is found in correspondingly high levels in all endospores with significant resistance to heat, but is absent in the vegetative bacterial cells *(8)*. When sterilization researchers developed the inactivation kinetic rates (survival curves) for various bacterial endospores, they observed that endospores first emerge from a dormant state, and the cellular energy required to do this is called "activation energy." This is the initial step in the inactivation process and also occurs prior to cellular growth. Grecz et al., in 1972, determined that this step involved the dissolution of a calcium salt of DPA. The rate of DPA loss is proportional to levels of intrinsic thermal resistance of the endospores *(9)*. Endospores of different genera and species often demonstrate widely differing levels of intrinsic resistance to different sterilizing agents. A classic example of this observation is seen with heat applications. For moist heat sterilizing processes, endospores of *G. stearothermophilus* provide the greatest challenge for this process, whereas their resistance to dry heat is very low. *Bacillus atrophaeus* (formerly *B. subtilis* var. *niger*) endospores have greater resistance to dry heat than to moist heat (3). Another example illustrates this point. A curious, extremely slow-growing bacterium, *Bacillus xerothermodurans*, was isolated from soil collected near the National Aeronautics and Space Administration (NASA) Vehicle Assembly Building (VAB) at Cape Kennedy, FL, in the 1970s *(10,11)*. Endospores of this microorganism exhibited an extreme level of intrinsic resistance to dry heat (i.e., at 125°C, the length of time needed to reduce the number of surviving spores by 90% was **139 hours**). In contrast, endospores of *B. atrophaeus*, the standard challenge microorganism used to design and monitor dry heat or ETO sterilization cycles, showed a 90% reduction of surviving spores when exposed for 15 *minutes* to dry heat at 125°C. In other words, *B. xerothermodurans* is >500-fold more resistant to inactivation by dry heat than is *B. atrophaeus*. Interestingly, endospores of *B. xerothermodurans* are extremely sensitive to inactivation with moist heat (i.e., a 90% reduction of surviving spores occurs when exposed to moist heat at 80°C for **61 minutes**). Although serving as an illustration of the spectrum of spore resistance, these contrasting extremes offer little practicality for this novel microorganism being used as a biological indicator. It may, however, eventually serve as a useful research tool in the ongoing study of microbial resistance to heat.

Extrinsic Resistance

The presence of soil, organic matter, and/or bioburden on the surface of a medical device or instrument will interfere with the ability of the sterilant to make contact with those surfaces, thereby interfering with and diminishing the effectiveness of the sterilization process. The protective effect of organic matter has been recognized for several decades. With respect to moist heat (e.g., steam under pressure) sterilizing processes, the presence of residual organic matter can extend the time to inactivate bacterial endospores by six to eight times compared with the time required to inactivate spores in a less organically contaminated milieu *(12)*. Further, organic bioburden not only provides physical protection but may also contain massive numbers of microorganisms with widely varying levels of resistance, thereby increasing the potential for highly resistant microorganisms to be present. Bioburden and inorganic matter can pose challenges for other sterilizing processes as well. Dry heat is an oxidative process, and anything that prevents oxygen from reaching its targets will confer resistance (3,*13,14*). For example, the inclusion of bacterial endospores inside inorganic, water-soluble crystals can extend the dry-heat inactivation times by 15-fold to 20-fold *(15)*.

Cleaning

Cleaning is a process using water and any of a variety of salts, surfactants, ultrasonic energy, or enzymes to break covalent bonds between surfaces and visible soils, organic matter, and microorganisms, thereby enabling the dispersion and removal of these foreign materials from the item. Cleaning is, therefore, absolutely essential in efforts to enhance the efficacy of any terminal reprocessing step and is equally important for both sterilization and disinfection processes (4). A number of instrument design factors can pose challenges to effective cleaning. These include the presence of lumens, closely mated surfaces, acute angles, springs and valves, inaccessible areas, and roughened surfaces (16). Cleaning can be done manually, removing soil via water, detergent, and physical scrubbing, or by using an automated process such as enzymatic detergents and ultrasonic cleaners. Ultrasonic cleaning involves waves of acoustic energy in liquid, using cavitation and implosion to loosen soils from surfaces (17). An efficient cleaning process is capable of reducing microbial bioburden on instrument surfaces by several orders of magnitude. A number of researchers have demonstrated that microbial bioburden on typical medical instruments is generally low ($<10^3$ colony-forming units [CFU]/device) before cleaning, but ≥80% will have $<10^2$ CFU/device after cleaning *(18–20)*. In one series of experiments, Rutala et al. *(20)* observed that approximately 30% of cleaned medical instruments had no detectable contamination by the sampling and culture methods being used. Some of the microorganisms isolated from cleaned instruments have included coagulase-negative *Staphylococcus aureus,* diphtheroids, *Bacillus cereus*, *Bacillus* spp., and *Stenotrophomonas maltophila*. This observation supports the notion that while cleaning is essential to the overall efficacy of any terminal reprocessing, cleaning by itself is not by any means sufficient

to render a critical medical device or instrument safe and ready for use on the next patient. Such devices and instruments must *always* be subjected to a validated sterilization process prior to use.

This question has been asked on many occasions—is it safe to use a reusable medical device with residual foreign material after the device has undergone a sterilization process? The risk of infection in this instance is difficult to estimate, but the current consensus is that this questionable work practice (the state of "sterile but dirty") does not meet a proper surgical standard. The proper course of action in this instance is to return the instrument or lot of instruments to the central sterile supply unit (CSS) to be recleaned and resterilized. Even if the risk of infection is negligible, the possibility exists that such residual foreign matter may cause localized irritation and subsequent inflammation in the surgical site or may trigger an immune response, all of which may contribute to a possible surgical site adverse event. The aesthetics of such a lack of physical cleanliness is self-evident.

Sterility Assurance Levels and Engineering a Sterilization Cycle

Historically, the development of a sterilization cycle involved the determination of a SAL by using a specific biological challenge microorganism (e.g., representative bacterial endospores of *significantly* high resistance), constructing an inactivation curve, and obtaining a *D*-value. Death in this instance is a first order exponential or logarithmic function. In general, a *D-value* is the time required at a specific temperature to inactivate a given microbial population by 90% (i.e., a one $\log_{10}$ reduction, examples of which were given earlier). As mentioned previously, activation energy is required to bring spores out of dormancy as the very first step of inactivation, and when plotted in an inactivation curve, this may distort the initial shape of the curve depending on the innate characteristics of the endospore population being tested (3). *D*-values, therefore, are valid only when treatment temperatures are high enough to discount the effect of activation and the population of challenge microorganisms is of uniform resistance (3). This approach is illustrated in Figure 81-1. The inactivation rate is linear, and the *D*-value can be obtained for a given set of sterilization parameters. In practice, a survivor curve spanning six logs of inactivation can be determined by using quantitative spore assays. A six-$\log_{10}$ reduction in this discussion is considered a *half cycle* (1). An additional six $\log_{10}$ inactivation can be deduced by extrapolation of the linear survivor curve. In other words, the time at temperature required for the half cycle is doubled, resulting in a 12-$\log_{10}$ level of lethality for a *full cycle*. This procedure is used to construct a sterilization cycle with an SAL of 10^{-6}, meaning that the probability of a single survivor in the initial challenge of highly resistant endospores would be 1 in 1 million *(21)*. In the development of sterilization cycles, this approach is extraordinarily conservative. Accordingly, manufacturers of sterilization systems, including low-temperature systems, employ this high degree of conservatism in designing their cycles (Box 81-1).

In reality and as mentioned previously, most reusable medical devices have a bioburden $<10^2$ CFU/device after cleaning, and the residual microorganisms consist primarily of vegetative bacteria that are killed much more rapidly than are bacterial endospores. In the design and validation of the sterilization cycle, a challenge of one million bacterial endospores highly resistant to the process is used, and the survival curves reflect the highly conservative nature of this approach. This design conservativism, in conjunction with consistently efficient instrument and device cleaning, results in a significant level of overkill, thereby ensuring a huge margin of sterilization success and a high degree of patient safety (1,*22*).

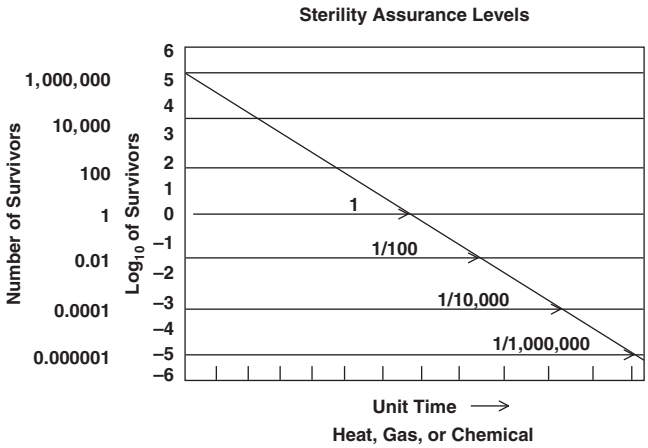

FIGURE 81-1 Numbers of surviving microorganisms compared to a starting population of 1,000,000 microorganisms are as follows: 6 $\log_{10}$ = 1,000,000; 5 $\log_{10}$ = 100,000; 4 $\log_{10}$ = 10,000; 3 $\log_{10}$ = 1,000; 2 $\log_{10}$ = 100; 1 $\log_{10}$ = 10; 0 $\log_{10}$ = 1. Three examples of the probability of a surviving microorganism as inactivation time continues are noted in the chart. (Adapted from Figure 43.2 in Favero MS, Bond WW. Chemical disinfection of medical and surgical materials. In: Block SS, ed. *Disinfection, sterilization, and preservation*. 5th ed. Philadelphia, PA: Lippincott, Williams and Wilkins, 2001:881–917.)

When engineering a sterilization cycle, regardless of the type of sterilant used (e.g., steam under pressure, gas plasma, and dry heat), researchers will take the following parameters into account: time, temperature, relative humidity (RH), pH of any suspending medium used with challenge microorganisms, and a standardized load configuration. Time and temperature, as mentioned previously, are the basic parameters evaluated when constructing inactivation curves and determining *D*-values. RH is defined as the ratio of the actual water vapor pressure in a system

BOX 81-1

Sterilization Cycle Design Considerations

- An assumption that the bioburden on a device is 10^6, consisting of bacterial endospores most resistant to the process
- In challenge tests, the placement of endospores is in the most occluded location in the device
- Use of spores contained in an organic and inorganic burden
- Application of simulated use conditions
- Documentation that a complete cycle produces a six $\log_{10}$ of measurable kill with a 10^{-6} probability that one spore survives

to the saturated water vapor pressure of the system at the same temperature. Water activity is the relative water availability in a cell or spore and depends on the RH *(23)*. There appears to be an inverse relationship between cell resistance and water activity *(23)*. The more water available to cells or spores, the faster the inactivation process whether it be moist heat or dry heat *(24)*.

Standardized sterilizer loading configurations are important for a number of reasons. Regardless of the process used, the sterilant must be able to make contact with all surfaces in the load in order to effect microbial inactivation. Load configurations take into account the packaging of devices, placement in secondary containment, etc., in efforts to identify spatial challenges to sterilant penetration. Such challenges can include "cold spots" in the load where temperature is less than that specified for the cycle and air pockets due to insufficient air evacuation processes. Once the manufacturer of the sterilizer has validated the sterilization cycle parameters and confirmed effectiveness with standardized loads, in-use instructions can then ensure that hospitals will be able to use the equipment effectively and safely.

STERILIZATION PROCESSES

In the United States, the Food and Drug Administration (FDA) recognizes three categories of sterilization methods used to sterilize medical devices in manufacturing settings. As described in draft guidance for industry, these categories are (a) *traditional* sterilization methods, (b) *nontraditional* sterilization methods, and (c) *novel nontraditional* sterilization methods (25). Traditional sterilization methods are those that have a long history of safe and effective use as demonstrated by ample literature, 510(k) clearances or approvals of premarket approval applications, and satisfactory quality systems (QS) inspections, and for which there are voluntary consensus standards for validation that are recognized by the FDA (25). Sterilization methods in the traditional category include dry heat, ETO in a fixed chamber, moist heat, and irradiation (e.g., gamma ray, electron beam). Nontraditional sterilization methods are those that do not have a long history of safe and effective use and for which there are no FDA-recognized standards but for which published information on the validation of these methods exists and for which the FDA has previously evaluated data as part of a QS evaluation and determined the methods to be adequate (25). Hydrogen peroxide gas plasma and ozone are the two methods currently listed under the nontraditional category. Of the six sterilization methods/sterilants listed in these two categories, all with the exception of irradiation are commonly available for use in US healthcare facilities. ETO, hydrogen peroxide gas plasma, and ozone are available in CSS settings as low-temperature processes for heat-sensitive instruments. Novel, nontraditional sterilizing methods are newly developed methods for which there are no FDA-recognized standards, no FDA inspection history, and no FDA comprehensive evaluations of sterilization validation data (25). There is also little or no published information on process validation for these methods. Furthermore, a novel, nontraditional method is one that has not been evaluated by the FDA as part of a QS evaluation and that employs sterilization methods that the FDA has not reviewed and determined to be adequate to provide a reasonable assurance of safe and effective use. Methods included in this category are chlorine dioxide, ETO in a bag, high-intensity light or pulsed light, microwave irradiation, sound wave energy, ultraviolet light, and vaporized chemical sterilant systems (e.g., hydrogen peroxide or peracetic acid [PAA]) (25). These novel, nontraditional methods/sterilants will not be addressed in this chapter, given their current status as emerging, developing technologies.

It is interesting to note that sterilization using liquid chemical sterilants is not included in this FDA discussion of sterilization methods. A liquid chemical sterilization process is by design problematic, time-consuming, and has no procedure or method to ensure or maintain the sterility of the device once it has been removed from the chemical. One possible explanation for the omission is that the draft guidance containing the definitions for the three sterilization method categories is intended for the device industry, and device manufacturers would be asked to identify the sterilization method used to render devices sterile before marketing. In view of the fact that liquid chemical sterilization methods involving device immersion do require long contact times and there is a risk of contamination of the devices upon removal from the chemical, it is unlikely that device manufacturers would employ a liquid chemical sterilization method. Liquid chemical sterilization, however, is a method available for use in the healthcare setting (i.e., the device customer) for the reprocessing of reusable, heat-sensitive devices.

STERILIZATION BY HEAT

Heat-based sterilization processes in healthcare facilities are based on either moist heat (steam under pressure) or, to a lesser degree, dry heat.

Moist Heat (Saturated Steam under Pressure)

Moist heat technology for terminal reprocessing of heat-stable reusable medical instruments and devices is the most common, efficient, and economical sterilization process in use. Furthermore, as a properly conducted sterilizing process, it leaves no chemical residues or byproducts on the surfaces of the medical instruments. Its lethal property is the result of mass transfer of heat to a surface via convection, with steam condensing as it loses heat. Thus, steam kills quickly and efficiently and does this by coagulation and denaturation of enzymes and structural proteins (17). The basic steam sterilizer (autoclave) is a steel-walled chamber surrounded on the sides by a jacket of trapped steam. The autoclave chamber may be sealed at the back of the chamber, or it may be designed as a "pass-through" chamber with doors located at either end. Pressure gauges, safety relief valves, temperature indicators, steam entry portals, and drain vents are some of the main engineered components of this equipment.

One of the major concerns of autoclave design and engineering is the removal of air from the load and the chamber. Although there are several different engineering approaches to air removal, the two main mechanisms used to accomplish air removal are gravity displacement and air evacuation (3). There are three types of general-purpose

steam sterilizers that use these methods of air removal: (a) gravity displacement sterilizers, (b) dynamic air-removal sterilizers, and (c) steam-flush pressure pulse sterilizers (26). Equipment employing vacuum evacuation of air was previously referred to as "prevacuum" or "porous load" sterilizers, but the Association for the Advancement of Medical Instrumentation (AAMI) now identifies these as *dynamic air-removal sterilizers* (27).

Gravity displacement autoclaves are typically used to sterilize nonporous instruments and devices, laboratory media, liquids, and pharmaceutical products; for in-house sterilization of glassware, oils, or powders, see "Dry Heat" below (17). This type of autoclave can range in size from small, tabletop units commonly used in small clinical practice to larger-sized units suitable for CSS operations (26). When engineered on a very large scale, this type of sterilizer is also one of the most commonly used technologies for the decontamination of regulated medical waste. Gravity displacement autoclaves are generally not recommended for terminal reprocessing of dense, porous items because the gravity displacement method of air removal in this situation is very inefficient. Entrapped air in a porous load leads to reduced steam penetration, and subsequently, heating efficiency (17,*28,29*).

In the "conditioning" phase of the sterilization cycle for a gravity displacement autoclave, steam enters the chamber from a portal at the top of the chamber. A water separator unit located at the steam entry portal helps to entrap water mist, removing it from the steam and thereby improving steam quality to ≥98% saturated steam (i.e., <2% water) and also minimizing the wetness of the load during the cycle (3). A steam separator modulates the velocity of the steam entering the chamber so as to minimize steam mixing with the air. Steam is lighter than air, and as steam fills the chamber from the top, air is forced by gravity to exit the chamber at a drain portal located on the floor of the chamber.

A variety of time, temperature, and steam pressure parameters have been validated for these sterilizers, and the reader is referred to the American National Standards Institute (ANSI)/AAMI document ANSI/AAMI ST79:2010 for suggested cycle parameters (27). Users, however, should consult the manufacturer's written instructions for proper and effective operation of specific models of this equipment.

Dynamic air-removal autoclaves make use of a high-speed vacuum pump to remove air at the start of a cycle. Air evacuation can be accomplished in one step or by using several "pulses" of pulling a vacuum (i.e., pressure pulsing). High-vacuum air removal is a one-pulse evacuation. When the chamber pressure reaches a partial pressure <5 mm Hg, the steam is injected into the chamber, and the heating of the load is begun (3). This particular engineering design for a sterilizer has been associated with several problems, including dehydration of certain materials, generation of superheated steam in porous item packs, charring of fabric; accordingly, uses of high-vacuum air-removal sterilizers are being phased out (3). Other versions of dynamic air-removal autoclaves are designed to evacuate the air in several applications of a vacuum, all during the conditioning phase. This pressure-pulsing method of air removal is efficient at removing air entrapped in porous loads (3). Unlike gravity displacement autoclaves, dynamic air-removal sterilizers are known to have problems with air leaks and occasional inadequate air removal (17). The Bowie–Dick test is run on dynamic air-removal sterilizers at the beginning of the day to test for effective air removal (26,27). A Bowie–Dick test sheet is inserted into a porous load (e.g., clean cotton, surgical towels) and placed toward the front of the chamber over the drain. If the conditioning phase of the sterilizer fails to evacuate all entrapped air, a spot will appear on the Bowie–Dick test sheet (27). In this event, the autoclave should be taken out of service pending inspection, repairs, and a successful pass of a subsequent Bowie–Dick test (27).

A third type of general purpose steam sterilizer employs a steam-flush pressure pulse mechanism for air evacuation. Air is evacuated by drawing a vacuum to a predetermined pressure, at which point steam is introduced into the chamber, forcing air out through a vent in the chamber. This air removal process is repeated several times, and during this process, the load gradually comes to the predetermined exposure temperature (3). Unlike the dynamic air removal sterilizers, the steam-flush pressure pulse equipment is not prone to air leaks; Bowie–Dick testing is not required with this type of sterilizer (26).

As with gravity displacement sterilizers, dynamic air-removal equipment manufacturers have validated a variety of time–temperature–steam pressure combinations of parameters, and the ANSI/AAMI ST79:2010 summarizes these in thorough discussions (27). Written instructions of the sterilizer manufacturer must also be consulted when determining the appropriate cycle parameters for each type of recommended loading configuration (e.g., wrapped metal instruments or porous materials).

Sterilization using saturated steam under pressure is a demonstrably economical and effective process. However, there are three areas of concern that impact the proper operation of these pieces of equipment: (a) superheated steam, (b) load wetness, and (c) steam quality (3). Superheat is a temperature excess above the temperature of saturated steam at the same pressure (3). Superheated steam can be generated in several ways. If the temperature in the jacket is higher than the target temperature for the cycle, materials in the load can pick up this heat. When steam is introduced into the chamber, the steam picks up the heat from the load and the walls of the chamber, resulting in superheat in the surface layers of the load (3). Superheat can be deleterious to porous loads (e.g., fabrics). When heat is transferred from steam to fabric, that effect penetrates beyond the surface and into the materials deep in the load. Additionally, heat is released when moisture rehydrates dried materials (e.g., cotton fabrics, paper) *(30,31)*. As a result, temperatures in the center of a porous load can rise and, in some instances, cause charring of the materials.

Excessive load wetness after the completion of a heat cycle can be extremely problematic. In the 1950s, researchers demonstrated that bacteria can pass through wet or damp wrapping materials, thereby contributing to post-process contamination of the load *(32,33)*. Most sterilizers include a drying phase as the last step of the sterilizing process to prevent this unacceptable wetness.

Steam quality is critical to the success of a steam sterilization cycle. Ideal steam for sterilization is 100% saturated

steam by weight (3). The presence of water diminishes the quality of the steam, which in turn affects the efficiency of sterilization and appropriate drying of processed materials (3). Most steam sterilizers are designed to operate most efficiently using high-quality steam (e.g., ≥97% steam). As steam makes contact with the load, heat is released to the load as the steam condenses. The water used to generate the steam is now spread out as a wet film over the entire load *(34)*. A steam sterilizer's dry cycle is engineered to evaporate any water that has not drained out via the chamber steam trap drains (assuming high-quality steam). Diminished quality steam adds more liquid water to the load, and if this is more than the steam sterilizer's drying cycle can evaporate during its cycle, the load will end up with wet packs *(34)*. Items that become extremely wet during the sterilization cycle are correspondingly difficult to dry.

There are a number of causes for diminished steam quality. Boiler problems are often the first to be evaluated in this regard. Boilers must be serviced and maintained by trained personnel. The steam distribution system and piping, if not insulated, can secondarily cause condensation of steam to water en route to the sterilizers *(34)*. Dissolved salts and other minerals in the water used to generate the steam can also affect steam quality.

Flash Sterilization At times, during surgical procedures, a medical instrument in short supply may be inadvertently dropped to the floor or somehow becomes contaminated such that it needs to be cleaned and sterilized as quickly as possible. The process of "flash sterilization" was developed to address this circumstance. Underwood and Perkins outlined the parameters of this process as the sterilization of an *unwrapped* item at 132°C for 3 minutes at 27 to 28 lb of pressure in a gravity displacement sterilizer (17,*35*). Flash sterilization is, therefore, distinguishable from the more conventional "full-cycle sterilization," in which a clean device or instrument is wrapped and sterilized so that it may be stored and maintained in its sterile state for subsequent use *(35)*. Historically, the Centers for Disease Control and Prevention (CDC) recommended against using flash sterilization for routine sterilization of instruments, arguing that the process should not be done as a means of convenience, to avoid having sufficient surgical instrument inventory, or to accelerate the throughput of instruments to the next surgical case *(36,37)*. Additionally, CDC recommended at that earlier time against the use of flash sterilization for reprocessing surgical implants for the following reasons: (a) up until recently there were no rapid, reliable, validated biological indicators (BIs) available for monitoring the flash sterilization procedure; (b) there was a lack of protective wrapping to maintain the sterility of the instrument; (c) there existed a possibility of inadvertent contamination of the instrument during transport from the sterilizer to the sterile operative field in the operating room; and (d) the cycle parameters (time, temperature) were considered nearing minimal effectiveness. However, there are times when flash sterilization of an implant is unavoidable in an emergency. In this situation, the process may be optimized by paying particular attention to thorough record-keeping and documentation of the implant (lot/serial numbers, separate components, etc.), the cleaning and sterilizing parameters used, the technicians performing the reprocessing, the surgical procedure and the surgical team, patient information, day and time of the surgery, etc (17).

Carefully performed by trained personnel using modern equipment, materials, and techniques, flash sterilization can be considered an effective sterilizing process with sufficient SAL (10^{-6}) such that potential patient-to-patient transmission is interrupted with high confidence *(38,39)*. Flash sterilization can be done on heat-stable reusable medical instruments using a steam sterilizer—either a gravity displacement unit or dynamic-air-removal equipment. The instrument(s) must first be meticulously cleaned, thoroughly rinsed, and dried. There are a variety of factors that must be taken into consideration with regard to cycle parameters before running a flash-sterilization process. These include (a) the type of steam sterilizer used; (b) the type of load (nonporous or a mix of porous and nonporous); (c) whether or not the item is wrapped or otherwise contained; (d) the temperature; (e) the exposure time; and (f) whether or not a dry-time phase is part of the cycle. The reader is referred to the ANSI/AAMI ST79:2010 (27) for summary tables of suggested cycle parameters for two configurations of steam sterilizers, but most importantly the healthcare facility wishing to use flash sterilization should consult the sterilizer manufacturer's written instructions for information on validated cycle parameters (27). Additionally, some medical instruments and devices require longer exposure time, making it equally important to consult the manufacturers of these instruments and devices as well. Furthermore, if any sort of containment is used for the instrument or device undergoing flash sterilization, it is imperative to verify that said containment has been cleared by the FDA for this purpose, and the healthcare facility should follow the containment manufacturer's instructions carefully. Wrappers are generally used to facilitate aseptic transport from the sterilizer to the point of immediate use after the instrument has cooled down, whereas rigid containment may be considered for aseptic holding of the instruments for short periods of time (usually <24 hours), depending on the design configuration of the container.

Recently, AAMI convened a working group of professional associations and federal government agencies (including CDC) to consider revisiting flash sterilization as practice and policy. Given the variety of cycle parameters and possible uses for shortened steam sterilization cycles, the group felt that the term "immediate-use steam sterilization" more appropriately identified this process. The working group will release a statement of its findings, but at this writing, the group continued to support these key elements: (a) manufacturer instructions for validated cycle parameters are to be followed, and containment vessels/materials should be confirmed as FDA-cleared; (b) instrument inventories should be sufficient to meet anticipated surgical demand; (c) technicians should be thoroughly trained in all aspects of performing immediate-use steam sterilization; (d) instruments must be thoroughly cleaned before sterilization; and (e) the traditional recommendations *against* performing immediate-use steam sterilization on implants and those instruments for which validated cycle parameters are not available are retained. An additional advisory against the use of immediate-use

steam sterilization for instruments that have been used on patients known or suspected of having Creutzfeld–Jakob disease was also included in the draft statement.

Dry Heat

As mentioned previously, microbial inactivation due to exposure to dry heat is accomplished primarily as an oxidative process (3). Dry-heat sterilizers operate at atmospheric pressure, and although it is a relatively inefficient heat transfer agent, the fluid medium through which heat is dispersed to the surfaces of the load is air (3). Heat is transferred through air movement known as *convection*. Dry-heat sterilizers relying on natural convection due to temperature gradients in the chamber are the *gravity convection* type, while other, more efficient, equipment with fans to help with air movement are the *mechanical convection* or "forced-air" type of dry-heat sterilizers (3).

Dry-heat cycles are characterized by high heat, relatively long exposure periods, and sometimes lengthy lag times (especially in the gravity convection type equipment) as the load items are brought up to temperature. One factor that will impact the effectiveness of a dry heat process is the amount of water (intrinsic moisture) in the materials undergoing sterilization. The lower the RH, the longer the time required for sterilization using dry heat *(23)*. Table 81-1 lists current time–temperature relationships for a variety of dry-heat sterilization cycles.

Dry-heat sterilizers should not be overloaded since air must freely circulate amongst the items in the load in order for proper heat transfer to occur. Dry heat is typically used to sterilize those items that would be damaged by steam and/or moisture or are otherwise impenetrable by steam. Examples of such items are petrolatum, oils, powders, delicate sharp instruments, and glassware (3). One useful application in particular is the use of dry heat to render glassware free of endotoxin residues during sterilization since cycles in steam autoclaves *do not* inactivate endotoxins. An additional benefit to using dry heat is its reduced propensity to corrode materials and dull sharp edges. Some of the obvious disadvantages, however, are (a) high temperature damage to easily charred or combustible materials, (b) long exposure times, (c) damage to some materials due to oxidation, and (d) a potential for distinct temperature zones being generated in the chamber due to improper loading and subsequent inefficient air circulation (3).

TABLE 81-1

Time–Temperature Relationships for Dry Heat Sterilization (3,*40*)

Temperature	*Exposure Time in Minutes*[a]
170°C (340°F)	60
160°C (320°F)	120
150°C (300°F)	150
140°C (285°F)	180
121°C (250°F)	Overnight

[a]Does not include lag time for load to reach temperature.

STERILIZATION WITH GASES

Two gas sterilants have been used in CSS settings:ETO and, more recently, ozone. ETO was the first major sterilant to be used for low-temperature sterilization processes.

Ethylene Oxide

ETO (molecular formula C_2H_4O) was first registered by the U.S. Environmental Protection Agency (EPA) as a pesticide under the provisions of the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) in 1966 (41). It is a colorless gas with flammable and explosive properties (17). End-use formulations comprise a mixture of ETO and inert gases in varying concentrations to lessen combustible properties. In hospitals and healthcare facilities, ETO is used to sterilize heat-sensitive medical instruments, devices, and some laboratory devices (21 CFR §201). In the United States, approximately 7.4 million pounds of ETO is used for end-use healthcare applications annually (41).

ETO is an alkylating agent that interacts with proteins and nucleic acids (*42,*43). This chemical reaction with cellular components interferes with cell metabolism and replication (17). ETO is broadly antimicrobial, capable of inactivating bacteria, viruses, fungi, and bacterial endospores *(44–47)*.

The length and effectiveness of the ETO sterilization cycle is dependent on several factors: (a) ETO gas concentration, ideally in the range of 450 to 1200 mg/L; (b) temperature, ranging from 37°C to 63°C; (c) RH, ranging from 40% to 80%; and (d) length of the exposure phase (1–6 hours) (17,43,48,*49*). RH as a source of moisture is especially important as this enables ETO to penetrate the load. Gas concentration and temperature modifications may help to shorten the exposure phase of the cycle (17). The effectiveness of the process can be diminished by the presence of salts and organic matter (17,*50*).

There are five phases comprising the ETO sterilization cycle: (a) preconditioning and humidification, (b) gas introduction, (c) exposure, (d) evacuation, and (e) air washes (17). The preconditioning phase accomplishes several things to enhance the effectiveness of the process, namely, the preparation of the chamber by establishing correct humidity and temperature parameters. A vacuum is drawn, and ETO is introduced into the chamber in the next phase. The length of the exposure phase is determined in part by the size and configuration of the load (48). At the completion of the exposure phase, the gas is evacuated and air washes take place.

One of the characteristics of ETO is its ability to penetrate a variety of materials such as polymers and plastics (*42,*43). ETO is also a known carcinogen and toxic substance that, with short-term occupational exposure, can cause respiratory distress, nausea and vomiting, convulsions, muscle weakness, nerve damage, cognitive impairment, and eye and skin irritation *(51,52)*. ETO residuals in implant devices have been known to cause tissue burns in patients, and residuals in ETO-sterilized hollow fiber dialysis membranes have been shown to be neurotoxic (17,*53,54*). To prevent these adverse events, medical instruments and devices subjected to ETO sterilization must be sufficiently aerated to remove ETO residuals. Aeration can take from 8 to 12 hours and is typically performed at 50°C to 60°C (17). AAMI has promulgated a guidance document

detailing allowable ETO limits for devices (48). The use of the processed device (e.g., duration of use, method of use, and repeated use) is factored into allowable residual determinations (17,48). To protect healthcare facility employees from ETO exposure, EPA requires, as of February 28, 2010, that facilities must use a single-chamber process (i.e., sterilization and aeration occurring in the same chamber) when using an ETO sterilizer for the terminal reprocessing of instruments *(55)*.

ETO is currently the principal sterilant that may be used, if judged necessary, to sterilize rigid or flexible endoscopes or other lumened devices, but because some studies have shown that lumen diameter and length may hinder full ETO penetration throughout all channels, it is important for healthcare facility professionals to check with the endoscope manufacturer to determine if ETO sterilization has been validated for the device make and model (17,*50,56,57*). Additionally, the long aeration time required after ETO sterilization is a key factor to consider when determining if this process is suitable for lumened instruments, given the usual demand for rapid endoscopic instrument turnaround. This somewhat problematic and overtly lengthy, expensive process of endoscope sterilization using ETO is perhaps the main reason that virtually all endoscopes—in particular, the flexible ones—are reprocessed using a powerful disinfecting process, *high-level disinfection* (see below [Sterilization with Liquid Chemicals] and more detailed discussion of high-level disinfection in Chapter 80).

Ozone

Ozone has had a long history as a disinfecting gas, with applications typically noted for water and wastewater treatment *(58)*, aquaculture, heating and cooling unit treatment, process water treatment in industry, food processing, and paper pulp bleaching, among others (59). Ozone is an unstable three-atom form of oxygen (O_3) generated by the excitation of molecular oxygen (O_2) into atomic oxygen (O) in an energizing environment allowing the recombination of these atoms to form O_3 (59,*60*). Ozone is a powerful oxidizing agent, and its stability varies with its physical state. In the gaseous phase, the half-life of ozone in ambient atmosphere is approximately 12 hours, whereas in the aqueous phase, the half-life varies from hours to seconds depending on the characteristics of water (e.g., temperature, pH, and UV light) (59).

Ozone has broad antimicrobial properties and has been shown to inactivate bacteria, bacterial endospores, viruses, fungi, and yeasts (59). Greater levels of $\log_{10}$ reduction for bacteria (~4–5 $\log_{10}$) are observed with long contact times (~20 minutes) at concentrations ranging from 0.18 to 0.5 mg/L when the presence of organic matter is kept to a minimum (i.e., an ozone demand-free system) (59). For viruses suspended in water, reductions of 1–4 $\log_{10}$ have been documented for contact times ranging from 10 to 30 seconds at concentrations of 0.14 to 0.5 mg/L (59).

Ozone sterilizers are relatively new to the medical instrument reprocessing marketplace and provide another option for low-temperature sterilization of heat-sensitive reusable devices. As with any sterilizing process, the effectiveness of this process is affected by the presence of organic matter, materials and configurations of the devices (e.g., hinged instruments must be open to ensure gas penetration) and/or chamber loading, and the number and intrinsic resistance of any mixed microbial populations present. Therefore, devices must be thoroughly cleaned, rinsed, and dried before terminal reprocessing. A typical cycle for ozone sterilization involves three phases—two preconditioning and exposure phases followed by a ventilation phase *(61)*. In the preconditioning steps, a vacuum is drawn, humidification occurs, and chamber temperature is increased to slightly above room temperature (30.8–36°C) *(62)*. Ozone is generated within the sterilizer and introduced into the chamber to begin the exposure phase (63). After a brief repressurization of the chamber, these steps are repeated, followed by the ventilation portion of the cycle to remove residual ozone from the chamber *(61,62)*. The cycle time is longer compared to other sterilizers (4.5 hours).

Ozone sterilizers can be used to terminally reprocess a variety of medical instruments made of metal or plastics, but they are not recommended for sterilizing sealed ampoules, fabrics, liquids, or latex/natural rubber products (*62,*63). Laboratory studies of one ozone sterilizer have shown that ozone can penetrate lumens as narrow as 0.5 mm and as long as 70 cm and produce >6 $\log_{10}$ reduction of *G. stearothermophilus (61)*. Manufacturer literature advises that their sterilizer has not been validated for sterilization of surgical implants *(62)*. Devices ready to be sterilized should be packaged in nonwoven materials or reusable rigid sterilization container systems cleared by the FDA for use in ozone sterilizers (63).

STERILIZATION WITH GAS PLASMA

The sterilization of medical instruments and devices using gas plasma technology is a relatively recent development in the healthcare industry, gaining momentum in the 1990s, whereas heat-based and gas technologies have been in use for decades. One of the major factors driving this development was the emergence of medical instruments and devices manufactured from heat-sensitive materials (e.g., plastics and fiber optics). Gas plasma technology provides yet another alternative means of low-temperature sterilization, has reasonably rapid sterilization cycles, and minimizes or eliminates potentially hazardous residuals from being deposited on the instruments.

Plasma is the fourth state of matter. It typically consists of a cloud of ions, electrons, or neutral species, generated by very high temperature or by electric or magnetic fields. The type of plasma used in healthcare facilities is a "glow discharge" or low-temperature plasma (64). The two main methods of generating low-temperature plasmas are direct electric current and the use of radio frequency *(65,66)*. Of these, the radio frequency system is the most common, is easier to design into the equipment, and is characterized by higher ionization efficiencies (64). Plasmas are identified by the type of gas or vapor from which they are formed (64). The FDA-cleared technology marketed in the United States converts an aqueous chemical solution first to vapor in a vacuum, and radio frequency converts the vapor to plasma.

Hydrogen peroxide gas plasma has been shown to effectively inactivate bacterial endospores as well as a wide variety of other microorganisms (17,*44,46,67–70*). The mechanism of sporicidal activity, although not fully understood for this technology, is presumed to be due to the generation of chemical free radicals and other biologically active species as the chemical vapor and plasma are generated *(71)*. These free radicals and active species presumably penetrate and act on essential cell components (i.e., enzymes, nucleic acids, proteins) and disrupt microbial metabolic processes (17). The energy required to produce these active chemical species is very low (1–10 eV) (64). A hydrogen peroxide gas plasma sterilizer has several steps to accomplish before the exposure phase in which plasma is generated. First, a vacuum is drawn in the chamber, and a small amount of 59% aqueous hydrogen peroxide is introduced into the chamber. This is vaporized until a concentration of 6.0 mg/L is reached. Vaporized hydrogen peroxide also has antimicrobial properties and exerts some degree of inactivation in advance of the plasma phase. Pressure in the chamber is reduced, and radio frequency energy of 400 W is applied to the vapor, converting it to the plasma state (64). At the end of the plasma phase, free radicals decay to oxygen and water.

Research and development work by the manufacturer determined that adequate diffusion of the vaporized hydrogen peroxide to all items in the load is important so that the reactive chemical species are right at the surfaces of the items to be sterilized when the plasma is generated. This requires that the packaging or wrapping of the items be designed to allow penetration of the vaporized hydrogen peroxide. Packaging/wrapping materials that are suitable for use with hydrogen peroxide gas plasma sterilizers include Tyvek-Mylar pouches, polypropylene wrapping, or reusable containers cleared by the FDA for use with these sterilizers (63). Additionally, sterilant penetration of lumens with this technology is limited; thus, lumened devices with long or narrow channels cannot be adequately processed with this sterilizer (FDA-cleared versions in the United States). Healthcare facilities are advised to check with the sterilizer manufacturer to identify the lumened instruments that can be successfully sterilized with this equipment (63).

Medical instruments and devices that would normally be damaged by high heat and/or moisture can be processed with this technology with the exception of the following: linens; other materials containing cellulose; powders; liquids; and devices with long, narrow lumens or with blind lumens (63,64,*69*).

STERILIZATION WITH LIQUID CHEMICALS

The Food Quality Protection Act of 1996 exempted from the definition of "pesticide" (previously under FIFRA) the liquid chemical sterilants and high-level disinfectants intended for use in the reprocessing of reusable, clean, critical and semi-critical medical devices *(72)*. This Act conferred upon the FDA sole regulatory jurisdiction over these classes of chemicals used for medical device reprocessing. A "sterilant" is defined as an agent (including select, sufficiently potent liquid chemicals) that destroys all viable forms of microbial life, including high numbers of highly resistant bacterial endospores (1). For the liquid chemical sterilants, these agents must demonstrate this potency under standard laboratory test conditions as specified by the AOAC International (AOAC). Traditionally, a "high-level disinfectant" is a sporicidal germicidal chemical that, under conditions of use, inactivates all microbial pathogens except *high* numbers of the bacterial endospores (1,*15*). FDA further elaborates on this definition of high-level disinfectant with a process aspect, defining a high-level disinfectant as a sterilant used under the same contact conditions, except for a shorter contact time *(72)*.

FDA requires manufacturers of liquid chemical sterilants/high-level disinfectants to submit laboratory data in support of antimicrobial claims as part of the official clearance process. Typically, potency testing using a validated test method for sporicides (AOAC Sporicidal Test 6.3.05: 1995, Official Method 966.04) demonstrates the chemical's capability to inactivate bacterial endospores effectively. Simulated-use tests provide a slightly different perspective on the chemical's performance, namely, to determine the penetrating capability of the germicide and identify the conditions under which the chemical will fail *(72)*. Chemicals to be marketed as high-level disinfectants first have to qualify as a sterilant by passing the AOAC Sporicidal Test and worst-case condition testing with simulated-use tests. Additional potency testing using another AOAC method (6.3.06: 1995, Official Method 965.12, Tuberculocidal Activity of Disinfectants) or a quantitative suspension test *(73)* and simulated-use testing would then be conducted using an appropriate mycobacterial challenge microorganism (e.g., *Mycobacterium terrae, Mycobacterium bovis*) with the same contact conditions except for a shorter contact time *(72)*. Additional details of the methods and data requirements for FDA clearance of these classes of germicides are thoroughly outlined in the agency guidance *(72)*. Historically, all of the germicides tested in this regulatory process had sufficient potency to be cleared as liquid chemical sterilants with indications for device sterilization and use conditions for the chemical to function as a high-level disinfectant. More recently, however, several germicidal chemicals capable of sporicidal activity have failed to meet the stringent criteria as a liquid chemical sterilant but have performed adequately in the simulated-use testing for high-level disinfectants. The FDA has allowed the qualified marketing of these chemicals for indications for high-level disinfection only (e.g., *ortho*-phthalaldehyde, hypochlorite/hypochlorous acid) (74).

Although the terms appear similar, "liquid chemical sterilization" is significantly different from "traditional sterilization." The FDA recognizes that sterilization with liquid chemical sterilants does not deliver to a "sterile field" a device with the same SAL as one sterilized using physical or thermal sterilization methods *(72,75,76)*. Traditional sterilization, from FDA's perspective, is a validated, reliable, economical process used to render a product free of all forms of viable microorganisms (*72,*77). In most cases, thermal methods, such as steam, are used to achieve sterilization. Thermal sterilization methods have been studied and characterized extensively, and it is well known that inactivation kinetics/survivor curves are log-linear for these methods, and therefore, easy to extrapolate. In contrast, the survival

BOX 81-2

Practical Limitations of Liquid Chemical Sterilization Processes

1. Liquid chemical sterilants are very sensitive to extraneous organic material.
2. Liquid chemical sterilants are slower acting compared to heat.
3. Liquid chemical sterilants do not penetrate by convection as compared to heat.
4. The item to be processed cannot be wrapped.
5. Biological monitoring of liquid chemical sterilization is problematic (e.g., the indicator microorganisms cannot be hermetically sealed for validation).
6. The item must be aseptically removed from the liquid with sterile gloves and garb.
7. The item must be handled aseptically and rinsed with sterile water.
8. The rinsed item must be dried with sterile towels.
9. The item must be placed in a sterile container if it is to be transported or is not used immediately.

(Data from references *72,75,76,*77, and *78.*)

curve data for liquid chemical sterilants may not exhibit log-linear kinetics; the shape of the curve can vary on any number of factors including the formulation or chemical stability of the particular sterilant *(72)*.

There are several limitations to the overall efficiency of liquid chemical sterilization. Although a spectrum of oxidative or fixative liquid chemical agents are capable of inactivating large numbers of resistant bacterial endospores, the *process* of liquid chemical sterilization, appropriate only for a limited variety of heat-sensitive instruments, is much more fragile than traditional heat (or gas or irradiation) sterilization because of the limitations listed in Box 81-2.

The users of this fragile method of reprocessing medical instruments must be fully aware that the probability of an SAL of 10^{-6} being presented to a "sterile field" is nil after all the postprocess manipulations. In other words, from a standpoint of killing bacterial endospores, the state of "sterility" (10^6 spores killed in a half-cycle test) *may be* achieved during the exposure/immersion period (see Practical Limitation No. 5 in Box 81-2). However, when the item is simply removed from the liquid, that "state of sterility" no longer exists. The subsequent manipulation of the item further reduces the "assurance level."

Table 81-2 summarizes the theoretical probabilities of contamination and infection for the different types of terminal microbial inactivation processes *(79)*.

Thorough cleaning must precede the terminal reprocessing step. Those critical instruments that are heat-stable should be steam sterilized (1). Those critical instruments that are not heat-stable must be sterilized using a low-temperature sterilization procedure, of which liquid chemical sterilization, as qualified above, is an option. However, given the information in Table 81-2, it should be clear that heat sterilization methods provide an optimal SAL and are the most efficient and cost-effective methods. Therefore, it makes no sense to subject a heat-stable reusable medical instrument or device to a liquid chemical sterilization process. The debit of process efficiency is self-evident, and if given a quest for economy or speed in reprocessing, this practice should be discouraged.

Liquid Chemical Sterilants and High-Level Disinfectants

As of June 2010, 22 FDA-cleared liquid chemical sterilants and high-level disinfectants with general claims of reprocessing reusable medical devices are known to be marketed in the United States. Table 81-3 provides summary information on these chemicals *(80)*. This list does not include chemicals exclusively linked as a component of a machine-liquid chemical "system."

All liquid chemical sterilants are required to demonstrate sufficient potency to kill bacterial endospores, but as is evident from Table 81-3, in many instances the

TABLE 81-2

Theoretical Probabilities of Residual Contamination and Infection Transmission Post–Terminal Reprocessing

Procedure	*Indications*	*Probability of Contamination*	*Probability of Infection*
Heat sterilization	Heat-stable critical devices	10^{-6}	0
Chemical sterilization (long immersion)	Heat-sensitive critical devices	A. 10^{-3} B. 1	A. 0 to ? B. 1 to ?
High-level disinfection (short immersion)	Heat-sensitive semi-critical devices	A. 1–10^{-2} B. 1	A. 1 to ? B. 1 to ?
Low-level disinfection	Noncritical devices; environmental surfaces	1	1 to ?

Note: A. During immersion time. B. After postimmersion manipulation (rinsing with sterile water, drying with sterile towels, aseptic transport to a sterile field or to a sterile container).

Readers are urged to update this table periodically at *http://www.fda.gov/MedicalDevices/Safety/AlertsandNotices/ucm194429.htm*. Accessed May 22, 2010.)

contact time required to achieve liquid chemical sterilization is quite long, making sterilization generally impractical as a process. Furthermore, instrument exposure to some of these potent chemicals for such long periods of time may result in serious damage to the instrument. In these situations, these chemicals are used only at shorter contact times sufficient to inactivate mycobacteria (i.e., to be *tuberculocidal*) and small numbers of endospores (i.e., the process of high-level disinfection). These are the chemicals, listed in Table 81-3, that have no legal clearance or indication for sterilization *(80)*. The use of liquid chemical sterilants for high-level disinfection is discussed in detail in Chapter 80.

Glutaraldehyde

Glutaraldehyde is a saturated dialdehyde related to formaldehyde but it has been shown to be two to eight times more sporicidal than formaldehyde *(81)*. The mode of action of glutaraldehyde on microorganisms is by alkylation, reacting with amino and sulfhydryl groups of proteins and ring nitrogen atoms of purine bases (1). This acts as a protein fixative and disrupts the integrity of nucleic acids. The sporicidal potency of glutaraldehyde can be affected by pH, temperature, and ultrasonic energy (1). The microbiocidal activity of aqueous glutaraldehyde appears to increase when the pH is alkaline but declines after storage or repeated use *(81)*. Neutral to acidic formulations are also sporicidal, and this activity is increased by the addition of heat or in the presence of ultrasonic energy *(82,83)*.

Manufacturer's use instructions indicate the conditions for repeated use of glutaraldehyde formulations and the use-life period for working solutions. Chemical indicators (CIs) are typically used to monitor active ingredient concentration before and during use. In practice, any liquid chemical sterilant used for more than one sterilization (or disinfection) cycle will lose potency for a variety of reasons. These include dilution from repeated exposure to wet or moist instruments, dilution from use in certain automated disinfecting machines, accumulated organic material from improperly cleaned instruments, excessive heating, or other innate chemical degradation (1). In other words, chemical germicides (including glutaraldehyde) invariably lose potency if reused, and the rate of loss is more dependent on patterns and intensity of usage rather than the age of the solution *(84–86)*.

Glutaraldehyde-based germicides are the most widely used liquid chemical sterilant/high-level disinfectant products legally marketed for between-patient reprocessing of heat-sensitive medical instruments and devices. Manufacturer instructions for these products indicate their use *only* as immersion chemicals. That is, there is no indication for the use of glutaraldehyde products as surface disinfectants in any environmental or institutional setting. Proper ventilation and personal protective equipment (e.g., gloves and face protection) are required to prevent toxic or sensitization reactions in healthcare personnel (1).

Hydrogen Peroxide

Hydrogen peroxide has been recognized as a reliable germicide for more than a century. It is available in a stabilized form (2% H_2O_2) and in several low concentration formulations of hydrogen peroxide and PAA. At present, only the hydrogen peroxide/PAA formulations are legally marketed for device sterilization *(80)*. The mode of action is that of an oxidative chemical reaction with cellular components. Hydrogen peroxide in high concentrations is bactericidal, virucidal, and sporicidal *(87,88)*. Hydrogen peroxide in concentrations between 3% and 7% or in mixtures with PAA constitutes a useful class of chemical agents for sterilizing and disinfecting medical devices *(89)*.

Peracetic Acid

PAA, a powerful chemical oxidizer, has been known for decades as an effective antiseptic. In the 1800s, for example, PAA was used as a hand wash product, and it is capable of denaturing proteins and other cellular components (e.g., enzymes) and affects cell wall permeability (17,90,*91*). PAA is a strong, broad-spectrum germicide, with potency demonstrated against gram-positive and gram-negative bacteria, fungi, viruses, and yeasts (17,90). When used as a disinfectant/sterilant, instruments must be meticulously cleaned since organic matter will rapidly diminish the potency of PAA (17,*92*).

It was only recently (within the last 25 years) that the sporicidal properties of PAA were evaluated and put to commercial use. In 1988, the FDA cleared a PAA chemical sterilant as part of a liquid chemical sterilizing system (Steris System 1, S20 sterilant). As a low-temperature sterilizing process, this system was commonly used to terminally reprocess heat-sensitive, lumened devices such as endoscopes and bronchoscopes. In 2008, however, the FDA found that this equipment and its liquid chemical sterilant were adulterated, misbranded products *(93)*. As a consequence, this "system" (machine and sterilant cartridge) has been withdrawn from the market *(94)*. As of this writing, healthcare facilities have until August 2011 to seek out an alternative for this system (95,*96*), and the FDA has provided a list of currently available replacement equipment and chemicals *(80)*. Final FDA clearance to market new equipment and the PAA agent for a reprocessing system from Steris was granted in April 2010 (Steris System 1E) *(97)*. However, when the present content of the revised 510(k) summary of the device is compared to the FDA web page description of the system, the current status of this new PAA-based equipment is unclear, pending further action from the company and/or FDA *(97,98)*. A 510(k) is a written, premarket notification/submission to the FDA documenting the equivalence between a new product and a predicate device. Required documentation elements are annotated in 21 CFR Part 807, and include product labeling, product/device description, and a comparison of the new device to another legally marketed device, which is called a predicate. The threshold for market clearance is the demonstration of substantial equivalency of the new device to the predicate *(99)*.

MONITORING THE STERILIZATION PROCESS

As mentioned previously, the state of absolute sterility is difficult to prove and certainly cannot be measured or validated with post-process sampling and testing. It is common to define sterility in terms of the probability that a contami-

nating microorganism will survive a sterilization process. As mentioned previously, sterilization is defined as a microbial inactivation process in which the probability of any one microorganism (a bacterial endospore) surviving on a device is 10^{-6} or lower. This concept has been used to develop and monitor cycles for steam autoclaves, ethylene oxide sterilizers, hydrogen peroxide gas plasma sterilizers, ozone sterilizers, and radiation sterilization (used in industry). Since the survivor curve kinetics are log-linear for these physical, gaseous, or radiation sterilizing processes, the time needed to inactivate an additional six $\log_{10}$ of bacterial spores can be determined by extrapolation of the curve (see Fig. 81-1) (1). A physical, gaseous, or radiation-based sterilization cycle engineered based on this concept produces a great degree of overkill as well as a quantitative assurance of sterilization. In contrast, it is difficult to evaluate liquid chemical sterilization or disinfection processes using these criteria, in part, because the inactivation kinetics in these procedures are not log-linear. Additionally, biological indicators with bacterial endospores (i.e., BIs [discussed below]) used to validate sterilization processes need to come into contact with the sterilant while at the same time maintaining their hermetic integrity. Common proprietary BIs are packaged in containment, designed to allow sterilant penetration while the indicator microorganisms remain in place within the packaging. The indicator organisms can neither escape the "carrier" nor become contaminated from external sources. If such an indicator is used with a liquid chemical sterilization system, it is necessary to remove the filter paper carrier with the bacterial endospores from the hermetic packaging in order to effect contact with the liquid chemical. Under these circumstances, it is evident that a portion of the reduction in numbers of active spores on the carrier strip will be due, in part, to spore on the carrier strip removal or wash-off (100,*101*). This could easily give a user of such a system (naked indicator strip in an agitated liquid system) a false sense of potency of the process being "monitored."

There are three major categories of monitoring devices used for more traditional sterilization processes in healthcare facilities. These are BIs, CIs, and physical or parametric monitors. Of these, the BIs and the majority of CIs are placed in the sterilizer chamber appropriately among the load to react to the conditions within the chamber during the sterilization cycle. Physical or parametric monitors built into the sterilizer equipment are used to monitor and document cycle parameters such as time, temperature, pressure for steam sterilizers; time and temperature for dry-heat sterilizers; and time, sterilant concentration, temperature, and humidity for gaseous sterilizing equipment. Some CIs are designed to measure specific key functions of the sterilizer equipment. Air-removal indicators for test packs, for example, are CIs specifically used to determine effective air evacuation from the chamber of dynamic air-removal steam sterilizers prior to terminal reprocessing of devices and instruments. A more detailed discussion of each of the process indicators is found in Chapter 70. According to AAMI, each monitor or indicator device is essential to sterility assurance as each serves a different function in process monitoring (27).

Biological Indicators

BIs are classified by the FDA as Class II devices and are the preferred standard for monitoring the effectiveness of a sterilization cycle as a complete inactivation process. These viable microorganism indicators respond to time, temperature, and other operative parameters of the cycle. Their ability to withstand the sterilization process is also affected by other miscellaneous conditions such as superheat and the physical characteristics of the load (e.g., placement in the load and sterilant penetration of the load) (3). BIs verify that the conditions at the most occluded location within the load were adequate to kill a population of microorganisms resistant to the sterilization process and demonstrate the lethality of said process (26). BIs are generally contained within a "process challenge device" (PCD), which is designed to simulate the products being sterilized and to present a defined challenge to the sterilization process (26).

BIs are generally manufactured as filter paper strips impregnated with a standardized preparation of bacterial endospores, the numbers of which typically are 10^6 to 10^7. The selection of endospores depends on the type of sterilant used in the sterilization process. Box 81-3 lists the challenge bacterial endospore genus and species cleared by the FDA for use with the commonly used sterilants.

As mentioned previously, levels of spore resistance vary according to species and inactivating treatment. Virtually all spores resistant to moist heat are sensitive to dry heat. Conversely, those resistant to dry heat are sensitive to moist heat. Recalling the discussion of survivor curves and the kinetics of inactivation, sterilization cycles are engineered to be capable of inactivating 12 $\log_{10}$ of resistant challenge microorganisms. Since BIs will have approximately 10^6 bacterial spores on a carrier, it follows that a BI is, in reality, a *half-cycle* indicator (1). At the completion of the sterilization cycle, the BI is incubated and observed for growth or no growth compared to positive and negative controls (incubation temperatures are very important and must be exact according to the manufacturer's directions). If the BI shows growth, this indicates that the sterilization process may have been ineffective. For instance, if a spore (BI) indicator failure occurs, at worst, this result indicates a possibility that >50% of the potency of the sterilization cycle was not delivered to the BI. However, because sterilization processes are designed with significant overkill, the load from the cycle with the positive-growth BI may not have to be recalled. Other

BOX 81-3

Biological Indicator Microorganisms Used to Monitor Sterilization Processes in Healthcare Facilities

BI Microorganism	*Sterilant*
Geobacillus stearothermophilus	Moist heat (steam under pressure)
Bacillus atrophaeus	Dry heat
B. atrophaeus	Ethylene oxide
G. stearothermophilus	Ozone
G. stearothermophilus	Hydrogen peroxide gas plasma

process indicators and monitors need to be evaluated and considered (e.g., physical parameters such as temperature, time, and pressure; CIs). If these other indicators and monitors suggest that the sterilization cycle was operationally correct, a follow-up run with a BI in the sterilizer should be done using the same cycle and load parameters. If the BI in this follow-up run shows no growth, it is likely that the previous BI was inadvertently contaminated post–sterilization cycle, and the load can be released (17). If this follow-up BI reads positive for growth (i.e., a bacterial spore-former [the indicator microorganism]), the sterilizer should be taken out of service, repaired accordingly, and the subsequent dry run sterilizer cycles should be reevaluated with additional follow-up BIs (with appropriate challenge packs) (17). No growth in subsequent BIs from these dry runs signals that the equipment can be returned to service. Healthcare facilities should have clearly defined and regularly updated CSS standard operating procedures that address the action to be taken when a potential sterilizer failure occurs.

Some contemporary BIs will have an enzyme-based "early readout" capability in addition to a bacterial endospore response (27). This feature reduces the time required to obtain a load release decision. Manufacturer's instructions for this device should be followed precisely for proper interpretation of results. Additionally, it is important to periodically verify the accuracy of the enzyme reading by continuing to incubate the BI and by observing for growth or no growth (27).

Sterilizers should be monitored with the appropriate BIs at least on a weekly basis (17). If a sterilizer is used for several loads on a daily basis, it is advantageous to use a BI for the sterilizer each day. This will facilitate early discovery of sterilizer failure or procedural errors, thereby, minimizing subsequent load recall and patient surveillance (17,*102*). A BI should be included for every sterilizer load containing implantable devices, the release of which is dependent on the negative growth reading for the indicator (17).

Chemical Indicators

CIs are designed to display a chemical or physical change in the response to one or more of the physical conditions in the chamber during a sterilization process (27). For example, if a CI is designed to respond to temperature, the indicator will exhibit a visible change signifying that the target temperature had been reached at some point in the sterilization cycle. However, this may not be interpreted that the temperature remained at target for the duration of the exposure phase of the cycle. Nevertheless, the use of CIs provides additional information to complement the results of BIs and physical parametric monitoring. Proprietary CIs specific for each type of thermal or gaseous sterilizer have been cleared by the FDA.

AAMI defines six classes of CIs available to healthcare facilities (27,48,*103*). These are listed in Box 81-4.

Class 1 indicators are external CIs. That is, these are affixed to the outside of the pack. The purpose of this type of indicator is to differentiate processed packs and items from those that have not been processed. Class 1 CI reactions should not be interpreted as evidence of an adequate sterilization cycle but only that the packs or items have been exposed to the "trigger" temperature. A Class 1 CI should be affixed to each pack or item in the load. The exception to this approach occurs when the packaging for the medical devices has see-through areas that allow for visual inspection of any CIs inserted into the pack. Class 2 indicators (i.e., Bowie–Dick test pack indicator) are used for equipment control and evaluation of sterilizer performance (27,48,*103,104*). A Bowie–Dick test pack indicator, as mentioned previously, is used to monitor the effectiveness of the air-removal process in a dynamic air-removal steam sterilizer only. Classes 3, 4, 5, and 6 indicators are all designed to be inserted into a pack to demonstrate that the target parameter(s) (e.g., temperature) has been achieved. Class 3 CIs measure a single parameter of the sterilization process, most commonly temperature. There are specific Class 3 CIs for each target or specific temperature value (e.g., 121°C, 134°C, etc.) for the exposure phase of the sterilizer cycle. Class 4 CIs are designed to react to multiple variables of the sterilization cycle (e.g., time, temperature) *(104)*. Class 4 CIs will provide the sterilizer operator more information about the cycle performance compared to the information from a Class 3 indicator. Classes 5 and 6 CIs are the most recent additions to the chemical indicator product line and are used for pack control. Class 5 integrating CIs react to all critical variables of the sterilizing cycle. Class 5 CIs are the most accurate of the internal CIs when used in accordance with the manufacturer's instructions *(104)*. Class 6 emulating CIs are also used for pack control and react to all critical variables of the sterilizing cycle, but these devices must be specified for specific sterilization cycles *(104)*. Consequently, the CSS must have a different Class 6 emulating CI for each sterilizer time/temperature combination used *(104)*. Because

BOX 81-4

AAMI Classification for Chemical Indicators (CIs) (27,48,*103*)

Class 1—process indicators. Used with individual packs or items to indicate that the pack or item was exposed to a sterilizing cycle.

Class 2—specific test indicators. An example of this type of indicator is the Bowie–Dick type indicator that is used specifically to determine the efficacy of the air-removal process for dynamic air-removal steam sterilizers.

Class 3—single parameter indicators. Designed to react to one of the critical parameters of the sterilization process.

Class 4—multiparameter indicators. Designed to react to two or more of the critical parameters of the sterilization process.

Class 5—integrating indicators. Designed to react to all of the critical parameters over a specified range of sterilization cycles.

Class 6—emulating indicators. Designed to react to all of the critical variables of specified sterilization cycles, with stated values having been generated from the critical variables of the specified sterilization process.

the availability of Class 6 emulating CIs is a recent event in the US healthcare market, readers should consult ANSI/AAMI ST79:2010 for more detailed information regarding the use of this CI (27). The performance of Class 5 integrating CIs and Class 6 emulating CIs have been correlated to the performance of a BI when manufacturer instructions are followed. However, these indicators are not intended to replace or to be used to the exclusion of a BI. CI Classes 1–6 are available to monitor steam sterilization applications. CI classes appropriate for use with dry-heat sterilizers and ETO sterilizers are Classes 1, 3, 4, 5, and 6 (48,105). BIs and CIs cleared by the FDA specifically for use with ozone sterilizers and hydrogen peroxide gas plasma sterilizers are available; consult the sterilizer manufacturer's instructions/recommendations for the selection of these indicators (63).

The use of CIs can help to identify sterilizer equipment malfunction and is especially important if a given sterilizer run does not have a BI in the load. CIs are designed to show visible changes when the stated value or endpoint of the cycle variable being measured is reached. If a CI fails to display a visible change (i.e., a failure), the pack or item is set aside and an assessment is made as to the status of that pack. Other indicators (e.g., BI, physical monitors, other CIs placed elsewhere in the load) are considered in this determination, and if the other indicator results point to proper sterilization cycle performance, the pack in question may be released (17). If the results of BI assessment are not readily available, it may be prudent to quarantine the load in question until the BI results become available (105).

Process Challenge Devices

According to AAMI, a PCD assesses the performance of a sterilization process by providing a challenge to the process that is equal to or greater than the challenge posed by the most difficult item routinely processed (27). Depending on the type of load (i.e., one with implantable devices vs. one with no implantable devices), a PCD may contain (a) a BI; (b) a BI and a Class 5 integrator CI; (c) a BI and an enzyme-only indicator; (d) a Class 5 integrator; or (e) an enzyme-only indicator (27). For loads containing implants, the PCD must contain a BI at the minimum. For loads with no implantable devices, the PCD options are (a) a device with a BI only; (b) a BI plus a Class 5 integrator or an enzyme-only indicator; or (c) a Class 5 integrator or an enzyme-only indicator [a CI challenge test pack] (27).

PASTEURIZATION

Pasteurization is not a sterilization process and should not be considered as the terminal reprocessing step for critical medical instruments. Historically, the process has been used to reduce the numbers of pathogenic microorganisms in liquids while preserving product integrity. However, pasteurization is not sufficiently potent to inactivate bacterial endospores. The process typically involves heating of materials to approximately 60°C for 30 minutes, although other time/temperature combinations have also been used. Pasteurization as a microbial inactivation process has limited application in modern healthcare; its use in today's world is almost exclusively found in the food industry such as the production operations for dairy and other foods where quality would be compromised if the product was exposed to high heat. Examples of medical applications of pasteurization are some of the disinfecting processes employed in hemodialysis centers. For instance, some dialysis machines (e.g., Fresenius 2008 E, Fresenius 2008 H, Fresenius 2008 K, B Braun Dialog system, and Gambro Phoenix dialysis system) employ a heat disinfecting cycle that will heat the internal fluid pathways of the machine to approximately 83°C ± 0.8°C for ≤60 minutes. Some water systems (e.g., Gambro CWP and Mar Cor Purification System) will recirculate hot water throughout the distribution system and the storage tank. With the Gambro CWP, hot water of temperature between 85°C and 90°C is recirculated throughout the loop. Despite the fact that pasteurization does not inactivate bacterial endospores, hot water pasteurization in the past has been used as an alternative to high-level disinfection to reprocess respiratory therapy and anesthesia equipment (17,*106–111*). Pasteurization as a disinfecting process is achieved in this instance by exposing the cleaned devices to >70°C for 30 minutes *(106)*. Wet pasteurization at 70°C for 30 minutes with detergent cleaning has been used to reprocess semicritical devices such as rubber tubing and catheters, polyethylene tubing and catheters, thermometers, and some hinged instruments (17).

ACKNOWLEDGMENTS

We thank Matthew J. Arduino, DrPH, from the Division of Healthcare Quality Promotion, CDC, for information on heat disinfection processes used in dialysis centers, and Sheila Murphey, MD, from the Office of Device Evaluation, FDA, for information regarding regulatory developments re: liquid chemical sterilants.

SECTION XII

Prevention of Infections Acquired by Patients in Healthcare Facilities Related to Design, Construction, Renovation, Demolition, and Ventilation Systems

CHAPTER 82

Elements of Design Aimed at Infection Prevention and Patient Safety in the Built Environment of the Healthcare Facility

Judene M. Bartley and Russell N. Olmsted

INTRODUCTION

The Institute of Medicine's consensus report, *Crossing the Quality Chasm: A New Health System for the 21st Century,* identified the following key domains aimed at improving the safety and quality of patient care:

- *Safe*: avoiding injuries to patients from the care that is intended to help them
- *Effective*: providing services based on scientific knowledge to all who could benefit and refraining from providing services to those not likely to benefit
- *Patient-centered*: providing care that is respectful of and responsive to individual patient preferences, needs, and values, and ensuring that patient values guide all clinical decisions
- *Timely*: reducing waits and sometimes harmful delays for both those who receive and those who give care
- *Efficient*: avoiding waste, including waste of equipment, supplies, ideas, and energy
- *Equitable*: providing care that does not vary in quality because of personal characteristics such as gender, ethnicity, geographic location, and socioeconomic status *(1)*

The built environment can both compromise and facilitate the achievement of many of these domains. Regarding the latter, one of the more critical devices in the built environment needed to prevent cross-transmission—the hand washing sink—was recently found to be a direct and indirect source of *Pseudomonas aeruginosa* infections among critically ill patients (2). Conversely, the emphasis on single occupancy patient rooms in national consensus guidelines (3) is supported by new epidemiologic evidence that finds up to an 11% increased risk of acquisition of important pathogens associated with multi-occupancy rooms and the number of roommates per day of hospitalization *(4)*. These domains, therefore, serve as important signposts for preventing healthcare-associated infections (HAIs) and improving patient safety.

Patient Safety, Yes, But What About Personnel?

Healthcare is likely the most complex and chaotic of all industries as its standardization is difficult given the unpredictability of patient responses to therapeutic interventions. Layered on top of this are factors such as the increasing acuity of patients, an aging population being served, increasing economic constraints, and challenges

and demands on care providers that require multitasking and almost continual interruptions. Gurses et al. *(5)* reported that critical care nurses at seven healthcare systems found workflow, supply access, and the built environment were among several obstacles that affect their ability to provide high quality, reliable care. In addition, nurses' work activities are interrupted at a high frequency of 10 times per hour, which illustrates the complexity of this work environment and underlies the reasons that errors are made *(6,7)*. To ignore the needs and function of direct care providers when designing the built environment is to invite potential for adverse patient outcomes *(8)*. In fact, studies have identified that equipment/supplies and facility issues are the two key issues that account for operational failures *(9)*. The 2010 Facility Guidelines Institute (FGI) guidelines emphasize the involvement of personnel who work in patient-care areas during planning and design. Infection prevention aspects of the work activity can also be addressed by the inclusion of direct care providers in the Infection Control and Risk Assessment (ICRA) management process. Details of ICRA are addressed elsewhere in this text (see Chapter 83).

Re-emerging Emphasis on the Role of the Environment and Cross-Transmission of Pathogens

In the 1970s, there was intense focus on the environment as a primary reservoir of pathogens. As a result, several interventions were promulgated, including delivery of disinfectants by fogging large areas or patient-care rooms, walk-off mats to "remove" contaminants prior to entering an operating room (OR), and routine environmental microbiologic sampling of the environment. Subsequent analysis and evidence failed to support these interventions as effective and the Centers for Disease Control and Prevention stated in its 2003 environmental infection control guideline:

> *… Although microbiologically contaminated surfaces can serve as reservoirs of potential pathogens, these surfaces generally are not directly associated with transmission of infections to either staff or patients … Disinfectant fogging is not recommended for general infection control in routine patient-care areas … (10)*

Fast forward to the 21st century, and one can find renewed interest and study of the role of the environment. Most of this has been driven by the ongoing challenges presented by multidrug-resistant organisms (MDROs) and the emergence of new strains of *Clostridium difficile* that have resulted in increasing incidence and are associated with considerable morbidity and mortality *(11–13)*. In addition, there have been several studies finding microorganisms persist in the environment and that admission to a room previously occupied by a patient either colonized or infected with an MDRO increases risk acquisition for the next patient (*14,*15,*16*). Coincident with studies of cross-transmission, disinfecting by use of whole-room, no-touch methods such as fogging or use of handheld ultraviolet germicidal irradiation (UVGI) devices have appeared in the literature as they undergo evaluation for efficacy and feasibility *(17,18)*. Therefore, the design of the environment is undergoing renewed scrutiny in terms of patient safety.

DESIGNING FOR PATIENT SAFETY AND INFECTION PREVENTION

The usual process involved in design and ultimate construction of healthcare facilities progresses in this order:

- Assessment of role and program
- Functional programming (e.g., engaging personnel to understand the patient-care processes and use this to assess design needs)
- Examination of adjacencies
- Development of schematic design
- Develop detailed design and mechanical engineering documents
- Contractor bid specifications/documents
- Construction

Reiling has identified two crucial aspects involving design (19,*20*). The first is to employ principles of human factors engineering—meaning how people interact with equipment and their environment. A clear illustration of the importance of this is the study of frequency of interruption of nurses during patient care and the potential for designs to mitigate or lessen these distractions *(6,7)*. The second is to incorporate principles of safety for patients and personnel into design. Key recommendations from these are provided in Table 82-1 (19).

TABLE 82-1

Principles of Safety for Design of the Environment

Design around latent conditions
- Noise reduction
- Scalability, adaptability, flexibility
- Visibility of patients to staff
- Patients involved with care
- Standardization
- Automate where possible
- Minimize fatigue
- Immediate accessibility of information, close to the point of service

Design around precarious events/active failures
- Operative/post-op complications/infections
- Events relating to medication errors
- Deaths of patients in restraints
- Inpatient suicides
- Transfusion-related events
- Correct tube–correct connector–correct hole
- Patient falls
- Deaths related to surgery at wrong site
- MRI hazards

(From Reiling JG. Creating a culture of patient safety through innovative hospital design. *Advances in patient safety: from research to implementation*. Vols 1–4, AHRQ Publication No. 050021-2. Rockville, MD: Agency for Healthcare Research and Quality, 2005. Available at *http://www.ahrq.gov/qual/advances* [cited May 2010].)

Evidence-Based Design—and Infection: Is the Evidence Complete and Definitive?

The Center for Healthcare Design The Center for Healthcare Design (CHD) has coordinated a vast amount of work on defining and encouraging "evidence-based design" (EBD). The CHD defines EBD as "the deliberate attempt to base building decisions on the best available evidence with the goal of achieving the best possible outcomes for patients, families, and staff, while improving utilization of resources" *(21)*. EBD has been developing on a path that is parallel to emerging emphasis on evidence-based practice to prevent HAIs since the 1970s and has made impressive progress in its goal to improve patient outcomes (22). The CHD, formally established in 1993, functions as a major center of research, communication, and development of a body of knowledge while it seeks to sort out the best approach to identifying EBD. In its pursuit to ensure that basic principles are incorporated by healthcare design professionals, the CHD engaged top research design professionals and developed the "Evidence-Based Design Accreditation and Certification (EDAC): Introduction to Evidence-Based Design." The guide provides a comprehensive look at the EBD background, roots, and current developments, serving as a study guide to certify professionals in this field. Infection prevention professionals seeking to better understand many of the proposals that surface early in the ICRA design phase (e.g., patient safety based on IOM report, the Planetree and Pebble Projects, the influence of the military's health research, and more) would find this guide an excellent overview of EBD findings and one that also addresses issues beyond the scope of this chapter.

Sustainability As is noted later, more and more professional architects, interior designers, and engineers consider sustainability as critical to design, and IPs are increasingly faced with these proposals when participating in long-term design planning. From the design professionals' view, they are increasingly aware of the critical relationship between the environment and infection prevention and control issues, highlighting the importance of continued dialogue. Nowhere is this better demonstrated than in the consensus development work that occurs during the FGI standards review process, which includes infection prevention experts as well as an incredibly broad range of other disciplines ranging from engineering to interior design, all focused on development of the built environment to facilitate safer patient care and health outcomes.

HAI and the Environment In 2004, Ulrich et al. *(23)* published the results of their review of a substantial body of evidence on the impact of the environment on safety and quality. They found the environment has a significant impact on patients and others in healthcare facilities and that design that is based on solid evidence can improve safety and quality. However, studies of the efficacy of changes in the built environment in preventing HAIs remain incomplete. A systematic review of one aspect of design—single patient rooms—has reinforced that this gap continues to need more research (24).

The reasons for this include the multifactorial nature of HAIs, short lengths of stay that limit the ability to assess impact on HAIs, long incubation period between exposure and onset of infection (e.g., surgical site infection), and the need to use meaningful metrics of both processes and outcomes that are epidemiologically sound. By illustration, a well-designed study by Rupp et al. *(25)* involving hand hygiene and validated outcome metrics was not able to demonstrate a significant correlation between improved adherence with hand hygiene and reduction in HAIs. This need not discourage further research, but it is important that investigators use several measures of impact of environment-based interventions, assess the statistical power of their study, and avoid sole reliance on environmental microbiologic studies on which to make claims of efficacy.

A recent survey of key opinion leaders involved in design identified several critical issues going forward. These include addressing problems encountered during delivery of care, safety of care (e.g., need to prevent HAIs, medication errors, falls), patient satisfaction, and operational efficiency *(26)*. Of note, HAI was ranked by the survey respondents as the topic of most importance in terms of the need for improving the current state.

DESIGN LAYOUT TRENDS

Information Technology

The EHR and other devices such as wireless communication, newer methods for imaging and procedures, and wireless control of environmental conditions such as temperature control by the patient, are all elements of design in the 21st century *(27)*. Regulatory issues may set limits for new technology since regulations frequently lag in addressing newer, more efficient design innovations. Enforcement of the National Fire Protection Association Life Safety Code comes to mind as an example of the efforts needed to modify the codes for the installations of alcohol-based hand rub (ABHR) dispensers in the corridors. CMS will frequently offer interpretations of Conditions of Participation standards to resolve conflicts for issues not anticipated decades ago. For example, wall-mounted computers in the egress corridors were recently addressed by the CMS in light of regulations governing egress corridor width *(28)*.

Sustainability

Principles aimed at sustainability of the environment are also being used in over 80% of active projects based on a survey from 2008, and this is likely to continue *(27)*. These include enhanced efficiency of heating, ventilation and air-conditioning (HVAC) systems; building utilities (power and water); surface and furnishing treatments that lessen use of volatile organic compounds (VOC); the use of natural lighting; low-emission glass; and waste reclamation.

Assessment of Environmental Sustainability Leadership in Energy and Environmental Design (LEED) was developed by the U.S. Green Building Council that verifies a construction project is designed and built using environmental sustainability strategies. The certification process promotes accountability and greater attention to sustainability issues among contractors, building owners, and building occupants *(29)*. A comparable group, Green Globes (GG), developed by the Green Building Initiative has similar goals but, until recently, was primarily used for

commercial building and is now engaged in healthcare as well *(30)*. LEED and the GG systems are both environmental assessment methodologies that score buildings and award a ranking. These green building rating systems consist of a large set of questions relating to water efficiency, energy usage, construction materials, indoor air quality, and the building site. Details of the operational aspects have been published elsewhere (31,*32,33*). As noted above, as the EBD framework developed, the concept of sustainability has been incorporated as basic, and now all groups are attending more closely to environmental infection issues, as being just as critical for patient and worker safety.

Patient-Centered Care

Patient-centered care has emerged as the norm in acute care settings. As a result, hospitals have adapted the environment of care (EC) to accommodate increasing presence of family and other visitors, including lessening of restrictions in visiting hours.

Intensive Care Unit In light of this trend, the American College of Critical Care Medicine and the Society of Critical Medicine have published recommendations to support family involvement in the care of their critically ill loved ones (34). Many of these impact EC design and include the following:

- Open visitation but determined collaboratively between caregivers and family
- Single-bed rooms with space for families
- Opportunity to participate in patient-care rounds by clinic personnel

Neonatal Units Pediatric areas have not been as thoroughly studied as neonatal intensive care units (NICUs) *(30)*. NICUs, which have special challenges for sound and acoustic control, need to balance these with efforts aimed at infection prevention. NICUs have also undergone major transformations and, similarly, have focused on private rooms as well as space for family participation, remaining cognizant of HAI-reduction issues. Removing sources of loud noises, instituting quiet hours, educating staff and parents, putting in sound-absorbing ceiling tiles and flooring, and providing single patient rooms (as opposed to open wards) have been found to be effective in reducing noise levels, but these surfaces raise HAI-related questions. White's recommended standards for NICUs provide valuable and detailed information on both acoustics and floor covering balanced with HAI concerns (*21,*35,36).

Universal or Acuity Adaptable and Single-Occupancy Patient-Care Room

Transfers from one room to the next is disruptive to the patient, can result in hand-offs, and can increase the probability of errors or elevate the risk of HAI. Regarding the latter, frequent transfer of ventilator-dependent patients can increase the risk of ventilator-associated pneumonia *(37)*. To address these issues, the "universal" or "scalable acuity" room—defined here as the ability of the environment to accommodate a variety of patients, including those who are critically ill—is an emerging design element *(38)*. In addition, an emerging ICU practice involves not only emphasis on extubation from mechanical ventilation but also on early ambulation *(39)*. This latter care intervention will have implications for design as space will need to be expanded to permit ambulation in the room, as well as the number of personnel that will be needed to assist the patient, for example, physical therapy and nursing.

Even as the trend toward the acuity-adaptable room grew, the decentralization of nursing services became another factor influencing the design of the patient-care unit to ensure the close proximity of the nurse to the patient *(40)*. This desire for proximity of the caregiver to the patient resulted in a "racetrack" configuration—single occupancy rooms on the periphery of a common corridor with workstations (including viewing windows) in between every two rooms, increased attention to windows and use of natural lighting, and zones of space dedicated for personnel and family. Others, however, have suggested that for some units such as the ICUs, a central nursing station surrounded by private rooms permits easier visualization and response to rapid changes in patient status and should be a strong consideration for the physical design of critical care units (CCUs) *(41)*. Another aspect related to visualization is real time, rapid communication and collaboration between personnel to respond to unexpected changes in the patient's condition. Regardless, architectural design that enhances spatial separation of patients and facilitates communication can improve safety for patients and personnel.

Single-Occupancy Room

The FGI research committee commissioned a study led by Chaudhury et al. to assess the benefits of single-patient rooms as a design element (42). Chaudhury found reduction in the risk of cross-infection and greater flexibility in operation. The 2006 FGI guidelines review committee reached a consensus on requiring the single room as a minimum standard. However, it made provisions for the state plan reviews, accomplished by the authority having jurisdiction (AHJ), to consider two-bedded rooms dependent on the facility's programmatic needs. The Department of Defense independently supported the use of private rooms for its facility planning criteria at about the same time (22). More recent evidence has supported this direction in room design *(4,43,44)*. The upfront cost of building a single-patient room is higher compared to multi-bed rooms but benefits for the safety and comfort of the patient over the life of this room balance this initial investment. Detsky and Etchells *(45)* have also found this design enhances privacy/noise abatement, supports patient-centered care, results in fewer transfers, enhances flexibility with adaptable acuity, and offers spatial separation to mitigate cross-transmission of pathogens. Interestingly, some patient populations have expressed a preference for multi-bed rooms, whereas personnel favor single-patient room design (42,*46*). This highlights a need to involve patients in the design, if feasible.

Of note, the single-patient room has received ongoing scrutiny by others, especially in countries where multi-bed wards are more the norm. As highlighted earlier, others have called for more research on this design element (24). This design by itself is also not a panacea for infection prevention, as evidenced by the investigation by Hota et al. (2) of an outbreak described earlier in an ICU where all rooms

were single-patient occupancy. Overall, the single-patient room is likely to remain a significant design element, does provide some transmission limits, and continues to be a minimum requirement for new construction in the FGI's 2010 guidelines (3).

SPECIFIC ELEMENTS OF DESIGN FOR INFECTION PREVENTION

Hand Hygiene

Hand hygiene is the foundation of preventing cross-transmission of organisms and ultimately HAIs. Accessible, efficient, and effective use of hand hygiene by personnel is an essential element of care for which the infection preventionist/healthcare epidemiologist is the primary advocate.

Alcohol-Based Hand Rub ABHR is the cornerstone of both 2002 Centers for Disease Control and Prevention and 2009 World Health Organization (WHO) hand hygiene guidelines *(47,48)*. Functional programming—undertaken by architects in collaboration with direct care personnel, infection preventionists (IPs), and hospital epidemiologists (HEs)—is used to identify location, number, and design of ABHR dispensers. ABHR dispensers are not intended to supplant the inclusion of plumbed hand washing stations (HSs) for use by personnel.

Hand Washing Stations FGI guidelines for new construction recommend the minimum number of HSs for patient rooms as one in the toilet room and one in the patient room outside of the patient-care zone (e.g., beyond the area of a privacy curtain) to ensure healthcare personnel can carry out standard precautions. Having a sink in a patient/resident room and in the toilet room facilitates infection prevention by enabling hand washing as needed for standard precautions and addresses reluctance by personnel to use facilities dedicated to the patient's personal use. The IP/HE needs to work with facilities and patient-care staff to recommend the *location/height* of the HSs. FGI guidelines note that HSs placed outside the room in an anteroom or alcove are acceptable but cannot replace the HS in the patient room—again to support caregivers' needs for standard precautions. Hota et al. (2) described placement of sinks that were in close proximity of care delivery, but the sink design, a shallow basin depth with faucet directly over the drain, resulted in splashing of contaminants to adjacent surfaces and directly onto the patient. Therefore, IP/HE input is essential on the HS *selection* as well, noting that the HS design to reduce splashing requires sufficient depth with the spigot having a slight offset so that the water flow is not directed straight into the drain. Ideally, the flow should contact with the curve of the sink. Key aspects of FGI design requirements are listed in Table 82-2 (3).

Hands-Free Operation Nontouch design has been identified as a method to minimize recontamination of hands after completion of hand washing. There are several types of hands-free water activation for sinks: infrared-activated, touch-activated, and paddle/foot/knob activated. Long blade handles are intended to be used with the back of the hand to minimize contamination from soiled fingers, but are not optimally utilized. Current thinking has focused on automatic infrared activation of water flow. It has been discovered that the initial water out of a spigot *regardless of the type of activation* may contain higher bacteria levels

TABLE 82-2

Sink Design Features

Sink Design Features: Guideline for Design and Construction of Healthcare Facilities 2010	
Sinks in handwashing stations *shall* be designed with deep basins to prevent splashing; designed to prevent splashing to areas where direct patient care is provided, particularly those surfaces where sterile procedures are performed and medications are prepared	Basin: porcelain, stainless steel, or solid surface materials. If the basins are set into plastic laminate countertops, at a minimum, the substrate *shall* be marine-grade plywood (or equivalent) with an impervious seal
The number and location of handwashing stations *shall* be determined by the functional program and the ICRA	The water pressure at the fixture *shall* be regulated. (Pressure *should* be adjusted to reduce forceful discharge into the sink at maximum flow.)
Hand washing stations *shall* be convenient and accessible for healthcare personnel and other users	Design of sinks *shall* not permit storage beneath the sink basin
Sinks *shall* have well-fitted and sealed basins to prevent water leaks onto or into cabinetry and wall spaces	Faucets should not discharge directly above the drain as this causes splashing (i.e., water *should* be angled away from the drain)
Sensor-regulated water fixtures shall meet user need for temperature and length of time the water flows. Electronic faucets *shall* be capable of functioning during loss of normal power	Design of sinks *should* accommodate ADA requirements for clearance under the sink basin
Hand towels shall be dispensed so that users need touch only the towels and not the dispenser	Sink size and depth—ANSI standards *should* be considered for sink design

Note: Features using ***shall*** are requirements; features using ***should*** are appendix language for consideration.

depending on when the sink was last used. The bacteria levels drop drastically with flow after the stagnant water is flushed *(49)*. Collection or use of the initial water flow may increase bioload on hands and in contained water. Well-designed systems with manual temperature controls will encourage their use and reduce problems of bacterial load.

Aerators Lower water-flow rates reduce splashing risks, but aerators also assist in delivering a controlled flow of water and mitigate splashing; some aerators, not surprisingly, also have bacterial contamination occurring inside them. The study of ICU sink design, however, identifies that aerators are not the root cause of contamination; instead, in this case, it was splashing up from the heavily contaminated biofilm in the sink drain (2). The FGI guidelines do not prohibit their use in these fixtures.

Toilet Rooms and the Disposal of Human Waste in the ICU

The trend toward single-occupancy rooms and increased focus on patient privacy raised the issue of including attached toilet rooms in ICUs. This feature facilitates disposal of human waste but also requires additional space, fixtures, utilities, and energy. Also, patients in medical and surgical ICUs are often intubated and sedated, so they are less likely to use an attached bathroom. The level of acuity of other patients, such as those in cardiac ICUs, is different, and they are encouraged to ambulate. Historically, there were attempts to address this gap by providing Swivettes (Whitehall Mfg.) inside the ICU room. However, these devices were often unreliable, too low to the floor for use by patients and personnel, and there is a theoretical concern for the contamination of the environment when flushed. Barker and Jones *(50)*, using an *in vitro* study of the dispersal of *Serratia marcescens* and a bacteriophage during flushing of a toilet fixture, demonstrated significant release of these microorganisms over short ranges and contamination of the fixture. Finally, because of the risk of spills and contamination, patient-care personnel should not carry human waste for long distances to a soiled utility room flush sink.

Options There is an increasing effort to have patients ambulate sooner in other ICUs, not just in CCUs *(39)*. Infection preventionists/healthcare epidemiologists need to work with ICU personnel and environmental services professionals to determine the safest design for the patient *and* staff. Options include having an attached toilet room for emptying bedpans without leaving the patient room area or transporting waste material to the unit's utility room with a clinical/flushing rim sink. One of these is either a toilet room or a clinical (flushing rim) sink between two patient rooms. Current 2010 FGI guidelines require one of these options for major renovations or new constructions but clarify that a dedicated toilet room for airborne-infection isolation rooms (AIIRs) is required in all locations, including ICUs (3).

An alternative is a point-of-care, automated bedpan-cleaning/disinfection device. This equipment utilizes a reusable bedpan, wherein the bedpan is inserted into the washer/disinfecting equipment and the waste is discharged into the sanitary sewer followed by a cleaning and disinfection cycle. This design feature will require mechanical reengineering for current facilities but is a potential solution depending on the needs of care providers—whether in the patient room or the toilet/utility room as described.

Flooding Prevention Whether using a toilet, bedpan washers, or flushing rim sinks for the disposal of waste, inappropriate management of disposable cloths into the sanitary sewer systems can block water flow and result in the backup of a plumbing fixture or floor drains. Not only can this contaminate the environment but residual water damage to wallboards can also lead to mold contamination. Proper disposal into regular waste containers can avoid this situation and illustrates the important connection between the environment of care (EOC) and human occupants. Such decisions require joint input by the infection prevention program (IPC) team, addressing the need for procedures to avoid this type of consequence and preplanning contingencies if it does occur (51,*52*).

Surfaces and Furnishings

Multiple types of surfaces in all units require considerations for ease of cleaning, whether floor coverings or countertops around HSs. Some specific aspects include flooring (identify precise location of soft or hard surfaces); walls (coverings for inside or outside walls); headwall components; windows; doors; countertops; plumbing fixtures (i.e., sinks, faucets, handles, etc.); lighting (covered); electrical outlets; furnishings (e.g., bed, chairs, bedside tables); and computers, equipment, and supplies storage areas. This may include details as small as the type of drawer handles, considering whether they will be readily cleaned where actually touched. Choices should also consider the selection of latex-free construction materials for all items, sizes, dimensions, colors, finishes, securement, and seams. Counter space required for various activities should have countertops that are seamless, nonporous, and durable against multiple germicidal cleanings.

Ideally, surfaces are designed to include cleanability; problems can be avoided if surfaces near plumbing fixtures are smooth, nonporous, and water resistant. Operating and delivery rooms and isolation and sterile processing areas also need smooth finishes that are free of fissures or open joints and crevices that retain or permit passage of dirt particles (3,*53*).

Planning may include the consideration of light fixtures/covers that have flat surfaces for ease in wiping clean. Window ledges are dust-collecting horizontal spaces that can be eliminated with a minimal width of nonporous material. Seamless, sealed floors are required to be clean, not waxed, and have rounded corners and edges to aid in reducing the accumulation of debris from traffic, fluids, and dirt. Non-cloth furniture resists the absorption of moisture and stains, making cleaning more effective and efficient. Stainless steel surfaces, in particular, are both resilient and easily sanitized. Selection of surface materials, therefore, must balance use life, cleanability, cost, and maintenance (51,*54*). Interior designers and IPs have inquired about furniture design standards that would assist this process; some standards may be in development but have yet to be published.

Wall Surfaces The 2010 FGI guidelines continue to require that wall finishes be washable, noting that design for a healthy and productive indoor environment can be

accomplished through measures such as the use of low VOC finishes and reduced moisture entrapment, and cannot conflict with healthcare safety and infection control codes and standards. This aspect and related topics are discussed at length in the Association for Professionals in Infection Control and Epidemiology, Inc. (APIC) 2009 text on ventilation *(55)*.

Floor Coverings Selecting hard or soft floor covering materials poses major dilemmas for all facilities, considering material that is easily cleaned but also enhances patient comfort, noise, and safety. Newer floor coverings focusing on sustainability better address the balance of concerns with patient comfort (noise), patient safety (reduced slips, falls and injury), staff back injury (rolling beds, carts, stretchers), life cycle costing (maintenance and replacement), and cleaning (equipment and staff). However, studies on methods for assessing cleaning processes have highlighted the importance of selecting cleanable surfaces. All of these concerns are raised in the guidelines, requiring decisions by the ICRA panel.

Soft Coverings Carpeting has not been directly associated with HAIs *(56)*. Recent studies have found that although bacterial contamination per unit of carpet may be higher than for hard-surface floors, they have failed to implicate carpeting as the source of HAIs, though patient population needs and location are crucial components to factor into the final decision (*57*). Some studies suggest it is possible to strike the right balance of padding, low pile, and larger wheels to minimize the problem of mechanical friction and staff back injury; however, they should have an impermeable backing featuring heat- or chemically welded seams (36,*58,59*). One additional benefit from soft flooring materials such as carpeting is the mitigation of noise pressure levels that can disturb certain populations such as critically ill neonates (*21,*35,36).

Hard Flooring In terms of hard floors, there are many more selections today of resilient floor coverings, such as medical-grade rubber, that are easily cleaned, do not need waxing or stripping, and are environmentally friendly *(60)*. FGI guidelines support floor surfaces that can withstand frequent cleaning/heavy traffic and permit cleaning without the use of hazardous chemicals. In relation to ABHR, an area of concern to environmental services professionals involves spillage of ABHR onto floor coverings and potential for stains or need to remove any finish materials. IPs and HEs should investigate this issue early during planning and design with manufacturers of flooring.

Use of Antimicrobials for Surfaces and Finishes Given the notable increase in either the replacement or extensive renovation of healthcare facilities in the United States, there has been interest in designing an environment that promotes safety but also prevents cross-transmission of infectious agents. Current evidence demonstrating the efficacy of antimicrobials when applied or incorporated into or onto inanimate surfaces, patient-care equipment, fixtures, or finishes—including carpeting—specifically for prevention of HAI is lacking. The guidelines emphasize cleanability and do not support antimicrobial treatments including hard metal surfaces with similar claims. They do support privacy curtains/partitions that are washable or, preferably, wipeable fabrics with a smooth surface.

Given the current media attention to metals such as copper, a search for evidence demonstrating that copper surfaces have decreased actual HAIs (not just reduction of microbes on the surface) remains elusive. Investigation of other studies of MDROs using antimicrobial/disinfectant treatment provides evidence that recontamination of surfaces after treatment can still occur—in particular, soon after patients and personnel reoccupy the room (*44,*61,62).

General Soft Surfaces Current evidence is lacking that demonstrates the efficacy of antimicrobials applied to surfaces of patient-care equipment, fixtures, or furnishings—including soft carpeting in patient rooms—specifically for the prevention of HAIs. They can claim only that these treatments act as preservatives of the treated substrate submitted to the U.S. Environmental Protection Agency (EPA). Textiles such as carpeting or cubicle curtains with antimicrobial features including textiles developed to absorb sound have never been demonstrated to reduce infectious outcomes *(10,63)*.

Metal–Copper Surfaces Copper has recently been the focus of investigation as one possible solution to reducing reservoirs of environmental pathogens by using this preferentially for high-touch surfaces rather than the more common stainless steel *(64)*. For the first time, the EPA has approved a new label claim for copper and its alloys, as submitted by the Copper Development Association (CDA), but the approval has limitations. The label addresses only *reduction of microbes* (requiring 2 hours for a three-log reduction on surfaces and fixtures), and cannot make claims to reduce infection transmission or reduction in infection rates. Specifically, the EPA label states:

> *"The use of a copper alloy surface is a supplement to and not a substitute for standard infection control practices; users must continue to follow all current infection control practices, including those practices related to cleaning and disinfection of environmental surfaces. The copper alloy surface material has been shown to reduce microbial contamination, but it does not necessarily prevent cross-transmission."* (65)

The surfaces cannot be coated, waxed, or lacquered. Additional research is needed to provide evidence that a change to copper surfaces would decrease HAI rates, as opposed to CDA's numerous lab studies that kill bacteria. The laboratory results may be difficult to apply in natural settings. Other studies by Airey and Verran compared six copper alloys with other alloys using a model to simulate clinical care environments where disinfectants such as dilute sodium hypochlorite (bleach solution) are commonly used. There was a notable buildup of cells and soil on copper with signs of corrosion whereas stainless steel remained clean over the course of the 5-day study when deployed in a natural patient-care setting (61). The CDA is funding three hospital studies to look at HAI reduction, but results are not anticipated until late 2010.

Summary Manufacturers that do add fungicides or antimicrobials to their product may not make health claims, and such additives should not be a criterion when selecting floor coverings. The EPA's bulletin "Consumer Products Treated with Pesticides, August 2003" requires claims for treated articles or substances to use language such as, "This product contains a preservative (e.g., fungicide or insecticide) built-in or applied as a coating only to protect the product" *(66)*. Any pesticide-treated product that is not registered by the EPA cannot make public health claims. The EPA's policy is predicated on the fact that no scientific evidence exists that these products prevent the spread of germs and harmful microorganisms in humans. IPs/HEs need to use their critical thinking skills and assessment of the scientific literature when determining the efficacy and cost-effectiveness of such design elements when asked for their input into a construction project.

UTILITIES: VENTILATION DESIGN

Ventilation, Filters, and Filtration Requirements

General Planning General planning requires attention to ventilation mechanical systems referred to as "air handlers" or HVAC systems (including recommended ventilation and filtration specifications) and mechanical systems involving water supply and plumbing.

Ventilation Parameters Basic parameters for HVAC and water use have been discussed in Chapter 80. However, ventilation parameters found in the Table 7-1 of the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) Standard 170 (Chapter 6 of the FGI guidelines and single standard for ventilation guidance) have been updated with the recommended ranges (3) (see Chapters 80 and 81).

Filters and Filtration One necessary function of HVACs is air filtration, requiring the selection of filters by filtration efficiency for different spaces. Currently, efficiency is expressed as a Minimum Efficiency Reporting Value or MERV, as opposed to a percent. Table 6-1 in Standard 170 provides the recommended filters by MERV with a change to be published in the near future. HEPA filters are no longer labeled with a MERV designation since the efficiency testing is made on a different basis. The only space in the standard requiring a HEPA filter is the protective environment (PE) (initially labeled MERV 17); the approved correction is posted on ASHRAE's Addenda website and will be incorporated with the next publication of Standard 170 *(67)* (see Chapter 80).

Operating-Room HVAC

FGI OR Design The 2006 and 2010 editions of the FGI guidelines recommend ORs be designed so primary nonaspirating supply diffusers provide airflow that is *unidirectional* and moves vertically downward with *average velocity* 25 to 35 cfm/ft^2 (127 –178 L/s/m^2). Supply diffusers need to be concentrated to provide this airflow pattern over the patient and surgical team (68). The area of the primary supply diffuser needs to extend a minimum of 12 in. (305 mm) beyond the footprint of the surgical table on each side. The foundation is based on landmark studies using computational fluid dynamics (CFD) or airflow modeling to assess the dispersion of particles (which include contaminants such as microorganisms) in the OR. The power of CFD studies is that several variables can be modified, and the impact of each can be studied in detail as compared to challenges for this control in a real-world OR. The OR CFD analysis found a significant effect of the heat from both the patient and other devices creates a thermal plume that actually prevents deposition of particles into the surgical site. In addition, using this analytical tool, the study found that increasing the number of air changes per hour (ACH)—currently 20—did not improve protection of the site since deposition requires particles to be released close to the site (68).

Low Velocity Design and Maintaining Normothermia One of the important consequences of low-velocity, unidirectional airflow is not cooling the tissue, and therefore, maintaining normothermia—as opposed to the cooling from older high-velocity laminar air flow (LAF) systems *(69)*. This may explain the unexpected findings of Brandt et al. *(70)*, who saw an association of higher infection rates with LAF in orthopedic surgery. A critique of the Brandt study compared to the National Institutes of Health/FGI design is described elsewhere (71). Additional methods of ensuring normothermia include keeping the OR temperature closer to 70°F and using forced-air warmers (FAW). Questions have been raised in the United Kingdom concerning the impact of heat from other devices, including FAW on the airflow over the patient, but studies by Moretti and validated by Memarzadeh concluded that "… forced-air warming technology does not increase the risk of surgical wound infection." Furthermore, if the OR ventilation system is designed properly, contaminating particles from staff around the patient will not impinge on the surgical wound due to 'thermal plume' dynamics (72,73). Parameters of this design include maintaining positive pressure with respect to all adjoining spaces. Optimal location of return (exhaust) vents is spacing two low sidewall vents at opposite corners with the bottom of these grills installed approximately 8 inches (203 mm) above the floor.

Special Ventilation Areas and UVGI

AII and ORs UVGI has been available for decades as a supplemental means of disinfecting air and water as is useful for disinfecting dialysis water and biological safety cabinets. A recent National Institute for Occupational Safety and Health report summarized published evidence of its efficacy in tuberculosis (TB) control *(74)*. UVGI does have antimicrobial properties; the challenges, however, include allowing sufficient time and proximity to the surface or material that one intends for disinfection. For example, studies show that the added value of UVGI in a properly designed AIIR that is providing 12 ACH is *minimal (75)*. The exchange and mixing of filtered ventilation to an AIIR results in the dilution and removal of contaminants in an efficient and safe manner. A ceiling-mounted UVGI is less likely to inactivate organisms on surfaces near and around

the patient. Organisms transmitted by droplets do not have the aerobiological properties to be pulled up past the UVGI lamps for their inactivation. Experimental research has indicated that mechanical ventilation of up to four to six ACH does not have a significant effect on the effectiveness of upper-room UVGI systems; studies are needed to examine whether the mechanical ventilation of six ACH even *decreases* the effectiveness of upper-room UVGI systems. Memarzadeh et al. (76) conclude that UVGI does not appear to have a role in properly designed AIIR or the OR, where air changes are well above four to six ACH, with the improved low-velocity design described above and required by the 2010 FGI guidelines.

In Duct Applications UVGI lamps can be installed in various locations in an HVAC system. One possible location is inside the air-handling unit (AHU), typically in front of the cooling coils and drip pan. There are anecdotal reports that this configuration results in energy conservation and maintenance-cost savings, but more rigorous study is needed to reproduce and validate these claims. Some manufacturers of these systems have also made claims of a reduced incidence of HAIs with the use of UVGI in AHUs. To date, however, there is little, if any, supportive evidence in the peer-reviewed scientific literature. The available literature indicates claims of reduced HAIs from AHU-installed UVGI in healthcare facilities remain unfounded (76).

Alternative HVAC Designs

Displacement Ventilation Displacement ventilation (DV) has been under active investigation as an alternative to traditional mechanical or overhead ventilation (OHV) in healthcare facilities. DV and OHV have equivalent filtered air sources but distribute the air differently. OHV systems generally supply air from the ceiling, resulting in a mechanical mixing at relatively high velocity of all air inside a room. DV, by contrast, introduces air at low velocities and at a low level on the sidewalls of the room and has been used in commercial buildings. This design uses natural buoyancy and convective forces (created by heat sources such as people, lighting, equipment, etc.) to move contaminants and heat upward from the occupied zone to the return located in the ceiling. The driver for DV is reducing first, that is, capital costs and operating costs, improving energy expenditure, ensuring environmental comfort, ensuring ventilation effectiveness, and controlling airborne particulates.

A two-phase research study that utilized CFD modeling has been completed on the benefits of DV *(77)*. The results are being used in support of an amendment to ASHRAE's Standard 170, clarifying that the Standards do not preclude the use of DV as a design strategy for mechanical engineering HVAC design in healthcare *(78)*. Although two pilot tests have been conducted on patient rooms, practical applications or unintended consequences if used on a large scale remain a concern. For example, blocking the airflow into the room (obstructed vents) or heat gains from natural light could have negative effects. It is likely that DV will gain support over the next decade as it supports sustainability principles in energy conservation, but it remains under intense review.

Natural Ventilation Open windows or the use of outdoor air to change and condition indoor air has been considered for some occupancies. Except for a few temperate climates found in several regions in North America, the severe climatologic changes preclude the use of this in most facilities. Some evidence exists that demonstrates that natural ventilation (NV) can be used to promote the removal of airborne contaminants in buildings that lack traditional OHV systems *(79,80)*. This applies, most typically, to facilities located in under-resourced countries. The WHO has published a guideline on the control and prevention of TB in facilities discussing DV and NV *(81)*. Specifically, WHO recommends the choice of ventilation system be based on facility assessment and informed by local climatic, programmatic, and socioeconomic conditions. Simple NV can be optimized by maximizing the size of window openings, using high ceilings, and locating the windows on opposing walls for facilities in countries lacking the resources to operate mechanical ventilation systems. It is unlikely that NV will be utilized in US acute-care facilities as it compromises building envelope integrity, allowing the entry of nonfiltered air with outdoor air contaminants such as fungal spores.

Airborne Infection Isolation Room and Protective Environment

AIIRs and PEs are addressed in detail in other publications (e.g., APIC text) and will not be detailed in this review. Several recent design concerns are worth noting, however.

Room Sealing Recent studies of AIIR pressure relationships in a large number of hospitals in the United States found only 32% met the recommended negative pressure differential; 9% were actually found to have airflow out of the rooms *(82,83)*. A major factor for this suboptimal performance was unintended air leakage in the AIIRs studied. The complexities of *maintaining* air balances have been investigated, and findings reinforce the critical importance of tightly sealed rooms *(82,83)*. More recent work reinforces the importance of a tightly sealed room in the "bundle of elements" essential for AIIRs and PE rooms to truly protect patients, along with monitoring the room periodically for air leakage *(55,84)*.

Anteroom There have been concerns regarding whether one needs anterooms for AIIRs and PEs, and if so, what the alternatives may be for ventilation design. Several sources affirm that anterooms are not required for either AIIRs or PE rooms (3,51,*80,85*). However, a clarification has been added in the 2010 FGI guidelines by creating a new category—the Airborne Infection Isolation (AII)/PE—the only type of room that *requires* an anteroom with special ventilation. Units with PE rooms should have at least one AII/PE for the immunosuppressed patient with an airborne infection, that is, a patient who needs clean air coming into the room but requires the anteroom and toilet room to exhaust used, contaminated air from the room.

The ventilation tables and text of ASHRAE 170's Ventilation Table 7-1 delineates what the direction of the airflow should be and precisely where to conduct the pressure measurement *if* (whether required or not) an anteroom is present (3).

Summary Points

Proactive Planning and Design The IP/HE is a key member of planning and design of the built environment. Importantly, their input must occur as early as possible in the design/planning phase of a new project to avoid the incorporation of elements that are not supported by scientific evidence *and* to incorporate key environmental elements that are effective. Incorporation of the latter into design plans at later stages is inefficient and expensive.

Designing for Prevention of HAIs and Patient Safety This review highlighted several elements aimed at prevention of HAIs and other complications during care of patients. Key elements and emerging trends include the following:

- **EBD**: Use of evidence has and will continue to be important not only for preventing HAIs during procedures such as insertion of a central line but also for the environment in which care is provided. We have highlighted some instances where problems have been identified when EBD is not used. The IPs/HEs must be leaders in the application of this for infection prevention and control. Collaboration with other members of the design team is critical as IPC is not the sole domain of importance, and this collaboration needs to be sensitive to other issues. This likely will require the IP to be flexible and facile in maintaining infection prevention principles in an open-minded approach.
- **Single-Patient Room and Family-Centered Care**: The FGI has adopted single-patient room design as a key design element for a broad range of reasons. We see this trend as one with longevity, but as stated, flexibility may be needed based on input from patients and personnel in addressing the needs of some populations. Accumulating evidence points to this element as effective in preventing cross-transmission of pathogens that cause HAIs. Providers should also expect increasing involvement of family into the care delivery. This trend is also evidenced in requirements of providers from accreditation and regulatory authorities as well as consumer advocacy organizations.
- **HS and Hand Hygiene**: This has and will continue to be key subject matter expertise that the IP/HE brings to the design and planning team. New findings from the literature have identified the design of fixtures, basins, and surrounding surfaces as critical to the creation of an optimal HS (Table 82-2). The functional programming will identify strategies and locations for HSs but equally important are dispensers of ABHR. Both are critical elements of design for prevention.
- **Acuity Adaptable/Critical Care Units:** In the United States, the demographic trends of an aging population with a multitude of underlying chronic diseases will continue to drive the need for rooms that can be adapted to the patient's needs but also support critical care when needed. The latter includes medical gases, monitoring capabilities, patient lifting equipment, mechanical ventilation, etc., all without necessitating transfers in and out of several rooms.
- **Surfaces and Furnishings**: This is increasingly a key focal point for the IP/HE. The manufacture and subsequent marketing of complete "infection prevention solutions" that incorporate antimicrobials will escalate. It will be important for the IP/HE to apply their knowledge and wisdom in assessing the veracity of such claims and then apply a critique of these that will best serve the patient population. To date, there is ample evidence that the critical factors are thoroughness and frequency of cleaning, and not whether the surface incorporates an antimicrobial ingredient (86).
- **HVAC Systems:** Focus on energy consumption and environmental sustainability will continue to press for better design of HVAC systems. The IP/HE will need to emphasize, however, that dynamic flow and removal of contaminants remain a key goal of this element of the built environment. Optimal design of areas that require special ventilation parameters, OR/procedure rooms, AIIR, and PE will continue to be areas that the IP/HE address in their affiliate's ICRA. Good design and operation of these spaces are important to ensure these spaces provide optimal conditions throughout their use.

CHAPTER 83

Prevention of Infections Related to Construction, Renovation, and Demolition in Healthcare Facilities

Judene M. Bartley and Russell N. Olmsted

Construction, renovation, and remediation of the built environment are a constant process in healthcare facilities. The former aspect, new construction, may be infrequent in any single facility, but the latter are typically encountered in all settings as the use of the built environment is much higher compared to other business occupancies, and the unique nature of care delivery requires extraordinary effort to provide comfortable and safe conditions. The focus of this chapter, therefore, is on planning for proper containment and protection of occupants during construction/renovation and remediation plus operational aspects that are related to the built environment. New concepts of design elements and the key roles that healthcare epidemiologists (HEs) and infection preventionists (IPs) play are reviewed elsewhere in this text (see Chapter 82).

PATIENT SAFETY INITIATIVES

A decade has passed since the Institute of Medicine's first report on patient safety in 1999 seized the nation's attention, focusing on the importance of the healthcare environment's effect on patient outcomes *(1)*. The Agency for Healthcare Research and Quality was charged with developing a plan to reduce adverse outcomes and improve the safety of workers and patients. This focus on medical safety continues to develop in healthcare organizations across the United States *(2)*. Care delivery processes occur in physical structures intended to be healing environments, enhancing patient's health outcomes. Coincident with the emphasis on patient safety, accreditation agencies such as The Joint Commission (TJC) continue to encourage and require facilities to ensure that the environment of care (EOC) in facilities does not serve as a reservoir for pathogens. Implicit in this emphasis on the EOC is preventive maintenance for critical utility systems that deliver ventilation and water to patient-care areas.

MICROBIAL HAZARDS ASSOCIATED WITH CONSTRUCTION AND RENOVATION

The physical environment in a healthcare facility may pose risks to occupants (e.g., patients, personnel, and visitors) if enhancements to the environment are carried out without a basic understanding of the potential for creating hazards and the associated morbidity and/or mortality. Physical hazards, infectious risks among them, may occur as the result of well-intentioned designs that may have unexpected consequences. For example, HEs and IPs need to balance proposals for a water feature, such as a water wall, with potential risks of disease from waterborne opportunistic infectious agents (e.g., *Legionella* species). Newer designs of ventilation systems aimed at sustainability and energy efficiency must be evaluated for risks of airborne contaminants. A clearer picture of infectious hazards associated with care delivery environments has emerged over the past decades. HEs and IPs increasingly recognize that such risks occur during construction, renovation, remediation, and preventive maintenance or from damage following natural or manmade disasters. Knowledge gained from disease outbreaks and successful interventions can be incorporated by architects and engineers to improve designs, resulting in truly healing environments. It is essential that architects, engineers, HEs, IPs, infectious diseases and safety specialists, and other stakeholders balance planning for construction and renovation with a thorough knowledge of infectious hazards, preventive techniques, and effective interventions to ensure the safest and most patient-friendly environment. Lessons are learned from prior outbreak investigations and related environmental issues. Experiences do provide information on mitigating risks and designing the EOC to prevent disease transmission as designs and materials are selected and approved in a process involving infection disease expertise *(3)* (see Chapter 82).

Airborne Microorganisms

Most studies that have associated airborne disease transmission with demolition, construction, or renovation have involved improper or ineffective environmental containment, incorrect ventilation design, or lack of planning prior to maintenance or remediation that allowed the exposure of highly immunocompromised populations, such as bone-marrow transplant patients, to opportunistic pathogens (e.g., *Aspergillus* species). Exposure to airborne infectious agents (e.g., fungi) can have a severe effect on the health of patients and healthcare personnel (HCP). The mechanisms of this exposure usually involve disruption and release of contaminants into the indoor air during the demolition of existing areas or removal of existing walls or surfaces in areas where there was an incidental encounter of prior water intrusion plus subsequent fungal contamination. Construction in these situations can result in a "burst" or release of fungal conidia into the surrounding air, which can then travel through the heating, ventilation, and air-conditioning (HVAC) system and result in the exposure of susceptible occupants. Insights gained from outbreak investigations involving construction/renovation activities have been used to mitigate the risks of healthcare-associated exposure. Effective interventions deployed during these outbreaks have been incorporated into recommendations for proactive planning and interventional strategies by guideline setting agencies (4,5). Selected examples of risk mitigation or prevention are summarized in this section to underscore the importance of specific design issues such as controlling the dissemination of particulates and airborne pathogens during demolition or remediation and ensuring that the design of HVAC or air-handler systems meet the needs for general and special patient-care areas (e.g., operating rooms [ORs], interventional cardiology/radiology units, airborne infection isolation rooms [AIIRs], protective environment [PE] rooms). Sources of airborne contaminants and infectious agents are closely related to water- and moisture-related conditions. Representative outbreaks are also discussed to illustrate the risk of exposure and cross-transmission of relevant infectious agents.

Construction and Dissemination of Airborne Microorganisms Air-quality management during construction is central to preventing the transmission of opportunistic microorganisms to susceptible patients, most notably highly immunosuppressed patients. Key publications of outbreaks related to the *Aspergillus* species and related fungi received increased attention in the 1970s and are summarized elsewhere *(6,7)* (see Chapter 57). The transmission of airborne infectious agents may originate from patient reservoirs, from laboratories, and from dust and soil introduced into the facilities during construction (8,9). The relationship between facility HVAC and airborne healthcare-associated infections (HAIs) is discussed elsewhere in this text (Chapter 84). Numerous studies have confirmed the process by which construction activity brings outdoor contaminants into a building normally "protected" by multiple systems. Key findings and interventions from investigations describing airborne microbial contamination associated with construction between 1976 and 2010 are summarized in Table 83-1 (*10–30*,31, *32–53*,54,*55–62*,63,*64,65*,66,*67*,68).

Soil and dust become vehicles for particulates, which carry microorganisms, leading to infection and disease in specific populations. This process has been described in several excellent studies *(23,24,69,70)*. Dust particles from excavation (aside from irritation from fumes and chemicals) become the vehicle for introducing opportunistic microorganisms into the HVAC systems *(33,71)*.

External Demolition and Implosions

Excavation has been cited as the major problem with external demolition and implosions *(72)*. Reports regarding the impact of large-scale demolition (e.g., implosion) have provided important information about whole-building HVAC and air pressurization (i.e., the importance of not permitting a whole building to become negative, resulting in outside air flowing into the building). Facility-associated cases of aspergillosis have been documented from temporal depressurization, in which contaminants were drawn into a facility adjacent to another building that was imploded (54,*73*,74) (see Chapter 84). Intrusion of contaminants during nearby building implosions produce high concentrations of dust, soil, and microbial contaminants in or on these substances; importantly, proper planning can reduce the risk from this increased burden of contaminants in outdoor air (*64,65*,68,*75,76*). Preemptive measures may include canceling elective surgery for patients at high risk, sealing windows and doors, adding extra filtering for air intake, and maintaining positive air pressure for patient-care areas where immunocompromised or other susceptible patient populations are located. Similarly, a fire in a nearby building may also have resulted in transmission of the *Aspergillus* species through open windows by imbedding spores in carpeting *(36)*.

Indoor Environment

Aspergillus species and *Rhizopus* are among the most important fungi introduced during construction and are characterized by an ability to grow in an indoor environment under favorable temperature and moisture conditions *(13,14,24)*. Other fungi that gain access through building penetrations include the *Penicillium* species, *Cladosporium* species, and similar airborne contaminants *(33,70,77)*. Reservoirs of these may also be created in the indoor environment from the undetected intrusion of water into walls or cabinetry in patient-care units.

Air Handlers

Many publications have addressed the importance of appropriate measures for the containment and protection of air-handling units (AHUs) during construction to reduce the risk of transmission of airborne pathogens such as the *Aspergillus* species to susceptible patients. Appropriate containment may include zonal use of portable high-efficiency particulate air (HEPA)–filtered air (used in negative air machines), provision of negative air pressure *(39,45,78,79)*, dedicated exhaust, and physical isolation of the construction area from patient-care areas *(24,32,40)*. Numerous patient outbreaks of bacterial and fungal infections associated with aerosols from contaminated ventilation ducts, grills, damaged barriers (e.g., bird screens, ventilation fans), and vacuum cleaners reinforce the importance of maintaining an intact air-handling system *(11,43,50)*.

TABLE 83-1

Airborne Microbial Contamination Associated with Construction—Selected Studies by Year and Microorganism

Year	*Author*	*Microorganism*	*Population/Location*	*Epidemiologic Factors*	*Remedial Measures or Preventive Measures*
1976	Aisner et al. *(10)*	*Aspergillus flavus, Aspergillus fumigatus, Aspergillus niger, Aspergillus* spp.	Hematology Solid tumor	False ceilings, moisture fireproofing materials	Solid, sealed ceiling
1976	Kyriakides et al. *(11)*	*A. fumigatus*.	Renal transplant	Ventilation contaminated with bird droppings	Replaced bird screen, repaired malfunctioning exhaust fan
1978	Arnow et al. *(12)*	***A. fumigatus***	Hematology	Building materials, wet	Replace water-damaged materials
1982	Lentino et al. *(13)*	*A. flavus*, *A. fumigatus*, *A. niger*, *A.* spp.	Hematology Renal transplant	Contaminated window AC units; road construction	Removal of window AC units (suggested)
1982	Sarubbi et al. *(14)*	*A. flavus*.	Medical–Surgical	Construction dust; non functioning air handler	Repair of defective air handler
1984	deSilva et al. *(15)*	Bacterial, multiple	Cardiac surgery	Ineffective operating room (OR) air handler; unacceptable surgical site infection	Increased air changes per hour (AC/H); improved filters; constant temp/ relative humidity (RH), increased positive pressure
1985	Anderson et al. *(16)*	*Varicella zoster*	Pediatrics	Isolation rooms without negative pressure	Negative pressure, no anterooms; no cases of nosocomial transmission
1985	Krasinski et al. *(17)*	*Penicillium, Zygomycetes Aspergillus* sp.	Newborn	Improperly functioning air handler	Barriers/negative pressure in construction area
1986	Opal et al. *(18)*	*A. flavus, A. fumigatus, A. niger, Aspergillus* spp.	Hematology, medical intensive care unit (ICU)	Construction/renovation activity; i neffective barriers and air handler	Physical sealed barriers; portable HEPA filter machines. Air handler treated
1987	Allo et al. *(19)*	*A. flavus*	Hematology; OR	Contaminated OR ventilation system	Cleaned ventilation system
1987	Ruutu et al. *(20)*	*A. fumigatus*	Hematology; bone marrow transplant (BMT)	Contaminated OR ventilation system	Cleaned ventilation system; ducts; filters changed, HEPA filter framing sealed
1987	Perraud et al. *(21)*	*A. fumigatus*	Hematology	False ceilings, acoustic insulation	Barriers; evacuate high-risk patients during renovation
1987	Sherertz et al. *(22)*	*A. flavus, A. fumigatus*	BMT	Efficiency of laminar airflow (LAF) HEPA filtration	Horizontal LAF HEPA filtration improved outcome
1987	Streifel et al. *(23)*	*Penicillium* spp.	BMT	Moisture; rotted wood released spores into room air	Replace with nonporous surfaces around sink
1987	Weems et al. *(24)*	*A.* spp. *Rhizopus;* *Mucorales* sp.	Hematology; renal transplant, BMT	Construction/demolition activity; excessive dust; improperly functioning air handler; open windows	Construction plans: HVAC; permanently sealed barriers against infiltration from windows
1989	Barnes et al. *(25)*	***A. fumigatus***	BMT	Construction	LAF units
1989	Hopkins et al. *(26)*	***A. fumigatus***	Renal transplant Hematology	Construction in centrally located radiology suite	Preventive measures in treatment areas, not pt. room
1990	Mehta *(27)*	***A. fumigatus*, *A.* ssp.**	Open heart surgery; OR	Ineffective air handler; bird nest adjacent to air intake; no preventive maintenance	Pigeons' nest removed; change of prefilters; use of HEPA filtration
1990	Fox et al. *(28)*	*Penicillium* sp. *Cladosporium* sp. *A.* ssp.	OR	Ventilation duct lined with contaminated fiberglass insulation	Decontamination of air handler ductwork; filter replacement

TABLE 83-1

Airborne Microbial Contamination Associated with Construction—Selected Studies by Year and Microorganism (*Continued*)

Year	*Author*	*Microorganism*	*Population/Location*	*Epidemiologic Factors*	*Remedial Measures or Preventive Measures*
1990	Jackson et al. *(29)*	***Sporothrix cyanescens***	Bronchoscopy suite	Renovation of suite pseudoepidemics from dust	Appropriate barriers and negative pressure
1991	Arnow et al. *(30)*	***A. flavus, A. fumigatus***	Hematology	Improperly sealed air filters	Air filters removed; water damage addressed
1991	Everett and Kipp (31)	**Bacterial, multiple**	Surgical patient	Inefficient OR ventilation system	Changes in OR air changes; OR temperature
1991	Humphreys et al. *(32)*	***A. fumigatus, A.* ssp.**	ICU	Perforated ceiling; fibrous insulation	Solid ceiling; proper insulation
1992	Abzug et al. *(33)*	**Mucorales Zygomycetes**	Pediatric Leukemia	Air intakes proximity to heliport	Modifications to helipad design and HEPA filters
1992	Hruszkewycz et al. *(34)*	***Penicillium* spp. *Aspergillus* sp.**	Laboratory pseudo-outbreak	Improper airflow during renovation near lab; false ceiling in work area	Sealed ceilings; proper use of lab hoods; appropriate air flow controls
1993	Flynn et al. *(35)*	*A. terreus*	ICU, BMT, hematology	Renovation adjacent to ICU affecting ventilation duct; false ceiling removal	Adjusted pressure relationships between ICU and renovation, including stairwell; elevators
1994	Gerson et al. *(36)*	***A. flavus, A. fumigatus***	BMT; leukemia	Open window; fire-contaminated carpet	Modifications of carpet cleaning/extraction procedures
1994	Iwen et al. *(37)*	*Aspergillus* sp. Mixed fungi	BMT unit Hematology	Improper airflow; suspected infiltration from windows	Sealed windows and balanced airflow; replaced HEPA filters
1995	Stroud et al. *(38)*	Multi–drug resistant *M. tuberculosis*	AIDS patients	Improper air changes and pressure relationships for isolation rooms	Adjusted ventilation according to CDC guideline for MTB prevention
1995	Alvarez et al. *(39)*	*Scedosporium prolificans*	Hematology unit	Internal renovation; ventilation system	Move patients to another floor level
1996	Bryce et al. *(40)*	*A. fumigatus, A. niger, A. terreus*	Med Surg ICU, burn unit patients	Renovation in central supply area, contaminated supplies used in ICU, burn patients	Sealed construction area with temporary vents; cleaning of supplies surfaces
1996	Cotterill et al. *(41)*	Methicillin-resistant *S. aureus*	ICU	Open window; improper air intake/exhaust	Windows closed; redesigned bed placement
1996	Fridkin et al. *(42)*	*Acremonium kiliense*	Ambulatory surgery	Poorly designed air handler; contaminated humidifier	Redesign; changed HEPA filters. Proper maintenance of pressure relationships
1996	Anderson et al. *(43)*	*A. flavus*, *A. fumigatus*, *A. niger*	BMT, pediatric oncology unit	Improper airflow from clinical waste disposal area; contaminated vacuum	Sealing of disposal room and ducts; use of HEPA-filter vacuum cleaners
1996	Leenders et al. *(44)*	*A. flavus*, *A. fumigatus*	Hematology	Environmental source not identified	Windows closed; new air handler
1996	Loo et al. *(45)*	*A. flavus*, *A. fumigatus*, *A. niger*	BMT, hematology unit	Construction; demolition; perforated ceiling tiles	Solid ceiling, HEPA machines; use of copper 8 quinolinolate
1996	Philpot-Howard *(46)*	*A.* ssp. and other filamentous fungi	Hematology patients	Construction; ventilation parameters	Preventive maintenance of air supply; use of barrier
1996	Pittet et al. *(47)*	*Aspergillus* sp.	COPD	Insufficient air filter replacement	Monitor filter function; replaced filters
1997	Dearborn et al. *(48)*	***Stachybotrys atra***	Infants	Residential water damage; potential release of toxin	Decontamination with diluted bleach

1998	Tabbara al Jabarti *(49)*	***A. fumigatus***	Cataract; OR ocular surgery	Hospital construction	Proper maintenance of physical structure
1998	Kumari et al. *(50)*	Methicillin-resistant *S. Aureus*	Orthopedic patients	Ventilation grills	Air handler cleaned, maintained proper pressure relationships
1999	Cornet et al. *(51)*	***A.* ssp.**	Hematology	Renovation and dust production	Use of portable HEPA filters versus LAF HEPA
1999	Garrett et al. *(52)*	*A.* ssp.	Rheumatology patients	Construction not sealed off; improper pressure relationships and air changes	Adjusted ventilation according to CDC guidelines (tuberculosis)
1999	Laurel et al. *(53)*	*A. niger*	Laboratory Pseudo outbreak	Construction; installation of ventilation duct adjacent to biological safety cabinet	Cleaning, prefilter; HEPA filter changes, construction protocols for laboratory
2000	Thio et al. (54)	*A. flavus.*	BMT Hematology	Pressure relationship of units to whole hospital; negative pressure	HEPA; readjust pressure relationships to ensure hospital as a whole slightly positive
2001	Burwen et al. *(55)*	*A. flavus*	Hematology–oncology	Distance from renovation; construction activity	Screen and use HEPA-filtered air; applicable CDC guidelines
2001	Lai *(56)*	*A. niger, A.* ssp.	BMT patient wards	Construction adjacent to BMT unit	BMT site tightly sealed; high-risk patients to avoid site during construction
2001	Oren et al. *(57)*	*A. flavus, A.* ssp.	Leukemia, BMT patients	Construction; natural ventilation	Ward with air filtration using HEPA filters
2001	Pegues et al. *(58)*	*A.* ssp.	Heart–lung transplant	Renovation; dust production	Removal of carpeting; replacement of ceiling tiles
2002	Hahn et al. *(59)*	*A flavus, A niger*	Hematology–oncology	Contaminated insulation in affected unit and nurses station	Installation of HEPA filters
2002	Kistemann et al. *(60)*	*A.* ssp.	COPD and corticosteroids	Reconstruction, pigeon droppings, water damage from leakage	Clean up of area; maintenance/precautions to reduce exposure to patients
2002	Raad et al. *(61)*	*A. fumigatus, A. flavus terreus, A.* ssp	Hematology	Construction dust outside of protected BMT area	High efficiency masks on patients during transport
2005	Adler et al. *(62)*	*Bacillus* sp.	NICU	Construction during relocation of the NICU	Case–control study identified association retrospectively
2006	Vonberg and Gastmeier (63)	*A. fumigatus, A flavus*	Hematology	Construction or demolition work	Reduce exposure of hematological patients to construction
2007	Nihtinen et al. *(64)*	*A. fumigatus*	Stem cell transplant unit	Heavily contaminated air outside at construction site	HEPA filters prevented fungal colonization
2009	Brenier-Pinchart et al. *(65)*	Filamentous fungi	Hematology wards	Outdoor and indoor risks identified; outdoor air higher load of fungal flora	HEPA filtration; more influence on protecting rooms plus cleaning
2009	Kidd et al. (66)	*A fumigatus*	ICU	ICU ventilation likely; definitive source not identified using typing	Cleaning/sealing all points of leakage: lights, vents, ceiling tiles.
2010	Jensen et al. *(67)*	*A.* spp.	OR; postop rooms	Postop environment showed high counts of conidia	Room air cleaning
2010	Fournel et al. (68)	*A.* spp.	Three high-risk patient units	Air contamination—extensive testing outside and indoors	Protective measures more effective than air cleaning in minimizing impact

Room Design and Location Room design must consider the location of supply air and exhaust vents as critical factors to interrupt the risk of transmitting airborne contaminants *(33,41)*. Negative air pressure in pediatric oncology units, for example, was shown to reduce the spread of varicella-zoster virus (VZV) among workers and patients *(16)*. Lower bloodstream-infection and mortality rates were reported for burn patients in enclosed intensive care unit (ICU) beds than for patients in open wards *(80)*. Multiple outbreaks related to *Mycobacterium tuberculosis* were terminated with properly designed and improved maintenance of negative air pressure (AII) rooms *(81)*.

The Surgical Suite Environment The OR environment has been studied extensively in an attempt to reduce infectious risks in patients undergoing clean surgical procedures such as orthopedic joint replacement. Other invasive procedures are increasingly being performed in a variety of locations such as procedure rooms, which mirror the desired conditions in an OR, and so the scope of this setting needs to extend beyond the surgical suite *(67)*.

The literature on reductions in surgical site infection (SSI) rates, primarily found in total joint arthroplasty, is reviewed elsewhere *(82–84)*. The focus for this chapter relates to contamination of the OR during construction and renovation from airborne fungi and other pathogens (*27,28*,31,*85,86*,87,*88–92*). A summary of the general issues and interventions to mitigate these problems have been reported elsewhere (8,9,*28,89,93*) (see Chapter 84). Multiple interventions in ORs have led to improvements in performance and outcome involving surgical patients. Many of these emphasize optimizing air quality and exchange. As a result, current standards include increased outside air and total air exchanges per hour, improved air filtration efficiency, proper humidification, and filter location in air handlers serving ORs (4,*15*,31,*42*). Major studies by Lidwell *(94,95)* focused on the use of ultraclean (laminar airflow [LAF]) HEPA-filtered air in clean orthopedic surgical procedures. These studies, together with other multisite studies (87,*96*), led to a better understanding of the independent contribution of ultraclean air in reducing clean SSIs; its effect is comparable to the use of preoperative prophylactic antibiotics. Although LAF using HEPA filtration has been considered for specific procedures such as orthopedic surgery, given the major resultant morbidity and mortality if the replaced joint becomes infected, definitive evidence on the efficacy of elaborate LAF in the prevention of SSIs has been lacking. The Centers for Disease Control and Prevention (CDC) 2003 guidelines, assessing available scientific literature, concluded: "No recommendation is offered for performing orthopedic implant operations in rooms supplied with laminar airflow …" (97). Brandt et al. recently published a multihospital study in Germany that suggested an *increased* risk of SSI was associated with ORs using LAF compared to standard turbulent-air ORs (*98*). Details of specific HVAC design at the participating hospitals are lacking in this investigation; however, these systems were older, vertical, high-velocity LAFs and are not comparable to the current design required in the United States in the 2006 Facility Guidelines Institute (FGI) guidelines (99) and the latest 2010 FGI guidelines (4) that use a low-velocity unidirectional airflow (100). For complete information on this design, see Chapter 82.

Waterborne Microorganisms

Water can be a reservoir of pathogens that can cause waterborne diseases but can also harbor other microbes (e.g., *Fusarium* spp. and *Aspergillus* spp.) that may propagate in the environment. Those at greatest risk are immunocompromised patients, and many outbreak investigations have identified potable water systems and storage tanks, showerheads, and ice machines as sources of waterborne pathogens *(101–104)*. Table 83-2 summarizes findings from investigations of clusters of infection caused by waterborne pathogens (*103,105–113*,114, *115–122*,123,124,*125*,126). *Legionella* species, for example, have been implicated in patient infections acquired through the inhalation of aerosols spread from contaminated storage tanks, shower heads, and equipment that used tap water, such as water baths, stagnant water on the roof (124), decorative water fountains (126), and/or entire water systems (114,*127–131*). A review of healthcare-associated waterborne infections excluding those caused by *Legionella* species revealed 43 outbreaks with associated deaths of almost 1,400 per year and called for the provision of sterile rather than potable water for high-risk patients during hospitalization *(132)*. Maintenance of potable water quality depends on good design, preventive maintenance, and conduits that support dynamic movement in a continuous fashion. Problems arise when portions of water-delivery systems are capped, permitting water to stagnate, and both biofilm and concentrations of microbes increase to high levels. Surveillance for HAIs related to water reservoirs, therefore, is an important component of the design and operation of this major utility. One study assessed the risk of bacterial pathogens in drinking water in an attempt to determine if dose–response relationships could be developed, and whether or not potable water poses a public health hazard *(133)*. The results included a ranking of water-associated microorganisms from studies reported primarily from medical centers. Although the purpose of the study was not directly related to construction, the review does confirm the expected frequency of opportunistic microorganisms causing serious infections associated with water. These opportunistic microorganisms are of concern because of their potential for direct or indirect transmission from taps and sinks or through the inhalation of aerosols generated from construction activities affecting patients and construction workers (124). One recent outbreak of *Pseudomonas aeruginosa* in an ICU and transplant unit resulted in serious morbidity and mortality due to water from sink drains contaminating patients and clean supplies *(125)*. See Chapter 82 for complete details of how sink modifications ended the outbreak. Even contaminated condensation from window air-conditioning units when combined with other work practices can lead to invasive infections such as the *Acinetobacter* species bloodstream infections in high-risk pediatric populations *(134)*.

Moisture and Fungi Excessive moisture around pipes and insulation, condensation in drain pans, and flooding from broken pipes can lead to extensive environmental fungal contamination. Such contamination has been associated, for example, with water-soaked cabinets in

TABLE 83-2

Water-Associated Contamination Associated with Construction Selected Studies by Year and Microorganism

Year	*Author*	*Microorganism*	*Population*	*Epidemiologic Factors*	*Remedial or Preventive Measures*
1981	Crane et al. *(103)*	*Pseudomonas paucimobilis*	Intensive Care Unit (ICU)	Contaminated tap water	Thermal decontamination of water system; revised procedures for tap water use for equipment
1981	Cordes et al. *(105)*	*Legionella pneumophila* serogroup 6	Hospital patient rooms	Contaminated water supply; shower heads	Decontamination shower heads
1986	Panwalker and Fuhse *(106)*	*Mycobacterium gordonae*	Hospital	Contaminated ice machines	Disinfection; preventive maintenance
1991	Burns et al. *(107)*	*Mycobacterium fortuitum*	Alcoholism rehab unit	Ward showers; tap supply	Disconnected and disinfected showers
1993	Hlady et al. *(108)*	*L. pn* ser. 1	Hotel	Decorative water fountain	Proper heat and maintenance
1993	Sniadeck et al. *(109)*	*Mycobacterium xenopi*	Hospital rooms	Water supply (pseudo-outbreak)	Maintain temperature (>120°F [49°C; preferably 54°C])
1994	Prodinger et al. *(110)*	*L. pn* ser. 1	Renal allograft	Water distribution system	Replaced central water supply with individual electric water heaters in each room
1995	Bangsborg et al. *(111)*	*L. pn* ser. 1 and 6	Heart–lung transplant	ICU kitchen ice machine	Disinfection of machine; preventive maintenance
1997	Graman et al. *(112)*	*L. pn* ser. 6	Vent patients	Ice machine	Replace supply line and treatment of water system
1997	Patterson et al. *(113)*	*Legionella pn, bozemanii, gormanii*	General hospital	Water storage and distribution systems	Maintain hot water above 58°C
1998	Kool et al. (114)	*L. pn, L.* ssp.	Transplant center	Water system	Hyperchlorination
1999	Biurrun et al. *(115)*	*L. pn.* ser. 6.	General hospital	Water distribution system	Copper–silver ionization and continuous chlorination system
1999	Weber et al. *(116)*	***S. maltophilia***	Surgical ICU	Potable water- aerators	Removal or routine disinfection
2000	Kappstein et al. *(117)*	*Acinetobacter junii*	Pediatric oncology	Contaminated aerators	Remove, use aerators with radially/ vertically arranged lamellae
2000	Knirsch et al. *(118)*	*Legionella micdadei*	Solid organ transplant	Hot water sources	Treat hot water supply
2000	Stout et al. *(119)*	*L. pn* ser. 1	LTC residents	Water distribution system	Install copper–silver ionization system
2000	Borau et al. *(120)*	*L. pn* ser. 6	ICU patients	Hot water system	Elevate hot water temperature
2002	Grove et al. *(121)*	*Legionella longbeachae*	ICU patients	Cooling tower; pigeon's nest 1–2 cm from vent; demolition	Removal of nest; PM cooling towers
2002	Darelid et al. *(122)*	*L. pn* ser.1	General hospital	Water distribution system	Maintain water temperature 55°C.
2009	Hota et al. (123)	*Pseudomonas aeruginosa*	ICU; Transplant unit	Biofilm inside drain; design of hand washing stations	HW stations redesigned to prevent splashing
2009	CCDR (124)	*L. pn* ser.1	Hospital workers; patients	Potential for condensing tower; stagnant water in kitchen roof	Water treatment; removal of dead legs; intensified surveillance; educate workers
2009	Rao et al. *(125)*	*Phialemonium curvatum*	Hospital hemodialysis center	Product water-source of bloodstream infection	Remediation of water distribution system and discontinuing use of waste handling option ports
2009	Palmore et al. (126)	*L. pn* ser.1	Radiation Oncology Center	Decorative fountain	Cases occurred even with filter and ozone generator. Unacceptable risk to maintain a fountain

medication rooms *(23,62)*. Static water systems can provide a reservoir of microorganisms in the healthcare environment by supporting their growth. Nonsterile water used for invasive patient-related procedures can result in direct or indirect transmission of microorganisms to patients *(103,109,135)*. Bloodstream infections due to the mold *Phialemonium curvatum* were identified in a hospital hemodialysis unit in which the product water was determined to be the source. Resolution required discontinuing the use of waste-handling option ports *(125)*. A report of fungal endophthalmitis from *Acremonium kiliense* following cataract surgery in an ambulatory surgery setting demonstrated the process by which contaminated humidifier water functioned as a reservoir for an infectious agent, eventually spreading through the airborne route by way of the ventilation system *(42)*. Typically, healthcare-associated transmission of fungi is airborne; however, there is emerging evidence that potable water in health facilities may also be a significant reservoir, suggesting that prompt disinfection of high water-use areas such as showers is an important measure to prevent exposure to fungal pathogens *(136)*.

Legionella Species Annually, there are estimates of between 8,000 and 18,000 hospitalizations for legionellosis *(137,138)*. However, reported hospital outbreaks predominate in the literature because of the fatal effects on susceptible patient populations; they have helped characterize *Legionella* and identify key risk factors from affected individuals *(139–142)*. Although each reported outbreak of legionellosis improved the epidemiologic understanding of this pathogen, endemic, sporadic cases (representing most of the observed cases) still evade full understanding. The mode of transmission implicates not only cooling towers, potable water reservoirs, and distribution systems *(140–144)* but also water-related equipment such as medication nebulizers *(145)* and potable water used for nasogastric feeding *(104)*. An investigation by the National Institutes of Health recently reported an outbreak associated with a decorative fountain in its radiation oncology center (126).

Legionella species from nearby environmental water sources enter hospital water systems, multiply in cooling towers and evaporative condensers, and/or contaminate the potable water system. Because infection develops after inhaling airborne water droplets containing *Legionella* species, any opportunity for contaminated water to aerosolize is of concern during construction and renovation. Major construction has been associated with numerous healthcare-associated outbreaks or clusters *(127)*. Potential mechanisms include the release of this microorganism from vibration or significant changes in water pressure. These disturbances loosen corrosion and disturb biofilms, thereby releasing *Legionella* species into water system pipes. Excavation permits the microorganism to be released from the soil; the microorganisms eventually enter cooling towers, air intakes, or water systems, leading to direct inhalation from water sources (146). Summaries of outbreaks have been described in the CDC guidelines and other government and private recommendations for detection and treatment (146,*147–151*) (see also Chapter 36).

CHANGES IN HEALTHCARE DELIVERY AND IMPACT ON CONSTRUCTION TRENDS

Construction Costs

Annual construction and design surveys in the United States indicate a continued major expenditure on healthcare construction and renovation. Changes in patient acuity, aging, and reduced capital funds have affected construction expenditures in a number of ways. Recent trends show dollars are spent primarily on inpatient specialty beds (e.g., cardiac and cancer) along with increasing demands for assisted-living and skilled nursing centers. A December 2009 survey of construction for hospitals, nursing homes, and outpatient facilities in 2009 totaled $61.1 billion for new construction and $25.8 billion for renovation (152). The distribution of projects continues the usual pattern of 70/30, that is, 72% of the projects involved renovation and 28% were new construction or replacements. These investments represent actual drops and delays due to the faltering economy in 2008 to 2009 that profoundly affected construction. The good news is that new construction and renovation also reflect new attention to infection prevention following FGI guidelines' (99) requirements and the inclusion of in-room sinks being among the five top features included in hospital design.

The increasing age of US healthcare facilities generates a constant need for repair and remediation work (cabling, room additions). These processes increase the risks of environmental contamination, affecting air and water quality. Natural and manmade disasters during construction (e.g., flooding) add extra opportunities for contaminating healthcare delivery sites. New concerns for protecting buildings from airborne contaminants from the intentional release of biologic agents or unintended manmade disasters have focused additional attention on the building envelope, ventilation management, and isolation room capacity *(153,154)*.

Costs of Healthcare-Associated Disease

Outbreak investigations documenting health outcomes resulting from contamination are associated with multiple healthcare settings but focus primarily on hospitals. Although the actual percentage of HAIs directly related to construction is unknown, one can consider costs in terms of one significant airborne infectious agent: *Aspergillus* species. Aspergillosis can be either community-acquired or healthcare-associated, but it is difficult to always distinguish between them. The total cost impact is enormous. For example, in considering aspergillosis alone for 1 year (1996), costs were estimated at $633.1 million. Although the number of aspergillosis-related hospitalizations are a small percentage of total hospitalizations, the average length of stay attributable to treating this disease is 17.3 days, costing an average $62,426 (95% confidence interval $52,670–$72,181) based on 176,272 hospital days (95% confidence interval 147,163–206,275 days) *(155)*. The case fatality rate for aspergillosis averages 58%, but for bone-marrow transplant recipients, it reaches 86.7% *(156)* (see Chapter 59). A better assessment of risks and their mitigation can enable architects to design

and plan for patient-friendly and safer facilities. Although there has been improvement with more recent improved therapies, prevention from environmental exposure remains critical to reducing these rates and cost (63,*157*).

DESIGNING FOR DISEASE PREVENTION AND HEALTH PROMOTION

Healthcare Study Design

This section focuses on the design and construction of healthcare environments that plan to reduce the risks of adverse outcomes learned from past experience and that emphasize infection prevention and control (IPC) during new construction and renovation (external and internal). Suggestions and recommendations to prevent and control infectious risks are based on published investigations occurring most frequently in hospitals; these recommendations may need tailoring for other healthcare delivery sites. Design professionals are increasingly interested in identifying individual variables that affect patient outcomes and worker productivity, forming a growing science around the relationship between the built environment and quality of care *(157)*. The *built* or physical environment is defined as any aspect of the environment that is constructed by design experts such as architects or designers. More attention is being given to designing facilities that are cost-effective, efficient, and functional for staff while cultivating a caring, healing environment for patients (see Chapter 82, Infection Control Elements in Design).

Current and Future Design and Materials

Because of the paucity of scientific evidence, HEs and IPs must rely on fundamental principles such as the epidemiology of infectious diseases to determine what interventions are most likely to be effective in preventing infection. Evidence from prevention of HAIs through the use of antimicrobial-impregnated medical devices is leading to the incorporation of an antimicrobial surface or polymer treatments to minimize environmental reservoirs of potential pathogens *(158,159)*. Because of the focus on the prevention of HAIs, many manufacturers are developing and marketing surface treatments that claim to be antimicrobial or self-disinfecting surfaces (e.g., copper) and oxidizing agents bound to surfaces utilizing normal light wavelengths or ultraviolet light *(160,161)*. Although none of these have yet demonstrated a reduction in HAIs and have limited results from laboratory studies, they are designed for healthcare settings to lessen the risk of cross-transmission. Other architectural and utility system features under study include ventilation systems that provide 100% exhaust, design of microbial-resistant building materials (e.g., glass mat faced gypsum board), the use of ultraviolet germicidal irradiation to prevent the biofouling of AHUs, and design features that minimize the buildup of biofilms in potable water systems *(162,163)*.

A number of engineering studies directed at determining ideal ventilation for patient rooms *(164)* or AIIRs *(165)* have provided a foundation for design recommendations *(166)*. Additional studies of areas needing special ventilation such as the OR suite have and will continue to drive changes in specific parameters for consensus guidelines. The National Institutes of Health computer modeling study of efficacy of OR HVAC design found that increasing the number of air changes per hour was not as important as air velocity, and as noted earlier, unidirectional airflow at the surgical site was more important than the location (high or low) of exhaust ducts (100) (see Chapter 82).

Floor covering materials such as carpeting have been studied extensively, and although it may be colonized with a variety of pathogens (e.g., *Clostridium difficile*), no direct link to patient infections has yet been found *(36,167,168)*. Accordingly, carpet in patient-care areas should be chosen with respect to aesthetics and cleanability and not because of risk to patients. Surface treatments or incorporation of antimicrobial products into the surface matrix to inhibit microbial growth are available commercially. However, most efficacy studies involve *in vitro* investigations; to date, there are no professional peer-reviewed publications to support HAI reduction related to antimicrobial treatment of environmental surfaces including patient-care equipment, fixtures or furnishings, and carpeting. There is evidence that antimicrobials can reduce the incidence of HAIs when incorporated into or onto devices that are placed in the patient (e.g., central venous catheters). Antimicrobial-treated environmental surfaces or products are submitted to the U.S. Environmental Protection Agency (EPA) by the manufacturer as preservatives of the treated substrate, and any claims of disease prevention that have come under scrutiny by the EPA are lacking supportive scientific evidence. Specifically, textiles such as carpeting or cubicle curtains with antimicrobial features, including textiles developed to absorb sound, have never been demonstrated to reduce infections in patients *(169)*.

REGULATORY AND ACCREDITATION AGENCIES' GUIDELINES AND STANDARDS THAT IMPACT CONSTRUCTION

Agencies with Impact on Design and Physical Environment

Standards and guidelines issued or enforced by the following agencies have had major impact on the physical structure of healthcare settings. There are many agencies and professional associations that have a direct impact or provide resources to plan, design, and better construct facilities; some of note include the following:

1. FGI: "2010 Guidelines for Design and Construction of Healthcare Facilities"—minimum standards for most states (4)
2. Centers for Medicare & Medicaid Services (CMS): "Hospital Conditions of Participation (COP)"—for Medicare & Medicaid *(170)*
3. TJC: "Comprehensive Accreditation Manual for Hospitals: The Official Handbook" *(171)*
4. CDC/Healthcare Infection Control Practices Advisory Committee: "Guidelines for Environmental Infection

Control for Healthcare Facilities" (97) and numerous other guidelines *(5,148,172–174)*

5. Other agencies
   - Occupational Safety and Health Administration (OSHA): tuberculosis, construction, bloodborne pathogens, and legionellosis *(149,175,176)*
   - National Institute of Occupational Safety and Health (NIOSH): HVAC, sharps containers, air sampling, testing, filtration *(153,177–179)*
   - State and local standards—for example, enforcement of national consensus guidelines by state-based "authorities having jurisdiction," who are professionals from a variety of backgrounds who review and approve plans for construction in healthcare facilities *(180)*
6. Professional organizations with resources and/or standards
   - Association for Professionals in Infection Control and Epidemiology (APIC): chapter on construction (8,9), and the infection control risk assessment (ICRA) (8,9,*181,182*) (www.APIC.org)
   - American Society of Healthcare Engineering (ASHE): contractor certificate program including ICRA; monographs (www.ASHE.org)
   - American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE): basic design research; design handbooks and American National Standards Institute ANSI/ASHRAE/ASHE Standard 170-2008, Ventilation of Health Care Facilities in the 2010 FGI guidelines (4) (www.ashrae.org)
   - The Center for Health Design supports research and development of science to support evidence-based design (www.healthdesign.org).
   - Green Guide for Health Care issues practice guidance for healthy and sustainable design, construction, and operation of healthcare facilities (www.gghc.org).
   - U.S. Green Building Council developed "Leadership in Energy & Environmental Design"; develops consensus-based standards for design and construction of sustainable or green buildings, oversees Leadership in Energy & Environmental Design certification, and offers education and training (www.usgbc.com).

Relationship between FGI Guidelines and Regulations

Facility Guidelines Institute The original *General Standards of 1947* used as regulations for the Hill–Burton program have evolved into today's *Guidelines for Design and Construction of Hospital and Healthcare Facilities*, *2010* under the guidance of the FGI founded in 1998 to ensure a process to keep the guidelines current (4). The American Institute of Architects was the publisher, a role now carried out by ASHE and the American Hospital Association press. The change to "FGI Guidelines" also highlights the multidisciplinary aspect of the >100-member "Healthcare Guidelines Review Committee" (HGRC)—the group that carries out the revision through consensus. The HGRC steering committee has always included at least one infection prevention expert representative. The 2010 guidelines expanded on the planning process of the ICRA, which first appeared in the 1996 to 1997 guidelines, developed further into the 2001 and 2006 editions and is now well-integrated into the complete "Planning, Designing, and Construction" section of the 2010 guidelines. As a consensus guideline, it relies heavily on input from groups such as ASHE and ASHRAE, increasingly from clinicians and organizations such as APIC and the Society for Healthcare Epidemiology of America (SHEA), and it references published guidelines from the CDC. The guidelines include ventilation requirements for negative air pressure rooms as specified in the 2005 CDC "Guidelines for Preventing the Transmission of *M. tuberculosis*" *(5)* and the design and ventilation recommendations in the 2004 "Guidelines for Preventing Health-Care-Associated Pneumonia, 2003" as well as the CDC/Healthcare Infection Control Practices Advisory Committee guidelines for environmental infection control in healthcare facilities. The combined effect of these guidelines has set in motion an increased opportunity for long-range and ongoing involvement of infection-prevention programs in planning for construction and major renovation. The current 2010 edition of the guidelines continues to improve the scope and importance of the ICRA and is viewed as a core element. The role of HEs and IPs in implementing the ICRA is multifaceted and is needed for long-range strategic planning and operational project initiatives and for ongoing maintenance activities.

Centers for Medicare & Medicaid Services Changes related to facility design aimed at reducing infectious risks are evident in many of the revised standards. CMS requirements are consistent with the FGI guidelines, although CMS uses additional physical plant standards to enforce the Hospital COP and Life Safety Codes (LSC). In addition to CMS, more than 42 states adopted the FGI guidelines as minimum design standards or adapted them with state-specific regulations governing physical plant and safety issues, transforming the guidelines to regulatory status. A large proportion of the FGI HGRC members are state and federal "authorities having jurisdiction" who review and enforce design plans as agents of CMS.

The Joint Commission Facilities accredited by TJC must consider the EOC standards because these impact LSCs and utility management standards for all facilities. TJC added specific standards for design and construction that reflect the FGI guidelines requirement for a risk assessment. These are primarily found in the EOC standards and elements in EC.02.05.01, which address the evaluation of ventilation and water for pathogenic biological agents, as well as referring specifically to the guidelines and EC 02.06.05, addressing demolition, renovation, and new construction. For example:
2010 Standard: EC.02.06.05

> *When planning for demolition, construction, or renovation, the hospital conducts a preconstruction risk assessment for air-quality requirements, infection control, utility requirements, noise, vibration, and other hazards that affect care, treatment, and services. Note: See LS.01.02.01 for information on fire safety procedures to implement during construction or renovation…the hospital takes action based on its assessment to minimize risks during demolition, construction, or renovation. (171).*

Centers for Disease Control and Prevention The CDC guideline for environmental infection control supports

many key guidelines and recommendations and provides strength-ranked recommendations based on peer-reviewed scientific evidence (97).

INFECTION CONTROL RISK ASSESSMENT—DESIGN AND CONSTRUCTION ASPECTS

Concept—The Infection Control Risk Assessment

Infection Control Risk Assessment—Construction Projects The FGI guidelines recognize that renovation and new construction in existing facilities can create conditions that may be hazardous to occupants. The 1996 to 1997 edition of the guidelines required construction and major renovation assessments during project planning related to specific risks. The current 2010 guidelines lend stronger weight to IPC input at the *initial stages* of planning and design of a project by requiring documentation of an ICRA (4). The ICRA is considered a process requiring documentation of *continued involvement* of IPC throughout specific projects. ICRA is a determination of the potential risk of transmission of various agents, particularly biologic, in the facility but expands far beyond determining optimal numbers of isolation rooms or the location of handwashing stations. Instead, ICRA supports design of the EOC toward systems that prevent transmission of infection and ensures a safe environment for patients, personnel, and visitors. For example, an important component of ICRA is determining locations and installation of dedicated exhausts when the cleaning and disinfection of medical equipment is anticipated. In 2006 and with additional clarifications in 2010, the guidelines clarified activities associated during *design planning*, *construction planning*, and actual *preparation for the construction* project referred to as "infection control risk mitigation recommendations" (ICRMR), addressing specific measures during a construction project. Specifically, the ICRA is now summarized as follows:

> *The ICRA shall be conducted by a panel with expertise in IPC, risk management, facility design, construction, ventilation, safety, and epidemiology. The panel shall provide documentation of the risk assessment together with updated mitigation recommendations throughout planning, design, and construction and commissioning. The owner shall also provide monitoring of the effectiveness of the applied ICRMR during the course of the project. The owner shall ensure that construction-related ICRMR- and ICRA-generated design recommendations are incorporated into project requirements.*

ICRA elements related to *building design features* include the following:

1. Numbers, location, and types of AII and PE rooms
2. Location of special ventilation and filtration of HVAC units serving such areas as emergency department waiting and intake areas
3. Air handling and ventilation needs in surgical services, AII and PE rooms, laboratories, local exhaust systems for hazardous agents/chemicals, and other areas with special needs
4. Water systems to limit *Legionella* spp. and other waterborne opportunistic pathogens
5. Location, design, and accessibility of hand-hygiene products and equipment (e.g., hand washing stations)
6. Furnishings and surfaces

ICRA elements related to *building site areas affected by construction* include the following:

1. Impact of disrupting essential services to patients and employees
2. Determination of the specific hazards and protection levels for each hazard
3. Location of patients based on susceptibility to infection and definition of risks to each patient
4. Impact of potential outages or emergencies and protection of patients during planned or unplanned outages, movement of debris, traffic flow, cleanup, and testing and certification
5. Assessment of external and internal construction activities
6. Location of known hazards

ICRMR Preparation for Actual Construction
The ICRA panel must also address the following:

1. Patient placement and relocation
2. Standards for barriers and other protective measures required to protect adjacent areas and susceptible patients from airborne contaminants
3. Temporary provisions or phasing for the construction or modification of heating, ventilating, air conditioning, and water supply systems
4. Protection of occupied patient areas from demolition
5. Measures to be taken to train healthcare facility staff, visitors, and construction personnel on the maintenance of interim life safety and ICRMR

Finally, the guidelines specifically require not only the "installation of infection control measures" but also "continuous monitoring for effectives throughout the project." This may be done by "in-house IPC, safety, or construction coordinator personnel" or "independent outside consultants." This major issue must be determined in the initial stages by the ICRA panel. In any case, "provisions for monitoring shall include written procedures for emergency suspension of work and protective measures indicating the responsibilities and limitations of each party (owner, designer, constructor, and monitor)."

There is no single best way for carrying out an ICRA or documenting the outcome that must be communicated to the architects and construction companies. Suggestions and examples for practical approaches may be found in the APIC's Construction SOAR and the third Edition Construction and Renovation Toolkit (8,9,*181*).

ICRA and Long-Range Planning and Design Although the ICRA as described by the guidelines is basic, it is equally important to step back and consider the long-range planning that goes into the overall master facility plan and the critical need for early and continuous input from IPC. Although the language of the ICRA clearly calls for input

during planning, it is applied most frequently to specific projects, which is the focus of this chapter. APIC published a strategy in 2000 for assessing healthcare facilities for infectious risks during construction in the APIC SOAR on construction and renovation and recommended an ICRA similar to that later required by FGI guidelines and the CDC 2003 environmental infection control (IC) guidelines. However, the tactics begin with developing a *construction and renovation policy (CRP), a multidisciplinary team, and a process to implement the policy* (9). See Chapter 82 for more on the ICRA and long-range planning.

Once a system is in place providing for oversight, the application of the guidelines fit into each specific project. The guidelines require documentation of an ICRA for each *specific* project; they are not retrospective and apply only to new construction or major renovation. However, the approaches may be applied to smaller repair or preventive maintenance projects as appropriate. Thus, development of a broad-based CRP is an efficient and effective method to address basic principles that affect all projects, using the CRP as a reference point for the facility. Recommended resources for a CRP include the FGI guidelines, the CDC environmental IC guidelines, the APIC SOAR and relevant chapters in the APIC Text, guidelines from Health Canada on the prevention of *Aspergillus* and *Legionella*, and construction guidelines from the Canadian Standards Association.

Infection Control Risk Assessment—Overview for Planning and Design

Teams Multidisciplinary planning committees vary in size, although all resources agree that an assessment panel must include professionals with expertise in IPC, risk management, facility design, construction, ventilation, safety, and epidemiology. The panel is most effective if it includes an administrator and major stakeholders such as environmental services and the patient-care manager most affected by the construction or renovation. If a CRP is developed and approved, it becomes the basis of the ICRA for major or minor processes. A key first step is the identification of a multidisciplinary planning group involving design professionals, engineers, risk and safety officials, IPC and epidemiology professionals, the IPC committee (or committee charged with development and review of the IPC policy), and administrators representing special program needs.

Construction and Renovation Policy A comprehensive CRP requiring IPC input is the fundamental strategy that ensures timely notification of the IP (or person with IPC responsibilities) for early program planning. Once established, the IP should be made aware of planned projects as a matter of routine. This, in turn, ensures that an IPC evaluation of the project will be provided from concept to completion as is now required by the ICRA. The evaluation should include the design of the EOC, construction preparation and demolition, intraconstruction operations and maintenance, project completion with postconstruction cleanup, and monitoring. The ICRA documentation process fits future projects from small to complex (8,9,*181*).

Construction and Renovation Policy Elements The policy should address overall planning, designing, and monitoring processes, anticipating that future projects will vary in degree of complexity. It should ensure that input is required in all phases (i.e., structural design and specific practices to protect occupants during the preconstruction, intraconstruction, and postconstruction phases).

Basic issues include the authority and responsibility for establishing internal and subcontractor coordination of each stage of the project. The policy should be submitted for approval by the facility's board of trustees and reviewed and approved periodically (e.g., annually). Specific elements that should be included in the policy include the authority and responsibility for establishing internal and subcontractor coordination of (a) construction preparation and demolition, (b) intraconstruction operations and maintenance, (c) project completion and postconstruction cleanup, and (d) monitoring.

A comprehensive policy is the basis of *individual project* ICRAs and should include the ICRA elements listed earlier for prior to and during construction and potential remediation needs and educational needs of HCP as well as construction workers.

Integration of the CRP and ICRA Once approved, a CRP becomes the "driver" to ensure appropriate and continuous input from IPC into (a) the structural design processes to identify appropriate and timely IPC practices and (b) specific projects during each construction phase, focusing on patient and worker protection from construction activity.

Infection Control Risk Assessment

Budget Issues Healthcare epidemiology and infection prevention control (HEIPC) staff participation is critical in the initial planning and approval meetings during the programming or design phase. Issues frequently addressed include budget, space constraints including storage and equipment cleaning areas, AHUs, handwashing facilities, appropriate finishes, specific products with infectious implications, and applicable regulations. HEIPC staff should be prepared to support their position and recommendations with published citations whenever feasible, especially when a recommendation is not budget neutral (8,9,*93*). HEIPC staff frequently work with consultants during the planning phase of specific projects, including architectural and construction companies in a "partnering" process. Consulting an environmental expert might also be necessary if the size and complexity of construction provides considerable risk to highly susceptible patients because of location, prolonged time of construction, work conducted over continuous shifts, and likelihood of air handlers sustaining frequent interruptions. These variables increase risks to patients and personnel and may require environmental testing. If appropriate, budgets for environmental consultants and anticipated testing or environmental monitoring must be considered at the earliest stage of planning. Major design components that must be addressed include design to support IPC practice and design, number, and type of isolation rooms (i.e., AIIR or PE).

Special Environments—AIIR and PE New Construction or Renovation FGI guidelines outline the design characteristics for AIIR, and continue to not require anterooms. Anterooms may be useful for supplies and

accommodating personal protection equipment but are not needed to maintain negative air pressure of the room with respect to the adjacent corridor. The 2010 guidelines are clearer about what should be in place and the direction of the airflow *if* an anteroom is installed. The guidelines do not support dual-purpose positive and negative ventilation (i.e., rooms "switched" from negative to positive air pressure) because of concerns over reliability and maintenance of intended pressurization relationships. AIIR in new construction or renovation require a negative airflow of 12 air exchanges per hour. Although audible alarms may be used to monitor AIIR, current guidelines for new construction require permanently installed *visual* mechanisms to constantly monitor the direction of airflow (4). AIIRs also require self-closing doors and tight sealing of the room. If the air cannot be exhausted directly to the outside, it must be filtered through HEPA filters before it is recirculated through the areas' air handler system.

PEs are not required by the guidelines because they are dependent on the program of the organization. The 2010 guidelines are clearer about what the requirements are, especially when planning for a PE design (4). These designs are consistent with CDC guidelines regarding tuberculosis and pneumonia *(5,148)*. One condition that requires an anteroom to achieve proper airflow (i.e., a highly immunosuppressed patient who is infected with an airborne infectious agent like VZV requires positive pressure in the room to protect from other airborne infectious agents such as *Aspergillus* and also requires the removal of the air to ensure the protection of caregivers from VZV). The guidelines offer two designs to accomplish the pressure relationships, both requiring an anteroom.

Ventilation and Mechanical Systems and Basic Infrastructure Planning requires attention to key systems such as HVAC, including recommended ventilation and filtration specifications and mechanical systems involving water supply and plumbing. Key parameters for HVAC include filtration efficiency expressed today as a Minimum Efficiency Reporting Value or MERV as opposed to a percentage, air exchanges, pressurization relationships, humidity, and temperature. Recommended ranges for each of these are outlined in detail in the guidelines and elsewhere in this text (4) (see Chapter 84).

Rooms and Storage Supporting Infection Control Practice The guidelines require specific areas such as utility rooms (soiled and clean), instrument processing, holding, and workrooms. Storage of movable and modular equipment is critical from both a life safety and cleanliness viewpoint. The public perception of clutter is frequently associated with contamination and is seen as an IPC problem. Stretchers, wheelchairs, intravenous poles, and other large patient-care equipment are generally shared among units. Adequate space is needed to store, remove, clean, and maintain the items in an orderly fashion and reduce damage to surfaces, and they must be located away from normal traffic (4). In addition, CMS and state-based enforcement agencies emphasize clear, unobstructed corridors in healthcare facilities.

Design and Surfaces Ideally, surfaces are designed to include cleanability; problems can be avoided if surfaces near plumbing fixtures are smooth, nonporous, and water resistant. Operating and delivery rooms and isolation and sterile processing areas also need smooth finishes that are free of fissures or open joints and crevices that retain or permit the passage of dirt particles (4,*180,181*). Selection of surface materials, therefore, must balance use life, cleanability, cost, and maintenance.

Selection of Building Materials The construction materials vary for flooring (identify precise location of carpet or vinyl); walls; headwall components; windows; doors; countertops; plumbing fixtures (i.e., sinks, faucets, handles, etc.); lighting; electrical outlets; furnishings (e.g., bed, chairs, bedside tables); and computers, equipment, and supplies storage areas. Choices should consider selection of latex-free construction materials for all items, sizes, dimensions, colors, finishes, securement, and seams. Counter space required for various activities should have countertops that are seamless, nonporous, and durable against multiple germicidal cleanings.

IPC aspects associated with construction materials must be included along with those of local fire marshal requirements and state and local mandated codes and standards. General IPC considerations include nonporous surfaces that are easily cleaned with EPA-registered germicides. They should also consider hands-free, foot-pedal, or sensor-activated faucets; lids; handles; dispensers; and controls to the extent feasible. HEIPC staff should evaluate materials that withstand harsh chemical contact without corrosion, staining, or disruption of function and durability. Modifications that reduce soil and debris reservoirs include seamless design, rounded corners, sealed seams, wall bumpers, handrails, and electronic door openers. Drawers and containers for storage should be constructed from seamless, molded materials with rounded corners to prevent cracks, crevices, or folded edges that attract soil and are difficult to clean *(183,184)* (see Chapter 82).

Furnishings, Fixtures, and Equipment *Furniture* Modular furniture that is not easily moved should be installed on raised platforms or suspended in some manner to achieve a minimum 6- to 12-in. clearance from the floor to allow pull out for cleaning or to allow cleaning underneath. Attention must be paid to storage units with electrical or computer connections. Upholstered furniture should be managed like carpeting (including disposal) in the event of major soaking and contamination as a result of floods, leaks, or sewage. If furniture is affected by only steam moisture, it can be dried. Hardwood with intact laminate can be cleaned and disinfected with dilute bleach. Laminated furniture that has exposed particle board beneath the surface or other furniture composed of pressed wood or chipboard supports fungal contamination and growth when wet and should be discarded if it becomes soaked (9,*71*).

Hand Washing Stations and Hand Cleaning Agent Dispenser Placement Design and placement of handwashing stations becomes more critical with the additional consideration of waterless alcohol-based hand rubs (ABHRs) and has an impact in the event of plumbing disruptions or lack of preventive maintenance.

Number and Design The guidelines for new construction recommend the minimum number of handwashing facilities for hospital patient rooms as one in the toilet room and one in the patient room beyond the privacy curtain to ensure that HCP can carry out Standard Precautions. Having a sink in a patient or resident room and in the toilet room supports essential IPC practices. IPC plays a critical role in recommending the proper placement of hand wash facilities. In addition, IPC support for a sink standard of minimum dimensions may prevent the installation of small "cup" sinks that challenge proper hand washing *(180)*. The guidelines describe permissible types of controls for hand washing facilities in various areas.

Placement Improper placement can add to the environmental reservoir of contaminants. Sinks must be convenient and accessible, but nearby surfaces should also be nonporous to resist fungal growth *(71,180)*. One source recommends a minimum distance of 15 ft from all inpatient beds or bassinets and 25 ft from outpatient chairs, stretchers, and treatment areas to ensure access *(180)*. Hand washing facilities should also be situated to avoid splashing (suggesting at least 36 in. from patients or clean supplies) or equipped with a splash guard to avoid splash contamination *(180)*. CDC hand hygiene guidelines *(185)* make a strong recommendation for the addition of waterless alcohol-based hand antiseptic agents as part of a facility's overall hand-hygiene program. Dispenser location has emerged as one of the critical issues to address for this class of products. For example, the CDC guideline recommends that these not be placed near the hand washing stations to reduce confusion between them and antimicrobial soap used with water. Since the publication of these guidelines, there has been an increase in the adoption of waterless ABHR by US healthcare facilities.

The concern about a potential fire hazard with the placement and storage of dispensers of alcohol-based formulations of hand sanitizers prompted a multiyear collaboration to address all the conflicts in LSCs among groups such as the National Fire Safety Association and the International Code Council, which develops the *International Fire Code*. The codes are enforced by regulators such as CMS and accrediting groups such as TJC. By 2007, all groups had completed their changes, and CMS and TJC now specify the proper conditions for placement and storage of ABHR dispensers for rooms and exit corridors *(186)*. Perceptions that waterless hand hygiene products will supplant the need for hand washing stations are also unfounded. Both traditional washing with soap and water and the waterless products are needed, especially in the management of clusters or outbreaks of new strains of *C. difficile* such as BI/NAP1/027, and the ICRA process should ensure adequate provision for hand hygiene by patients, visitors, and personnel in new construction and renovation *(187)*.

Sink Cabinets Areas beneath sinks should not be considered storage areas because of their proximity to sanitary sewer connections and risk of leaks or water damage. Clean or sterile patient items should not be placed beneath sanitary sewer pipe connections or stored with soiled items; cleaning materials such as reagents or chemicals are examples of the types of materials acceptable for storage under sinks, from TJC's interpretation posted on their website under Standards in 2009, noting that state and local jurisdictions may be more stringent *(171)*. Facilities may develop design standards excluding storage space beneath sinks, thus preventing misuse and the need for cleaning. As noted earlier, cabinet construction materials need to be nonporous to resist fungal growth.

Aerators Aerated sink faucets located near patients, particularly in ICUs, have been considered a potential risk because of their ability to enhance the growth of waterborne microorganisms. The faucet aerator has been identified as a reservoir and possible source of infection within the hospital. Rutala *(188)* noted that the most convincing evidence for the role of faucet aerators is provided by Fierer et al. In this study, premature infants became infected with *P. aeruginosa* from delivery room resuscitation equipment contaminated by a faucet aerator. Rutala concluded that the degree of importance of aerators as reservoirs for healthcare-associated pathogens remains unknown. Because *Legionella* species grow well in the sediment formed in aerators, Freije et al. *(151)* recommend aerator removal. More recently, the Hota report provides evidence of infection due to splashing from the contaminated sink drain (123). The interventions used to end the outbreak demonstrate that drains are the true reservoir, and splashing is the primary route of transmission. In fact, aerators used in proper sink design may actually assist in reducing splashing from the drain (4). Proper sink design and dimensions can reduce splashing and risks of general contamination, while eliminating concerns for aerators completely (see Chapter 82, Design).

Flush Sinks, Hoppers, and Toilets **Clinical sinks** are required in soiled utility rooms for the disposal of body fluids and liquids but warrant similar considerations for moisture and contamination. Clinical or "flushing rim" sinks remove contaminated fluids in a manner similar to toilets and are not intended as utility or instrument-cleaning sinks. Splashguards are valuable, but inclusion may depend on sink design and use. If staff members are not routinely required to use face protectors, a splashguard should be required.

Toilets and Disposal of Human Waste There is no safe, aesthetic management of stool and other human waste in bedpans; system design should provide for emptying bedpans without leaving the patient room or for minimal travel distance to clinical/flushing rim sinks in treatment areas.

Intensive Care Units Removal of human waste is especiallychallenging when caring for critically ill patients. One option is to equip all patient rooms with attached bathrooms, but a toilet room for each patient has been seen as a space issue since most patients needing this care are not ambulatory. Prior to 2010, toilet rooms were not required in ICUs, except in coronary care units, because patients are usually too ill to use them. In the 2010 edition, each ICU room must now have direct access to an enclosed toilet room ***or*** a soiled utility room for the disposal of bodily waste. The standard requires at minimum a toilet room and toilet equipped with a bedpan washer or a soiled utility room with a flushing clinical sink located between every two ICU rooms. All rooms in the ICU must have a

dedicated toilet room (i.e., not shared with an adjacent room) (4,*183,187*) (see Chapter 82, Design).

Whirlpool and Spa-like Bathing Facilities Various types of bathing facilities are now available for mothers in birthing rooms and, as an additional amenity, for some patient-care rooms. Recommendations for cleaning have been compared with hydrotherapy tanks and equipment-cleaning procedures (9). However, plumbing for a traditional whirlpool bath circulates water through piping and jets that are inaccessible to mechanical cleaning. Potential risks for cross-transmission of contaminants is, therefore, possible, especially if used during labor, given the likelihood of introducing blood or other body fluids, which can be trapped in the pipe system. Pipeless whirlpool baths are commercially available, and cleanability using an *in vitro* testing protocol has been verified by the National Sanitation Foundation (Sanijet Corp., Coppell, TX; *www.sanijet.com*). Controlled trials comparing traditional to pipeless whirlpool baths are lacking, and the evidence demonstrating disease transmission from these systems is anecdotal. Communication with state regulators, cleaning and disinfecting the tub and jets with specific spa-cleaning products and proper draining and flushing sequences are essential when considering installation (9). Recommendations for use and disinfection should be consistent with the American Physical Therapy Association recommendations for tanks and equipment. The CDC guidelines for environmental infection control provide a full description of the issues (97).

Eyewash Stations OSHA directs proper use and placement of eyewash stations with distance determined by the pH of the involved chemicals. Source water in stationary eyewash stations may stand unused in the incoming pipes at room temperature for long periods, providing a reservoir for potential pathogens *(188)*. After a report of *Acanthamoeba* in eyewash stations, OSHA issued a bulletin recommending cleaning and disinfection methods. The schedule follows the American National Standards Institute Z358-1981 recommendations for flushing the system for 3 minutes each week *(135)*.

Decorative Water Fountains, Water Walls, and 2006 and 2010 Guidelines Updates As organizations recognize the importance of care delivery sites as therapeutic environments, they need HE and IP input when considering where to install features such as fish tanks, decorative water fountains, water walls, or other water features. In balancing the risk of adding a potential reservoir of waterborne opportunistic pathogens, CDC recommends facilities avoid placing them in patient-care areas *(181)*. The FGI guidelines address conditions and maintenance issues if they are included (4). Use of water as an architectural element has also been associated with disease transmission in which preventive maintenance (filters, ozone generators) did not prevent *Legionella* growth (126,*188,189*).

Ice Machines Ice availability for human consumption and medical nursing treatment may be located in the nutritional area or a clean room. Since contamination frequently occurs with ice because of inadequate machine maintenance or during collection and handling of ice, an ice delivery method should be designed to minimize contamination. When ice-making equipment is accessible to patients or visitors, it should be self-dispensing to avoid touch contamination. The IP should ensure that the ice machine is designed to deliver ice without permitting the receptacle and human hands from coming in contact with the dispensing port. The drainage tray should permit routine cleaning and disinfection and eliminate any standing water source. Direct access and storage bins with ice scoops should be avoided *(190)*. If a wall collection and removal system is planned, then construction materials and mechanisms would need to address IPC aspects of containment and confinement with risk-reduction cleaning capabilities.

Sharps Containers Dispenser Placement The location of disposal containers should consider ease of visibility to avoid overfilling and should be within easy horizontal reach of the user. Systems should have secure locking and enable easy replacement. When containers are fixed to a wall, the vertical height should allow the worker to view the opening or access the container. NIOSH recommendations suggest ergonomic considerations for installation heights or creative approaches for specialty areas *(178)*. Sufficient temporary storage space for filled containers must be in design planning *(176)*. If a mobile cart mechanism is used, construction materials for the carts and containers must be fluid-resistant, have appropriate biohazard signage, be puncture-proof, and have a secure closure *(176)*. Sharps containers and needle boxes are currently wall-mounted in close proximity to the point of use; the containers are usually replaced when two-thirds full *(178)*. Location, placement on the wall, and so forth must consider use such as residents' needs for medication, the main medication preparation area, and treatment rooms. Although this may be addressed in furnishings, it is appropriate to consider it with waste management. CMS also addresses proper storage and containment of waste in dumpsters and the management of the loading dock (e.g., free of debris and covered receptacles) *(170)*.

ICRA for Construction and Renovation Projects—Process

Overview An effective CRP supports long-range planning, as discussed previously, and provides guidance for individual construction projects, large or small. An ICRA for a specific construction project ensures appropriate planning for major new construction that also involves excavation and/or demolition or basic steps for simpler renovation projects. The ICRA team reviews the plan with considerable attention to detail by making inquiries to clarify understanding before a sign-off is completed. HEIPC staff assess the plans, paying particular attention to the specific requirements cited for the building improvement. HEIPC staff should focus on both the general and specific design aspects that influence and/or impact desired IPC practices. If IPC input does not occur in the beginning phase, there may be problems later with the infrastructure systems, such as air, water, traffic, and disruptions that impact residents. For example, air quality may be compromised because of infrequent filter changes, leading to aerosolized fungi released from dust during the demolition phase (8,9)

(see Chapter 84). Water may become contaminated with microbes when numerous dead-end pipe junctions contain stagnant water or when old piping is disrupted in replacement phases. Problems also occur when chlorine and/or temperature interventions to control *Legionella* are not maintained. A recent report documents that plumbing in even newly constructed nursing homes was readily colonized with *Legionella (119)*.

Patients The ICRA team assesses the inherent susceptibility of the patient (e.g., degree of immunosuppression as in a bone-marrow transplant patient) and the risk associated with the degree of invasiveness for procedures (e.g., patient undergoing surgery). The degree of dust and moisture is also assessed according to the size of the project, the length of time of the project, and the frequency of shifts. After the assessment is made, a determination of the impact on the populations and the impact on areas adjacent to the construction site is made. Figure 83-1 describes one widely used process using a matrix that matches levels of patient risk with levels of anticipated construction dust *(182)*.

The risk score determines needed interventions based on the following:

- Construction activity—project complexity in terms of dust generation and duration of activity
- Patients—assessment of the population at risk and location in terms of invasive procedures
- The matrix grid format immediately leads to identifying the following:
- Number and types of necessary controls and IPC interventions
- Signatures of all parties, thus providing accountability for the mutually agreed-on plan (9,*181*)

The process is made efficient by incorporating the precautions that can be determined using a decision-support matrix and a checklist in the form of a permit with signatures. Submission of an IC permit is an additional step and a useful method that is designed to assess the complexity of the project as a matrix of risk groups (i.e., patients versus the degree of contamination in the environment) (Fig. 83-1). The Precautions, internal and/or external, include determining appropriate protection of occupants from problems due to demolition, ventilation, and water management following planned or unplanned power outages, movement of debris, traffic flow, cleanup, and acceptance of the final renovation from the constructor. Whether or not this matrix method is used, there are key issues that should still occur:

- Routine submission of scheduled project lists from facility management to IPC, enabling the IPC staff to be proactively aware of projects and to anticipate IPC needs
- Submission of an "IC permit" or "project approval signature block" before the beginning of projects, beyond required project lists (9,*181*). Formats may range from simple checklists to questionnaires designed to assist staff members in assessing risks and identifying prevention strategies

Worker and Contractor Expectations Contracting companies receiving the documentation that describes steps to take to protect patients must also consider management of contractor employees for security and IPC purposes. Requirements for contract workers must be spelled out in project manual specifications documents. Expectations include control methods such as badges (photos), point of entrance or access to the construction site, or entrance to the hospital. Check-in and checkout procedures, specific areas for donning and removing protective garb, and eating and toilet facilities should be identified well before the project begins. Health requirements and educational issues vary by project but should be included in principle as items that must be determined by mutual agreement between the owner (healthcare organization) and the construction company or companies.

Obtaining the cooperation of contractors is critical to ensure that the hired work crew observes appropriate behavior when entering a hospital site. Provision of training and education by IPs and healthcare professionals to contractors and subcontractors is the first step in creating a stronger sense of partnership. Training should include information on hygiene, traffic patterns, availability of protective wear (e.g., shoe covers and cover gowns), and other dust containment recommendations. Tendering documents should include all expected necessary containment recommendations. These recommendations may include that dust on clothing and boots be removed before entering the healthcare facility; that entrance to high-risk patient and staff traffic areas be avoided; that cover gowns and booties be made available for workers; and that workers be provided with portable toilets for their use only and with potable water to wash, preferably outside of occupied healthcare facility grounds. These precautions help limit the amount of dust that is introduced into the healthcare facility. A partnership with contractors helps ensure greater respect for IPC concerns among construction workers and raises the level of IPC awareness regarding the different phases of the project, particularly high dust-generating activities (e.g., demolition of a targeted building) (74). Select aspects that should be in place for contractors and subcontractors include the following:

1. Proof of liability and worker's compensation insurance
2. Training on owner (facility) safety and IPC policies and any other federal, state, and local authority having jurisdictional requirements
3. Identification of hazardous chemicals planned for use and material safety data sheets (MSDS) provided to owner
4. Spill response plans outlined for hazardous chemicals
5. Personal protective equipment (PPE) available and notice of anticipated generation of hazardous waste
6. Location and access to owner emergency care services
7. Assessment and documentation of interim life safety measures
8. Evacuation and fire safety response plans confirmed
9. Plans for worksite dust containment reinforced and attention to wall or floor penetrations

Infection Control Risk Assessment Matrix of Precautions For Construction & Renovation

Step One:
Using the following table, identify the Type of Construction Project Activity (Type A–D)

TYPE A	**Inspection and Non-Invasive Activities.** Includes, but is not limited to: ▪ removal of ceiling tiles for visual inspection only, e.g., limited to 1 tile per 50 square feet ▪ painting (but not sanding) ▪ wall coverings, electrical trim work, minor plumbing, and activities which do not generate dust or require cutting of walls or access to ceilings other than for visual inspection.
TYPE B	**Small scale, short duration activities which create minimal dust** Includes, but is not limited to: ▪ installation of telephone and computer cabling ▪ access to chase spaces ▪ cutting of walls or ceiling where dust migration can be controlled.
TYPE C	**Work that generates a moderate to high level of dust or requires demolition or removal of any fixed building components or assemblies** Includes, but is not limited to: ▪ sanding of walls for painting or wall covering ▪ removal of floor coverings, ceiling tiles and casework ▪ new wall construction ▪ minor duct work or electrical work above ceilings ▪ major cabling activities ▪ any activity which cannot be completed within a single workshift.
TYPE D	**Major demolition and construction projects** Includes, but is not limited to: ▪ activities which require consecutive work shifts ▪ requires heavy demolition or removal of a complete cabling system ▪ new construction.

Step 1 _____

FIGURE 83-1 ICRA matrix of precautions for construction and renovation and infection control construction permit. *(Figure continued on following pages.)*

Steps 1–3 adapted with permission from Kennedy V, Barnard B, St Luke's Episcopal Hospital, Houston, TX; and Fine C, CA. Steps 1–3 Adapted with permission V Kennedy, B Barnard, St Luke Episcopal Hospital, Houston, TX; Fine C, CA. Steps 4–14 Adapted with permission Fairview University Medical Center, Minneapolis, MN. Forms modified/updated and provided courtesy of Judene Bartley, ECSI Inc. Beverly Hills, MI 2002. Jbartley@ameritech.net. Updated 2009. Steps 4–14 adapted with permission from Fairview University Medical Center, MN.)

Step Two:

Using the following table, ***identify*** **the Patient Risk Groups** that will be affected.
If more than one risk group will be affected, select the higher risk group:

Low Risk	Medium Risk	High Risk	Highest Risk
▪ Office areas	▪ Cardiology ▪ Echocardiography ▪ Endoscopy ▪ Nuclear Medicine ▪ Physical Therapy ▪ Radiology/MRI ▪ Respiratory Therapy	▪ CCU ▪ Emergency Room ▪ Labor & Delivery ▪ Laboratories (specimen) ▪ Medical units ▪ Newborn Nursery ▪ Outpatient Surgery ▪ Pediatrics ▪ Pharmacy ▪ Post Anesthesia Care Unit ▪ Surgical Units	▪ Any area caring for immunocompromised patients ▪ Burn Unit ▪ Cardiac Cath Lab ▪ Central Sterile Supply ▪ Intensive Care Units ▪ Negative pressure isolation rooms ▪ Oncology ▪ Operating rooms including C-section rooms

Step 2_____

Step Three: Match the

Patient Risk Group (***Low, Medium, High, Highest***) with the planned **…**

Construction Project Type (***A, B, C, D***) on the following matrix, to find the **…**

Class of Precautions (***I, II, III or IV***) or level of infection control activities required.

Class I–IV Precautions are delineated on the following page.

IC Matrix — Class of Precautions: Construction Project by Patient Risk

	Construction Project Type			
Patient Risk Group	**TYPE A**	**TYPE B**	**TYPE C**	**TYPE D**
LOW Risk Group	**I**	**II**	**II**	**III/IV**
MEDIUM Risk Group	**I**	**II**	**III**	**IV**
HIGH Risk Group	**I**	**II**	**III/IV**	**IV**
HIGHEST Risk Group	**II**	**III/IV**	**III/IV**	**IV**

Note: Infection Prevention & Control approval will be required when the Construction Activity and Risk Level indicate that **Class III** or **Class IV** control procedures are necessary.

Step 3_____

Description of Required Infection Control Precautions by Class

	During Construction Project	Upon Completion of Project
CLASS I	1. Execute work by methods to minimize raising dust from construction operations. 2. Immediately replace a ceiling tile displaced for visual inspection	1. Clean work area upon completion of task.
CLASS II	1. Provide active means to prevent airborne dust from dispersing into atmosphere. 2. Water mist work surfaces to control dust while cutting. 3. Seal unused doors with duct tape. 4. Block off and seal air vents. 5. Place dust mat at entrance and exit of work area 6. Remove or isolate HVAC system in areas where work is being performed.	1. Wipe work surfaces with cleaner/disinfectant. 2. Contain construction waste before transport in tightly covered containers. 3. Wet mop and/or vacuum with HEPA filtered vacuum before leaving work area. 4. Upon completion, restore HVAC system where workwas performed
CLASS III	1. Remove or isolate HVAC system in area where work is being done to prevent contamination of duct system. 2. Complete all critical barriers i.e. sheetrock, plywood, plastic, to seal area from non work area or implement control cube method (cart with plastic covering and sealed connection to work site with HEPA vacuum for vacuuming prior to exit) before construction begins. 3. Maintain negative air pressure within work site utilizing HEPA equipped air filtration units. 4. Contain construction waste before transport in tightly covered containers. 5. Cover transport receptacles or carts. Tape covering unless solid lid.	1. Do not remove barriers from work area until completed project is inspected by the owner's Safety Department and Infection Prevention & Control Department and thoroughly cleaned by the owner's Environmental Services Department. 2. Remove barrier materials carefully to minimize spreading of dirt and debris associated with construction. 3. Vacuum work area with HEPA-filtered vacuums. 4. Wet mop area with cleaner/disinfectant. 5. Upon completion restore HVAC system where work was performed
CLASS IV	1. Isolate HVAC system in area where work is being done to prevent contamination of duct system. 2. Complete all critical barriers, i.e., sheetrock, plywood, plastic, to seal area from non work area or implement control cube method (cart with plastic covering and sealed connection to work site with HEPA vacuum for vacuuming prior to exit) before construction begins. 3. Maintain negative air pressure within work site utilizing HEPA-equipped air filtration units. 4. Seal holes, pipes, conduits, and punctures. 5. Construct anteroom and require all personnel to pass through this room so they can be vacuumed using a HEPA vacuum cleaner before leaving work site or they can wear cloth or paper coveralls that are removed each time they leave the work site. 6. All personnel entering work site are required to wear shoe covers. Shoe covers must be changed each time the worker exits the work area.	1. Do not remove barriers from work area until completed project is inspected by the owner's Safety Department and Infection Prevention & Control Department and thoroughly cleaned by the owner's Environmental Services Dept. 2. Remove barrier material carefully to minimize spreading of dirt and debris associated with construction. 3. Contain construction waste before transport in tightly covered containers. 4. Cover transport receptacles or carts. Tape covering unless solid lid. 5. Vacuum work area with HEPA-filtered vacuums. 6. Wet mop area with cleaner/disinfectant. 7. Upon completion restore HVAC system where work was performed.

Step 4. Identify the areas surrounding the project area, assessing potential impact

Unit Below	Unit Above	Lateral	Lateral	Behind	Front
Risk Group	Risk Group	Risk Group	Risk Group	Risk Group	Risk Group

Step 5. Identify specific site of activity, e.g., patient rooms, medication room, etc.

_____

Step 6. Identify issues related to: ventilation, plumbing, electrical in terms of the occurrence of probable outages.

_____

Step 7. Identify containment measures, using prior assessment. What types of barriers? (e.g., solids wall barriers); Will HEPA filtration be required?

_____

(Note: Renovation/construction area shall be isolated from the occupied areas during construction and shall be negative with respect to surrounding areas)

Step 8. Consider potential risk of water damage. Is there a risk due to compromising structural integrity? (e.g., wall, ceiling, roof)

Step 9. Work hours: Can or will the work be done during non-patient care hours?

Step 10. Do plans allow for adequate number of isolation/negative airflow rooms?

Step 11. Do the plans allow for the required number & type of handwashing sinks?

Step 12. Does the infection prevention & control staff agree with the minimum number of sinks for this project? (Verify against FGI Design and Construction Guidelines for types and area)

Step 13. Does the infection prevention & control staff agree with the plans relative to clean and soiled utility rooms?

Step 14. Plan to discuss the following containment issues with the project team. E.g., traffic flow, housekeeping, debris removal (how and when)

_____

_____

_____

Appendix:

Identify and communicate the responsibility for project monitoring that includes infection prevention & control concerns and risks. The ICRA may be modified throughout the project. Revisions must be communicated to the Project Manager.

Infection Control Construction Permit

	Permit No:
Location of Construction:	Project Start Date:
Project Coordinator:	Estimated Duration:
Contractor Performing Work	Permit Expiration Date:
Supervisor:	Telephone:

YES	NO	CONSTRUCTION ACTIVITY	YES	NO	INFECTION CONTROL RISK GROUP
		TYPE A: Inspection, non-invasive activity			GROUP 1: Low Risk
		TYPE B: Small scale, short duration, moderate to high levels			GROUP 2: Medium Risk
		TYPE C: Activity generates moderate to high levels of dust, requires greater 1 work shift for completion			GROUP 3: Medium/High Risk
		TYPE D: Major duration and construction activities Requiring consecutive work shifts			GROUP 4: Highest Risk

CLASS I	1. Execute work by methods to minimize raising dust from construction operations. 2. Immediately replace any ceiling tile displaced for visual inspection.	3. Minor Demolition for Remodeling
CLASS II	1. Provides active means to prevent air-borne dust from dispersing into atmosphere 2. Water mist work surfaces to control dust while cutting. 3. Seal unused doors with duct tape. 4. Block off and seal air vents. 5. Wipe surfaces with cleaner/disinfectant.	6. Contain construction waste before transport in tightly covered containers. 7. Wet mop and/or vacuum with HEPA filtered vacuum before leaving work area. 8. Place dust mat at entrance and exit of work area. 9. Isolate HVAC system in areas where work is being performed; restore when work completed.
CLASS III **Date** **Initial**	1. Obtain infection control permit before construction begins. 2. Isolate HVAC system in area where work is being done to prevent contamination of the duct system. 3. Complete all critical barriers or implement control cube method before construction begins. 4. Maintain negative air pressure within work site utilizing HEPA-equipped air filtration units. 5. Do not remove barriers from work area until complete project is checked by Infection Prevention & Control and thoroughly cleaned by Environmental Services.	6. Vacuum work with HEPA-filtered vacuums. 7. Wet mop with cleaner/disinfectant 8. Remove barrier materials carefully to minimize spreading of dirt and debris associated with construction. 9. Contain construction waste before transport in tightly covered containers. 10. Cover transport receptacles or carts. Tape covers. 11. Upon completion, restore HVAC system where work was performed.
CLASS IV **Date** **Initial**	1. Obtain infection control permit before construction begins. 2. Isolate HVAC system in area where work is being done to prevent contamination of duct system. 3. Complete all critical barriers or implement control cube method before construction beg ins. 4. Maintain negative air pressure within work site utilizing HEPA-equipped air filtration units. 5. Seal holes, pipes, conduits, and punctures appropriately. 6. Construct anteroom and require all personnel to pass through this room so they can be vacuumed using a HEPA vacuum cleaner before leaving work site or they can wear cloth or paper coveralls that are removed each time they leave the work site.	7. All personnel entering work site are required to wear shoe cover 8. Do not remove barriers from work area until completed project is checked by Infection Prevention & Control and thoroughly cleaned by Environmental Services. 9. Vacuum work area with HEPA-filtered vacuums. 10. Wet mop with cleaner/disinfectant. 11. Remove barrier materials carefully to minimize spreading of dirt and debris associated with construction. 12. Contain construction waste before transport in tightly covered containers. 13. Cover transport receptacles or carts. Tape covers. 14. Upon completion restore HVAC system where work was performed

Date:	Date:

PRECONSTRUCTION

Project Management ICRA Team Sets the Stage

Worker Risk Assessment and Education

Health, Training, and Education Health risk evaluations for potential exposures depend on the type of construction planned. Facility staff overseeing or working with outside contractors should assist in determining potential environmental risks for facility workers or contractors. Policies should include provisions for training and by whom (facility or contractor). Training must be appropriate to the task (e.g., staff entering air systems for preventive maintenance, such as changing filters, should be alerted to the potential for airborne dust containing spores of microorganisms and arrange to first turn off fans and don a mask). Staff members working in sanitary or septic sewage systems, drainage pipes, and so forth should be alerted to the risks of moisture and fungal contamination (8,9,*89,148,172,173,188*). Agreements should be developed appropriate to the project regarding provisions for pertinent health protection, vaccinations, tuberculosis assessment, and purified protein derivative skin testing, or related education before workers begin construction. Requirements vary with the degree of environmental risk and proximity to the patient population.

As agreements are completed, they should provide evidence that workers have received appropriate health protection, as noted previously, and should include the following information:

- Facility exposure control plan(s) for IPC, hazardous chemicals, and life safety
- How to seek help and report exposures (e.g., first-aid location and initial steps to report exposures)
- Use of particulate respirators and/or other PPE
- Risk prevention for unexpected safety issues, such as noxious fumes, asbestos, and so forth (9,*148,172–174*) (see Chapter 84).
- The facility should be satisfied that provisions have been made for effective IPC education designed to address facility-specific needs related to potential infectious risk exposures, as described previously (9,97,*148,172–174*)

Preparation for Demolition and Construction The project teams provide ongoing planning and monitoring during area preparation and throughout the demolition, construction, cleanup, preparation for return to service, and final project review (4,8,*171*). Before construction begins, the focus of preparations should be on isolation of the construction or renovation area. Some sources categorize projects in terms of minor or major risk based on the level of needed barriers; checklists are developed accordingly (9).

External Excavation Precautions External excavation is ideally conducted during off-hours so that air handlers can be adjusted; the goal is to protect the intake as much as possible. Small projects require similar planning and vary by degree, but preparation still requires early communication with facility management. Specific educational needs (e.g., OSHA), regulations, and health issues for patients and workers need to be addressed. A final customized checklist should be appended to the CRP (9).

Inspection of the Worksite Daily inspections should be made, particularly at the start of a project. Recording inspections and observations is recommended. The inspection should look at major areas, including the following:

- Dust containment barriers at the source are appropriate
- The frequency in wetting excavated soil or demolished building, truck, and equipment path is adequate
- Doors, windows, and other ports of entry located near the project are sealed or barred from use
- Construction worker behavior, such as removing dust and observing good hygiene before entering healthcare grounds, is acceptable
- Waste is kept to a minimum
- Materials delivered and stored outside for later installation are properly protected (e.g., shrink-wrapped covering)

It is recommended that an inspection worksheet or checklist be created, with daily inspections and observations recorded, and copies should be given to the designated individuals who can correct the situation when necessary. The worksheet should include key precautions to observe and a follow-up segment. These worksheets act as a means of communication, and if a problem arises, they become evidence that due diligence was exercised by IPs and other healthcare professionals (74).

Additional Consideration for External Construction Beyond Internal Issues Increased potential for contaminating dust and debris on air-intake filters may result in decreased filtration, allowing airborne spread of microorganisms via the ventilation system. HVACs may be disrupted and nonfunctional during certain periods of construction. Medical vacuum systems and water supply may be affected similarly. Finally, contamination of patient rooms, supplies, equipment, and areas patients may visit (e.g., procedure rooms) may occur.

Many interventions can decrease the risk during external excavation or construction. The steps begin with identifying the location of air intakes with respect to the location of high-risk patients. The team may consider the following:

- **Filter changes:** The frequency of changing the prefilters should be increased. When admission is necessary, high-risk patients should be located in areas as remote from the construction area as possible.
- **Cleaning:** Areas adjacent to construction activity should be cleaned with increased frequency.
- **Air-handler changes:** Beyond the barrier checklist outlined earlier, the team may have to consider closing down dampers temporarily in areas adjacent to construction to reduce the circulation of contaminated air or fumes.
- **Power disruptions:** When power is reestablished after a power interruption, and dampers and fans resume operation, dust released during this process may contain and transmit infectious agents to patients and staff. Policies or protocols should address issues such as communication, operating the HVAC for a specified time to run air out of the ducts, and immediate cleaning before putting the area (e.g., OR) back into service. Long-range follow-up includes preventive maintenance and cleaning of ducts near dampers to reduce the dust load; it also includes surveillance of airborne infectious agents or hospital-acquired infections

- **Verification of air-handler status:** It must be ensured that the hospital systems can provide the proper air exchange rates and pressure relationships in crucial areas near construction activity; it must be ensured that air is not being circulated from construction areas into other hospital areas.
- **Cleaning of air handler:** Facility engineers should be contacted about special maintenance and cleaning of the ventilation system likely to be affected by construction. After completion of construction, it must be ensured that the ventilation systems are balanced to design specifications and that scheduled maintenance is determined.
- **Final cleaning:** The new area must be thoroughly cleaned before installing furnishings, privacy curtains, and clean supplies and before patient admission.

Interruptions of Normal Water Service Special infection risks and hazards are associated with the disruption of normal water service utility during construction or renovation, requiring long-range planning. These hazards include (a) lack of potable water for drinking, food preparation, and ice; (b) lack of water for hand washing and bathing; and (c) lack of water for flushing toilets, clinical sinks, decontamination, sterilization, food service needs, and support services (e.g., laboratory). Anticipating and planning preventive and control interventions can minimize risks; the following should be considered:

- Schedule interruptions for low-activity times when feasible
- Plan and arrange for volume of potable water for drinking and food preparation
- Plan and arrange for supplies for patient care and cleaning
- Provide disposable towelettes or waterless alternatives for hand washing for patients and personnel

Internal Issues

Type and Extent of Construction Project complexity varies with time, numbers of workers, whether contractors work continuous shifts, scope and degree of activity (high or low dust generation), and proximity to patients with varying degrees of risk for infection.

Internal Renovations Internal projects require much additional planning compared to external construction. Patient areas or units that cannot be closed or that are adjacent to a major renovation require special planning (e.g., OR additions adjacent to an active surgical suite). These situations may justify environmental monitoring beyond visual inspection to detect increased airborne contamination and to plan interventions (4,*5*,8,9,*18,89*,97).

General Issues

Patient Location during Construction There should be no flow-through traffic in the area, meaning routing patterns for staff traffic and visitor access traffic must be planned and designated, and signage must be posted for ease in compliance. Adherence to existing codes and standards for the size of corridors and doorways remains in effect. Visitors or residents investigating progress during construction may place themselves and construction workers at risk. This requires considerable monitoring by staff to ensure a safe environment surrounding the renovation and/or construction.

Risk Factors Managing infectious risks during construction means collaboration among all personnel. These risks include dust and debris compromising the environment, airborne microbes carried to immunocompromised residents, an unbalanced ventilation system affecting air quality, water contamination, accumulated and multiple waste reservoirs, and ineffective dustproof barriers to name a few. Depending on the location of the construction and the proximity to resident-care areas, residents may have to be relocated to a safer unit. Meticulous maintenance of physical barriers and utility systems (i.e., air, water, etc.) are required as risk-reduction efforts. Airborne debris of particulate matter may carry microbes that contaminate the air and are especially hazardous to residents who may inhale the debris and develop respiratory infections and/or complications. Control of airflow patterns (e.g., clean to dirty); interruption of utility, building, and equipment services; and communication requirements should be specified in the project bid proposal to ensure construction-specification compliance.

Environmental Control and Containment

Containment Isolating the construction site by physical dust-control partitions requires floor to deck (solid compartment separation between floors above dropped ceiling) walls made of airtight fire-rated barriers, usually consisting of drywall or plywood with caulked seams or heavy-duty plastic with sealed seams and gasketed doorframes. The airflow should be from "clean to dirty," requiring some method to ensure isolation of the area from patients (4). Site access points are controlled entries for those authorized to enter. These egress paths are located where minimal debris can be transferred from the construction site to the cleaner areas of the facility. Personnel authorized for entry are commonly identified by badge and protective gear, such as hard hats. Emphasis is placed on dust control, which is a constant challenge during the project; diligent cleaning efforts are critical. Dust collection mats with an adhesive surface can also assist with minimizing the migration of dust and debris carried by construction personnel. These mats typically have several layers that can be removed as needed when the exposed surface becomes loaded with dust. Daily cleaning by gathering gross debris for disposal is necessary before damp mopping the area as a dust-control mechanism. Containment is further practiced when a debris exit path is marked and a delivery point of materials and supplies is designated.

Containment Also Includes HVAC Systems Measures such as sealing of grills or vents against construction debris; frequent changing of filters within the ventilation ducts; ensuring that the window seals are leak-proof and airtight; and if chutes are used to remove demolition materials, monitoring for negative pressure and ensuring that the chutes are closed when nonoperational or during duct cleaning are all important aspects to address.

Noise and Vibration The potential for vibration or disturbances to dislodge dust collected above suspended or false ceilings and the effect of vibration on contamination of plumbing should be recognized. Noise and vibration also may be disturbing or harmful to certain patient

populations (e.g., premature neonates, cardiac or stroke patients, pediatric or psychiatric patients).

Water During construction, unintentional water contamination of porous, acoustical ceiling tiles and/or fireproofing and filter materials may occur. Prompt removal of damaged, moisture-laden materials reduces the potential for fungal spore release (9,*71*,97,*183*).

Dust and Debris Control—Barrier Systems As noted, the area should be isolated, as the project requires. Small, short-duration projects generating minimal dust may use fire-rated plastic sheeting but should be sealed at full ceiling height with at least 2-ft overlapping flaps for access to entry. Any project that produces moderate to high levels of dust requires rigid, dust-proof, and fire-rated barrier walls (e.g., drywall) with caulked seams for a tight seal. Large, dusty projects need an entry vestibule for clothing changes and tool storage. The entry area should have gasketed door frames; tight seals should be maintained at the full perimeter of walls and wall penetrations in order to ensure the pressure differential and airflow into the construction site (4). An interim plastic dust barrier may be required to protect the area while the rigid impervious barrier is being constructed. Cleaning is required at the completion of the barrier construction; plans should also describe a terminal barrier removal process that minimizes dust dispersal (9,*71*).

Ventilation

Air System Flow It should be determined whether the construction area uses fresh (outside) or recirculated air; filters should be added or return vents covered as needed with filter material or plastic. Air must flow from clean to dirty areas (4,8,9) (see Chapter 84).

Negative Air Pressure The air within the construction area must be negative with respect to surrounding areas and with no disruption of air systems of adjacent areas. Constant negative pressure within the zone should be monitored with an alarmed device, which must be maintained and monitored by construction personnel. Exhaust from construction air should be directed outside or exhaust vents in the construction area should be sealed to prevent recirculation if possible. If there is no outside exhaust, rather than tying into a recirculated air system, it is acceptable to run exhaust air through a negative air machine and into the corridor. Exhausting air into the duct work even with use of HEPA filters, risks overpressurizing the duct work and risks contamination of adjacent areas. Necessary interruptions (e.g., fire drills) should be planned for to minimize risk (4,9,*71*). Portable HEPA filtration devices can also aid in the capture of particulates that might be aerosolized during the demolition of drywall, removal of flooring materials, and so forth. Such devices can also facilitate the creation of negative pressure. Other variables to address include the following:

- The status of sealed penetrations and intact ceilings should be verified in adjacent areas.
- Air exchange rates and pressure relationships: It should be verified that the facility can maintain proper rates in critical areas near construction activity, ensure air is recirculated using HEPA filtration from the construction area to internal areas, and provide accountability for and frequency of testing air pressures throughout the project (8,9,*71*).
- Vibration or disturbances: Drilling and other sources of vibration have potential to dislodge dust collected above suspended or false ceilings; vibrations loosen corrosion within water pipes as well. Plans should require vacuuming of affected areas and flushing debris from water systems before reoccupancy (8,*24,130,151*).
- Specification of temperature and humidity ranges: Determine limits as appropriate (4,9 *93,171*).
- Monitoring: Consideration must include risks of malfunction or complete loss of utilities. Both visual cues and particulate air monitoring may be used. The type and frequency of monitoring, evaluation of results, and follow-up action by designated parties are essential to planning (8,9,*71*).

Traffic Control

Control The safety approach to traffic control is signage that identifies construction areas and restricts entry to authorized construction personnel who have appropriate protective equipment. The IPC perspective is to divert nonessential traffic (e.g., patients, HCP, or visitors) from the site, thereby, reducing the risk of exposure to or dissemination of airborne pathogens carried by dust. If intersection of patient-care areas and construction is unavoidable, the route should be designed to minimize risks of exposure to infectious agents even if they have donned personal protective attire (masks). Visitors are guided to the most direct but safest route to visit residents. Because visitors are potential reservoirs of infectious agents transmissible to susceptible residents, they should be assessed for symptoms of communicable infectious diseases whether construction projects are in progress or not. Designated entry and exit procedures must be defined. Egress paths should be free of debris, designated elevators should be used during scheduled times, and only authorized personnel should be allowed to enter the construction zone. Signage should direct pedestrian traffic away from the construction area and materials (8,9,*24,71*).

Debris Management: Windows, Chutes

Debris Used materials should be removed in carts with tightly fitted covers, using designated traffic routes. Medical waste containers (sharps or other medical regulated waste) must be removed by the facility before the start of the project. Efforts should be made to minimize the use of elevators with transport during the lowest period of activity. Debris should be removed daily and at times specified by agreements. If chutes are used to direct debris outside, HEPA-filtered negative-air machines should be used, and the chute opening should be sealed when not in use. Filters should be bagged and sealed before being transported out of the construction area (8,9,*24,71*).

Exterior Windows Windows should be sealed to minimize infiltration from excavation debris.

Patient Equipment—Contamination of Patient Rooms, Supplies, and Equipment

Worksite Attire Contractor personnel clothing should be free of loose soil and debris before leaving the construction area. If protective apparel is not worn, a HEPA-filtered vacuum should be used to remove dust from clothing before leaving the barricade. PPE (e.g., face shields, gloves, respirators) is worn as appropriate. Contractors entering invasive procedure areas should be provided with disposable jumpsuits and head and shoe coverings. Protective clothing should be removed before exiting the work area. Tools and equipment should be damp-wiped before entry and exit from the work areas (8,9,*71*).

Barriers Areas around construction should be monitored to maintain protection of in-use patient-care areas, as described. Patient doors adjacent to the construction area should be kept closed, with appropriate traffic control (8,9).

Storage Sites should be designated for new and damaged construction materials (9).

Contractor Cleaning The construction zone should be maintained in a clean manner by contractors and swept or HEPA-vacuumed daily or more frequently, as needed, to minimize dust. Adjacent areas should be damp-mopped daily or more frequently, as needed. Walk-off mats may minimize tracking of heavy dirt and dust from construction areas (8,9).

Facility Cleaning Contracts should clearly specify responsibilities and expectations for routine and terminal cleaning before opening the newly renovated or construction zone (8,9).

Site Cleanliness Monitoring the area proximal to the barriers surrounding the project site is usually delegated to the housekeeping and support service. Frequent cleaning is basic to maintaining dust control. Project-site cleaning is an ongoing activity that should be viewed as a critical success factor in reducing risk. A question may be raised concerning the need for air testing of particulate matter to determine site cleanliness. A more productive approach is a preventive one, that is, to establish routine cleaning frequencies at the same rate that a facility might institute *if* air testing demonstrated that dust levels were high.

The IPC and safety aspects of maintaining a clean work area include reduced clutter and fall hazards, diminished exposure to airborne debris that may cause infectious or allergic responses, and enhanced visibility to perform the work at hand. CMS is also concerned with providing an environment that is free from hazards (e.g., wet floors not identified with signage or blocked access) *(170)*. Similar concerns arise throughout construction or renovation projects and require vigilance on everyone's part to maintain safety and control dust.

Standard housekeeping IPC practices are followed. Housekeeping equipment should be designated for this area. Fresh germicidal solutions are used and changed often. Chemically treated dust cloths and mop heads should not be shaken and are laundered daily. Vacuum and suction machines are equipped with high-efficiency filters and changed frequently for maximum benefit in controlling airborne dispersal of dust and microorganisms. Frequency of filter changes is workload-dependent and based on filter efficiency and performance effectiveness *(191)*.

INTRACONSTRUCTION PHASE AND THE ROLE OF A HEALTHCARE EPIDEMIOLOGY AND INFECTION PREVENTION AND CONTROL PROGRAM

Communication

Once renovation or construction has begun, the IP should be available to provide maintenance and operational input. Frequency of input or meetings depends on the scope of the project. Specific concerns must be customized in each project and include IPC practices, education, and monitoring. The IP is vital in educating and supporting staff in managing their area under construction (e.g., educating staff members on how to monitor their own performance as much as possible). In more complex projects, the IP may assist directly or make provisions for items already outlined. A number of areas involving specific IP involvement are discussed later.

Environmental Rounds

An efficient method to integrate key IPC and life safety issues is the use of rounds, using simple checklists based on the items addressed previously *(181)*. IPs can advise or participate in rounds, which should be scheduled as often as necessary and include a variety of observable "indicators" such as barriers (doors, signage), air handling (windows closed), project area (debris, cleaning), traffic control, and dress code. It may be necessary on occasion to schedule rounds after normal hours or on weekends if that is when construction or renovation is scheduled (8,9,*24,71*).

Environmental Monitoring Activities during Construction There are currently no recommendations for routine environmental culturing during construction. Enhanced targeted patient surveillance (e.g., respiratory illnesses consistent with aspergillosis or legionellosis) near construction areas should be part of the ICRA. Other control measures previously discussed must be continuously monitored. However, when an outbreak associated with construction is suspected or identified, water or air sampling may be indicated. It is vitally important to establish a hypothesis with clear and measurable goals. Culturing or sampling procedures should be defined before initiation (e.g., asbestos, fungal, or total particulates). Sampling procedures relative to the suspected agent(s) and sources should be used. The investigator must be cognizant of the many pitfalls associated with the interpretation of environmental data *(179)*. Therefore, as part of the investigation planning, it is important to establish parameters for interpreting collected data.

Outcome or Process Measures Projects may be approached as performance improvement initiatives using outcome measures (e.g., SSI rates) or process measures

(measuring compliance) using visual observations, airborne particulate monitors, satisfaction surveys, and so forth (9,*18*,97).

Impact on Special Areas

Patients requiring AIIRs need close monitoring to ensure that negative-pressure relationships are maintained, particularly when there is potential for disruption of pressure relationships (8,9,*32,192*). Intake areas such as emergency departments need planning to triage potentially infectious patients (4,*5*,97). If highly susceptible patients cannot be relocated, indicators should be identified to trigger planned intervention (8,9,*18,24,71*). Immunosuppressed populations in bone-marrow transplantation units or protected environments, ICUs, and so forth require special planning. The goal is to minimize patient exposure to major construction activity; therefore, nonemergency admissions should be avoided during periods of major excavation. If delaying admissions is not an option, patients should be located in areas as remote as possible from construction activity (8,9).

Patient Location and Transport

Healthcare providers should plan patient care activities to minimize exposure to construction sites. At least one study found that critically ill, ventilator-dependent patients transported from the ICU for diagnostic or therapeutic procedures was an independent risk factor for development of ventilator-associated pneumonia (9). To decrease exposure for patients during construction activities the following should be considered:

- Provide treatment in the patient's room
- Transport via an alternate route
- Schedule transport or procedures during periods with minimal construction activity
- Minimize waiting and procedure times near construction zones
- Mask patient or provide other barriers (e.g., covering open wounds) based on patient's clinical status

Emergent Issues—Interruption of Utility Services

Utility services may be interrupted during any type of construction. Infectious agents may contaminate air-handling units, medical vacuum, and water systems after planned or unplanned power disruptions. HEIPC can provide input into emergency preparedness to reduce the potential risks of contamination. Response plans should include assessment of the population at risk and cleanup should focus on steps to prevent, detect, and reduce risk from infectious hazards. For example, as power is reestablished after an interruption, dampers and fans of AHUs resume operation. Dust and particulate matter released during this process may transmit allergenic or infectious agents such as *Aspergillus* species to patients and staff (8,9,*17,24,71,135*). Therefore, IPC policies for areas in which invasive procedures are performed should require sufficient time to clear the air of potential contaminants before resuming the use of the room(s). Ventilation time should be based on the number of air changes per hour required by the area. The NIOSH chart for removal efficiency of airborne contaminants may provide guidance, but its use should be tempered by its assumptions *(5,160)*. In the event of major contamination of patient care areas, plans should specify responsibilities for these decisions and for intensified cleaning, environmental surveillance of airborne infectious agents, and restriction of water use until testing or flushing determines safe use.

POSTCONSTRUCTION

Postconstruction and Cleanup

Project Checklists Check-off lists of expected practices identified at the beginning of the project should be reviewed for items agreed on before the area is returned to full service or patient occupancy. A useful tool during review is the contractor's "punch list" to ensure that missed details have been addressed, such as installations of soap dispensers or designated types of hand washing and sink controls (8,9,*181*).

Owner Preinspection before Move-in Suggested checkpoints for inspections include validating air systems by verifying air balances and pressures, checking electrical current of wall outlets, testing suction capability of wall units, assessing oxygen and gas delivery ports for ease in delivery and control accuracy, checking illumination sources, flushing water systems, rechecking that sinks are in place and functioning properly, determining if aerators are absent, testing whether soap and towel dispensers are full and functional and whether sharps containers are properly placed.

Postconstruction Agreements

Cleanup agreements (e.g., cleaning, air balancing, filter changes, flushing of water systems, etc.) and other utility service checks and cleaning must be established in the early planning phase, as discussed previously. These include the following at minimum:

- Contractor cleaning to include area clearance, cleaning, and decontamination and wipe-down
- Cleaning after removal of partitions around construction area, minimizing dust production
- Facility-based routine and terminal cleaning before returning area to service
- Provision of timeframes for facility review (e.g., 2 weeks) after completion of the project to ensure that all issues were addressed properly
- Systematic review of outcomes in the facility's designated review process, whether by contract or committee structure. Items may range from sealed cabling and electrical penetrations and ceiling tile replacements to the completed punch list
- Cleaning and replacement of filters and other equipment if affected by major or minor disruptions or conditions that could have contaminated the air or water supply (9,*23,62*,63,*71*)

Steps before Occupancy

Checklists specific to the project should be developed for a walkthrough just before occupancy. Core IPC issues for inclusion are listed later as applicable. The designated team should do the following:

General Checks: Conducted as part of an operational project team. The facility's punch list is invaluable to assess and ensure items are completed before occupancy

- Airflow, pressures, filters, location of air intakes and vents
- Drains to the sanitary sewer system are connected and functioning
- Check whether surfaces in procedure and service areas are appropriate for use (e.g., smooth, nonporous, water-resistant)
- Verify that air balancing has been completed according to specifications
- Test whether air flows into negative-pressure rooms or out of positive-pressure room

Two weeks prior to opening:

- Use processing packs to check steam, gas sterilizers
- Verify correct water temperatures
- Complete written schedules and procedures for routine maintenance of equipment, cooling towers, and suction machines (central and portable); establish documentation
- Determine transportation systems
- Walk through the facility with local health department representative and facility management personnel to ensure compliance with local and state codes

One Week before Moving into New Facility:

- Evaluate HVAC supplying special areas, such as ORs and interventional cardiology rooms. Objective evidence should be requested from contractor that HVAC is providing air exchanges and filtration as designed, before owner acceptance. Assess methods for determining effectiveness of particulate matter removal
- Evaluate laminar air hoods for effective operation; ensure functioning according to manufacturer specifications. Ensure a maintenance contract has been arranged and testing has been accomplished
- Open all faucets simultaneously to test drain effectiveness
- Verify that sinks in critical patient-care areas have properly functioning fixtures
- Ensure that hand hygiene products are in dispensers and that dispensers function properly and are convenient to users, including hand-drying supplies
- Check floor drains, and ensure that traps have water seals to prevent sewer gases from entering rooms
- Ensure that contractors have completed their own cleaning and disinfecting; ensure housekeeping department has completed facility follow-up cleaning
- Ensure registered pest control and management is functioning and checked
- Be prepared to intensify surveillance for HAIs and monitoring of IPC practice

In conclusion, the role of HEIPC in construction and renovation remains a challenging and exciting one and is the ultimate demonstration of its multidisciplinary nature. Interaction and integration of efforts with other disciplines is consistent with the underlying foundation of HEIPC—disease prevention for patients, HCP, and visitors.

CHAPTER 84

Design and Maintenance of Hospital Ventilation Systems and the Prevention of Airborne Healthcare-Associated Infections

Andrew J. Streifel

A building ventilation system is expected to supply air at a comfortable temperature and humidity level (1–3). In the hospital setting, heating, ventilation, and air-conditioning (HVAC) systems must often provide specially conditioned air to protect the health of patients and staff. Certain patients (e.g., bone marrow transplant [BMT] recipients) are particularly vulnerable to infection from airborne pathogens *(4)*. Others, such as tuberculosis patients, are potential sources of airborne infection, which may put those around them at risk. To design a proper hospital ventilation system, one must be familiar with both the physical and biologic characteristics of airborne agents causing healthcare-associated infections. Knowledge of ventilation strategies and equipment used to reduce the potential for airborne transmission of disease requires an understanding of airborne particle management for contamination control *(5)*.

The science of aerobiology began with Louis Pasteur's discoveries in the middle of the 19th century. By this time, investigators had made great strides in characterizing airborne flora and fauna and in developing methods for accurate quantitative sampling of these populations. During the 1930s, William Wells published on the infectious capacity of droplets and droplet nuclei. He also studied the air-sterilizing properties of ultraviolet (UV) light. By the 1960s, investigators were reporting on the airborne transmission of a variety of infections, including tuberculosis, influenza, smallpox, and measles. From particle science and fluid dynamics has evolved the study of bioaerosols, which quantitatively describes the generation and dispersal mechanisms that dictate the behavior of airborne microorganisms *(6)*. By applying an understanding of these biologic and physical principles, the hospital can provide a ventilation system that can help protect against the spread of healthcare-associated or occupationally acquired airborne infection. Although these principles are well known, the challenge on a global scale is for the world's medical facilities to keep up with the advances in medicine. These advances are producing mainstream treatments for life-threatening diseases such as leukemia or solid organ failure. Medical schools can deliver trained personnel to utilize advanced medical treatments, but the buildings where patients are being treated cannot keep up with the demands for specialized treatment areas.

BIOAEROSOLS AND INFECTION

For an object to remain airborne, it must be small enough so that the viscosity of the air impedes its fall in response to gravity. Lewis Stokes *(7)* developed an equation that predicts the falling velocity of a particle as a function of its diameter. Stokes's law for determining the sedimentation velocity (V_s) of particles from 1 to 100 μm in diameter is as follows:

$$V = (2gr^2)(d1 - d2)/9\mu$$

where V is the velocity of fall (cm sec^{-1}), g is the acceleration of gravity (cm sec^{-2}), r is the "equivalent" radius of particle (cm), $d1$ = density of particle (g cm^{-3}), $d2$ = density of medium (g cm^{-3}), and μ = viscosity of medium (dyne sec cm^{-2}).

Gregory published a table of experimentally observed falling velocities for a number of microorganisms. It can be readily observed that many particles ranging in size from 1 to 5 μm have falling velocities in still air on the order of 1 yard an hour. Many spores, such as those of *Aspergillus fumigatus*, have roughened surfaces that tend to further enhance their buoyancy. Such particles can stay airborne almost indefinitely and can ride on air currents for thousands of miles from their point of origin *(7)* (Table 84-1).

The removal of these infectious particles is essential for ventilation efficacy. Newer concepts provide an understanding of the age of air (AOA) as a direct measure of ventilation performance. The principles concerning AOA (or the movement of particles around and eventually out of the rooms) are important for airborne infectious disease management.

Often, the focus for indoor air complaints is the inference that infections are caused by poor ventilation. We do, of course, want to ensure that ventilation is moving air approximately at design specification, because we also know that stagnant air and infectious aerosols prolong exposure potential and disease depending on

TABLE 84-1

Minimum Efficiency Rating Values (MERV)	*Average % Dust Removal Efficiency*	*Particle Size Range (μm)*	*Applications*	*Filter Type*
16	99.97	≤0.3	Clean rooms	HEPA
15	95	0.3–1.0	Hospitals	Cartridge
14	90	0.3–1.0	Hospitals	Cartridge pocket filter
1–13	<20–85	0.3 to >10.0	Industrial protection	All kinds

circumstances. This excuse of poor ventilation as a cause of healthcare-associated infection is a continuing challenge, and determining the AOA will be useful for proving or disproving ventilation issues (8). It is important to realize that if such small particles were entrained in a patient's respiratory airstream, they would be of the size most likely to elude the cilial and mucosal defenses of the upper respiratory tract and to deposit in the alveoli of the deep lung (Fig. 84-1). Since the early 1970s, investigators have enhanced the understanding of the respiratory fate of small particles as a function of their Stokes diameter.

Quantitative information about particles is as reliable as the measuring instrumentation. By knowing the airborne spore concentration in a given air body and the tidal volume of the lung, one can estimate the probability of inhaling a certain quantity of pathogenic material. Riley and Nardell *(9)* used the concept of infectious dose in the form of quanta to predict the probability of infection from the release of infectious particles. Using ventilation for infection control, one can achieve protection, to a degree, before reaching a point of diminishing returns *(10)*, especially for agents such as *Mycobacterium tuberculosis*.

Reliable assessment of biologic risks from airborne pathogens is difficult because of the variables that are intrinsic to living systems. Two *Aspergillus* spores or influenza virus particles may have widely differing potentials for causing infection, depending on such factors as viability of the spores or particles and the health status of the person inhaling them. To determine control strategies for such agents, it is first necessary to estimate what constitutes an infective dose and then to determine what sort of ventilation control system will reduce concentrations of the suspected pathogen to a safe or noninfective level *(11)*. The movement of the air is an important aspect of ventilation efficacy because particles <5 μm behave similarly to a gas. We can test such aspects of ventilation to find the optimal factors, such as air velocity, for ensuring air cleansing. Marshall utilizes the AOA concept for demonstrating ventilation efficacy in BMT rooms. This analysis of the air in various locations in the room will demonstrate the well-ventilated versus the poorly ventilated areas. The poorly ventilated areas have higher AOA readings, and hence, higher concentrations of infectious particles.

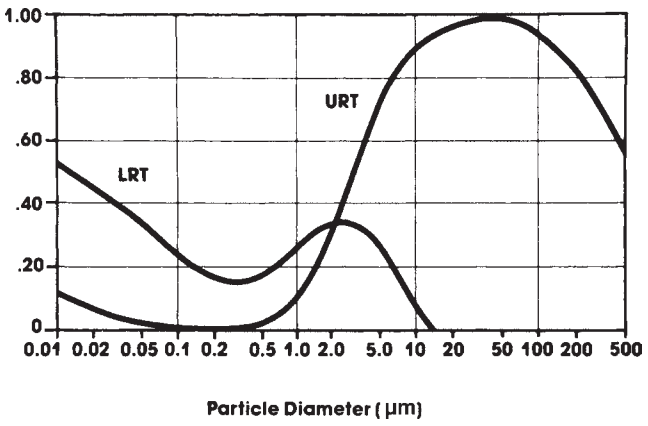

FIGURE 84-1 Upper and lower respiratory tract (URT and LRT) deposition of idealized spherical particles as a function of diameter. (From Rhame FS, Mazzarella M, Streifel AJ, et al. Evaluation of commercial air filters for fungal spore removal efficiency. Third International Conference on Healthcare-Associated Infections. Atlanta, GA, 1990, with permission.)

GENERAL VENTILATION PRINCIPLES

Although air is a gaseous mixture containing nitrogen, oxygen, carbon dioxide, and a number of trace elements, it behaves in accordance with the principles of fluid dynamics. In descriptions of ventilation systems, air is treated as though it were a liquid flowing through the system. Air moves in response to pressure. For liquids, the most common source of pressure is gravity. For gases, the most common source of pressure is temperature. The global system of air movement is powered by the rays of the sun. In a building HVAC system, pressure is provided by fans and blowers that push or pull air through the building. The most basic rule of airflow in a duct system is that air in must equal air out (12). For any two points in a closed duct, $A_1V_1 = A_2V_2$, where A_1 is the cross-sectional area (measured in square feet) and V_1 is the air velocity (in feet per minute). A_1V_1 gives the airflow in cubic feet per minute (cfm). This equation indicates that if the ducts contract (reducing A), air speed, V, must increase proportionally to maintain the same cfm flow rate.

The basic rule of air pressure is $TP = VP - SP$, where TP is the total pressure in the system, VP is the velocity pressure, and SP is the static pressure. Velocity pressure is measured in the direction of airflow and is directly proportional to V, the speed of the moving air. Velocity pressure is always positive. Static pressure is the pressure a body of air exerts on its container, and it can be measured in all directions. Static pressure may be either positive or

negative. It is pressure that tends to either burst (positive pressure) or collapse (negative pressure) the duct. If a body of air increases in speed, the velocity pressure increases, whereas the static pressure drops.

TP, the total pressure, may be either positive or negative and is the sum of the static and velocity pressure. As a body of air moves through a duct system in response to pressure generated by a fan, the total pressure in the system decreases because of frictional losses between the moving air body and the walls of its container, the duct system. This concept is illustrated by a third equation, $TP_1 = TP_2 - H_L$, which states that, for a body of air moving from point 1 to point 2, the total pressures at the two points differ by the frictional losses (H_L) caused by the intervening run of duct.

These three rules provide the conceptual framework within which ventilation systems are designed. In a simple recirculating model, the fan creates sufficient positive pressure to force air through the supply ductwork and sufficient negative pressure to draw the air out of the rooms into the return ductwork and back to the fan, completing the circuit. The pressure generated by the fan must be sufficient to overcome the energy losses created by friction between the moving air and the duct system through which it travels. The ductwork blows air into the various rooms through supply openings. The air circulates in the room and then moves toward return openings that draw air back into the return duct system with negative pressure (suction). With consideration for "ceiling real estate," the careful placement of supply and return/exhaust ducts in a room will help optimize the efficacy of particle removal.

The supply and return openings in the room illustrate an important difference between positive and negative pressure ventilation. An individual with healthy lungs can easily blow out a candle at arm's length. The same healthy lungs could not generate enough negative pressure, or suction, to cause the flame to even flicker (13). The supply duct is comparable to blowing out the candle, whereas the exhaust is attempting to suck it out. We refer to the strong directional flow of positively pressured supply air as "throw," whereas the negatively pressured exhaust duct has a "capture velocity" (Fig. 84-2). The control of such a ventilation system is facilitated by a sealed room. A tight seal on the room allows air to enter and escape only through the ducted openings, thus avoiding room surface air leakage problems. Such measures help to maintain consistent control of the ventilation (14,15). An additional advantage of a tight room seal is to control sound transmission. Important to hospital patient rights is the concept of the Health Insurance Portability and Accountability Act (HIPAA), which ensures patient privacy. Air is the medium for sound transmission, and the tight seal of a room enhances privacy as well as ensuring ventilation efficacy. To what standard of seal should we adhere? The standard for a weathertight house promotes a leakage rate per square foot of surface area in a house at 2.5 in^2/ft^2. This weathertight standard of leakage can apply to hospitals but should be expressed as the leakage volume of air at a specified pressure such as 0.1 cfm/ft^2 of surface in a patient room (15). By establishing this leak rate, it assures that the "make-up" air for the exhaust will, in fact, come from the supply rather than "holes" in the room. Many leak holes can provide sufficient air volumes to negate the effect of the offset between exhaust and supply air volumes. This can create confusion, because low pressure differentials can result in fluctuating airflow directions: for example, a room flipping from negative to positive airflow in and out of the room. Such confusion has spurred exposure investigations concerned with the lack of consistent airflow monitoring on infectious patients with diseases such as tuberculosis or disseminating varicella zoster.

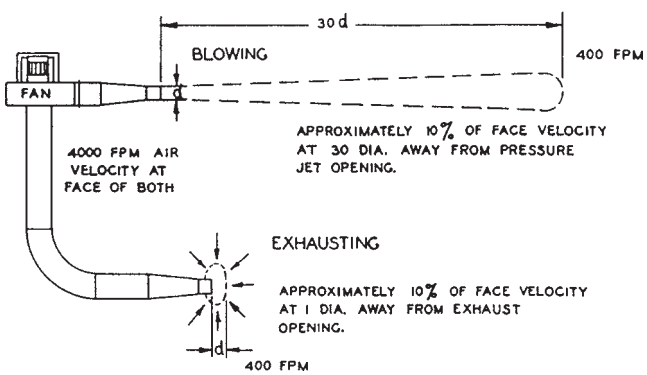

FIGURE 84-2 Basic difference between flow and pressure openings.

HOSPITAL VENTILATION SYSTEMS

In designing an HVAC system for any occupied building, one must properly size ducts and fans to provide the proper air pressures and duct velocities to meet the ventilation requirements of the entire building. Properly sized heating and cooling equipment and noise reduction enter into the total calculations, as does some sort of filtration or air-cleaning system. As air recirculates in a building, it builds up an increasing load of gaseous contaminants that are not readily removed by filtration. It is necessary to exhaust a certain percentage of this stale air and replace it with fresh outdoor air to ensure occupant health and comfort *(16)*. A wide variety of systems have been used to meet these criteria. A few of the more common types with an eye toward the needs of the hospital environment are considered below.

Energy management is a formidable challenge for building management in the future. Hospitals have among the highest utility costs per square foot of any industry. Strategies for controlling ventilation costs in climates where heating and cooling are extreme have shifted to energy-saving concepts. Displacement ventilation is one such concept *(17)*. Air is delivered from the bottom (low part of room) and, as the air is warmed, will rise to be extracted from the room. What we use today is contrary to physical forces: forcing air down when the natural tendency is for air to rise. Although energy savings are immense when allowing air to be discharged into a room at a higher temperature, the lack of space and/or design in most patient rooms does not allow for its large-scale implementation yet.

Central Air-Conditioning System

This system brings in fresh outdoor air and mixes it with recirculated air. This air mixture is filtered and conditioned for temperature and humidity according to institutional

requirements and then distributed to all building locations. This system is favored for its low cost and simplicity. In a large hospital, the major drawback of centrally conditioned air is the difficulty in adapting it to the specific requirements of local areas, which may have differing heating and cooling needs. This is a particular problem in cold climates in which rooms along the exterior shell require warmer air than rooms in the core. Large central supply ducts, which reduce noise by slowing airflow, require large amounts of space. Efforts to create local or zone conditions with additional equipment, such as extra heating and cooling coils or booster fans, rapidly increase costs and are often only partially effective.

Dual Duct System

This system has a central system that separately produces two air streams, one hot and the other cold, which are then parallel-ducted throughout the building. Each room is provided with a mixing box in which the two air streams are blended. This allows individual thermostats and volume controls for each room. Although more expensive and difficult to install, this system can provide a number of microclimates without much add-on equipment. The principle drawbacks are the degree of care required in installing the system and the sound baffling required to reduce the noise created by faster airflows within the smaller ductwork. Other variations in the air-handling system may be unique to a regional climate condition that design engineers have considered in the ventilation specifications. This may be a factor for consideration when humidifying or dehumidifying the air.

The control of water in the air-handling system is paramount for controlling potential allergens and pathogens associated with the growth of microorganisms on fibrous insulation *(18,19)*. There can be considerable air-handling system variation when designing for the climate. All designs, however, require careful maintenance and operational considerations for infection control. For example, a local fan coil system has often been used in hospital areas requiring supplemental cooling. Such climate control is often provided with local systems that recirculate ambient air and provide dehumidification and cooling. Such systems, although engineered for temperature control, do not accommodate air-purification control. The fan coil drain pans, if not properly maintained, become reservoirs for local fungal contamination *(20)*. Air conditioners may also be reservoirs for fungal growth or accumulation *(21,22)*. Such systems should be discouraged for areas in which immunocompromised patients are hospitalized. Recent outbreak investigations have demonstrated prolific mold growth on cold ducted systems, either on filters or associated with mixing boxes.

Filtration

Hospital HVAC systems are often required to perform additional tasks related to the prevention of healthcare-associated infections. By appropriate use of air-filtration technology, a hospital air-handling system can deliver air that is virtually particle-free to areas where such a level of protection is needed. The problem presented by such a rigorous filtration system is the energy cost involved. Most filters scrub the air by trapping particles in dense pleated media using impaction and interception for particles >1 μm and diffusion or electrostatic attraction for particles <1 μm. Dense filters impede the flow of air and cause a loss of system pressure. To maintain effective air velocities in the ductwork, a more powerful fan must be installed to overcome this pressure drop across the filter (23).

Filters are rated by their percentage of efficiency. A number of different test methods are used to rate air filters *(24,25)*. Most common are the dioctyl phthalate (DOP) and dust spot tests. The DOP test challenges an air filter with an aerosol 0.3 μm in diameter. A light-scattering instrument downstream measures the penetration of the filter by these particles. A filter that can arrest 99.97% of the DOP particles is referred to as a high-efficiency particulate air (HEPA) filter. This method actually counts particles as a measurement of efficiency.

The dust spot test is used to rate less rigorous filters. This test uses atmospheric air or a defined dust as the challenge. Air upstream and downstream from the tested filter is drawn through filter paper. The samples are then compared for opacity using a photometer. Although not quantitative in evaluating particle reduction, this test measures the ability of a filter to reduce the dirt load of an air stream. Kuehn *(26)* and Rhame et al. *(27)* have shown that dust spot methods can measure high-efficiency removal of particles.

Effective hospital filtration systems that have been evaluated for air cleaning demonstrate the removal of particles at the 90% efficiency level for the removal of particles >0.5μm in diameter. Often filter system failure is associated with defective filter housing rather than filter media failure. Outdoor air is initially filtered through 20% to 40% efficient media, mixed with recirculating air, and sent through a 90% dust spot–efficient filter. These 90% filters have been demonstrated to provide nearly 100% efficiency in removing particles 1 to 5 μm in diameter with a lower pressure drop than when the 99.97% HEPA filters are used. Modern filters designed with larger surface areas can provide high-filter efficiency while maintaining relatively low pressure drops compared with previous versions of the HEPA filter. Distributing such clean air throughout the system provides an additional layer of safety to all occupants at risk for airborne pathogens. Then, where required, rooms or zones can be HEPA-filtered for a higher degree of protection. Modern filtration technology is creating minimal pressure drop filters featuring enhanced fiber electrostatic qualities and increased surface area of the filter. Although reduced resistance pressure while maintaining high-filter efficiency is beneficial for cost savings, careful consideration for proven long-term efficiency is necessary to prevent problems such as filter failure due to a shielded charge on synthetic filter fibers (Raynor et al. *[28]*). High-efficiency filter innovation certainly helps provide sufficient air volume to assist in maintaining essential air quality parameters in hospitals (which often become deficient in air-volume delivery and exhaust as the building ages). Such systems reduce risks created by opening and shutting doors and from transporting vulnerable patients for procedures that cannot be performed in specially protected areas. Filtration and room air exchanges continue to dominate priorities for air quality (29,*30*) in prevention of aspergillosis. However, the combination of appropriate ventilation parameters (filtration, air exchanges, and especially pressure management) helps to ensure control of the many sources of opportunistic filamentous fungal infections plaguing the immunocompromised host (31).

AREAS REQUIRING SPECIAL VENTILATION

Certain areas in the hospital have special ventilation systems as described in the HVAC handbook (2) and Facilities Guidelines Institute's Guidelines for Design and Construction of Health Care Facilities (3), and now the ASHRAE Standard 170: Ventilation for Health Care Facilities (1). Air systems have been designed to meet these specific needs, most commonly, operating rooms, positive-pressure protective environments, negative-pressure isolation units, and local air control flow life islands (Table 84-2). Each of these situations has specific ventilation requirements related to the prevention of healthcare-associated infection or occupational exposure to airborne infectious diseases or medicated aerosols or gases. All operate on the underlying principle that clean air should move from less contaminated to more contaminated areas (clean to dirty airflow). To more clearly illustrate the principles involved, a specific patient, pathogen, or procedure is discussed here for each type of situation.

Protective Environments

Operating Room Surgery is by nature a process requiring invasive procedures that expose host tissues to the outside environment, creating the potential for exposure to external agents, such as bacteria and fungi. Therefore, in the operating room, the surgical site and instrument table should be considered the cleanest area, and infection control efforts should be directed toward providing protection through appropriate ventilation control.

Surgical site infection is a well-documented surgical complication *(32)*. Procedural practices including aseptic technique and prophylactic antibiotics provide the first line of defense, but it has been shown that removing bacteria and fungi from operating room air helps to minimize infection *(33,34)*. Microorganisms shed by humans are the most common airborne agents in a correctly designed operating room with appropriate air filtration *(35)*. Large volumes of air filtered through high-efficiency filters should be provided from panels in the operating room ceiling over the surgical site. The downward force of air from the ceiling supply diffuser provides a focused ventilated area around the surgical site that is constantly washed by a high-volume flow of clean air. Such airflow moves particles away from the operating table toward the air returns at the margins of the room. It is important that this directional airflow of filtered air is delivered in such a manner that infectious particles shed by the operating team are swept away toward the return ducts and not trapped and recirculated within the vicinity of the procedure. The more objects there are that interrupt the airflow pattern, the greater the turbulence will be. Special clean room laminar flow ventilation with HEPA filtration has been used in orthopedic cases to prevent the consequences of surgical site infections. A vertical flow system designed to provide a downward flow of air over the surgical site actually increases the air exchanges in the cleanest zone (*36,*37). Air delivery from a horizontal direction does not provide an extra benefit, because personnel and equipment in the way of the directed airflow cause turbulence and potential trajectory of problematic particles toward the surgical site. Vertical flow is preferred over horizontal airflow for space management and infection control considerations. Memarzadeh and Manning (38) performed computational fluid dynamic studies that reinforced the empirical findings of Lidwell (37) that a vertical flow with velocity from 30 to 35 linear feet per minute (lfpm) (0.15–0.18 m/s) could be achieved at the surgical site. If air supply can provide a laminar flow regimen albeit at a lower velocity than the official definition of laminar flow of 90 lfpm (0.45 m/s), control of the shed particles over the surgical site is realistic. In addition, AOA evaluations help establish (independent of test and balance report) the degree of ventilation efficacy. This can be conducted to check air transit times of any common gas, such as carbon dioxide, from which we can ascertain the time that it takes for a particle (<5 μm) to move from the source to the extractor vents in the respective rooms. Readings of 3 to 5 ft/s indicate satisfactory air movement (8).

Pressure management in the protective operating room environment is designated by a positive airflow out of the cleanest area of the operating room suites. This designation

TABLE 84-2

Summary of Special-Ventilation Hospital Areas

	Infectious Disease Isolation Room	*Compromised Host Ventilation*	*Operating Room*
Air pressure	Negative	Positive[a]	Positive
Room air changes	≥6 renovation ≥12 new construction	≥12	20
Sealed	Yes	Yes	Yes

does not give guidance for what is necessary to provide that pressurization. Murray et al. (14) have suggested that a differential air volume (supply vs. exhaust or return) exceeding 10% to 15% provides the required airflow. This concept works best in a high airflow volume environment like an operating room or in BMT rooms, which also require higher airflow volumes. Such suggestions have not been validated. Consistent management of pressure is a problem when windows are operable or doors are left open. Using an anteroom or door closure is an essential component for room-pressure management. Operating rooms have multiple doors, and if any of those doors are open, the pressure differential is eliminated until the door is closed. Procedural practice for operating rooms should include closed doors, except for egress, while the surgical site is open.

Investigations have shown value in properly clothing the operating room team for maximum contamination control. The surgical team is a potential reservoir of infection. The average person sheds approximately 10^7 particles of sloughed skin per day *(39,40)*. During an hour-long surgical procedure, each individual in the operating theater may shed 10^6 particles. Each one of these particles may be carrying bacteria that can infect a surgical site. However, in the properly ventilated operating room, such shedding should not pose an infection risk to patients. For operative procedures involving insertion of a prosthetic device and for which ultraclean air may be desired, shedding can be greatly reduced by providing surgical personnel with negatively pressurized evacuated gowns.

Opportunistic environmental microbes such as *Clostridium perfringens* or *Aspergillus* spores should be minimized in an operating room setting. These soil microorganisms are readily filtered from incoming air if filters are installed and maintained properly. Such microorganisms would be expected in air-supply systems that have leaks or tears in the filters. A lack of maintenance is also a problem, because it allows a reservoir of microbial growth in the air-delivery system. Such inadequate maintenance or installation must be avoided in the critical surgical areas.

Shed microbes from human attendants must be controlled with directed airflow and barrier protection. The use of masks for personnel and patient protection is one such control. However, Tunevall and Jorbeck *(41)* raised the issue that masks do not affect the presence of microbes in a surgical setting. This is a naïve notion given unexpected sneezing, coughing, and normal surgery room conversation creating droplets that are capable of falling into the wound. The range of microbial recovery from air sampling suggests that the use of barriers prevents the inadvertent shedding of microbes from exposed areas such as the mouth or hair. Barriers have also been shown to prevent contamination of drapes and the surgical site. Even with aseptic technique and appropriate ventilation, the exposed skin from both the patient and attendants becomes an important source for microbial exposure in the surgical setting *(42)*. Unclean floors from tracked dirt and accumulated debris could become an internal source for *C. perfringens* or other soil microorganisms *(43)* if disturbed. Human source microbes can be controlled with aseptic technique *(44)* and barrier protection *(45)*. A forced air ventilation system enhances the cleanliness of the critical surgery area. The ventilation system is essential for protecting the surgical site using particle displacement dynamics of properly directed purified air movement. The AOA concept has also been used to evaluate operating rooms thought to have ventilation problems. It is instructive to demonstrate that when extractor vents are blocked, the removal of contaminants is impeded. With the measurement of air movement in ft/second, we can demonstrate slow inadequate ventilation and dissipation rates in highly ventilated areas.

The patient is also a potential source for infecting the personnel in the operating room setting. The generation of aerosols during the use of cautery and lasers is a matter of concern. Information on the transmission of infectious agents by these procedures is minimal; however, scavenging devices are being used to minimize the presence of obnoxious odors or aerosols in the operating room setting. For example, such local exhaust and filtration systems can be used to capture problematic aerosols generated during the removal of extrapulmonary tuberculosis lesions.

Positive-Pressure Room (Protective Environments)

Oncology and Solid Organ Transplant Patients. Modern medical technology has provided methods for transplanting immunologically dissimilar tissue between donor and recipient. The immunosuppressive treatment necessary to prevent rejection of the transplanted organ or tissue puts the host at risk for opportunistic infections. Environmental pathogens causing legionellosis or aspergillosis are common (4,46,47) and must be controlled in a critical hospital setting. These environmental microorganisms pose little threat to the healthy individual protected by normal humoral and cellular immune defenses.

A. fumigatus is a common soil fungus. Its spores range in diameter from 2 to 3.5 μm and are commonly recovered from outdoor air samples. This airborne fungus is cosmopolitan and is commonly recovered when using a volumetric air sampler. This thermotolerant fungus poses a particular risk as a healthcare-associated pathogen because of its ability to reach the alveoli in the lung and its ability to thrive at 37°C. On inhalation by the granulocytopenic patient, these spores can cause a form of pneumonia that is difficult to diagnose and treat. Peterson et al. *(48)* noted that 17 of 19 patients with aspergillosis died in a series of 60 BMT patients. Opportunistic filamentous fungal infections seem to be less responsive to conventional antibiotic therapy. Providing spore-free air through filtration, ventilation, and local activity control is the best method for preventing infections transmitted by fungal spores *(49)*. Because some patients remain immunocompromised for up to several months, it is also necessary to minimize airborne environmental contamination by microbes in the environment of convalescent transplantation and oncology patients.

The basic ventilation approach in such facilities is to provide positive-pressure ventilation wherein the amount of HEPA-filtered supply air exceeds the amount of air exhausted by at least 10%. The offset should be approximately 125 cfm between the supply and exhaust/return to provide a substantial difference for ensuring a consistent pressure differential in the special ventilation rooms. This difference should be able to establish a pressure differential >0.01 in water gauge (2.5 Pa). By delivering air at a rate of between 6 and 10 air changes per hour, depending on heating and cooling requirements, and by using supply and

return air that ensures thorough mixing, the room can be kept relatively spore-free *(50)*. Supply air diffusers should be located in the ceiling and positioned to throw air down far enough into the room to ensure particle displacement and mixing. In the protected ventilation environment, the filtered air should flow from the vulnerable patient toward the corridor. Such clean to dirty airflow provides air movement that should prevent inhalation of common airborne fungal spores by the patient.

Bone-Marrow Transplantation Unit Simple positive pressure ventilation may not provide sufficient protection for the extremely vulnerable patient. Patients requiring BMTs are often housed in laminar airflow (LAF) rooms *(46)*. Such rooms are designed with one entire wall of HEPA filters. Fans blow air through these filters at high velocity (~100–150 lfpm *[51,52]*) and out through high-capacity return ducts located on the opposite wall. Although the term laminar flow is not an accurate description of the fluid dynamics of the airflow under such conditions, the effect is that smoke particles injected into the LAF air stream are swept straight across the room, parallel to the floor, and out through the return. It is as though a piston of clean air is being pushed across the room, driving any contaminants out through the return ducts. To enhance patient protection, all caregivers should work downstream from the patient so as not to impede the protective airflow across the bed. Such rooms provide more than 100 air changes per hour. The high velocity of the airflow can create uncomfortable drafts and excess noise. Housing patients in such an environment is an extreme measure and can be problematic during long periods of convalescence. Because of high cost and limited availability, these LAF systems are difficult to provide for all immunosuppressed patients. Therefore, less drastic ventilation control procedures are often recommended *(53,54)* (Table 84-3).

The problem most frequently associated with contaminated hospital air is construction activity (55). Control of aerosol generation, airflow, filtration, barrier penetration, and traffic requires careful monitoring and supervision to maintain specially ventilated areas (55). Air filtration and increased room air changes help to prevent infection in areas adjacent to construction activity *(56,57)*. Patients must be continuously confined in such rooms to be totally protected. Items brought into such areas can also be contaminated *(58)* with fungi from outdoors. The ventilation procedural practices in the patient's room and construction and maintenance practices must be carefully controlled throughout critical care facilities *(59)* (see also Chapter 83).

Airborne Infectious Disease Control

Negative-Pressure Isolation: Airborne Infection Isolation Room Hospitals should house patients, who have infectious diseases spread by the airborne route, in negative-pressure isolation rooms to prevent the escape of pathogens from the room to surrounding areas (Table 84-4). Patients harboring *M. tuberculosis* can pose an occupational risk to the caregiver (see also Chapter 38). With the development of antibiotic-resistant *M. tuberculosis,* infections may be difficult to treat and may be fatal in immunocompromised healthcare workers. During contagious stages of the disease, patients can create infectious aerosols by coughing, speaking, singing, or sneezing. The infectious droplets can dry in air to form droplet nuclei 1 to 5 μm in size and float for long periods, increasing the probability of inhalation. A single inhaled tubercle bacillus may be able to produce an infection. Although tuberculosis patients must be isolated to minimize the risk of transmission of infection, the other infectious diseases spread by the airborne route also require isolation using special ventilation *(11,60)*.

In designing ventilation for isolation rooms, the area of the infected patient should be considered dirty (Fig. 84-3). The current strategy is to provide negative pressure to ventilate the room with exhaust exceeding supply by more than 10% or by more than a 125-cfm difference. It must be noted that the relatively low differential for air volume requires significant sealing of the room to prevent leakage. A sufficient seal will allow achievement of the >0.01 inches of water column pressure requirement. This usually means sealing the electrical and plumbing as well as the ventilation connections in each room. The room air should be exhausted to the outside or, if returned for reuse, should be filtered through a HEPA filter. This prevents air contaminated by the patient from escaping into the rest of the hospital and reduces the concentration of airborne tubercle bacilli within the room.

The room air exchange rate has been studied with respect to particle removal *(11)*; a point of diminishing returns is reached at approximately 12 to 15 room air exchanges per hour. The retrofit of older space to the higher air exchanges is difficult and not practical unless new design and construction are planned. To maintain relative pressures, one must ensure that the ventilation in place is working. The control of the airflow depends on the anticipation of exhaust systems deterioration from the accumulation of dirt and lint on fan blades and turning

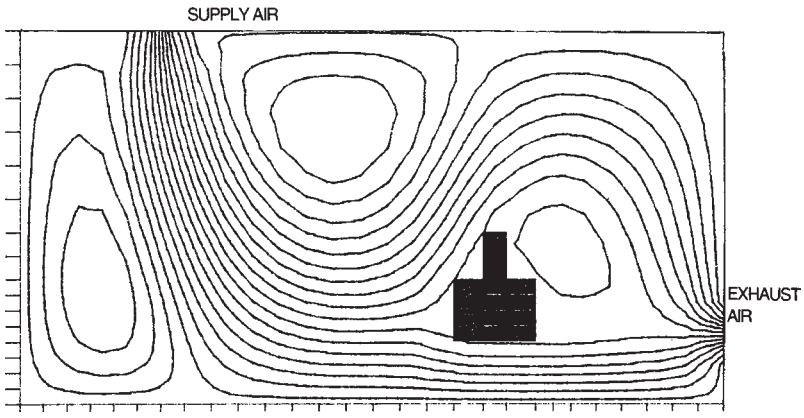

FIGURE 84-3 Computer simulation of airflow pattern in a patient room that can be used to visualize air patterns in special ventilation rooms. In this example, airflow from the supply air covers the healthcare worker area, passing the "dirty" patient before exhausting.

vanes. Cleaning the air pathway and exhaust fans helps to ensure consistent pressure relationships.

Installing effective negative-pressure ventilation is more challenging than installing positive-pressure ventilation. The negative-pressure system is easily compromised by air infiltration, and extra attention must be paid to sealing all ducts, doors, walls, and windows of the room. Even if the system is well sealed, it is more difficult to create directional airflow using suction. The clean (employee area) to dirty (patient area) airflow pattern should also be incorporated into isolation room design. The effectiveness of such design features, although intuitive and associated with clean room ventilation methods, must still be verified. There are difficulties in applying exhaust ventilation to clear a room of low concentrations of infectious particles. One study reported that when the concentration of microorganisms is low, a 14-fold increase in fresh air ventilation only reduces concentrations by 10% *(10)*.

Clearly, additional measures are required to make the room of the infectious patient safe. Source control measures, such as surgical masks for patients, local exhaust ventilation near the patient's head, and a respiratory protection plan for employees, are necessary for a comprehensive plan. UV light fixtures mounted high on the walls of the room have been shown to reduce the concentration of airborne bacteria. Mermarzadeh (61) redemonstrated that UV light is effective in reducing airborne contaminants. It must be remembered that when using UV light or portable filters to enhance ventilation for particle removal, the devices do increase equivalent room air changes for airborne infectious diseases control but do not satisfy fresh air requirements (13). Likewise, portable filters with extra features besides filtration are often extraneous and do not enhance air quality. Studies of filters-plus enhancers, like photo activation, have not been proven in a clinical setting to prevent disease.

Maintenance Considerations Design of sophisticated hospital ventilation systems must include ongoing routine maintenance as part of the budget for the project (14). Ventilation systems rapidly fail if not carefully installed, monitored, and repaired as needed. Deferred maintenance is a common problem in many hospital systems. In addition, sophisticated ventilation systems have failed to perform as specified because of inadequate installation. Failure to provide the designed supply of air in special ventilation areas by installing a fan with insufficient delivery capability will create ventilation deficiencies. Likewise, a void in the caulk around a window in a positive-pressure room can allow windblown spores to enter the patient's room, bypassing the filtration system and exposing the patient. Improperly installed humidification or cooling systems can allow moisture buildup, creating ideal growth conditions in the air-handling system for potentially lethal mold. Poorly designed gaskets and mounting apparatus can allow dirty air to bypass the HEPA filters and contaminate clean areas. The failure to maintain the system may cause the air balance to change because of increased accumulation of lint and dust on filters; this may decrease the exhaust ventilation. Such changes could alter the negative air balance and cause the room to become positively pressurized (Table 84-5).

When designing a high-performance air-handling system, it is vitally important that all components are easily accessible for routine inspection and maintenance. Filter change-out must be performed according to safe maintenance practice *(66)*. Filter efficiency actually increases during use as trapped particles increase the density of the filter media. At the end of a filter's useful life, it is so loaded with particles that it begins to impede system airflow. Monitoring devices such as manometers or gauges should be installed to measure the pressure drop across filters, and when the indicator exceeds manufacturer's specifications, the filter should be changed. Often, these measuring devices are not operable because of neglected maintenance (62). It is difficult to remove and replace the filter without dislodging trapped contaminants and sending them downstream. The point-of-use filter (placed at the end of the duct just above the diffuser) in the bone marrow transplantation unit minimizes this effect by preventing more than 95% of the released particles from reaching the patient-care area *(63)*.

Fans, cooling coils, and condensate pans must be readily accessible for cleaning and repairs. Studies and reports indicate that failure to design hospital HVAC systems with provisions for routine maintenance access can result in untoward clinical consequences (14). Training of personnel in the principles and importance of ventilation is essential. Often, maintenance personnel shut down critical fan systems without notifying persons in the affected areas. Such shutdowns are a real threat because of the lack of ventilation control during those times. Fan systems must be routinely maintained, and shutdowns must be carefully

TABLE 84-5

Ventilation Hazards

Problem	*Consequences*	*Possible Solutions*
Water-damaged building materials *(18)*	Water leaks can soak wood, wallboard, insulation, wall coverings, ceiling tiles, and carpeting. All can provide microbial habitat when wet. This is especially true for fungi growing on gypsum board	1. Incorporate fungi static compounds in building materials in areas at risk for moisture problems 2. Replace water-damaged materials 3. Test for moisture and dry in <72 h
Filter bypasses *(51)*	Rigorous air filtration requires airflow resistance. Air stream will elude filtration if openings are present because of filter damage or poor fit	1. Use pressure gauges to ensure that filter is performing at proper static pressure 2. Make ease of installation and maintenance criteria for filter selection 3. Properly train maintenance personnel in HVAC issues 4. Design system with filters downstream from fans 5. Avoid water on filters or insulation
Improper fan setting (62)	Air must be delivered at design volume to maintain pressure balances. Airflow in special vent rooms reverses	1. Routinely monitor airflow and pressure balances throughout critical parts of HVAC system
Ductwork disconnections *(63)*	Dislodged or leaky supply duct runs can spill into or leaky returns may draw from hidden areas. Pressure balance will be interrupted, and infectious material may be disturbed and entrained into hospital air supply	1. Design a ductwork system that is easy to access, maintain, and repair 2. Train maintenance personnel to regularly monitor airflow volumes and pressure balances throughout the system 3. Test critical areas for appropriate airflow
Airflow impedance (12)	Debris, structural failure, or improperly adjusted dampers can block ductwork and prevent designed airflow	1. Design and budget for a duct system that is easy to inspect, maintain, and repair 2. Alert contractors to use caution when working around the HVAC system during the construction phase 3. Regularly clean exhaust grills 4. Provide monitoring for special ventilation areas
Open windows *(11,22)*	Open windows can alter fan induced pressure balances and allow dirty-to-clean air flow	1. Use sealed windows 2. Design HVAC system to deliver sufficient outdoor dilution ventilation 3. Monitor CO_2 levels in all occupied areas to ensure adequate fresh air supply 4. Sign windows where fire code prohibits sealing
Dirty window air conditioners *(21,22)*	Dirt, moisture, and bird droppings can contaminate window air-conditioners, which can then introduce infectious material into the hospital room	1. Design such devices out of new construction 2. Where they must be used, make sure that they are routinely inspected and cleaned
Inadequate filtration *(60)*	Infectious particles pass through filter into vulnerable patient areas. Specify appropriate filters during new construction design phase	1. Specify appropriate filters during new construction design phase 2. Make sure that HVAC fans are sized to overcome pressure demands of filter system 3. Inspect and test filters for proper installation
Maintenance disruptions *(59)*	Fan shut-offs, dislodged filter cake contaminates downstream air supply and drain pans, compromises airflow in special ventilation areas	1. Be sure to budget for rigorous maintenance schedule when designing a facility 2. Design system for easy maintenance 3. Ensure good communication between engineering and maintenance personnel 4. Institute an ongoing training program for all involved staff members

(*Continued*)

TABLE 84-5

Ventilation Hazards (*Continued*)

Problem	*Consequences*	*Possible Solutions*
Duct contamination *(18,19)*	Debris is released during maintenance or cleaning	1. Provide point-of-use filtration in the critical areas 2. Design air handling system with insulation on the exterior of the ducts 3. No fibrous sound attenuators 4. Decontaminate or encapsulate contamination
Depressurized hospital building *(64,65)*	Infiltration of unfiltered air into the building during construction caused aspergillosis in oncology patients	1. Ensure building pressure by oversupply of air volume by rebalancing or upgrading building ventilation 2. Add doors and weather-stripping to prevent air movement during periods of air imbalance 3. Difficult issue with high-rise buildings

CO_2, carbon dioxide; HVAC, heating, ventilation, and air-conditioning.

planned. Likewise, plans for emergency outages must also include provisions for backup motors or redundant systems. For example, contingencies for failure of the ventilation system in a bone marrow transplantation unit should include changes of procedural practice during the absence of ventilation control. For example, on the patient-care unit, should the routine cleaning and patient visitation be temporarily suspended during fan outages? If malfunction is persistent, should supplemental ventilation be provided with portable systems? Such scenarios should also be considered for the ventilation for infectious disease isolation in anticipation of planned or unplanned outages. Finally, it is crucial that funds for ongoing maintenance and training are included in the hospital budget.

Provisions must be made for additional patient protection during construction and remodeling projects (62,*63*). When wall cavities are opened, large quantities of spores might be released from water-damaged areas hidden from view *(67)*. Protective air environments must be secured from penetration by dust and debris generated during remodeling projects. During a large construction project at a Midwestern hospital, the infection control team purchased an optical particle counter to monitor the operating theaters and ensure that the ventilation system was controlling the air quality during construction *(68)*. Microbiologic air monitoring can also be used, but baseline data must first be generated along with construction monitoring during the project. Results are often hard to interpret, and time spent would be lost to the more important aspect of monitoring the compliance with construction specifications related to infection control during construction. On the other hand, commissioning of ventilation systems by air sampling would ensure that specifications for filter installation and operation have been met.

Verification of Ventilation Parameters for Special Ventilation Rooms Infection control airflow design specifications should also be verified *(64)*. The parameters important for verification are associated with pressurization, room air exchanges, and filtration. Nicas et al. *(69)* and Rice et al. *(70)* showed considerable variation of airflow when special ventilation rooms were tested. Rice et al. reported a large pressure variation for positively pressurized rooms primarily because of the maintenance manipulation of dampers or fan belts. Negatively pressurized rooms had much lower pressure differentials and were considered more stable, but the airflow direction changed from negative to positive more frequently. Saravia et al. showed that most airborne infection isolation (AII) rooms, when tested, were deficient. In the name of preparedness for infectious diseases, verification of ventilation parameters is essential (71). The fluctuation from negative to positive was probably due in part to a low-pressure differential at or about 0.25 Pa (250 Pa per 1.0 inches water gauge). Recently, Streifel and Marshall (72) clarified parameters that could be measured before occupancy of special ventilation areas. Table 84-6 is a listing of the parameters, and notably, the pressure measurements are listed. The pressure performance must be considered as a range because of constant variation of outdoor conditions, elevator movement, and doors being used *(73)*.

Testing and proving that airflow is appropriate, air exchanges are sufficient, and filtration is appropriate permit mechanical ventilation to be ruled out as a source for acquisition of *Aspergillus*. Other considerations can, therefore, be explored.

Air-Sampling Methods The nonviable airborne particle can be detected with the use of a particle counter, optical or laser, that allows real-time air quality analysis. It is important to differentiate particle sizes. The most useful devices for measuring particle sizes are those that determine particle size diameters >0.5, 1.0, and 5.0 μm per cubic foot (74). The particles at >0.5 μm are used for assessing a clean room, and Military Standard 209 (e) The International Standards Organization Standards are used to classify clean rooms with particles per unit volume of air less

Media and Incubation Temperatures for Culturing Air Samples

Appropriate selection of growth media helps to expedite identification

Sabouraud, malt extract with inhibitor, inhibitory mold agar, etc.

Incubation temperature

At 25°C, greater numbers of airborne fungi will grow; lower temperatures help to distinguish infiltration or filtration deficiencies

At 35°C, the temperature selects for pathogen recovery; A. fumigatus and A. flavus are thermotolerant

than a certain number. The classification is based on increments of 10, and a HEPA filtered (99.97% efficient at 0.3-μm diameter particles) operating room or BMT environment with no people should be capable of class 1,000 clean room status or better. The definition of a class 1,000 clean room is that there are <1,000 particles per cubic foot >0.5 μm in diameter. Such information is especially useful for ensuring filtration integrity or infiltration in a critical environment before the areas are occupied. These devices are useful for determining the cleanest areas. Problem solving with particle counters and pressure gauges help determine potential sources of particles being generated. The class of the room designation can be a useful guideline but should not have such a specification for an absolute number that cannot be exceeded. Airborne particle counts vary a great deal in healthcare, the status quo should demonstrate low particle counts with no activity. The lowest counts should occur in areas with the best ventilation.

The viable airborne particle analysis is more complex, because laboratory expertise is necessary. The selection of media, incubation temperature, and skill for identification of environmental microbes are factors that must be considered if an environmental sampling program is initiated. The purpose for sampling should include determination of what the sampling is expected to evaluate. For example, an air-sampling search for human-shed microbes such as *M. tuberculosis* or staphylococcal species should not be considered because of the difficulty in culturing the slow-growing *M. tuberculosis* and because staphylococcal species are frequently shed from humans. Aerosols generated by a medical device such as a drill may be instructive for air sample evaluations but certainly are not routine in any setting. Air sampling from a practical point of view should be considered only for evaluation of the presence of airborne fungi *(75)*.

Evaluation of the air for airborne fungi yields information that may be helpful in preventing infection or determining the source of airborne opportunistic environmental fungi *(76)*. Air sampling for airborne fungi should be used for determining the levels in areas where patients are at risk for infections from these opportunistic fungi. The media used for sampling a hospital environment should be capable of isolating clinically relevant microorganisms. Because the fungi are capable of growth on a variety of media, clinical media such as Sabouraud or inhibitory mold agar provide direct morphologic identification from the recovered isolates. Some environmental media, although excellent for total recovery, may require extensive subculturing for identification (Table 84-7).

The presence of fungi capable of growth at body temperature is of particular concern. The difference between fungi that grow at room temperature (25°C) and body temperature (37°C) are generally greater than one order of magnitude except in highly filtered environments (Table 84-7). The most common in-hospital exposure occurs from improperly filtered incoming air or from internal sources that were disrupted because of construction or maintenance. Air sampling will not prevent infections during construction. Air sampling can provide information that should inform infection control professionals that the air quality is good enough for safe patient care, because control measures are in place. It is difficult to detect the short-term high-dose exposures that occur because of environmental disruption.

There are a variety of samplers capable of viable particle air sampling. These include volumetric samplers and slit or sieve impactors. It is important that a volume of air is sampled. Settle plates depend on gravity, but single spores <5.0 μm in diameter are buoyant aerodynamic particles that do not settle rapidly. Clumps of particles settle, but perhaps the most problematic particles are those that are capable of entering the lungs. These respirable particles are <5.0 μm in diameter. Collecting the particles in sufficient quantity is essential to detect low concentrations of spores causing healthcare-associated infection. Arnow et al. (18) reported infection rates of approximately 1.2% with *Aspergillus flavus* and *A. fumigatus* at 2.2 and 1.1 colony-forming units (CFU)/m^3, respectively. Rhame et al. *(76)* reported a 5.4% infection rate with *A. fumigatus* at 0.9 CFU/m^3. A major problem with most samplers used in hospitals is low sample volume capability. Most samplers are designed to sample dirty environments. Samplers that sample 1 cfm may

fail to detect spores at levels <1.0 CFU/m^3. Hospital air samples should be at least 17 ft^3 or 0.5 m^3 to detect low levels of spores. Disadvantages of many samplers include low-volume sampling, drying of media with long sampling times, difficult manipulation of culture plates, and difficult calibration. A slit to agar sampler with a timer up to 60 minutes may be the best choice of sampler dependent on the type of timer, noise levels, and portability.

Interpretation of Data Timing for detecting airborne fungal levels is important for interpretation of results. For example, activity evaluation with an air sampler may reveal high concentrations of airborne fungi during the renovation activity of a water-damaged bathroom. Rather than sample for the probability of specific pathogenic microorganisms, it is best to contain the bathroom before demolition to prevent migration of the problematic spores. The best use of air sampling is before occupancy to determine proper filter installation and room pressurization. The purpose of such sampling is to establish rank order for the cleanest areas. The best filtration should demonstrate the lowest particle or viable airborne fungal counts. Such numbers are best demonstrated as baseline before occupancy. Subsequent sampling should take into account people and conditions such as incorrect airflow in a protective environment. Exposure to high levels of an airborne infectious agent over a short time is probably the greatest risk to the host. The ability to capture such events is difficult. The sampling of the environment should be to determine if the ventilation systems work according to specification. Therefore, the areas with the best filtration, pressurization, and air exchanges should have the lowest airborne fungal counts. This should also be true for nonviable airborne particles detected with a particle counter.

If pathogens (*A. fumigatus*, *A. flavus*, or other opportunists capable of growth at body temperature) are recovered from protected environments, consideration should be taken for single-plate hits versus multiple-plate hits from pathogenic fungi. Random isolate recoveries may be represented by a single colony on a plate. Greater than two colonies, for example, *A. fumigatus*, may represent a point source within the patient-care environment. Repeat sampling under such circumstances should determine if it was a passing phenomenon (Table 84-8).

Interpretation of the results from air sampling requires a comparison of sample locations. If sampling is requested, the cleanest environment (i.e., operating rooms or BMT unit) should have the lowest numbers of microorganisms recovered. The basic comparison should be from clean to cleanest in CFU per cubic meter. For better results, such comparisons should be done with culture media incubated at room temperature. Room temperature incubation at approximately 25°C is more sensitive for fungal recovery. Falvey (77) in a 10-year study showed 82% more fungi grew at 25°C than at 35°C incubation temperature. The comparison samples for detecting filtration integrity or potential infiltration should also be incubated at room temperature. Qualitative analysis, however, of airborne pathogens such as *A. fumigatus* is better at close to body temperature (>35°C), because the other mesophilic fungi are inhibited, allowing the pathogens to be more easily detected. The pathogens are easily obscured when the samples are incubated at room temperature. Also, the rank order comparison is difficult at the higher temperature, because the differences in levels in highly filtered areas are not very great. For example, the difference in recovery from media incubated at room temperature for samples taken from the nurses' station in the BMT unit versus those taken from HEPA-filtered rooms might be 55 and 4 CFU/m^3, respectively, whereas the same samples incubated at 35°C might yield 10 and 4 CFU/m^3, respectively. The samples incubated at room temperature are intended to demonstrate ventilation deficiencies, whereas the samples incubated at body temperature should be able to detect pathogens. Pathogen content should be <1.0 CFU/m^3 with repeat sampling. Invariably *A. fumigatus* shows up as a single isolate with few, if any, other microorganisms on the sample plate. A combination of factors that demonstrate the cleanest environment with the lowest pathogen counts are important for data interpretation. The value of comparisons with outside recoveries is that levels of *A. fumigatus* are often higher outside the hospital than inside, for example, 9.0 vs. 1.0 CFU per sample. When adjusted for CFU per cubic meter, outside samples have much higher levels than inside ones, allowing an indoor-to-outdoor ratio of <1. However, if the inside levels are higher than outside levels (except during snow cover or after rain), then an internal source may be suspect. The recovery of two or more colonies of a pathogen from media incubated at 35°C may indicate an internal point source *(75)*.

TABLE 84-8

Interpretation of Air Sample Data

- Rank order determination
  - Clean to cleanest with the lowest counts in the areas with proper ventilation control (pressure, air exchanges, and filtration)
  - Lowest counts in the areas with best filtration
  - Comparison data necessary (outdoor vs. lobby vs. patient-care area)
- Indoor-to-outdoor ratio
  - I/O < 1 normal
  - I/O > 1 potential problems
- Consider outdoor conditions and comparison data colony types
- Qualitative information
  - Pathogen recovery with results >1 CFU pathogen per plate is a potential indoor source
  - Comparison to determine homogenous vs. heterogeneous population
- Temperature selectivity
  - Pathogens grow at temperatures >35°C
  - Total fungi more sensitive to I/O at 25°C

CFU, colony-forming unit.

CONCLUSIONS

It is important that infection control, environmental, engineering, and maintenance personnel actively monitor the proper operation of the HVAC system. Objective information, from

pressure gauges and particle counters, provides real-time analysis of the critical special ventilation environmental parameters. Careful management of all maintenance, surveillance, repair, and construction activities should be coordinated in such a manner as to ensure that precautions to protect the health and well-being of all patients and staff are implemented. Use of pressure (airflow direction), room air changes per hour, and filtration verification specifications are essential for effectively maintaining protective and AII environments. The coordination of safety issues surrounding the susceptible patients and economic pressures is a challenge for achieving energy management goals when reducing ventilation for cost savings is proposed. Vigilance using medical technology and environmental source management will do more for preventing the spread of airborne infectious diseases than environmental sampling will.

Protection from Bioaerosols

Concern for the protection of buildings is imminent, especially because terrorism is part of the current state of affairs in the world order. Likewise, keeping aging infrastructure up to code as the technology advances for patient treatment is a costly effort. Previous sections of this chapter consider the ventilation requirements for AII. For rooms, the described ventilation parameters will help maintain the individual room control of microbial agents spread by the airborne route. The concern for the emergency room waiting areas and sections of the hospital needing to house potentially infectious patients is a challenge. Current fire code requirements for smoke control will aid in the development of a strategic plan for isolating a ward. Hospitals are segmented into smoke control zones, which are smoke compartments. These zones have ventilation dampers and fire-stopped walls that will evacuate smoke if fires are detected in that zone. Engineering concepts are being explored to use the smoke-control dampers and exhaust systems to help isolate the areas with infectious agents. The criteria for isolation would not be as extreme as the smoke management requirements, but the mechanism should already be in place for establishing the depressurized zone for an AII patient-care unit. We can establish isolation methods for preparedness for a biological event by employing methods used by carpenters during construction in healthcare facilities (74,78).

http://www.cdc.gov/niosh/docs/2003-136.pdf

In maintaining the ventilation infection control systems, it is vitally important to focus on what works, especially on what works consistently. To provide the best possible hospital air quality, state-of-the-art technology is needed. It is equally important, however, to emphasize effective communication and common-sense procedures that will account for the human element, permit the system to function as designed, and meet the goal of providing the best in healthcare. Too many facilities are focused on air sampling for preventive measurements of air quality. The results using culture to determine if an area is dirty allows time to pass before decisive action is taken. Common sense would tell us that if the floor is dirty with dust, cleaning it before culturing provides safety and efficacy. Efforts must be taken to ensure ventilation proficiency with the ventilation parameters that will help to control the airborne infectious agents that are potentially pathogenic to humans.

SECTION XIII
Antimicrobial Agents in Healthcare Epidemiology and Infection Control

CHAPTER 85

Mechanisms of Bacterial Resistance to Antimicrobial Agents

Usha Stiefel and Louis B. Rice

The vast majority of antimicrobial agents employed in clinical settings are either natural products or chemical derivatives of natural products. The producers of these agents in nature are generally the microbes themselves. The purpose of this antibiotic production by microbes has traditionally been attributed to gaining a selective advantage in a mixed microbial environment. More recently, recognition that the natural production of antibiotics occurs at generally low levels and that exposure to subtherapeutic concentrations of some antibiotics alters bacterial transcription profiles has led to the concept of antibiotics as "signaling molecules" in nature. Since the production of antibiotics has been occurring in the microbial environment for (presumably) eons, it stands to reason that mechanisms to avoid their lethal action have been developed as well, either by species that produce the antibiotics or those that must share limited space and resources with those that do. In many instances, therefore, our discovery and growing use of antibiotics has led not to the development of resistance genes in bacteria but merely to the natural selection of intrinsically resistant species or the efficient scavenging of preexisting resistance genes by normally susceptible human pathogens. The emergence of *Lactobacillus* species during therapy with vancomycin and of *Stenotrophomonas maltophilia* during therapy with imipenem are examples of selection of intrinsically resistant species. Other phenotypes of resistance reflect more of the ease with which susceptible bacteria can mutate either structural or regulatory genes intrinsic to their species in a manner that results in decreased antibiotic susceptibility. Examples of this type of resistance include extended-spectrum cephalosporin resistance in *Enterobacter* species, fluoroquinolone resistance in many different species of bacteria, or the emerging resistance to linezolid in enterococci and staphylococci. Resistance to some antibiotics, in some species, is not readily achievable by mutation, and thus, must be acquired from other sources. This so-called acquired resistance accurately characterizes many different resistance phenotypes, including ampicillin resistance in *Escherichia coli*, penicillin resistance in staphylococci, and vancomycin resistance in enterococci. Finally, when antimicrobial agents are developed specifically to avoid the lethal action of acquired resistance genes, mutations within the acquired genes can lead to resistance to the newer agents. The emergence of resistance to extended-spectrum cephalosporins in *Klebsiella pneumoniae* and *E. coli* can represent this sort of amplified resistance.

Antimicrobial agents are effective because they target metabolic pathways or enzymes that are specific to bacteria and not to the host. A variety of mechanisms have been shown to result in bacterial resistance. Among these mechanisms are alterations in the antibiotic target such that binding or inhibition of function is decreased to the point of clinical irrelevance, decreased permeability that results in the inability of the agent to reach its target at a critical concentration, efflux of the agent from the cell, and destruction or modification of the antibiotic.

The expression of resistance and virulence by bacteria is often linked but sometimes in unpredictable ways. Selection of rifampin or streptomycin-resistant mutants in the laboratory is often associated with a decrease in the virulence of the strains when tested in animal models (1).

It is presumed that the point mutations in the targets (RNA polymerase in the case of rifampin, the ribosome in the case of streptomycin) lead to subtle but not fatal decreases in function in these resistant strains, conferring a competitive survival disadvantage relative to wild-type strains. Interestingly, continued passage in animals in the absence of antibiotic selective pressure does not always result in reversion to the susceptible genotype. Instead, compensatory mutations frequently occur that mitigate the deleterious effects of the primary mutation, restoring virulence while maintaining resistance (1). Acquired resistance and virulence determinants may also coalesce in environments that favor them, such as the modern hospital. Reports suggest that the worldwide rise of ampicillin- and vancomycin-resistant *Enterococcus faecium* is because of the emergence and spread of genetically related strains enriched for high levels of ampicillin resistance as well as a variety of putative virulence determinants *(2)*.

ANTIMICROBIAL RESISTANCE TRANSFER

Although the primary concern of the healthcare epidemiologist is the prevention of the spread of bacterial strains among hospitalized patients, it is worthwhile to consider mechanisms by which resistance genes can spread among bacterial strains. A full discussion of the mechanisms of resistance transfer is beyond the scope of this chapter. Nevertheless, a few basic concepts should be understood.

Antimicrobial resistance determinants are commonly incorporated into extrachromosomal, independently replicating elements known as plasmids. Plasmids vary greatly in size (3 to >200 kb) and in the number of incorporated resistance determinants. In addition to genes responsible for replication and for antibiotic resistance, many plasmids also possess genes that stimulate their transfer between strains within a given genus, and occasionally, between strains of different (although usually closely related) genera. Large, transferable plasmids have been implicated in the spread of ceftazidime resistance among strains of Enterobacteriaceae, particularly in intensive and chronic care settings (*3,*4). Many of these plasmids also possess genes encoding resistance to a range of non–β-lactam antimicrobial agents, resulting in the elimination of several antibacterial options with a single transfer event (*3,*4). Transferable plasmids have also been identified in gram-positive genera, perhaps best characterized by the pheromone-responsive plasmids found in strains of *Enterococcus faecalis* (5). The widespread emergence of high-level gentamicin resistance in enterococci (see below), resulting from the production of a modifying enzyme most commonly encoded on plasmids, is a testament to the efficiency of plasmids in disseminating resistance determinants in this genus *(6,7)*. Enterococci are also known to possess "broad host-range" plasmids. These plasmids transfer at a lower efficiency than do the pheromone-responsive plasmids but have the advantage of being able to transfer to a wide variety of species. Evidence implicates broad host-range plasmids in the exchange of important resistance genes between enterococci and staphylococci, including β-lactamase production and high-level vancomycin resistance *(8,9)*.

Plasmids need not encode their own transfer genes in order to spread between strains. Nonconjugative plasmids may be mobilized for transfer by conjugative plasmids. In addition, the presence of insertion sequences (ISs) (small regions of DNA capable of independent movement between replicons) has been shown to facilitate the co-integration of conjugative and nonconjugative plasmids, resulting in a larger, conjugative element *(10)*. Appropriately sized plasmids may also be spread by transduction, resulting from the aberrant incorporation of plasmid rather than bacteriophage DNA into the phage head.

In addition to plasmids, antimicrobial resistance determinants are frequently incorporated into mobile elements known as transposons. Transposons may be rather simple elements whose mobility results from the presence of ISs flanking an antimicrobial resistance determinant (composite transposons), an arrangement in which mobility is due entirely to functions encoded by the ISs *(11)*. Alternatively, transposons may be complex structures incorporating several genes. Tn*21* is a Tn*3*-family transposon that has been found to contain a genetic locus (*tnpI*) that serves as a "hot spot" for the integration of a variety of antimicrobial resistance genes *(12)*. Consequently, several Tn*21*-like transposons conferring resistance to a number of different antimicrobial agents, in varying combinations, have been described *(13)*. These loci, referred to as integrons, appear to be important mechanisms for the dissemination of antimicrobial resistance genes in many gram-negative bacilli *(14,15)*. Integrons may be critical vehicles of microbial genetic evolution and have only recently been employed by bacteria for purposes of stockpiling resistance determinants (16). Another Tn*3*-family transposon, Tn*1546* *(17)*, confers resistance to vancomycin and teicoplanin in enterococci and, more recently, in *Staphylococcus aureus*. It encodes nine genes involved in the regulation of transposition and the expression of glycopeptide resistance. More recently, a Tn*21*-based complex transposon carrying β-lactamase-mediated carbapenem resistance has been described in *K. pneumoniae (18)*.

In general, transposons participate in the transfer of antimicrobial resistance determinants by virtue of their ability to move between bacterial chromosome and transferable plasmid. Exceptions to this rule are the conjugative transposons of gram-positive bacteria, which can transfer between strains without the necessity of a plasmid intermediate *(19)*. These transposons possess their own genes responsible for transfer between microorganisms. In general, conjugative transposons encode resistance to tetracycline via the *tetM* gene, although some have been found to encode resistance to multiple antimicrobial agents *(19)*. In addition to the transfer of the elements themselves, some investigators have found that the presence of conjugative transposons stimulates the transfer or deletion of unrelated chromosomal genes, raising the possibility that these elements could be involved in the transfer or deletion of a range of unrelated resistance determinants *(8,20,21)*. A transposon in the Tn*916* family has been described that encodes VanB-type vancomycin resistance in *E. faecium (22)*. Conjugative transposons may also transfer determinants for antibacterial activity as well as antibiotic resistance. Several lactococcal and one enterococcal Tn*916*-like elements encoding determinants for production

of the antibacterial peptide nisin have been described *(20)*. Many larger conjugative elements, especially those from gram-negative bacteria, have been generally categorized as integrating conjugative elements *(23)*.

Other mobile elements involved in the spread of antimicrobial resistance are the IS elements. These elements do not encode antimicrobial resistance themselves but may aid in the spread of resistance determinants via the formation of composite transposons or by serving as areas of homologous recombination between plasmid and chromosome. Insertion of IS elements may also result in the activation of poorly expressed genes via the presence of promoter sequences within the end of the mobile element *(11)*. Evidence indicates that the expression of imipenem resistance in some strains of *Bacteroides fragilis* is due to the insertion of IS elements upstream of an unexpressed chromosomal gene encoding a carbapenemase *(24)*. IS elements have also been implicated in plasmid:chromosome integration with subsequent transfer of chromosomal segments using the plasmid origin of transfer in *E. faecalis (25)*.

Our ability to thwart the spread of resistance determinants between bacterial strains in the natural environment is poor. Factors affecting transfer between strains are poorly understood, but, in some cases, may involve exposure to antimicrobial agents. Transfer of conjugative transposons, for example, has been shown to be increased *in vitro* and *in vivo* after exposure of the donor strain to tetracycline *(26,27)*. It is, therefore, reasonable to presume that environmental pressure from the overuse of antimicrobial agents plays some role in the spread of these determinants. In addition, the comingling of resistant strains of bacteria in the human gastrointestinal tract resulting from hospital and antibiotic exposure as well as from inattention to appropriate infection control techniques probably plays a role in the spread of resistant strains. In some cases, institution of infection control measures (such as barrier precautions for infected and colonized patients) has been shown to abort serious outbreaks of resistant microorganisms *(28,29)*. In others, decreasing use of an antibiotic has been associated with a reduction in the prevalence of resistant strains in an institution *(30)*. As such, judicious use of antimicrobial agents and proper attention to infection control recommendations are likely to be our best weapons to combat the spread of resistant bacteria for the foreseeable future.

β-LACTAMS

Mechanism of Action

Targets of β-lactam antibiotics are a series of enzymes involved in the last step of peptidoglycan (cell wall) synthesis. This step involves a cross-linking reaction carried out by transpeptidases in which the terminal D-alanine of the pentapeptide stem of the peptidoglycan is cleaved. The energy resulting from this cleavage is used to form a peptide bond between the fourth residue of the pentapeptide (also D-alanine) and the cross-bridge, which is itself linked to the e-amino of diaminopimelic acid (in gram-negative microorganisms) or lysine (in gram-positive microorganisms) (Fig. 85-1). This cross-link is absolutely required for structural integrity of the bacterial cell wall. β-Lactam antibiotics, such as penicillin, are structural analogs of the pentapeptide terminal D-alanyl:D-alanine target covalently bound by the transpeptidases. The fact that these transpeptidases also bind penicillin (and other β-lactams) covalently has resulted in referral to them as penicillin-binding proteins (PBPs).

Mechanisms of β-Lactam Resistance

Target Resistance The binding affinity of β-lactams for their targets, the PBPs, varies with the β-lactam and the PBP. Enterococci, for example, are intrinsically resistant to the cephalosporins because these β-lactams do not bind one enterococcal PBP with high affinity *(31)*. Within the genus *Enterococcus*, *E. faecium* tend to be more resistant to penicillins because many strains express a low-affinity PBP (PBP5) that carries out cell-wall synthesis at penicillin concentrations that inhibit the other PBPs *(32)*.

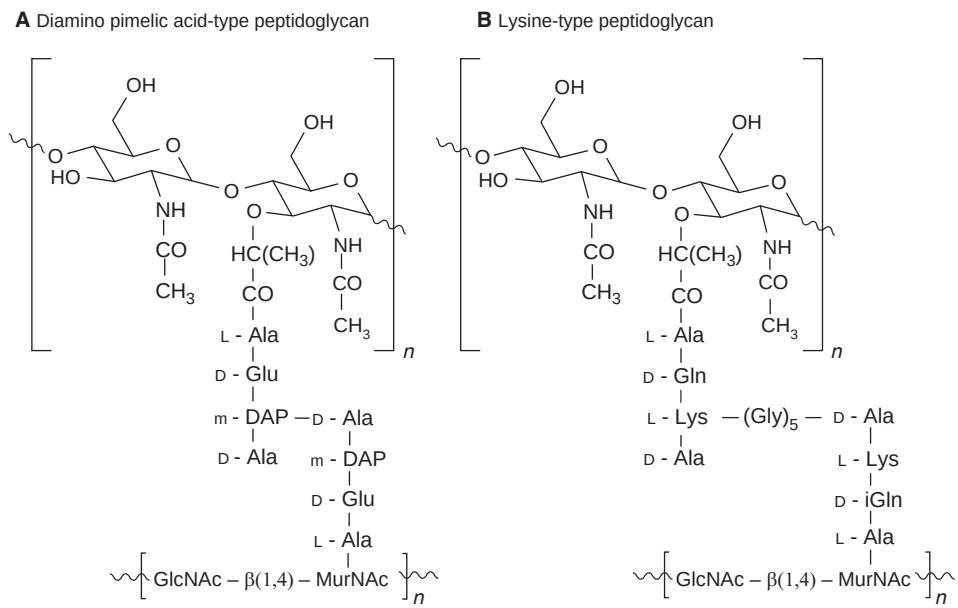

FIGURE 85-1 The two major peptide cross-links found in bacterial peptidoglycan. **A:** Cross-link between diamino pimelic acid and D-alanine, commonly found in peptidoglycan of gram-negative bacteria. **B:** Cross-link between Lysine and D-alanine, more commonly found in gram-positive species. The pentaglycine linkage in this figure represents the cross-links found in *S. aureus*. (Adapted from Royet J, Dziarski R. Peptidoglycan recognition proteins: pleiotropic sensors and effectors of antimicrobial defences. *Nat Rev Microbiol* 2007;5(4):264–277).

Many cases of PBP-mediated β-lactam resistance result from the intrinsic characteristics of the PBPs of a given strain. PBP-mediated resistance may also be acquired. Resistance resulting from mutation can be readily demonstrated in the laboratory *(33)*. Resistance to oxacillin in clinical *S. aureus* strains has been attributed to point mutations in PBP genes *(33)*. In species that are naturally transformable (that can absorb naked DNA from the environment), the formation of mosaic PBP genes is common. Cloning and sequencing of *Streptococcus pneumoniae* or *Neisseria gonorrhoeae* genes encoding abnormal, low-affinity PBPs responsible for penicillin resistance has shown significant sections of these genes to be of foreign origin. In *S. pneumoniae*, the origin appears to have been from oral streptococci *(34)*; in *N. gonorrhoeae*, from oral commensal neisserial species *(35,36)*. The evolution of mosaic genes most likely occurred via DNA transformation followed by homologous recombination across areas of PBP sequence homology between the native and foreign DNA. Entire low-affinity PBPs can also be acquired by normally susceptible bacteria. Methicillin-resistant *S. aureus* (MRSA) has most commonly acquired low-affinity PBP2a, encoded by the *mecA* gene. The *mec* region is located within a larger mobile element (designated SCC*mec*) that varies in size depending on how much extra DNA it contains *(37)*. Healthcare-associated strains (which are resistant to several unrelated classes of antimicrobial agents) contain a larger SCC*mec*, reflecting the insertion of additional DNA, some of which encodes additional antimicrobial resistance. In contrast, the recently described MRSA arising in the community (which is generally susceptible to a range of other antimicrobial agents) contains a relatively small SCC*mec* that encodes only resistance to methicillin *(38)*. The *mec* region may have been acquired from coagulase-negative staphylococcal species *(39)*.

The expression of resistance encoded by mosaic or acquired PBPs is often dependent on very specific conditions. Several staphylococcal genes, called *fem* (factors essential for methicillin resistance) or *aux* (auxiliary) factors, have been identified—the inactivation of which results in reversion to susceptible phenotype despite the expression of PBP2a *(40)*. In most cases, these *fem* genes encode enzymes responsible for the synthesis of peptidoglycan precursors. Similarly, the expression PBP-mediated resistance in *S. aureus*, *E. faecalis*, and *E. faecium* is dependent upon the presence of specific glycosyltransferases with which the low-affinity transpeptidases can work *(41–43)*.

Enterococci are intrinsically resistant to some β-lactams, especially the cephalosporins, at high levels. Resistance is related to the low affinity of these compounds for the enterococcal PBP5 *(32,44)*. Strains resistant to even higher levels of the penicillins, in the absence of production of β-lactamase, have been described with increasing frequency *(45,46)*. These strains include several species, but *E. faecium* is most commonly reported from clinical laboratories. Most of these high-level resistant strains have one or more point mutations in *pbp5* that are thought to lower the affinity for penicillin and other β-lactams *(47)*. Accumulation of point mutations has been associated with lowered affinity and elevated minimum inhibitory concentrations (MICs) in the laboratory, supporting the notion that these point mutations contribute to higher levels of resistance *(48)*. Enterococcal strains expressing high levels of resistance to β-lactams through low-affinity PBPs are also more resistant to β-lactam–aminoglycoside synergism, even in the absence of high levels of aminoglycoside resistance *(49)*. Single-agent β-lactam therapy is precluded for such strains, leaving the glycopeptides as the antibiotic class of choice. The continued spread of glycopeptide resistance in penicillin-resistant enterococci (see below) is a problem at many large centers *(46)*.

β-Lactamase–Mediated Resistance A more important (than target resistance) and frequent mechanism of bacterial resistance to β-lactam antibiotics, especially in gram-negative bacteria, is the production of β-lactamases—enzymes that hydrolyze the β-lactam ring (Fig. 85-2). The reactive β-lactam ring is required for the formation of a covalent bond between the antibiotic and its PBP target. Destruction of this ring results in the loss of antimicrobial activity. The β-lactamases form a broad family of enzymes and, along with the PBPs, are classified as serine D, D-peptidases *(50)*. The homologies between many β-lactamases and PBP have led to the suggestion that β-lactamases have evolved from PBPs.

Two classification schemes for the β-lactamases are widely used. The first is based on primary structure and has been proposed by Ambler et al. *(51,52)* (Table 85-1). The other scheme (Bush–Jacoby–Medeiros classification) relies on the substrate specificity of the enzymes (53) (Table 85-2). There are many more classes and subclasses in this scheme, since single-point mutations in the gene encoding an enzyme may result in substantial changes in substrate specificity. The Ambler scheme is more frequently employed, likely because of its comparative simplicity.

Staphylococcal β-lactamase production became widespread within a few years of the clinical introduction of penicillin *(54,55)*. By the mid-1940s, β-lactamase–producing *S. aureus* strains were prevalent within hospitals, necessitating the introduction of vancomycin and semisynthetic penicillins such as methicillin, nafcillin, and oxacillin. In contrast to observations of class A enzymes in gram-negative bacilli, staphylococcal β-lactamase has not evolved to a broader spectrum over the decades. The importance of β-lactamase production in gram-positive bacteria remains essentially restricted to staphylococci.

The epidemiology of β-lactamase–mediated resistance in gram-negative bacilli is far more complex than in gram-positive bacteria. Hundreds of different β-lactamases have been described in gram-negative bacteria over the past 3 decades. The most problematic and prevalent of these enzymes are those that confer resistance to expanded spectrum cephalosporins. Earlier versions of these extended-spectrum β-lactamases (ESBLs) were progeny of narrower spectrum enzymes that fall, like the staphylococcal β-lactamase, into Ambler class A. The most common enzymes of this class among clinical isolates are related to the widely prevalent TEM-1 and SHV-1 enzymes (53). TEM-1 is widely prevalent as the cause of ampicillin resistance in *E. coli*, *Haemophilus influenzae*, and in some cases *N. gonorrhoeae*, whereas SHV-1 is the chromosomal β-lactamase found in most *K. pneumoniae* strains. TEM-1 and SHV-1 are broad-spectrum β-lactamases that hydrolyze

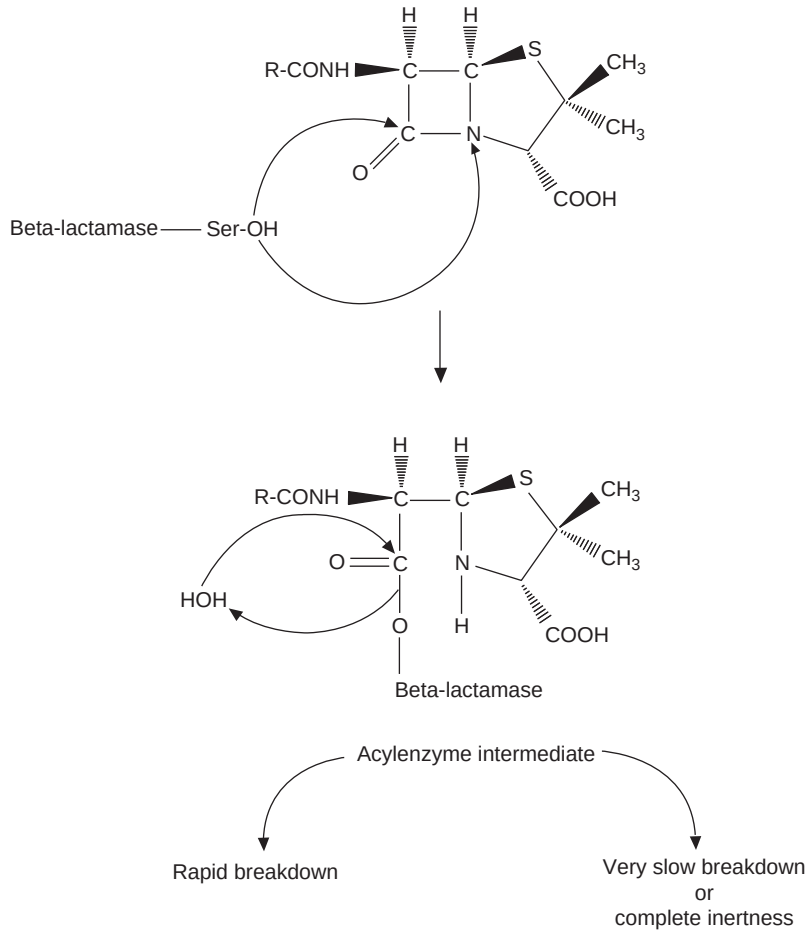

FIGURE 85-2 Reactions of serine-type peptidases (which include many β-lactamases) with the four-membered β-lactam ring of β-lactam antibiotics. Rapid breakdown is characteristic of lactamases, whereas slow breakdown or complete inertness is characteristic of PBPs. (Modified from Ghuysen JM. Serine β-lactamases and PBPs. *Annu Rev Microbiol* 1991;45:37–67).

the penicillins (ampicillin, mezlocillin, and piperacillin) with greater efficiency than the cephalosporins *(56)*. ESBLs result from the accumulation of point mutations within the TEM-1 or SHV-1 enzymes that serve to "open up" the active site of the enzyme, allowing binding of the bulky extended-spectrum cephalosporins. These point mutations are often found in association with cellular characteristics that serve to enhance the phenotypic expression of resistance, such as the location downstream of strong promoters (leading to increased β-lactamase quantity) and reductions in the expression of outer membrane proteins (OMPs; porins that serve as conduits for the entry of antibiotics into the periplasmic space). Genes encoding TEM- and SHV-related ESBLs are most commonly found on transferable plasmids with resistance determinants to numerous other antimicrobial classes. Strains elaborating ESBLs, most commonly *Klebsiella*, have been responsible for several outbreaks of infection and colonization in Europe and the United States. Outbreaks have been ascribed to clonal dissemination, plasmid dissemination, or both *(30,57,58)*.

TABLE 85-1

Molecular Classification of β-Lactamases

Class	*Examples*
A	TEM, SHV (gram-negative microorganisms), PC1 (*S. aureus*)
B	Metallo-β-lactamases of *S. maltophilia*, recently described NDM-1 in *Klebsiella* and others.
C	AmpC (clinically relevant particularly for *Enterobacter* spp., *C. freundii*, *S. marcescens* and *P. aeruginosa*)
D	OXA-type enzymes (found commonly in *A. baumannii*)

(From Ambler RP. The structure of β-lactamases. *Philos Trans R Soc Lond B Biol Sci* 1980;289:321–331.)

Mutations to extend the spectrum of TEM-1 or SHV-1 and allow hydrolysis of extended-spectrum cephalosporins commonly yield increased susceptibility to inhibition by β-lactamase inhibitors. In the clinical setting, however, the production of multiple enzymes and/or overproduction of individual enzymes often confer *in vitro* resistance to β-lactam/β-lactamase inhibitor combinations in ESBL producers. The relative scarcity of ESBL producers has made controlled studies of the efficacy of different therapies impractical, but carbapenems have been most effective in animal studies of infections with ESBL producers as well as in case reports and small series. Most of the clinical experience has been with imipenem *(57,59)*.

In the past decade, resistance to extended-spectrum cephalosporins in Enterobacteriaceae has been increasingly attributed to the expression of β-lactamases of the CTX-M family. They are naturally resistant to cephalosporins. They fall into Ambler class A, are generally more active against ceftriaxone and cefepime than

TABLE 85-2

Bush–Jacoby–Medeiros Functional Classification Scheme for β-Lactamases

Group	*Description*	*Examples*	*Molecular Class*
1	Cephalosporin hydrolyzing enzymes not inhibited by clavulanic acid	AmpC	C
2a	Penicillin hydrolyzing enzymes inhibited by clavulanic acid	*Bacillus licheniformis* 749, TEM	A
2b	Broad-spectrum enzymes inhibited by clavulanic acid	TEM-1	A
2be	Extended-spectrum enzymes inhibited by clavulanic acid	TEM 3–26	A
2c	Carbenicillin hydrolyzing enzymes inhibited by clavulanic acid	PSE-1.3.4	A
2d	Cloxacillin hydrolyzing enzymes inhibited by clavulanic acid	OXA-1–11	D
2e	Cephalosporin hydrolyzing enzymes inhibited by clavulanic acid	Inducible cephalosporinase from *Proteus vulgaris*	A
3	Metallo-β-lactamases	*S. maltophilia* GN12873	B
4	Penicillin hydrolyzing enzymes not inhibited by clavulanic acid	*B. fragilis* G237	?

(From Bush K, Jacoby GA, Medeiros AA. A functional classification scheme for beta-lactamases and its correlation with molecular structure. *Antimicrob Agents Chemother* 1995;39(6):1211–1233.)

ceftazidime, are susceptible to inhibition by β-lactamase inhibitors, are plasmid-mediated, and unlike the ESBL TEM and SHV variants, are very commonly found in *E. coli* as well as *K. pneumoniae*. In fact, the growing worldwide problem of increasing cephalosporin resistance in *E. coli* is almost exclusively attributed to the spread of CTX-M-type enzymes (60). The expression of these enzymes is frequently associated with resistance to fluoroquinolones, creating significant problems for empirical therapeutic regimens for community-acquired *E. coli* infection (60).

Resistance to extended-spectrum cephalosporins may also be conferred by the expression of regulatory mutants of Ambler's class C β-lactamases. These enzymes are broadly active cephalosporinases (which also hydrolyze penicillins) and are resistant to clinically achievable concentrations of β-lactam/β-lactamase inhibitor combinations (53). They are encoded by the *ampC* gene—a chromosomal gene widely disseminated among Enterobacteriaceae and *Pseudomonas aeruginosa*. In some species, such as *E. coli*, *ampC* is poorly expressed and not under regulatory control due to the absence of the *ampR* gene. The product of the *ampR* gene interacts with different cell wall breakdown products in a manner that results in AmpR becoming either a suppressor or an activator of *ampC* transcription *(61–63)*. Under normal circumstances, cells with inducible AmpC β-lactamases employ AmpD (a cellular amidase encoded by *ampD*) to reduce intracellular quantities of cellular breakdown product anhydro-muramyl-tripeptide, which results in an excess of uridine diphosphate (UDP)-muramyl-pentapeptide. UDP-muramyl-pentapeptide interaction with AmpR maintains AmpR as a repressor of *ampC* transcription. When exposed to certain antibiotics that favor the production of anhydro-muramyl-tripeptide (such as cefoxitin, clavulanic acid, and imipenem), the ability of AmpD to convert this substrate is overwhelmed, and interaction between anhydro-muramyl-tripeptide and AmpR converts AmpR into an activator of *ampC* transcription (induction). *ampR* is present and *ampC* is under regulatory control in *Enterobacter* species, *Serratia marcescens*, *Citrobacter freundii*, and *P. aeruginosa*, among others *(63–65)*. Imipenem is an efficient inducer of *ampC* expression, but it is a poor substrate for the *ampC* β-lactamase. It therefore remains active even in the presence of induced β-lactamase (as long as a concomitant mutation that decreases the entry of imipenem into the periplasmic space is not present—see below). Newer cephalosporins such as ceftazidime, ceftriaxone, and others are efficiently hydrolyzed by the AmpC but are poor inducers, and therefore, appear active *in vitro* against bacteria expressing inducible AmpC.

Unfortunately, the oxyiminocephalosporins (e.g., ceftazidime, cefotaxime, and ceftriaxone) are very good selectors of mutants that express high levels of the ampC β-lactamase constitutively. Their ability to select constitutive mutants results from their status as weak inducers. Constitutive AmpC production commonly results from null mutations in *ampD*, with subsequent intracellular accumulation of anhydro-muramyl-tripeptide and constitutive activation of *ampC* expression *(61)*. Thus, from among a population of microorganisms, the small number (1 in 10^{6-7}) of preexisting cells with mutations *ampD* are selected for growth by the presence of antibiotic with potent activity against strains in which *ampC* expression is repressed. Once constitutive expression occurs, the strains are essentially resistant to all β-lactams except for carbapenems and cefepime *(64)*. Cefepime's major advantage in this regard appears to be its status as a zwitterion, allowing it to achieve high periplasmic concentrations by rapid passage through the outer membrane. Caution should be exercised in using cefepime to treat deregulated *ampC* mutants of *Enterobacter* species, however, since reports of the emergence of cefepime resistance (associated with a reduction in an OMP) in these strains during therapy have been published *(66)*.

In a study of *Enterobacter* bacteremia by Chow et al. *(67)*, the major class of antibiotics associated with selection of resistance was the newer cephalosporins as opposed (especially) to the newer penicillins. Concomitant use of aminoglycosides did not prevent the emergence of this resistance.

In this study, resistance developed in 19% of all patients treated with newer cephalosporins. Therapeutic failure occurred in about half of those patients. For all patients infected with a multiply resistant strain, the mortality rate was significantly increased. Infection with a multiply resistant strain was closely associated with prior use of a new cephalosporin. Although cephalosporins have been most frequently associated with the emergence of AmpC mutants in the clinical setting, virtually any antibiotic active against repressed strains but inactive against overexpressing strains should be avoided when treating *Enterobacter* infections.

Plasmid-encoded versions of AmpC enzymes have been observed in several species of Enterobacteriaceae, including *E. coli* and *K. pneumoniae*, among others *(68)*. These strains express high levels of the AmpC enzyme constitutively and have resistance profiles identical to multiply β-lactam–resistant *Enterobacter* species and *P. aeruginosa*. The most prevalent of these enzymes is CMY-2, derived from the *Citrobacter* AmpC enzyme *(69)*. The carbapenems are the only therapeutically reliable β-lactams against these strains. It is noteworthy, however, that one such enzyme, designated ACT-1, was identified in a porin-deficient strain of *K. pneumoniae*, where it conferred resistance to imipenem and was associated with failures of this antibiotic in clinical settings *(70)*.

Resistance to β-lactam/β-lactamase inhibitor combinations can result from several different mechanisms, all of which involve the production of β-lactamase. As noted above, expression of an AmpC enzyme confers resistance to both cephalosporins and β-lactam/β-lactamase inhibitor combinations. Resistance to inhibitor combinations alone can be conferred by increased production of a normally susceptible enzyme (i.e., TEM-1), permeability defects, or a combination of both mechanisms *(71)*. Specific inhibitor-resistant enzymes can also result from mutation of TEM-1 or SHV-1, similar to extending the cephalosporin spectrum of these β-lactamases *(72)*. Resistance to both extended-spectrum cephalosporins and β-lactam/β-lactamase inhibitor combinations is quite common in the clinical setting. This phenotype can be conferred by production of AmpC enzymes, by the increased production of an ESBL, or by the expression of more than one enzyme (one an ESBL, the other a more common enzyme such as SHV-1) *(73,74)*.

Carbapenem hydrolyzing enzymes are increasingly identified. *S. maltophilia* is an intrinsically carbapenem-resistant species that can emerge as an important pathogen in clinical settings *(75)*. It owes its resistance to the synthesis of an inducible, zinc-dependent carbapenemase encoded on the chromosome. Cation (usually zinc)-dependent β-lactamases (generally classified as IMP or VIM enzymes) capable of hydrolyzing carbapenems have been described in several species *(76)*. Among anaerobic bacteria, a French study showed that approximately 1% to 2% of examined *B. fragilis* isolates carried a carbapenemase gene, although the gene was expressed in only about half of these *(77)*. In *Acinetobacter baumannii*, carbapenem resistance has been associated with the expression of class D enzymes (OXA type) *(78)*. Finally, class A carbapenemases—previously described as chromosomally encoded enzymes occurring in scattered isolates of *Enterobacter* and *Serratia (79)*—have now spread among gram-negative bacteria via plasmids. The most common variants are the *K. pneumoniae* carbapenemases (KPCs). In 2001, a novel class A carbapenemase, encoded on a 50-kb nonconjugative plasmid, was described in a clinical *K. pneumoniae* isolate displaying high-level imipenem resistance (16 μg/mL) and termed at that time KPC-1 *(80)*. Kinetic studies revealed that the purified enzyme hydrolyzed not only carbapenems, but penicillins, cephalosporins, and—in stark contrast to the class B metallo-carbapenemases—aztreonam as well. Concomitant losses of porin genes (*ompK35* and *ompK37*) were also felt to play a small role in carbapenem resistance, as MICs for carbapenems were reduced in *E. coli* transformants with $bla_{\text{KPC-1}}$ as compared to the parent strain (although still above the susceptible range). Shortly after this report, an outbreak of KPC-producing *K. pneumoniae* was described among ICU patients in a New York medical center (81); over the succeeding years, KPC β-lactamases have disseminated not only among most continents on the earth but also among numerous other Enterobacteriaceae and to other families of microorganisms, such as *P. aeruginosa (82)*. The combination of carbapenem resistance, an inhibitor-resistant phenotype (83), resistance to monobactams, and the (largely unexplained) success of *Klebsiella* species expressing these enzymes at, disseminating geographically render these microorganisms particularly difficult to treat.

β-Lactamase Expression Combined with Reduced Access

The ultimate outcome of an interaction between a β-lactamase molecule and a β-lactam antibiotic will depend not only on the intrinsic activity of the β-lactamase but also on the quantity of the two molecules present at the time of interaction. Weak β-lactamases in sufficient concentration will be able to successfully defend against β-lactam attack, whereas even highly active β-lactamases can be overwhelmed by a sufficient quantity of β-lactam antibiotic. The ability of gram-negative bacilli to restrict β-lactam access to the periplasmic space and to concentrate β-lactamases within that space offers a powerful advantage for tilting the balance of power in favor of the β-lactamase. In *P. aeruginosa*, a single OMP—OMP D2—is required for transport of imipenem into the periplasmic space (84,*85*) (Table 85-3). Strains that decrease the expression of OMP D2 are resistant to imipenem only in the presence of the expression of the AmpC β-lactamase, even though it is an inefficient hydrolyzer of imipenem (84). This same combination of mechanisms has been shown to lead to carbapenem resistance in *Enterobacter* species and *Proteus rettgeri (67,86,87)*. Clinical isolates of carbapenem-resistant *K. pneumoniae* expressing a plasmid-mediated AmpC β-lactamase combined with the loss of expression of two nonspecific porins have also been reported *(70)*.

The balance can also be tipped in favor of the β-lactamases by pumping the β-lactam molecules out of the periplasmic space. A full description of the different pump classes is beyond the scope of this chapter. The reader is referred for more detailed information to an excellent review *(88)*. Analysis of the *P. aeruginosa* genome suggests the presence of as many as 12 RND (resistant-nodulation–cell division) tripartite efflux pumps—pumps characterized by their broad substrate specificity (Table 85-4). Most of these pumps are minimally expressed at baseline, but their expression can be augmented by mutations that

TABLE 85-3

Susceptibility of Mutants of *Pseudomonas aeruginosa* M2297 to Carbapenems in Relation to their Expression of Chromosomal β-Lactamase and D2 Porin

Class I β-Lactamase[a]	*D2 porin*	*Imipenem*	*Ceftazidime*
Inducible[b]	+	1	1
Derepressed	+	1	32
Basal	+	0.12	1
Inducible	–	16	1
Derepressed	–	16	32
Basal	–	0.5	1

[a]The amount of β-lactamase produced by the inducible microorganisms depended on the presence and concentration of inducers. Derepressed mutants made the enzyme copiously regardless of induction, and basal mutants had only a trace level.
[b]Note that β-lactamase–inducible or derepressed microorganisms were less susceptible to imipenem than were the basal mutants. This protection gave clinical resistance (MIC ≥ 8 μg/mL) only when D2 porin was absent. Moreover, loss of the β-lactamase from the D2 porin-deficient microorganisms caused almost full restoration of imipenem susceptibility, confirming that resistance required both the enzyme and the impermeability. Ceftazidime, which is a labile weak inducer of the class I enzyme and which cannot traverse the pores formed by D2 porin, retained equal activity against β-lactamase-inducible and basal microorganisms irrespective of their D2 porin expression. However, its activity was lost against the derepressed mutants.
MIC, minimal inhibitory concentration.
(From Livermore DM. Carbapenemases: the next generation of β-lactamases. *ASM News* 1993;59:129–135.)

can be selected by exposure to antimicrobial agents. The degree of resistance conferred by pump activity alone is generally relatively modest, but their expression can augment the levels of resistance associated with more potent mechanisms of resistance, such as the expression of β-lactamase. One emblematic outbreak of infection caused by *P. aeruginosa* strains expressing the combination of the MexAB–OprM and MexEF–OprN RND pumps in association with β-lactamase expression and OMP reduction involved 67 patients and required cefepime–amikacin combinations (to which the strains were modestly susceptible) for successful treatment *(89)*.

TABLE 85-4

Resistance-Nodulation–Cell Division (RND) Pumps Characterized in *Pseudomonas aeruginosa* and their Substrate Specificities

RND Pump	*Substrates*
MexAB–OprM	Q, M, T, L, C, novobiocin, β-lactams except imipenem, aminoglycosides under low ionic strength conditions
MexCD–OprJ	Q, M, T, L, C, novobiocin, penicillins except carbenicillin and sulbenicillin, cephems except ceftazidime, flomoxef, meropenem
MexEF–OprN	Chloramphenicol, quinolones, trimethoprim, carbapenems
MexXY–OprM	Q, M, T, L, C, aminoglycosides, penicillins except carbenicillin and sulbenicillin, cephems except cefsulodin and ceftazidime, meropenem

Q,M,T,L,C, quinolones, macrolides, tetracyclines, lincomycin, chloramphenicol.

CYCLIC GLYCOPEPTIDES

The cyclic glycopeptides include vancomycin, teicoplanin (not available for clinical use in the United States), as well as a number of compounds such as avoparcin, ristocetin, actaplanin, and others that have not been used in human infections *(90)*. These antibiotics are highly active against gram-positive bacteria. Teicoplanin is more active against enterococci, whereas vancomycin tends to be more active against the staphylococci. Molecular weights of cyclic glycopeptides range from 1,200 to 2,000 Da. They all have a central-core heptapeptide, of which three amino acids are highly conserved. Some of these amino acids are crucial to the mode of action of this class. Other important glycopeptide components include the chlorine substituents and the sugars *(90)*.

Gram-positive bacteria, most commonly enterococci, expressing resistance to the cyclic glycopeptides have now been described throughout the world and are causes of significant morbidity and mortality in hospitalized patients *(91,92)*. The large majority of vancomycin-resistant enterococci (VRE) are *E. faecium* that also express resistance to ampicillin—the other major antimicrobial agent used to treat enterococcal infections *(46)*. They are also frequently resistant to fluoroquinolones, macrolides, penicillins, and to high levels of aminoglycosides *(93)*, rendering most therapies inactive. In the past few years, four new agents (quinupristin–dalfopristin, linezolid, daptomycin, tigecycline) have been introduced with *in vitro* activity against VRE, although only two (quinupristin–dalfopristin, linezolid) are approved by FDA for the treatment of VRE infections.

The cyclic glycopeptides bind to acyl-D-alanyl:D-alanine at the terminus of the pentapeptide of the peptidoglycan precursor *(90)*. Glycopeptides prevent cleavage of the terminal D-Ala that is required for establishing the peptide cross-link between adjacent peptide chains. Glycopeptide binding of D-Ala:D-Ala is also thought to cause a "steric" inhibition of transglycosylation, because the bulky antibiotic prevents the transglycosylase from interacting with the peptidoglycan. The vast majority of bacterial species synthesize peptidoglycan precursors terminating in D-Ala:D-Ala. The size exclusion limits of the porin proteins of gram-negative outer membranes preclude activity against gram-negative bacilli.

Enterococcal vancomycin resistance has been attributed to several different genetic clusters (*VanA–E*, *G*, and *L*) *(94–98)*. A seventh gene cluster conferring vancomycin resistance (*VanF*) has been described in the biopesticide *Paenibacillus popillae* but has not been found elsewhere *(99)*. The vancomycin resistance operons can be broadly separated into two groups: those that synthesize peptidoglycan precursors terminating in D-lactate (*vanA*, *B*, and *D*, hereafter referred to as the lactate operons) and those that synthesize precursors terminating in D-serine (*vanC*, *E*, *G*, and *L*, hereafter referred to as the serine operons). The lactate operons (specifically *vanA* and *vanB*) have spread widely throughout the world and are the predominant operons conferring acquired glycopeptide resistance. They are focused primarily in *E. faecium*. The serine operons are either intrinsic to some minor species of enterococci (*VanC* in *Enterococcus casseliflavus*, *Enterococcus flavescens*, and *Enterococcus gallinarum*) or have been described in only very rare isolates of *E. faecalis* (*vanE*, *G*, and *F*). *vanA* and *vanB* have been described in transposable elements *(21,24)* and are generally transferable to enterococcal recipients *in vitro*, whereas neither *vanD* nor the serine operons have been shown to be transferable. Structural comparisons of representative lactate and serine operons are shown in Figure 85-3.

Three functions of the different operons are essential to confer resistance to glycopeptides. First, the resistant substrate must be synthesized (Fig. 85-4). The *vanH* genes of the lactate operons encode a dehydrogenase that converts cellular pyruvate to D-lactate, whereas the *vanT* genes of the serine operons convert cellular L-serine to D-serine (hatched genes in Fig. 85-3). The second critical function is ligating the resistant substrate to D-alanine, forming the depsipeptide that is linked to the precursor UDP-muramyltripeptide to form the pentapeptide precursor. The ligase genes carry the designation specific to the different operons, *vanA*, *B*, *C*, *D*, *E*, or *G* (in black in Fig. 85-3). The third essential function is the depletion of the cellular pool of normal D-Ala–D-Ala dipeptide, ensuring that the precursors produced are almost exclusively of the resistant variety. In the lactate operons, the *vanX* gene encodes a dipeptidase that efficiently cleaves D-Ala–D-Ala, thereby ensuring incorporation of D-Ala–D-Lac into the pentapeptide precursors. The *vanY* gene of the lactate operons encodes a carboxypeptidase that cleaves the terminal D-Ala from normal pentapeptide precursor, depriving it of the bond breaking that provides the energy to make the peptide cross-link. The *vanY* gene is not essential for resistance but serves to amplify the level of resistance when it is expressed. The *vanC* operon encodes an enzyme with both dipeptidase and carboxypeptidase activity ($vanXY_C$). A homologous gene is also found in the *VanE* serine operon. The *vanG* operon, however, contains two open reading frames with *vanY* homology ($vanY_{G1}$, $vanY_{G2}$). It has been hypothesized that one or both of these enzymes may also possess dipeptidase activity *(97)*. The *vanA* operon contains a seventh gene, *vanZ*, that results in increased levels of teicoplanin resistance by an unknown mechanism *(100)*. The *vanB* operon contains a seventh gene, designated *vanW*, whose function is unknown at present *(101)*, but it is not required for resistance.

In all of the operons, expression of resistance is regulated by two-component regulatory systems encoded by the *vanS* and *vanR* genes (gray in Fig. 4) that are stimulated by the presence of one or more glycopeptides in the milieu *(101,102)*. VanR regulates the transcription of the

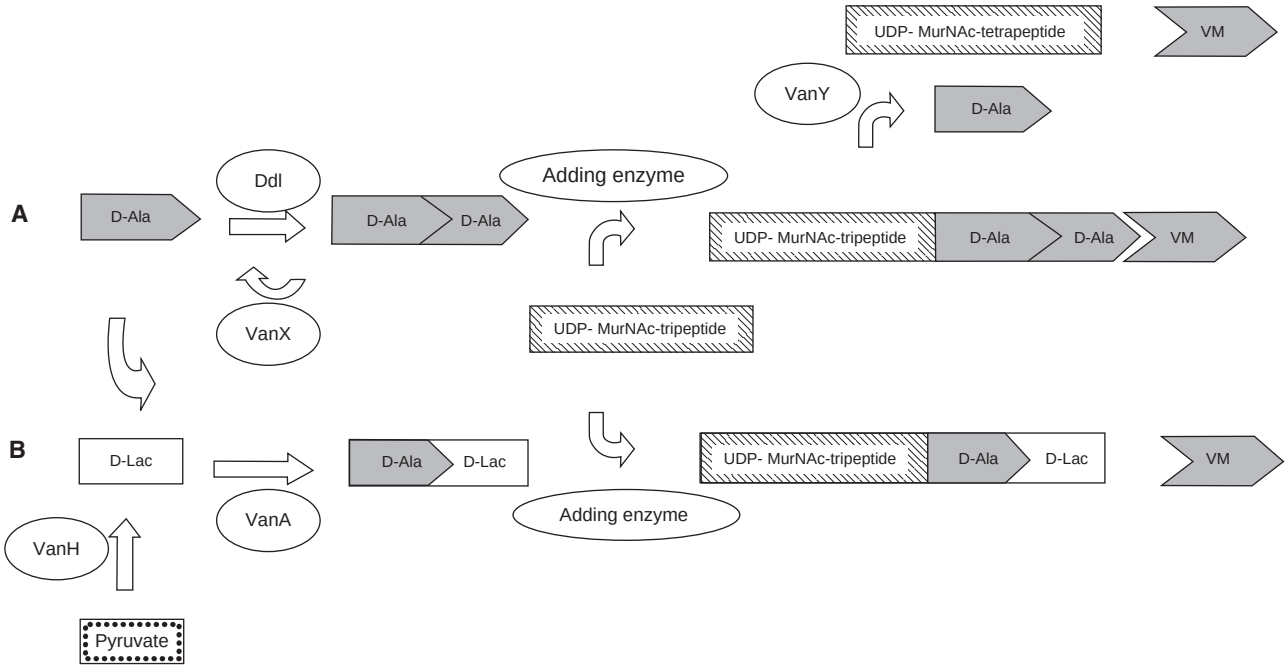

FIGURE 85-4 Schematic representation of peptidoglycan biosynthesis in glycopeptide-susceptible **(A)** and glycopeptide-resistant (VanA-type) **(B)** cells. The end result in vancomycin-resistant cells is peptidoglycan precursors terminating in D-lactate or D-serine, which bind vancomycin poorly. (From Gold HS. Vancomycin-resistant enterococci: mechanisms and clinical observations. *Clin Infect Dis* 2001;33(2):210–219).

polycistronic message that encodes the three proteins essential for vancomycin resistance. Depending on its phosphorylation state, VanR can serve as either a repressor or activator of transcription. The phosphorylation state of VanR is determined by VanS, the transmembrane sensor component of the two-component system. *vanA* strains are resistant to both vancomycin and teicoplanin, because the presence of both antibiotics induces expression of the *vanA* operon. *vanB* strains remain susceptible to teicoplanin because the operon is not induced by the presence of teicoplanin. Teicoplanin is not a viable therapeutic alternative, however, since mutations resulting in either constitutive expression of the operon or sensitivity of $vanS_B$ to induction by teicoplanin are frequent enough to lead to the emergence of resistance on therapy *(99)*.

Both *vanA* and *vanB* operons have been shown to be mobile. The *vanA* operon is characteristically encoded by a ca. 10-kb Tn*3*-family transposon designated Tn*1546 (17)*. This transposon has been found on plasmids, and it is presumed that the transfer of conjugative plasmids explains most of the genetic variability observed in *vanA* clinical isolates. *vanB* is characteristically encoded in the bacterial chromosome, although reports of plasmid-mediated *vanB*-type resistance have been published *(103,104)*. Transfer of *vanB*-type resistance to enterococcal recipients *in vitro* has been observed and is usually accompanied by the acquisition of large segments of chromosomal DNA *(105)*. Two transposons or transposon-like *vanB* elements have been described. Tn*1547* is a composite transposon whose mobility is conferred by flanking copies of IS*256*-related IS elements *(106)*. Tn*5382* (and its identical relative Tn*1549*) is a 33-kb transposon with similarities to the conjugative transposons seen frequently in many species of gram-positive cocci *(22)*. The contribution of these various transposons to the genetic variability observed in *vanB*-type enterococci is probably substantial.

Soon after the discovery of the vancomycin resistance operons in enterococci, *in vitro* studies suggested that the *vanA* operon could be transferred and expressed in *S. aureus*. As of early 2010, nine total cases of so-termed vancomycin-resistant *S. aureus* have been identified in the United States, with an additional two cases reported from India and Iran (107). Not all of these cases have undergone extensive genetic investigation. Fortunately, neither intra- nor interhospital spread of any of these microorganisms has been documented.

Mutational resistance to vancomycin in *S. aureus* has been sporadically reported over the past few years. In many cases, these strains have been isolated from patients (generally dialysis patients) who have been treated with long-term vancomycin therapy. Resistance is associated with enlargement of the staphylococcal cell wall, and the cell wall itself contains large numbers of unlinked precursors, which can potentially serve as targets for vancomycin binding (*108,*109). It has been postulated that resistance results from vancomycin being sequestered within the enlarged cell wall (soaked up like a sponge), preventing achievement of adequate concentrations of vancomycin at the cell membrane, where precursors are added to the growing peptidoglycan. It is likely that this mechanism of resistance is favored only in the setting of persistent and significant vancomycin exposure, since spread to other patients has not been documented and reversion to normal (susceptible) phenotype commonly occurs when *in vitro* selective pressure by vancomycin is removed. Animal data does suggest, however, that despite marginal MICs (*ca*. 8–16 μg/mL), this type of resistance will result in vancomycin treatment failure *(110)*.

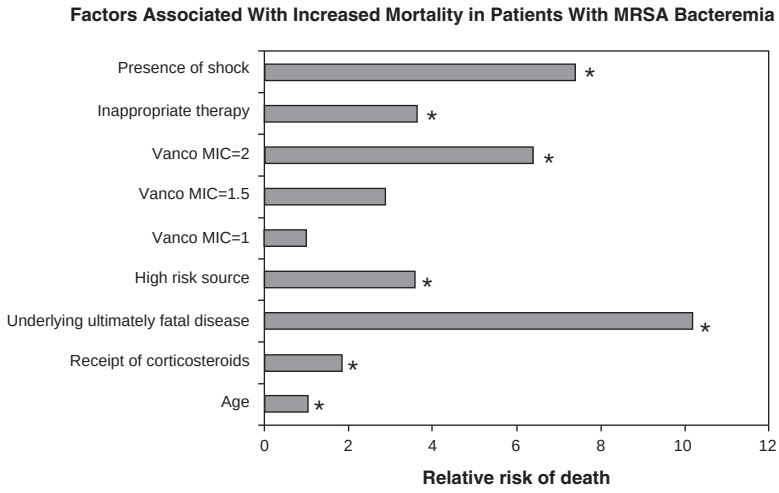

FIGURE 85-5 Factors associated with increased mortality in patients with MRSA bacteremia. * = $p \leq .05$. Note that vancomycin MIC of ≥2 is associated with nearly a sevenfold increase in the relative risk of mortality when empirical vancomycin therapy is used. (Adapted from Soriano A, Marco F, Martinez JA, et al. Influence of vancomycin MIC on the treatment of methicillin-resistant *S. aureus* bacteremia. *Clin Infect Dis* 2008;46(2):193–200.)

A more subtle type of resistance to glycopeptides in *S. aureus* is perhaps best termed as "MIC creep." In recent years, some investigators have noted that, on average, MICs for vancomycin in staphylococci have been increasing. Some strains exhibit MICs that are 2 or 4 μg/mL, which were still within the susceptible range until both CLSI and EUCAST recently lowered their susceptibility breakpoints to ≤2. The rationale for this lowering of the breakpoints is the accumulating evidence from both laboratory and clinical studies that strains with vancomycin MICs >2 μg/mL respond poorly to vancomycin therapy (Fig. 85-5) *(111,182)*. These clinical and laboratory data are supported by pharmacodynamic estimates suggesting that appropriate targets cannot be reached with safe vancomycin doses for strains that exhibit that level of susceptibility.

AMINOGLYCOSIDES

Structure and Mechanism of Action

The aminoglycosides are made of three amino sugars in glycosidic linkage. As such, they are polycationic compounds. They are divided into two classes: the streptidine class, of which streptomycin is the only member in clinical use, and the 2-deoxystreptamine class, which includes all other clinically used aminoglycosides. Uptake of aminoglycosides into bacterial cells is via active transport through the cytoplasmic membrane. The intracellular target of all aminoglycosides is the 30S subunit of the ribosome. For streptomycin, only a single ribosomal-binding site exists, whereas for the others, multiple binding sites are available. In gram-negative microorganisms, aminoglycoside uptake probably occurs via a two-stage process in which the cationic antibiotic displaces magnesium ions linking lipid A subunits. This displacement results in disruption of the outer membrane and diffusion of the antibiotic into the periplasmic space. It seems likely that, in addition to its activity at the ribosome, disruption of the cytoplasmic membrane also plays a role in the activity of these agents. Binding to the 30S ribosomal subunit results in extensive translational misreading and synthesis of abnormal proteins, many of which integrate into the membrane, resulting in further disintegration. It is the sum of these effects that is thought to lead to the bactericidal activity of the aminoglycosides.

Mechanisms of Resistance

Simple mutation of genes encoding ribosomal proteins can result in streptomycin resistance, since only a single binding site exists for this antibiotic. Ribosomally resistant mutants have been described clinically, primarily in enterococci and mycobacteria. These mutants remain susceptible to the other aminoglycosides. Mutants with altered membrane transport (the so-called small colony–formers) can also be resistant to aminoglycosides. These cells have altered membrane proton motive force and are unable to transport aminoglycosides across the cytoplasmic membrane. Such mutants are less virulent than their wild-type parents *(112)*.

The primary mechanism of bacterial resistance to aminoglycosides is enzymatic modification of the antibiotic *(113)* (Fig. 85-6). Such chemical modifications prevent binding of the aminoglycoside to the ribosome and may also decrease transport. Three major classes of modifying enzymes have been described that depend on the particular modification involved: phosphorylases, adenyl transferases, and acetyl transferases (Table 85-5). Resistance to all aminoglycosides is achievable by a combination of different enzymes.

The emergence of enzyme-mediated resistance to aminoglycosides in enterococci is a significant clinical problem. Because of their intrinsic tolerance to the bactericidal activity of all cell wall–active agents, effective treatment of serious enterococcal infections requires the synergistically bactericidal combination of a cell wall–active agent and an aminoglycoside. Since the most common genes encoding aminoglycoside resistance in enterococci were derived from the staphylococci, these two genera will be discussed together. Gentamicin resistance in strains of *S. aureus* and *Staphylococcus epidermidis* first appeared in the United States and elsewhere in the mid-1970s *(114)*. In 1979, the first case of high-level resistance to gentamicin, which results in resistance to synergistic bactericidal activity in enterococci, was reported (115). Resistance to aminoglycosides has spread widely in both genera since the first reports.

High-level resistance to gentamicin in both staphylococci and enterococci results most commonly from modification of the antibiotic by the 6′-acetyltransferase-2″phosph otransferase (6′-AAC-2″-APH) bifunctional enzyme, encoded

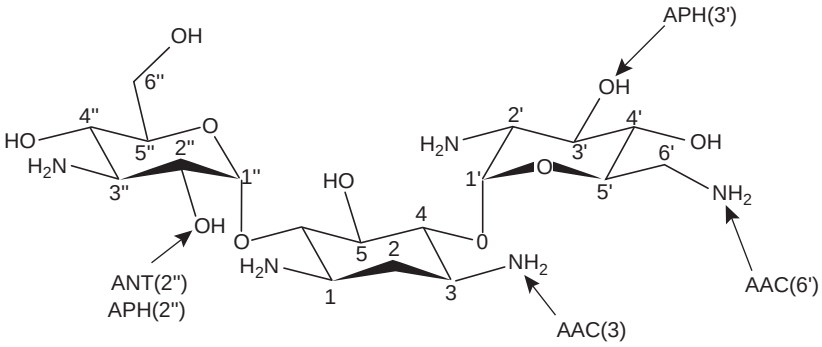

FIGURE 85-6 Prototypic aminoglycoside showing sites available for modification and modifications that have been shown to occur. (From Kotra LP, Haddad J, Mobashery S. Aminoglycosides: perspectives on mechanisms of action and resistance and strategies to counter resistance. *Antimicrob Agents Chemother* 2000;44(12):3249–3256).

by the *aacA–aphD* resistance gene *(116)*. The 6′-AAC component of the bifunctional enzyme confers resistance to amikacin, kanamycin, and tobramycin, whereas the 2″-APH component is primarily responsible for resistance to gentamicin and netilmicin. All strains that possess this gene are resistant to all of the above-mentioned aminoglycosides. Streptomycin, which is inactivated by a separate enzyme, is the single clinically available aminoglycoside not inactivated by the bifunctional enzyme. The nucleotide sequences of the genes responsible for the production of the bifunctional enzyme are identical in *S. aureus* and *E. faecalis*, and probably in *E. faecium*, *S. epidermidis*, and *Streptococcus agalactiae* as well *(116–121)*. These genes are often integrated into conjugative plasmids in both staphylococci and enterococci. In addition, the bifunctional enzyme gene has been found integrated into similar transposons in *S. aureus* (Tn*4001*), *S. epidermidis* (Tn*4031*), and *E. faecalis* (Tn*5281*) *(122–124)*. Two additional genes that confer resistance to aminoglycosides in enterococci have been described *(125)*. Unlike the bifunctional enzyme, these phosphotransferases do not confer resistance to a wide range of aminoglycosides. In addition, they may confer only relatively low levels of resistance (256 μg/mL) when tested by standard techniques, and therefore, may be missed in screening assays designed to detect the more common enzymes. Despite these lower levels of resistance, they do confer a resistance to cell wall–active agent–aminoglycoside synergism, so that they may prove to be important for the treatment of endocarditis.

(From Rather PN. Origins of aminoglycoside modifying enzymes. *Drug Resist Update* 1998;1:285–291.)

High-level gentamicin resistance in enterococcal isolates has spread rapidly in some hospitals, with one center reporting 55% of healthcare-associated enterococcal isolates resistant to gentamicin *(7)*. Gentamicin-resistant enterococci appear to be transmitted in the hospital setting on the hands of caregivers. Measures undertaken to limit such transmission have proven effective in containing outbreaks of infection and colonization with these microorganisms *(126)*. A growing body of evidence suggests that serious infection with these strains is associated with a worse prognosis than is associated with infections caused by susceptible isolates *(127–129)*. Episodes of failure (resulting in death or requiring surgical intervention for cure) in the treatment of enterococcal endocarditis caused by gentamicin-resistant strains have been reported *(119,128)*. Fortunately, most enterococcal infections can be successfully treated with a single agent. For more serious infections, it is essential to test all enterococcal isolates for high-level resistance to both gentamicin and streptomycin. Depending on the center, anywhere from 0% to 45% of enterococcal strains exhibiting high-level gentamicin resistance are reported to remain susceptible to streptomycin *(120,127)*. Combinations of cell wall–active agents and streptomycin should be effective in the treatment of strains exhibiting high-level gentamicin resistance but lacking high-level resistance to streptomycin, and vice versa *(119,121)*. At present, there is no reliable bactericidal combination of antibiotics against strains exhibiting high-level resistance to both gentamicin and streptomycin.

In gram-negative microorganisms, aminoglycoside-modifying enzymes are the most important mechanisms of resistance. In general, genes encoding such enzymes are carried on plasmids or transposons and are expressed constitutively. However, in the case of *S. marcescens* and *Providencia stuartii*, aminoglycoside acetyltransferases are normally encoded by chromosomal genes but are not well expressed *(130,131)*. It appears that, in these species, the chromosomally encoded acetyltransferases represent intrinsic housekeeping genes that are responsible for acetylating peptidoglycan *(132)*. Aminoglycosides bear structural resemblance to peptidoglycan and are acetylated as well. Normally these enzymes are produced in amounts sufficient to acetylate peptidoglycan but not to result in

resistance. Mutants that express these enzymes at high levels can be easily selected and probably account for many of the aminoglycoside-resistant strains of these species.

In recent years, a significant number of plasmid-encoded ribosomal methylase genes have been described as causes of aminoglycoside resistance in gram-negative bacteria. These enzymes methylate the ribosome, preventing aminoglycoside binding to the target sites. They have been described from both human and animal-derived isolates *(133)*.

Gram-negative bacteria also employ efflux pumps to assist with aminoglycoside resistance. In *P. aeruginosa*, the MexXY–OprM system is most commonly implicated in aminoglycoside efflux *(134)*, but MexAB–OprM and an analog of the *E. coli* small multidrug resistance type pump *emrE* (*emrE*$_{Pae}$) may also be involved *(135)*. The MexAB–OprM pump effluxes aminoglycosides *in vitro* but only when tested in low ionic strength media. An RND pump (AdeABC) has also been implicated in aminoglycoside resistance in *A. baumannii (136)*.

RESISTANCE TO THE FLUOROQUINOLONES

Structure and Mechanism of Action

The quinolone class of antibiotics can be historically traced to nalidixic acid. These antibiotics are potent inhibitors of cellular topoisomerases—enzymes required for winding and unwinding supercoiled, double-stranded DNA *(137)*. Quinolone antibiotics act by inhibiting DNA synthesis. Their targets are two Type 2 topoisomerases: DNA gyrase and topoisomerase IV. These two enzymes both exist as tetramers composed of different subunits (GyrA and GyrB of DNA gyrase; ParC and ParE of topoisomerase IV). DNA gyrase maintains negative supercoiling of DNA, whereas topoisomerase IV separates interlocked DNA strands formed during replication, facilitating segregation into daughter cells. Fluoroquinolones bind to the topoisomerase–DNA complexes and disrupt cellular processes involving DNA (replication fork, transcription of RNA, DNA helicase) *(138–140)*. The end result is cellular death by unclear mechanisms.

Fluoroquinolone affinity for the two targets varies with the compound, explaining to some extent differing potencies. The enzyme for which a particular fluoroquinolone has the greatest affinity is referred to as the primary target *(141–143)*. It is generally but not universally true that DNA gyrase is the primary target of fluoroquinolones in gram-negative bacteria, whereas topoisomerase IV is the primary target in gram-positive bacteria.

Alterations in Target Enzymes The most common mechanism of fluoroquinolone resistance is point mutations of the topoisomerase genes resulting in structural alterations in the topoisomerase enzymes. In *gyrA* and *parC*, resistance-associated mutations are often localized to a region in the enzyme that contains the active site tyrosine covalently linked to the broken DNA strand. This 130 base pair (bp) region of *gyrA* has been referred to as the quinolone-resistance-determining region (QRDR) *(144)*. X-ray crystallographic studies of a fragment of the *gyrA* enzyme suggest that QRDR mutations are clustered in three dimensions, supporting the hypothesis that this region constitutes a part of the quinolone binding site *(145)*. Frequent sites for resistance-associated mutations are serine 83 and aspartate 87 of DNA gyrase and serine 79 and aspartate 83 of *parC (146)*.

The level of resistance conferred by a point mutation in the primary target enzyme depends on the change of enzyme affinity created by the mutation and the affinity of the specific fluoroquinolone for the secondary target. As such, fluoroquinolones exhibiting strong affinity for both target enzymes may be less likely to promote the emergence of resistant strains in the clinical setting, since the activity against the secondary target may be enough to inhibit the bacterium even in the presence of primary target mutation. Consistent with this hypothesis, fluoroquinolone-species combinations for which single mutations result in significantly higher MICs (such as ciprofloxacin and *S. aureus* or *P. aeruginosa*) have readily selected resistant mutants in the clinical setting *(147)*.

Most highly resistant strains exhibit more than one mutation in both the *gyrA* and *parC* enzymes. It is noteworthy, in this context, that fluoroquinolone resistance conferred by enzyme mutations is, to some degree, a class resistance in which the activity of all fluoroquinolones is impacted. Thus, although single-point mutations conferring resistance to one fluoroquinolone may not yield MICs with clinically significant levels of resistance for another, the MICs for all fluoroquinolone will inevitably be increased. These preexisting mutations may then serve as the template to select additional mutations that result in more broad-spectrum fluoroquinolone resistance. Some experts suggest that this phenomenon should prompt clinicians to always use the most potent fluoroquinolone when treating infections, to prevent the emergence of resistance *(148)*. Some degree of skepticism about such recommendations is warranted, since potency varies with the microorganism (moxifloxacin may be more potent against *S. pneumoniae* than ciprofloxacin, but the reverse is true for *P. aeruginosa*), and fluoroquinolone concentrations achievable in many areas of the body (such as the gastrointestinal tract) may not approximate those needed to prevent the emergence of resistance. Such recommendations, therefore, should be tested in controlled clinical trials before they are widely adopted.

Mutations in *gyrB* and *parE* are less common than in *gyrA* and *parC* and cluster in the midportion of the subunit *(137)*. The true impact of these mutations on the expression of resistance remains to be determined.

Resistance Due to Decreased Intracellular Activity, Accumulation, or Extrusion Fluoroquinolones penetrate the outer membrane of gram-negative bacteria through porins, and so the absence of specific porins may theoretically impact the susceptibility. However, diffusion through outer and cytoplasmic membranes is generally sufficient to retain activity against strains solely lacking porins *(149)*. More important in reducing intracellular accumulation of fluoroquinolones is the expression of multidrug resistance pumps *(146)*. All of the pumps described above for *P. aeruginosa* have been shown to efflux fluoroquinolone antimicrobial agents *(150,151)*. A plasmid-mediated fluoroquinolone

efflux pump gene (*qepA*) has also been described, coexisting on a plasmid harboring resistance determinants to aminoglycosides, β-lactams, and other antibiotics *(152)*. By themselves, pumps generally confer only a low level of resistance to fluoroquinolones. However, their expression may amplify the level of resistance conferred by point mutations within the topoisomerase genes. By so doing, they may increase the risk that a given fluoroquinolone will select out resistant mutants through single-point mutations.

Transferable, plasmid-mediated resistance to fluoroquinolones through a gyrase protection mechanism has also been described (153,*154*). The genes conferring this resistance have been designated *qnr*. At least five similar proteins have now been described (QnrS, QnrB, QnrC, and QnrD), and this plasmid-borne mechanism of resistance to fluoroquinolones has now achieved worldwide spread *(155)*. By 2006, 20% of ceftazidime-resistant *K. pneumoniae* and 31% of ceftazidime-resistant *Enterobacter* species in a collection were found to possess at least one of the three then-known *qnr* genes *(156)*.

Enzymatic Modification of the Antibiotic The prevalence of a plasmid-associated gene encoding a variant of a common aminoglycoside acetyltransferase (*aac(6′)-Ib*-cr) was found to be over 50% in a collection of 78 fluoroquinolone-resistant isolates of *E. coli* from Shanghai (157). While acetylation (and inhibition) of ciprofloxacin was found to occur at the amino nitrogen on its piperazinyl substituent in isolates possessing this gene, this phenomenon was not observed for fluoroquinolones that do not possess an unsubstituted piperazinyl group. This mechanism of resistance, which may indeed be far more common than *qnr*-mediated resistance, can coexist with the latter as well as with topoisomerase mutations. It is likely that high-level resistance among fluoroquinolone-nonsusceptible microorganisms often results from a combination of the mechanisms described above.

Resistance to Newer Antimicrobial Agents

The emergence and spread of multiresistant enterococci in the past decade, accompanied by the inexorable increase in the prevalence of MRSA, has amplified the importance of finding new agents with clinically important activity against resistant gram-positive cocci. In contrast to the rather dismal situation with regard to novel antimicrobial agents directed at gram-negative pathogens, fully five such agents active against gram-positive bacteria have been licensed in the past decade or so and are discussed below. Indeed, the first four agents discussed exhibit activity *solely* against gram-positive pathogens.

Quinupristin–dalfopristin is a combination of two pristinamycins (one of the streptogramin A class, the other a streptogramin B) that have synergistic activity against *E. faecium* (although they are ineffective against *E. faecalis*) and *S. aureus*. The overall use of this combination has been limited by considerations of cost and toxicities and by the need to administer through a central venous catheter. Despite its limited use, two forms of resistance have already been noted in *E. faecium*. The first is a low-level resistance whose mechanism remains to be fully defined but which may involve activation of an efflux pump. Data from a recent clinical study reported that 21% of *E. faecium* isolated exhibited such low-level resistance *(92)*. This type of resistance has not been shown to be transferable, and its impact on therapy remains to be determined. High-level resistance to these mixtures can result from resistance to streptogramin A alone and was first described in staphylococci conferred by genes encoding streptogramin A acetyltransferases [*vat*(A), *vat*(B), and *vat*(C)] or adenosine triphosphate–binding efflux genes [*vga*(A), *vga*(B)]. Two acetyltransferase genes have now been described that confer resistance to quinupristin–dalfopristin in *E. faecium*—*vat*(D) [previously *sat*(A)] and *vat*(E) [previously *sat*(G)]. In most cases, these resistance genes are found along with an *erm* resistance gene *(158)*, suggesting that resistance to both streptogramin A and B may be necessary to confer clinically significant levels of resistance to quinupristin–dalfopristin in *E. faecium*. These genes have been found on transferable plasmids, suggesting that the potential for spread is significant.

Linezolid is the first licensed member of the oxazolidone class of antibiotics. It is active against most multiresistant gram-positive cocci including multiresistant enterococci and *S. aureus*. Linezolid acts by binding to the conglomeration of ribosomes, messenger RNA, and transfer RNA, known as the protein synthesis initiation complex. Resistance to linezolid has been associated with point mutations in the 23S ribosomal RNA (rRNA) subunit *(159)*. The most common mutation found in resistant isolates of staphylococci and enterococci has been a G → U change at position 2576 (*E. coli* numbering scheme). The degree of resistance seen in enterococci is related to the percentage of rRNA genes that have this mutation (160). This type of resistance has not been transferable in any of the cases examined to date. However, the known transferability of enterococci themselves within the healthcare setting creates concern that these strains could become prevalent. An outbreak of such strains in a liver transplant unit has been reported *(161)*. A more recent mechanism of resistance is encoded by the *cfr* gene, originally described as a chloramphenicol resistance mechanism in *Staphylococcus sciuri (162)*. The enzyme encoded by this gene provides posttranscriptional methylation of the 23S rRNA at position A2503 and affects the binding of at least four antimicrobial classes, leading to a multidrug-resistant phenotype. In 2008, the first report of *cfr*-mediated resistance to linezolid in staphylococcal clinical isolates (one *S. aureus*, one *S. epidermidis*) in humans in the United States was published *(163)*. The gene was found to be plasmid-borne in both isolates. This report was followed by other case reports, including one describing a clinical outbreak among 12 patients in a tertiary-care hospital in Spain (164), where clonally related strains of LRSA (linezolid-resistant *S. aureus*) were isolated from 11/12 patients, and all LRSA isolates possessed the *cfr* gene, whereas the G2675T substitution was identified in none. This outbreak was the first reported worldwide outbreak of LRSA and certainly the first outbreak depicting *cfr* gene–mediated linezolid resistance. The clinical consequences of this mechanism of resistance are only beginning to be described but could be severe. Although dissemination of *S. aureus* possessing this mechanism of resistance has thus far appeared to be secondary to clonal spread of a dominant isolate, the

occurrence of genetic transfer of resistance—multidrug resistance, at that—remains a possibility, given that the *cfr* gene is plasmid-borne.

Daptomycin is the first drug in the lipopeptide class of antibiotics to be licensed for therapeutic use in the United States. In 2003, daptomycin was approved for the treatment of complicated skin and skin structure infections; subsequent approvals were obtained for the treatment of *S. aureus* bacteremia *(165)*. The bactericidal action of this antimicrobial agent is confined to gram-positive microorganisms, including clinically important pathogens such as MRSA, VRE, coagulase-negative staphylococci, and penicillin-resistant pneumococci, and systemic delivery is achieved solely via the parenteral route. Daptomycin is a "natural" product, derived from the fermentation of *Streptomyces roseosporus*, and appears to act by forming pores in the bacterial membrane in the presence of physiological concentrations of calcium, resulting in ion leakage and cell death. Friedman et al. *(166)* have reported an accumulation of a variety of mutations in disparate genes (a lysylphosphatidylglycerol synthetase, a histidine kinase, and subunits of RNA polymerase) as being associated with resistance to this antibiotic. Muthaiyan et al. *(167)* have reported the results of transcriptional profiling studies of the action of daptomycin on *S. aureus*, arguably the most clinically significant microorganism treated with this drug. Induction of a complex cell wall stress stimulon (including genes encoding proteins involved in peptidoglycan biosynthesis and currently defined as genes altered in their expression by cell wall–active agents such as oxacillin, D-cycloserine, and bacitracin, as well as those shown to be controlled by the two-component regulator VraSR upon vancomycin challenge of *S. aureus*) was demonstrated with exposure to daptomycin, suggesting that the mode of action of this antibiotic does include the inhibition of cell wall synthesis. However, comparison of the daptomycin transcriptosome with the membrane-active agents carbonyl cyanide *m*-chlorophenylhydrazone and nisin also suggested a membrane-depolarizing action of daptomycin. The latter is consistent with previous studies of this agent, where the bactericidal activity of daptomycin was correlated with bacterial membrane depolarization *(168)*. The relative contributions of each of these potential mechanisms of action to the activity of this drug against any particular isolate have not yet been fully elucidated. When examining well-characterized isolates of MRSA rendered resistant to daptomycin via serial passage in sublethal concentrations of the antibiotic, resistant strains have demonstrated decreased cell membrane fluidity, increased synthesis, and positional shifting of total lysylphosphatidylglycerol and increased expression of a gene associated with the latter phenotype *(169)*. Additionally, the expression of the *dlt* operon, which increases positive surface charge, was increased in resistant isolates. Since daptomycin is itself a cationic antimicrobial peptide, this might be postulated to decrease binding; however, relative net positive surface charge was not increased in the mutants despite increases in the *dlt* operon, suggesting that a simple charge repulsion mechanism could not entirely explain the daptomycin-resistant phenotype. Most interestingly, daptomycin-resistant mutants demonstrated a thickened cell wall, resulting in a parallel increase in MICs to the glycopeptide antibiotic vancomycin. Although not universal *(170)*, these latter findings of cell-wall thickening have been substantiated elsewhere *(171)*, suggesting an explanation for the often observed—and clinically challenging—co-resistance to daptomycin and vancomycin manifested in clinical isolates of MRSA. Finally, although not a classic mechanism of resistance, it must be noted that the use of daptomycin in patients with pulmonary infections caused by gram-positive agents has been seriously compromised by the propensity of this drug to bind to pulmonary surfactant. In *in vitro* test-tube studies with bovine-derived surfactant, daptomycin showed a 16-fold to 32-fold loss of potency against *S. aureus* in 1% surfactant and a >100-fold loss in a 10% surfactant media (172). Insertion of daptomycin into surfactant aggregates likely represents the mechanism of inhibition of the antibiotic in this scenario. Daptomycin is, thus, not recommended for the treatment of pneumonia.

Telavancin, the newest antimicrobial agent in the gram-positive arsenal, is a lipoglycopeptide antibiotic approved for clinical use earlier this year. Telavancin is a semisynthetic derivative of vancomycin, possessing a hydrophobic side chain appended to the vancosamine sugar *(173)*, as well as another hydrophilic group. The mechanism of action of this drug involves the inhibition of peptidoglycan synthesis via binding to D-Ala–D-Ala-containing residues of peptidoglycan intermediates, similar to the mechanism of action of vancomycin; however, unlike vancomycin, a second mechanism of action may involve perturbations of bacterial membrane function *(173,174)*. Lunde et al. have demonstrated in flow cytometry assays that telavancin caused membrane depolarization (without cell lysis) in phenotypically diverse, actively growing *S. aureus* cultures that was both time- and concentration-dependent. This depolarization was found to be linked to interaction with the cell wall precursor lipid II. As yet, there is a paucity of literature regarding resistance to telavancin among gram-positive bacteria, although resistant microorganisms have been created in the laboratory via serial passage through antibiotics. As is the case with vancomycin and teicoplanin, telavancin induces the *vanA* operon in *vanA*-containing strains of enterococci, thus rendering these microorganisms intrinsically resistant; similar to the antibiotic teicoplanin, induction in *vanB* strains does not take place to the same degree *(175)*. Resistance in *S. aureus* appears as yet to be rare.

Tigecycline is a broad-spectrum antimicrobial alternative for treating infections due to several resistant pathogens, including MRSA and ESBL-producing *K. pneumoniae*. Tigecycline's broad spectrum is due to its resistance to the commonly encountered tetracycline-resistance efflux or ribosomal protection mechanisms. *P. aeruginosa* and *Proteus* spp. are resistant to tigecycline because they express efflux pumps that effectively extrude the antibiotic *(176)*. Resistance to tigecycline in other gram-negative species has also been reported in association with the activation of normally repressed AcrAB-type RND efflux pumps *(177)*.

CONCLUSION

Despite our best efforts, the elusive promise of the "perfect" antibiotic has not been realized. Experience with the use of antibiotics in the clinical setting has taught us that

resistance often emerges soon after the clinical introduction of any antibiotic, and in some cases, these resistance determinants spread rapidly once they are present in human pathogens. Resistance may be promoted by the excessive and injudicious use of antimicrobial agents, as well as by poor infection control practices employed in the hospital, day-care centers, and the home. Guidelines for the prevention of resistance in hospitals have been issued jointly by the Society for Healthcare Epidemiology of America and the Infectious Diseases Society of America (178). The guidelines suggest a number of strategies including some aimed at testing the hypotheses and proposals contained within the document. We hope that these suggestions will be implemented, so that optimal programs based on data can be introduced.

Since it is our behavior and practices that have amplified the problem of resistance, it stands to reason that altering these behavior patterns may contribute to its control or eradication. A detailed understanding of the mechanisms by which resistance emerges within and spreads among bacterial species is an essential component of any strategy to control antimicrobial resistance in the hospital setting. Intelligent, mechanism-based strategies employing an appropriate mix of infection and antibiotic control offer the best hope for controlling the spread of resistance as well as for the conservation of important and increasingly scarce economic resources.

CHAPTER 86

Antimicrobial Resistance and Healthcare-Associated Infections

Gary L. French

HOSPITAL PATHOGENS TEND TO BE ANTIMICROBIAL RESISTANT AND MULTIPLY RESISTANT

To be successful as hospital pathogens, healthcare-associated bacteria must be able to establish themselves and survive in the hospital environment, colonize the mucosa and skin of patients and staff members, survive on various surfaces during patient-to-patient transmission, and resist antibiotic and sometimes antiseptic therapy (1). Inherent multiple antibiotic resistance, and the ability to acquire additional genetic resistance factors in the face of increasing use of antibiotics, are important for survival. Numerous reports show that microorganisms causing healthcare-associated infection and colonizing patients and healthcare workers are more antibiotic-resistant than those in the community and that, within the hospital, resistance rates are high in units (such as intensive care, hematology and oncology, and renal and liver units) where antimicrobial use is highest. Indeed, risk factors for colonization and infection with multidrug-resistant (MDR) pathogens include prolonged hospital stay, prior antimicrobial therapy, and admission to intensive care units (ICUs).

EMERGENCE OF ANTIBIOTIC RESISTANCE IN HEALTHCARE-ASSOCIATED PATHOGENS

Innate and Acquired Antimicrobial Resistance

In his initial studies in 1929, Fleming noted that penicillin was highly active against some microorganisms, especially the gram-positive staphylococci and streptococci, but inactive against others, especially the gram-negative coliforms *(2)*. This phenomenon of innate susceptibility or resistance to different agents among different bacterial species continued to be seen with broad-spectrum antimicrobials. For example, *Klebsiella pneumoniae* is usually resistant to ampicillin; *Enterobacter* spp. to ampicillin and many cephalosporins; enterococci to cephalosporins and quinolones; and *Pseudomonas aeruginosa* to pencilin, ampicillin, cephalosporins, and other groups. The β-hemolytic streptococci remain susceptible to penicillin and the anaerobes to metronidazole, but increasing numbers of isolates of many other species have acquired resistance to agents to which they were initially innately susceptible.

Free-living environmental bacteria are of low virulence for humans but are often inherently resistant to common antimicrobials. This is probably because they are adapted to live in soil and water where they are exposed to naturally occurring antimicrobial substances. Environmental species with inherent antimicrobial resistance include various *Pseudomonas* spp., *Acinetobacter, Burkholderia, Stenotrophomonas,* and *Ralstonia*. Although they rarely infect healthy individuals, these microorganisms may contaminate hospital environments and equipment and then colonize and infect compromised patients, producing antibiotic-resistant opportunistic infection.

Naturally sensitive bacteria may acquire antibiotic resistance caused by a number of mechanisms, with the most common probably being the production of drug-destroying enzymes (*3,*4). This is the typical mechanism by which microorganisms such as *Staphylococcus aureus* and *Escherichia coli* and other gram-negative bacteria acquire resistance to ampicillin, aminoglycosides, and chloramphenicol. There may be alterations in the permeability of the cell wall, preventing antibiotics from reaching their target sites, or there may be increased antibiotic efflux, resulting in the same effect. This is the common mechanism of tetracycline resistance and is one of the ways in which microorganisms such as *P. aeruginosa* may acquire broad-range resistance to several aminoglycosides and other agents simultaneously. Alterations in target sites prevent antibiotics from binding to their sites of action. Changes in the affinities of penicillin-binding proteins result in methicillin resistance in staphylococci, penicillin resistance in pneumococci, and ampicillin resistance in enterococci. Alterations in ribosomal-binding sites may produce acquired resistance to rifampin, fusidic acid and the macrolides, and alteration of DNA gyrase is the common mechanism of quinolone resistance. Alterations (or substitutions) of enzymes in metabolic pathways are responsible for resistance to sulfonamides and trimethoprim that block bacterial folate metabolism.

Acquired resistance may emerge by genetic mutation, which occurs relatively frequently in rapidly multiplying microorganisms or by acquisition of resistance genes

from other bacteria. The horizontal spread of resistance genes among bacteria by plasmid transfer is sometimes called "infectious resistance." The transmission of DNA between bacteria may occur by bacteriophage transduction (as in the transmission of penicillinase-mediated penicillin-resistance in *S. aureus*), conjugation (the common mechanism of transfer between gram-negative species), or transformation. Transformation was previously regarded as a relatively unimportant mechanism of resistance transfer in clinical bacteria, but there is increasing evidence for its importance in the emergence of resistance in gram-positive microorganisms. Although the host range of many plasmids is restricted and gram-positive and gram-negative microorganisms tend not to share resistance genes, plasmids can be exchanged between different bacterial species. For example, most ampicillin resistance in *Haemophilus influenzae* is mediated by a β-lactamase that probably originated from *E. coli*.

Resistance genes may be encoded on a variety of transferable elements, including transposons and integrons that can insert into both chromosomes and plasmids. The combination of several insertion elements may create large multiple resistance-gene packages *(5)*. Integrons encoding multiple antimicrobial resistances are now widespread in *Enterobacteriaceae* in both hospitals and the community *(6,7)*. There is continuous horizontal transfer of these resistance genes between and within species, and acquisition of multiple resistances favors the proliferation of certain cross-infecting microorganisms in hospitals *(8)*. Some species of both good and opportunistic pathogens appear to have a special ability to accumulate multiple resistance genes and become increasingly MDR. Examples of successful MDR healthcare-associated pathogens include *S. aureus* and coagulase-negative staphylococci (especially methicillin-resistant strains), *Enterococcus faecium* (especially glycopeptide-resistant strains), *K. pneumoniae, Acinetobacter baumannii,* and *P. aeruginosa*.

Antibiotic Use and Antibiotic Resistance

Hospital patients often have compromised host defenses due to treatment or underlying disease and are therefore at risk of acquiring infection with both virulent and opportunistic pathogens. Since antibiotic use is concentrated in hospitals, both types of pathogen are more likely to survive and proliferate in the hospital environment and colonize patients if they are resistant to common antimicrobials. Antibiotic therapy tends to suppress innately sensitive commensal bacteria and encourage their replacement with resistant microorganisms. Initially, the more resistant members of generally sensitive species are selected (a shift within a species to a population with increased resistance), and then the inherently resistant genera emerge (a shift to colonization with more resistant species). Patients who receive multiple courses of antibiotics commonly become colonized by increasingly resistant microorganisms, often suffering sequential infections with bacteria such as *Klebsiella*, *P. aeruginosa*, enterococci and *Acinetobacter,* and finally with antibacterial resistant fungi such as *Candida* spp. The tendency for antibiotic use to promote the emergence of resistant pathogens is called "antibiotic pressure" and is an inevitable evolutionary process. Despite methodological difficulties, there are many reports of resistance rising during increased antibiotic use and falling after a reduction in use (9).

A change in the pattern of serious healthcare-associated infection after the introduction of antibiotics was first noted by Finland and his colleagues in 1959 *(10)*. Between 1935 and 1957, antibiotic-sensitive gram-positive pathogens were replaced by penicillin-resistant *S. aureus* and multi-resistant gram-negative bacteria such as *E. coli*, *Klebsiella*, and *Proteus* spp. Once the emergence of resistant opportunistic pathogens had been recognized, new, more effective drugs were developed for their treatment. The worldwide problem of the multiresistant "hospital staphylococcus" in the 1960s diminished after the introduction of methicillin and other penicillinase-stable penicillins *(11)*; outbreaks of gentamicin-resistant *Klebsiella* and other gram-negative microorganisms seen in the 1970s waned in the 1980s with the use of newer aminoglycosides and cephalosporins.

After the 1980s, the pattern changed again with a dramatic increase in healthcare-associated infections with multiply resistant gram-positive bacteria (1,*12*). Methicillin-resistant *S. aureus* (MRSA), resistant to all β-lactams and to many other previously effective agents, has emerged as a worldwide cause of healthcare-associated infections and outbreaks associated with serious morbidity and mortality *(13–15)*. Coagulase-negative staphylococci are increasingly common healthcare-associated pathogens, partly because they too are often resistant to methicillin and other agents but also because many strains produce an extracellular slime (16,*17*) that enables them to colonize the intravascular and other plastic prostheses that are increasingly used in modern medicine. Finally, many antibiotics used for gram-negative healthcare-associated infections, including ampicillin, the aminoglycosides, cephalosporins and quinolones, are ineffective against enterococci, which have also emerged as important causes of healthcare-associated infection *(18)*.

This is, of course, a continuing dynamic situation. Resistant gram-positive bacteria remain a major feature of healthcare-associated infection but MDR gram-negative bacteria continue as important healthcare-associated pathogens, especially with the emergence of extended-spectrum β-lactamase (ESBL)-producing and multiply resistant strains of *K. pneumoniae*, *Enterobacter, Serratia*, and, most recently, *E. coli* (19). Broad-spectrum antibiotic use encourages the proliferation of antibiotic-resistant and toxigenic strains of *Clostridium difficile* in the bowel that cause diarrhea and pseudomembranous colitis. There has recently been an increase in community and healthcare-associated infections with *C. difficile* associated with the worldwide dissemination of highly virulent strains (20). Thus, healthcare-associated infection is now microbiologically heterogeneous, often being caused simultaneously by several different species of MDR gram-positive and gram-negative bacteria. Table 86-1 shows the distribution of healthcare-associated pathogens reported in the United States in 2003 *(21)*.

Table 86-2 shows the rates of antibiotic resistance in bacterial isolates from hospitals taking part in the U.S. National Nosocomial Infections Surveillance (NNIS) system from 1992 to 2004 *(22)*. Antibiotic resistance rates

TABLE 86-1

Percentage of Bacterial Isolates Associated with Healthcare-Associated Infection of Different Types in Intensive Care Units Reported to the National Nosocomial Infections Surveillance System, 2003

Pathogen	*Pneumo (n = 4,365)*	*BSI (n = 2,351)*	*SSI (n = 2,984)*	*UTI (n = 4,109)*
Gram-negative				
Escherichia coli	5.0	3.3	6.5	26.0
Klebsiella pneumonia	7.2	4.2	3.0	9.8
Enterobacter spp.	10.0	4.4	9.0	6.9
Serratia marcescens	4.7	2.3	2.0	1.6
Pseudomonas spp.	18.1	3.4	9.5	16.3
Acinetobacter spp.	6.9	2.4	2.1	1.6
Other	14.1	3.8	9.8	10.7
Gram-positive				
Coagulase-negative staphylococci	1.8	42.9	15.9	4.9
Staphylococcus aureus	27.8	14.3	22.5	3.6
Enterococci	1.3	14.5	13.9	17.4
Other	3.2	4.5	5.8	1.2

Pneumo, pneumonia; BSI, bloodstream infection; SSI, surgical site infection; UTI, urinary tract infection. (From Gaynes R, Edwards JR; the National Nosocomial Infections Surveillance System. Overview of nosocomial infections caused by gram-negative bacilli. *Clin Infect Dis* 2005;41:848–854.)

were highest in ICUs, followed by non-ICU wards, and then outpatients, reflecting the levels of compromise, antimicrobial courses, and length of hospitalization of the patients in these three areas. ICUs had especially high rates of methicillin resistance in both coagulase-negative and coagulase-positive staphylococci, high rates of quinolone and carbapenem resistance in *P. aeruginosa*, and high rates of resistance to third-generation cephalosporins in *Enterobacter* spp.

Table 86-3 shows results from the NNIS system comparing resistance rates in US ICUs for various pathogens isolated in 1994 to 1998 and 1999 *(22,23)*. During this period, there was a dramatic increase in resistance rates for several important healthcare-associated pathogens. In particular, there was a 47% increase in vancomycin resistance in enterococci, a 43% increase in methicillin resistance in *S. aureus*, and an increase in resistance in *P. aeruginosa* of 35% and 49% to imipenem and the quinolones, respectively.

The European Antimicrobial Resistance Surveillance System (EARSS) has been reporting on antimicrobial resistance rates in invasive (mainly bloodstream) isolates from European countries since 1999. In 2008, the EARSS network comprised almost 900 microbiological laboratories serving more than 1,500 hospitals in 33 countries and provided susceptibility data on more than 700,000 invasive isolates *(24)*. The annual reports from this organization give good data on European trends and can be used to illustrate the generally growing problem of antimicrobial resistance in clinically important bacteria while emphasizing significant regional and geographical differences. EARSS data on resistance trends are discussed under the individual pathogens, later in this chapter.

THE CLINICAL AND ECONOMIC IMPACT OF ANTIMICROBIAL RESISTANCE

Increasing antimicrobial resistance and multiple resistance results in increasing difficulties in the treatment of bacterial infections. Resistance leads to inappropriate empirical therapy; delay in starting effective treatment; and the use of less effective, more toxic, and more expensive drugs *(25)*.

Evaluation of the effect of resistance on outcomes and costs is difficult, because the risks of acquiring resistant infection—such as prior antimicrobial therapy, prolonged hospital stay, and admission to intensive care—are themselves associated with poor prognoses. Nevertheless, when adjusted for other risks, mortality rates and length of hospital stay are generally at least twice as great for patients infected with resistant bacteria as it is for those infected with susceptible strains of the same species (*26,27,*28,*29*).

In serious infections due to *Enterobacteriaceae*, resistance to third-generation cephalosporins (which is nearly always associated with multidrug resistance) tends to worsen clinical outcome *(30–33)*. A meta-analysis of bacteremia caused by ESBL-producing *Enterobacteriaceae (34)* showed significantly increased crude mortality and significantly increased incidence of delay in effective therapy. Mortality rates were higher for infections with imipenem-resistant (*K. pneumoniae* carbapenemase [KPC]–producing) *Enterobacter* spp. (11/33) than with susceptible

TABLE 86-2

Pooled Means of the Distribution of Antimicrobial Resistance Rates (%) by All ICUs Combined, Non-ICU Inpatient Units and by Outpatients, January 1998 through June 2004

Antibiotic Resistant Pathogen	*ICU*	*Non-ICU*	*Outpatients*
MRSA	52.9	46.0	31.1
Methicillin-resistant CNS	76.6	65.7	50.2
Vancomycin-resistant *Enterococcus* spp.	13.9	12.0	4.6
Ciprofloxacin-resistant *P. aeruginosa*	34.8	27.7	23.4
Imipenem-resistant *P. aeruginosa*	19.1	12.3	7.0
Ceftazidime-resistant *P. aeruginosa*	13.9	8.8	4.6
Cef3-resistant *Enterobacter* spp.	27.7	21.0	9.6
Carbapenem-resistant *Enterobacter* spp.	0.7	1.0	0.5
Cef3-resistant *Klebsiella pneumoniae*	6.2	5.8	1.8
Cef3-resistant *Escherichia coli*	1.3	1.5	0.6
Quinolone-resistant *E. coli*	7.3	8.2	3.6
Penicillin-resistant pneumococci	18.9	18.2	16.8
Ceftriaxone-resistant pneumococci	7.5	7.6	4.8

MRSA, methicillin-resistant *S. aureus*; Cef3, third-generation cephalosporin; CNS, coagulase-negative staphylococcus.
(From National Nosocomial Infections Surveillance. NNIS report, data summary from January 1992 through June 2004, issued October 2004. *Am J Infect Control* 2004;32:470–485.)

TABLE 86-3

Mean Resistance Rates in Selected Pathogens Associated with Healthcare-Associated Infections in ICU Patients, January–May 1999 Compared with the 5 Years 1994–1998 and January–December 2003 Compared with the 5 Years 1998–2002

	% Increase in Resistance	
Antimicrobial/Pathogen	*1999 vs. 1994–1998*	*2003 vs. 1998–2002*
Vancomycin/enterococci	47%	12%
Methicillin/ *Staphylococcus aureus*	43%	11%
Methicillin/coagulase-negative staphylococci	2%	1%
3rd Cephalosporin/*E. coli*	23%	0%
3rd Cephalosporin/ *K. pneumoniae*	–1%	47%
Imipenem/*P. aeruginosa*	35%	15%
Quinolone/*P. aeruginosa*	49%	9%
3rd Cephalosporin/ *P. aeruginosa*	<1%	20%
3rd Cephalosporin/ *Enterobacter* spp.	3%	-6%

3rd, third generation.
(From National Nosocomial Infections Surveillance. NNIS report, data summary from January 1990-May 1999, issued June 1999. *Am J Infect Control* 1999;27:520–532; National Nosocomial Infections Surveillance. NNIS report, data summary from January 1992 through June 2004, issued October 2004. *Am J Infect Control* 2004;32:470–485.)

strains (3/33) *(35)* and 14-day mortality was 9/19 patients with bacteremia due to KPC-producing *K. pneumoniae (36)*. However, a lack of controlled studies limits the assessment of causality in all these studies.

The impact of drug resistance on the outcome of *P. aeruginosa* infection has been investigated in a few studies, but the results are not consistent. This may be in part because it is often difficult to distinguish *P. aeruginosa* colonization from infection and also because invasive disease and bacteremia tend to occur in highly compromised patients with underlying poor prognosis *(37–40)*.

Individual studies of *S. aureus* infections have shown variable results, but meta-analyses show that infections with MRSA have worse outcomes than those due to methicillin-sensitive *S. aureus* (MSSA) strains. For example, MRSA bacteremias have twice the mortality of those caused by MSSA *(41),* and MRSA surgical site infections have significantly greater 90-day mortality, length of hospitalization, and hospital charges *(42)*.

Serious enterococcal infection, especially bacteremia, is associated with severe underlying disease, which itself has a poor prognosis. Some studies find no independent effect of vancomycin resistance on outcomes of enterococcal infections *(43,44)*; others show a significantly worse outcome (measured as treatment failure, attributable mortality, prolonged hospital stay, recurrent bacteremia, endocarditis, ICU admission, surgical intervention, and increased healthcare costs) *(45–49)*.

The general effect of antimicrobial resistance has been assessed by considering outcomes with "appropriate" or "inappropriate" therapy. Therapy is inappropriate when it is ineffective *in vitro* against the infecting microorganism or not given promptly by a suitable route (50). Failure to provide prompt, effective antimicrobial therapy may result in treatment failure and death. There is, for example, a significant association between inappropriate treatment and clinical outcome in bacteremia and ventilator-associated pneumonia *(51–54)*.

Delayed response alone is associated with increased morbidity, prolonged hospital stay, additional investigations, procedures and treatments, and increased complications, which, in conditions such as meningitis or bone and joint infection, may result in severe disability. This is costly. Additional costs and lost bed days are incurred by the need to control the spread of antimicrobial-resistant microorganisms within hospitals. Thus, even apart from mortality and morbidity, antimicrobial resistance is hugely expensive in terms of its socioeconomic impact on patients and on the cost-effectiveness of healthcare delivery.

MULTIRESISTANT PROBLEM MICROORGANISMS

Gram-Negative Bacteria

Escherichia coli *E. coli* is the commonest cause of hospital-acquired gram-negative urinary tract infection (UTI) and septicemia. *E. coli* is relatively fastidious in its nutritional requirements and does not survive well in the environment and, until recently, did not tend to cause cross-infection or person-to-person spread. For these reasons, most healthcare-associated *E. coli* infections are endogenous, arising from commensal bowel flora of the affected patient. The species is naturally susceptible to ampicillin but now about 50% to 60% of both healthcare-associated and community isolates are resistant, usually by the production of β-lactamases, enzymes that bind and destroy β-lactam antibiotics. The most common type of β-lactamase in *E. coli* is TEM-1, accounting for about 80% of such resistance *(55–57)*. TEM-1 is encoded on transferable plasmids and has disseminated throughout the world since its discovery in 1965 *(58)*. Some strains of *Enterobacteriaceae*, including *E. coli*, produce TEM-2—a similar enzyme that differs from TEM-1 only in a single amino acid and confers similar phenotypic resistance. Although ampicillin is now unreliable for the treatment of *E. coli* infection, other drugs usually remain effective, including cephalosporins, quinolones, and aminoglycosides. *E. coli* can also be treated by the combination of a β-lactam with a β-lactamase inhibitor, such as amoxicillin/clavulanic acid (co-amoxiclav) and ampicillin/sulbactam. The β-lactamase inhibitors prevent the action of TEM-1 or TEM-2 and restore the activity of the β-lactams. This combination may be ineffective, because some *E. coli* strains can produce excessive amounts of TEM-1 that swamp the effect of the β-lactamase inhibitor *(59,60)* or are resistant to it *(57)*.

Mutations in TEM-1 and TEM-2 have resulted in new ESBLs that can break down newer cephalosporins, and thus, render *E. coli* resistant to them. These ESBLs are named TEM-3, TEM-4, etc., and >100 of them have been reported *(3,61,)*. They are often plasmid-borne and are associated with aminoglycoside and other resistances encoded on the same plasmid. However, until recently, *E. coli* has remained generally antibiotic-sensitive and relatively easy to treat and has not caused much cross-infection or spread within hospitals or the community.

This situation changed with the emergence of *E. coli*–producing CTX-M ESBLs in the 1990s. CTX-M–producing *Enterobacteriaceae* first appeared in South America but have now become distributed worldwide *(62,63)*. Compared with other ESBLs, CTX-M enzymes are more active against cefotaxime than against other third-generation cephalosporins. They appear to have originated from the *Kluyvera* spp. of environmental bacteria, and more than 50 different types have been identified. They are associated with plasmids and transposons and have disseminated widely among the *Enterobacteriaceae*.

In addition to resistance to penicillins and cephalosporins, CTX-M–producing *E. coli* are usually also resistant to other previously active agents such as the aminoglycosides and quinolones. Furthermore, these new MDR *E. coli* appear to be highly transmissible both in the community and in hospitals and have disseminated worldwide. Most isolates are clonally unrelated, but large single strain community outbreaks occur *(64)*. Increasing asymptomatic fecal carriage raises the possibility of spread by food sources and international travel.

This world pandemic of CTX-M–producing *E. coli* has resulted in a new epidemiology for MDR coliforms (19,*65*). Opportunistic healthcare-associated outbreaks with mainly single clones of SHV- and TEM-type ESBL-producing *K. pneumoniae* have been replaced by sporadic and epidemic community infections with heterogenous clones of more virulent MDR CTX-M–producing *E. coli*. Spread occurs among healthy elderly people at home and in long-term care facilities; admission of these groups to hospital or care homes may result in healthcare-associated outbreaks with consequent further dissemination. Infections tend to occur in the elderly, although younger healthy patients may also be involved. The common presentation is UTI (sometimes complicated by bacteremia) in catheterized, elderly, community, or newly admitted hospital patients. The features of the new community MDR *E. coli* infections compared with the older MDR KES healthcare-associated infections have been reviewed by Pitout and Laupland (19) and are summarized in Table 86-4.

The U.K. Health Protection Agency reviewed *E. coli* bacteremias reported from hospitals in England, Wales, and Northern Ireland in 2008 *(66)*. There were about 22,000 such bacteremias in 2007. Resistance to third-generation cephalosporins in *E. coli* blood isolates increased from about 2% in 2001 to 12% in 2007 (Fig. 86-1); resistance to ciprofloxacin rose from 1% to 23%; and resistance to gentamicin rose from 1% to 8.5%. Resistance to carbapenems was rare and was ≤0.2% in 2007. There were far fewer *Klebsiella* bacteremias—about 6,000 in 2007—and among these, resistance to third-generation cephalosporins was about 14% (up from 4% in 1994); to ciprofloxacin, about 15%; and to gentamicin, about 10%. (Resistance to carbapenems was not reported.) Thus, in 2007, multidrug resistance in UK hospital blood isolates of *E. coli* was similar to or higher than in *Klebsiella*, and there were many more of them compared with *Klebsiella*.

Klebsiella, Enterobacter, and Serratia spp. *Klebsiella, Enterobacter*, and *Serratia* spp. are common opportunistic gram-negative pathogens that have similar epidemiologies and clinical presentations. They are all inherently resistant to ampicillin, and *Enterobacter* spp. and *Serratia* spp. are resistant to first-generation cephalosporins. These *Enterobacteriaceae* have a great facility for acquiring and disseminating resistance plasmids and *Enterobacter* spp. may develop chromosomally mediated resistance to second- and third-generation cephalosporins *(67,68)*.

Enterobacter spp. possess an inducible chromosomally encoded class I β-lactamase that is normally suppressed by a repressor gene and is produced in large amounts only after exposure to certain β-lactams. Full resistance to second- and third-generation cephalosporins results when stably derepressed mutants appear that express the class I β-lactamase constitutively. These mutants are selected by cephalosporin therapy and produce the β-lactamase continuously.

TABLE 86-4

Characteristics of Infections Caused by Extended-Spectrum β-Lactamase–Producing Bacteria

	Older Klebsiella spp. etc.	*Newer Escherichia Coli*
Virulence/place	Less virulent/HAI	More virulent/Community and HAI
Type of ESBL	SHV and TEM types	CTX-M (especially CTX-M15)
Infection	UTI, respiratory, intra-abdominal, blood	Usually UTIs, but also blood, gastroenteritis
Resistances	All β-lactams; usually quinolones and cotrimoxazole; usually aminoglycosides	All β-lactams; usually quinolones and cotrimoxazole; often aminoglycosides
Molecular epidemiology	Most often clonally related	Usually not clonally related, but clonal outbreaks described worldwide, including UK
Risk factors	Longer hospital stay; severity of illness; time in ICU; ventilation; urinary or vascular. Catheterization; previous exposure to antibiotics (especially cephalosporins)	Repeat UTIs/underlying renal pathology; previous antibiotics including cephalosporins and quinolones; previous hospitalization; nursing home residents; older people; diabetes; liver pathology

HAI, healthcare-associated infection; UTI, urinary tract infection.
(From Pitout JD, Laupland KB. Extended-spectrum β-lactamase-producing *Enterobacteriaceae*: an emerging public-health concern. *Lancet Infect Dis* 2008;8:159–166.)

To a greater or lesser extent, all three of these species colonize the human bowel and patient's skin and may spread from person to person via staff members' hands. They may then go on to colonize the urinary and respiratory tracts of patients treated with β-lactams and may produce bacteremia in the compromised host. They are relatively free-living and can also survive and multiply in nutritionally poor wet environments at room temperature. Because of this, they may contaminate food, enteral feeds, and infusion fluids, leading to widespread common-source outbreaks.

K. pneumoniae is the most frequently isolated member of this group and the most virulent. It is naturally resistant to ampicillin, usually by the production of SHV-1, a β-lactamase similar to TEM-1 and TEM-2, which may be encoded on either the chromosome or, less commonly, on a transferable plasmid *(69)*. The carriage rate for healthy people is low but increases in hospitalized patients, especially during prolonged hospitalization or antibiotic therapy.

During the 1970s, there were frequent reports of hospital outbreaks of gentamicin-resistant *K. pneumoniae*, sometimes associated with significant mortality when highly compromised patients were involved *(70,71)*. The microorganisms often spread between hospitals and into the community. They became endemic in some hospitals and were sometimes associated with the simultaneous appearance of multiple resistances in other strains of *Klebsiella* and in other species of *Enterobacteriaceae (72,73)*. In these cases, *K. pneumoniae* appeared to be acting as an engine of resistance dissemination, especially resistance to aminoglycosides *(74)*.

Once the epidemiology of resistant *Klebsiella* infection was understood, and following the introduction of newer cephalosporins, these outbreaks became much less common. However, strains of *K. pneumoniae* (and also *Klebsiella ozaenae*) then appeared that are resistant to third-generation cephalosporins by the production of ESBLs and can spread to produce hospital outbreaks (*61,75–78*). The ESBLs are usually the result of mutations in the genes encoding TEM-1, TEM-2, or SHV-1. They are encoded on plasmids that can transfer to other species, and they are often associated with other multiple resistances, including

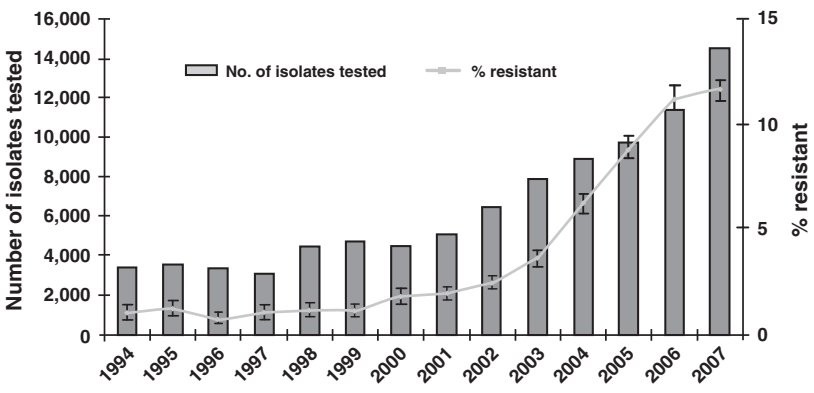

FIGURE 86-1 Resistance to ceftazidime in *E. coli* from bacteremias in England, Wales, and Northern Ireland, 1994–2007. (From Health Protection Agency. *Antimicrobial resistance and prescribing in England, Wales and Northern Ireland, 2008*. London, UK: Health Protection Agency, 2008.)

resistance to aminoglycosides *(79)*. Although ESBL-producing strains are usually susceptible to β-lactam-β-lactamase-inhibitor combinations such as amoxicillin/clavulanate and ampicillin/sulbactam, healthcare-associated isolates may be resistant by hyperproduction of the ESBL *(76,80)*. These multiresistant strains may also acquire resistance to quinolones by mutation. Thus, recent isolates are often resistant to all the common β-lactams, aminoglycosides, and quinolones and are reliably susceptible only to the carbapenems. Outbreaks with these new multiresistant *Klebsiella* spp. have an epidemiology similar to that of the gentamicin-resistant *Klebsiella* outbreaks of the 1970s.

MDR *Klebsiella* spp. are now widespread, and some strains have also picked up the CTX-M type ESBLs that have recently emerged in *E. coli*. For all these *Enterobacteriaceae*, the treatment of last resort are the carbapenems. The recent emergence of carbapenem resistance is therefore a matter of concern.

Carbapenem resistance in *Enterobacteriaceae* can be mediated by a variety of mechanisms, including permeability/efflux changes, hyperproduction of *ampC* β-lactamases or ESBLs, or production of specific carbapenemases. A range of different carbapenemases have been reported, most of them rare or uncommon. They include Ambler class B metallo-β-lactamases such as verona imipenemase and imipenemase; class D OXA-48 β-lactamase, mostly in *K. pneumoniae* from Turkey, Lebanon, and Belgium; class A clavulanic-acid-inhibited carbapenemases; chromosomally encoded non-metallo-β-lactamases of *Serratia* spp. and plasmid-mediated KPCs *(81)*.

In Europe, carbapenem-resistant *Enterobacteriaceae* are rare (except in Greece), but KPC-producing bacteria are now widespread in certain parts of China, Israel, Greece, South America, and the United States (*36,*82).

In 2009 a new metallo-beta-lactamase gene, NDM-1 (New Dehli metallo-beta-lactamase-1), conferring resistance to carbapenems, was identified in *K. pneumoniae* isolates from India (82a). Since then, it has become apparent that NDM-1 is widely distributed in coliforms in parts of India, including the gut flora of healthy people, sewage and the environment and has disseminated internationally (82b,82c,82d). Although the number of clinical infections with NDM-1-producing Gram-negative bacteria is small, the threat of these potentially untreatable infections is very serious.

The carbapenems remain the agents of last resort for the treatment of infections with *Enterobacteriaceae* and other MDR gram-negative bacteria. By analogy with CTX-M producing *E. coli,* there is a serious risk of worldwide spread of pan-drug-resistant carbapenemase-producing bacteria. Prudent antibiotic use combined with very strict infection prevention and control is essential to prevent further spread of these potentially dangerous microorganisms. All high-risk units should ensure continuous good practice and effective surveillance and have plans in place to deal with these pathogens when they arise and international cooperation is needed for worldwide control.

Resistance Rates in European Isolates of Enterobacteriaceae Antimicrobial resistance and multi-resistance have increased dramatically among European bloodstream isolates of *E. coli* in the last few years *(24)*. Resistance to ampicillin/amoxicillin ranges from 32% to 78%, and aminopenicillins are therefore no longer appropriate for empirical therapy. Although 14 of 33 European countries reported <5% resistance against third-generation cephalosporins, resistance rates to these agents have increased in 19 countries since 2004. In 2008, two east European countries reported rates above 25% (Bulgaria, 29%; and Turkey, 42%). EARSS does not identify resistance mechanisms, but the continuing rise in resistance to third-generation cephalosporins is likely to be due to ESBL production. Only four European countries reported resistance rates to fluoroquinolones of <10%; 16 had rates between 10% and 25%, 10 had rates >25%, and 3 had rates >35% (Italy, 38%; Cyprus, 45%; and Turkey, 52%). Aminoglycoside resistance is also common: only six European countries reported rates of <5%, 16 had rates of 5% to 10%, and in southern and eastern Europe, most countries reported rates of 10% or more, with the highest rates being reported by Bulgaria (31%) and Turkey (35%). Overall, in 2008, although 47% of all European bloodstream isolates of *E. coli* remained susceptible to aminopenicillins, third-generation cephalosporins, fluoroquinolones, and aminoglycosides, 8% were resistant to two of these classes, 3% to three, and 3% to four *(24)*. Data on carbapenem resistance in *E. coli* were not collected by the European Antimicrobial Resistance Surveillance System (EARSS) in 2008.

Antimicrobial resistance in bloodstream isolates of *K. pneumoniae* also varies widely. In 2008, many northern European countries had resistance rates of <5% to third-generation cephalosporins, fluoroquinolones, and aminoglycosides; however, high rates of resistance and multiple resistance to these agents, sometimes >50%, were seen in central and southeastern European countries. EARSS noted that carbapenem resistance was generally uncommon in European bloodstream isolates of *K. pneumoniae*: most countries reported no resistance and seven had rates of 1% to 5%. However, three countries had much higher rates: Cyprus, 10%; Israel, 19% (among 350 isolates); and Greece, 37% (among 1,074 isolates) (see also Chapter 34).

Pseudomonas and Pseudomonas-Like spp. These are nonfermenting, aerobic, gram-negative bacteria, which are widely distributed in nature, are nonfastidious in their nutritional requirements, and can survive and multiply in many wet environmental sites, often at ambient or low temperatures. They also readily colonize the mucous membranes of compromised patients who have been treated with multiple courses of antibiotics. Although they have little pathogenicity for normal individuals, they are resistant to many common antimicrobials and disinfectants and flourish as environmental opportunistic pathogens in intensive care and similar units.

Although many species of *Pseudomonas* and *Pseudomonas*-like microorganisms have been isolated from clinical material, the ones that cause most problems of antibiotic-resistant healthcare-associated infection are *P. aeruginosa*, *Stenotrophomonas* (formerly *Xanthomonas* or *Pseudomonas*) *maltophilia*, *Burkholderia* (formerly *Pseudomonas*) *cepacia,* and *Ralstonia* (formerly *Pseudomonas or Burkholderia*) *pickettii*. *Achromobacter xylosoxidans* is a nonfermenting gram-negative bacillus that behaves like *Pseudomonas* and causes similar healthcare-associated infections.

P. aeruginosa is the most common pseudomonad isolated from clinical specimens and the most frequent species causing invasive infection. It accounts for about 10% of all healthcare-associated infections and is roughly the third most common cause of healthcare-associated

gram-negative bacteremia after *E. coli* and *K. pneumoniae*. It is a normal commensal of humans, colonizing skin, nose, throat, and stool in a widely varying number (0–40%) of healthy subjects (83).

Many studies have shown that several different types may be in circulation during an apparent outbreak, and although person-to-person spread does occur, endogenous infection is common *(84–86)*. Carriage of clinically undetectable resistant *P. aeruginosa* may be common in healthy persons, and this resistant population may emerge under antibiotic pressure in hospitals to cause environmental colonization and endogenous infection.

P. aeruginosa is inherently resistant to most penicillins and cephalosporins, tetracyclines, chloramphenicol, sulfonamides, and nalidixic acid. It is naturally susceptible to the aminoglycosides, antipseudomonal penicillins and cephalosporins, quinolones, and carbapenems. However, acquired antibiotic resistance in *P. aeruginosa* is common. The microorganism can exchange antibiotic resistance plasmids with other gram-negative bacilli while colonizing patients *(87)*, but acquired resistance to aminoglycosides and other agents is probably more often the result of changes in membrane permeability *(88)*. Resistance to fluoroquinolones (due to mutations in DNA gyrase, membrane permeability, or both) has emerged relatively rapidly in *P. aeruginosa,* and now about a third or more of healthcare-associated isolates are resistant *(23,89,90)* (Table 86-2). This microorganism can develop resistance to ceftazidime by mutation to constitutive production of chromosomal class I β-lactamase *(68,91)*. It may also, though less readily, develop resistance to carbapenems such as imipenem and meropenem, usually by changes in membrane permeability (4,*92,93*). In the NNIS studies for the periods from 1994 to 1998 and 1999, resistance to quinolones and carbapenems in ICU isolates of *P. aeruginosa* increased by 49% and 35%, respectively, and resistance to third-generation cephalosporins (ceftazidime) increased by 20% between 1998 and 2003 (Table 86-3).

Acinetobacter baumannii *Acinetobacter* spp. are nonfermenting gram-negative coccobacilli, found widely distributed as free-living saprophytes in soil and water. They also colonize the skin and mucous membranes in about 25% of healthy people (94). The most frequently isolated *Acinetobacter*—the one most likely to acquire multiple antibiotic resistance and the most common cause of healthcare-associated outbreaks—is *A. baumannii*. Healthcare-associated outbreaks originate from contaminated environmental sources or follow hand transmission from the skin of colonized patients *(95,96)*. These microorganisms can also survive for long periods on dry surfaces *(97,98)* and can probably be transmitted via dust and fomites *(99)*. Most clinical isolates represent colonization rather than infection *(96)*, but serious and sometimes fatal infections occur in compromised patients, including septicemia, endocarditis, meningitis, and pneumonia *(100,101)*.

In the early 1970s, *Acinetobacter* spp. were usually susceptible to many common antimicrobials, including gentamicin and the cephalosporins, and they were relatively uncommon healthcare-associated pathogens *(100)*. By the mid-1980s, however, healthcare-associated outbreaks with multiply resistant *Acinetobacter* strains were being frequently reported (94). Many healthcare-associated strains are now resistant to the aminoglycosides and to older and newer cephalosporins, and some have developed resistance to the quinolones *(102,103)* and carbapenems *(104)*. The ability of *A. baumannii* to acquire multiple resistances, as well as to survive on skin and in the environment, undoubtedly contributes to its success as a healthcare-associated pathogen (see also Chapter 35).

Gram-Positive Bacteria

Staphylococcus aureus *S. aureus* is usually the second most common bacterial isolate in hospital laboratories after *E. coli* and is associated with wound infections and septicemia. Surface isolates often represent colonization, but invasive infection causes high morbidity and may be fatal. *S. aureus* is naturally susceptible to many classes of antimicrobials, including penicillins, cephalosporins, macrolides, sulfonamides, trimethoprim, tetracyclines, chloramphenicol, lincosamines, aminoglycosides, quinolones, and glycopeptides, but it has a great ability to develop resistance to many of these drugs simultaneously. Antibiotic resistance facilitates the survival and spread of these microorganisms in the hospital environment, and multiresistant strains are often responsible for large and serious outbreaks of healthcare-associated infection. Since the 1950s, many different resistance problems have been encountered *(11,105)*. Penicillin resistance due to the production of plasmid-mediated penicillinase appeared in *S. aureus* soon after penicillin was introduced, and now most strains are resistant. During the 1950s, multiresistant strains of *S. aureus* began to appear, and large epidemics of healthcare-associated infection with microorganisms resistant to penicillin, tetracycline, erythromycin, chloramphenicol, and other drugs were seen throughout the world. Many of these outbreaks were caused by virulent microorganisms of phage type 80/81, a group that became known as "the hospital staphylococcus" *(106,107)*. The healthcare-associated staphylococcus was greatly feared, because infections were often untreatable, and outbreaks were associated with high mortality rates. In the 1970s, some hospitals experienced outbreaks with gentamicin-resistant *S. aureus,* but the incidence of healthcare-associated infection with multiply resistant staphylococci gradually declined. The exact reasons for this are unclear, but the decline was associated with the introduction in the 1960s of the penicillinase-stable semisynthetic penicillins, methicillin, nafcillin, oxacillin, and cloxacillin (which are active against penicillinase-producing staphylococci); an apparent loss of virulence in the phage type 80/81 strains; and improvements in infection control.

Strains of MRSA were noted soon after methicillin was introduced into clinical practice *(108)*, but they were generally rare until the 1980s despite widespread use of methicillin, cloxacillin, and related drugs. In the late 1970s, however, MRSA emerged as a major pathogen of hospital infection in most countries and regions of the world *(15)*. In both the United States and Europe, around 30% to 50% of hospital isolates of *S. aureus* are now methicillin-resistant *(24,90)* (Table 86-5), although in the Netherlands and Scandinavia, rates are 3% or lower.

In the EARSS surveillance data for 2008, 21% of all (~32,000) invasive *S. aureus* isolates from 33 European countries were resistant to methicillin. However, MRSA

(From European Antimicrobial Resistance Surveillance System. *Annual report 2008*. Bilthoven, The Netherlands: EARSS, 2009.)

rates varied from <1% in the north (in the Netherlands and the Nordic countries) to over 50% in some southern European countries. The EARSS reports show that MRSA rates generally increased in most European countries between 2001 and 2004, but since then, they have fallen significantly in several countries (Table 86-5), possibly as the result of improved control measures. The Netherlands and Nordic countries continue to have strikingly low rates of MRSA but have increased (although only from <1% to 3%) in Denmark, possibly because of the emergence of the pig-associated community strain of MRSA.

Methicillin resistance is mediated primarily by the production of an abnormal PBP called PBP-2a or PBP-2′ *(109)*. β-Lactam antibiotics bind to normal bacterial PBPs and inhibit their activity, preventing proper formation of cell wall peptidoglycan and leading to cell death by osmotic lysis. PBP-2a binds poorly with most β-lactams and can fulfill the functions of the so-called essential PBPs 1, 2, and 3. Microorganisms producing PBP-2a are, thus, resistant to most available β-lactams, including methicillin and the isoxazolyl penicillins. Although they may appear susceptible to some β-lactams *in vitro*, the agents so far tested are clinically ineffective and should not be used for therapy.

The production of PBP-2a is encoded by the *mecA* gene located on the chromosome. This gene appears to have been derived from coagulase-negative staphylococci—hospital strains of which many are now frequently methicillin-resistant *(110)*. Recent genetic studies suggest that MRSA has repeatedly emerged from MSSA at different times in different parts of the world (*111,*112).

MRSA strains are resistant to methicillin, oxacillin, and other penicillinase-stable β-lactams, including the carbapenems, and to several other classes of antibiotic. Following the rapid emergence of resistance to quinolones, many strains of MRSA remain reliably susceptible only to the glycopeptides vancomycin and teicoplanin, the oxazolidinone linezolid and the lipopeptide daptomycin. Because of the current importance of vancomycin and teicoplanin in the treatment of severe MRSA sepsis, the emergence of glycopeptide resistance in MRSA is greatly feared. Unfortunately, several types of glycopeptide resistance have emerged in MRSA in recent years.

The glycopeptides are normally slowly bactericidal for *S. aureus*. However, some recent isolates of MRSA exhibit glycopeptide tolerance; that is, they are inhibited by normal concentrations of these agents but are not killed *(113,114)*. Tolerance has been associated with treatment failures, but its exact clinical significance is unclear. Glycopeptide tolerance is not routinely tested, and tolerant strains usually go undetected.

There have been reports of *S. aureus* strains with reduced vancomycin susceptibility from Japan, North America, and Europe (115*,116,117*). These strains have non-plasmid-mediated low-level or intermediate resistance to vancomycin, with vancomycin minimum inhibitory concentrations (MICs) of 8 μg/mL and have been associated with treatment failures. They have been designated "vancomycin-intermediate *S. aureus*" (VISA). In a given population of these strains, the majority have vancomycin MICs of 2 to 4 μg/mL, but there is a subpopulation with MICs of 5 to 9 μg/mL that may emerge under glycopeptide pressure. The mechanism of vancomycin-resistance in these microorganisms has not been fully elucidated but may result from increased amounts of normal D-Ala-D-Ala residues in the cell wall, which "absorb" therapeutic concentrations of vancomycin (118). These VISA strains appear to be rare and their true clinical significance is uncertain. As with glycopeptide tolerance, VISA strains are not routinely identified in the laboratory but may be identified retrospectively after treatment failure *(119)*.

High-level, inducible, transferable resistance to both vancomycin and teicoplanin is now seen quite commonly

in enterococci (vancomycin-resistant enterococci, VRE) and is encoded by a series of genes, including *vanA* (see below). This *vanA* resistance is usually plasmid-borne and was transferred to *S. aureus* in the laboratory in 1992 *(120)*. Ten years later, two clinical isolates of MRSA that contained the *vanA* gene and had vancomycin MICs of >128 μg/mL and teicoplanin MICs of 32 μg/mL were reported from the United States *(121)*. Such strains are still exceptionally rare; by 2009, only 12 had been reported worldwide *(122)*. However, since both MRSA and VRE are widespread in hospitals throughout the world, there is continuing fear that fully glycopeptide-resistant MRSA will become more common in the future. It is essential to avoid any unnecessary use of glycopeptides that might encourage the emergence of such strains, to maintain vigilant surveillance for their appearance, and to strictly isolate any cases that do occur to prevent further spread.

Within hospitals, the sources of cross-infection with MRSA are usually infected or asymptomatic patients who may be colonized in the nose, pharynx, rectum, wounds, and chronic skin lesions. Nasal carriage by staff members is usually low, on the order of 1% to 8%, but staff members may transfer MRSA between patients via hand contact, either directly from patient to patient or via fomites *(123)*. Although MRSA may be spread by airborne transmission, this appears to be less common than with MSSA. The risk of colonization and infection with MRSA increases with the length of hospitalization, the severity of the underlying disease, the number of operations or manipulations, and previous exposure to antibiotics, especially cephalosporins and aminoglycosides *(124,125)*. Although some types of MRSA appear sporadically and rarely cause outbreaks, epidemic strains spread rapidly in hospitals and may become endemic.

Topical mupirocin is widely used for the clearance of nasal carriers of MRSA during outbreaks *(126)*. Susceptible strains have MICs of <1 μg/mL, and the ointment contains 20,000 μg/mL. Resistance to mupirocin is uncommon, but rates tend to be higher in patients given prolonged treatment such as those in dermatology clinics and during outbreaks of mupirocin-resistant strains. Mupirocin acts by inhibiting bacterial isoleucyl-tRNA synthetase, and resistance appears to be mediated by the production of modified enzymes. Isolates showing low-level resistance have a single chromosomally encoded modified synthetase, whereas those with high-level resistance also have a second enzyme encoded on a plasmid *(127,128)*. Staphylococci can be trained to low levels of mupirocin resistance (MICs < 64 μg/mL) *in vitro*, and similar low-level resistance may emerge during therapy. The clinical significance of such resistance is uncertain, since topical mupirocin concentrations are very much higher than these MICs, and carriage of low-level resistant strains can be eradicated with normal mupirocin therapy. More important are isolates showing high-level resistance (MICs > 1,024 μg/mL), which cannot be cleared by mupirocin therapy *(129)*. This type of resistance may be carried on a conjugative plasmid or transposon and can transfer to other microorganisms *(130)*. Since mupirocin is so useful in the management of *S. aureus* outbreaks, the use of this agent should be carefully controlled to preserve its effectiveness.

MRSA strains are usually brought into hospitals by asymptomatic carriers—either patients or staff members. An important control measure is to screen patients admitted from other hospitals and keep them in isolation until they are shown not to be carriers. Similarly, new staff members who have recently worked at other hospitals (including agency staff members) should not be allowed to work until they have been shown to be free of MRSA. It is also good practice to inform other hospitals if infected or colonized patients are to be transferred to them.

Until recently, MRSA infections presenting outside of hospitals were caused by MRSA strains acquired during previous hospital or healthcare contact *(131)*. (Healthcare-associated MRSA, HA-MRSA) True community-acquired or community-associated MRSA (CA-MRSA) caused by strains distinct from HA-MRSA in patients without prior healthcare contact began to emerge in the 1990s (132). These CA-MRSA clones appear to have emerged by the acquisition of the SCC*mec* cassette by community strains of MSSA. Although HA-MRSA strains tend to cause infection in hospitalized, compromised, elderly patients, often with a history of surgery or indwelling devices, CA-MRSA, like community strains of MSSA, affect younger, healthy people and can spread readily in community settings and hospitals. Unlike HA-MRSA, but like the MSSA strains they are derived from, CA-MRSA are often virulent, causing primary skin infections and invasive sepsis in healthy people. CA-MRSA are characteristically susceptible to most non-β-lactam antimicrobial agents, contain SCC*mec* types IV or V, and produce the Panton-Valentine leukocidin toxin (PVL), a putative virulence factor. Although the role of PVL is debated, PVL-positive CA-MRSA has been associated with severe skin sepsis and fatal necrotizing pneumonia (*133,*134). Nevertheless, not all CA-MRSA produce PVL; some strains have become multiply antibiotic resistant, and CA-MRSA is increasingly the cause of hospital outbreaks (135).

The prevalence of CA-MRSA is particularly high in the United States, where CA-MRSA is now the most common cause of both hospital and community *S. aureus* infections in certain cities. European CA-MRSA prevalence rates are low but increasing. The United States is dominated by a single successful clone, the PVL-positive USA300, but CA-MRSA strains from most other parts of the world are characterized by clonal diversity with only about half expressing PVL *(136)*.

The shuttling of CA-MRSA between hospital and community may result in more frequent MRSA infections in the community, more severe MRSA infections in hospitalized patients, the spread of MRSA to previously spared hospital specialties such as pediatrics and obstetrics, more frequent MRSA infections in less-compromised patients and in healthcare workers, and the emergence of multiply resistant CA-MRSA strains. This new MRSA epidemiology will require new control measures, both in hospitals and in the community (see also Chapters 28 and 29).

Coagulase-Negative Staphylococci There are many species of coagulase-negative staphylococci, of which the most common to be isolated from clinical material is *Staphylococcus epidermidis*. At one time, coagulase-negative staphylococci were regarded as insignificant pathogens of humans, but they are now recognized as important causes of infection in hospitalized and compromised patients. Many of these microorganisms are multiply antibiotic-resistant

(137) and can produce an extracellular "slime" that allows them to stick to plastic prostheses and survive on foreign surfaces within a protective biofilm (16,*17,138*). As a result, infections with coagulase-negative staphylococci are being seen with increasing frequency in compromised patients. These include bacteremia (associated with intravascular catheters and vascular grafts), endocarditis (prosthetic heart valves), meningitis (ventricular shunts), peritonitis (peritoneal dialysis catheters), and infection of joint prostheses. Coagulase-negative staphylococci are now common isolates from blood cultures, usually associated with vascular lines, especially indwelling and long-term ones such as Hickman lines *(138)*.

About half the strains isolated in hospitals show multiple antibiotic resistance, including resistance to methicillin (and other β-lactams) and gentamicin. Methicillin-resistant strains tend to be more multiply resistant than methicillin-sensitive ones. Healthy individuals are normally colonized by relatively sensitive microorganisms, primarily *S. epidermidis*. After admission to the hospital, and especially after exposure to multiple courses of antibiotics or surgical prophylaxis, patients become colonized with multiply resistant strains and with other more resistant coagulase-negative species such as *Staphylococcus hemolyticus (139)*. Resistance in coagulase-negative staphylococci appears to be increasing, probably under the pressure of antibiotic use *(140)*. Sensitive staphylococci may receive plasmid-borne resistance factors from other microorganisms during contact on the skin surface, and there is evidence that coagulase-negative staphylococci may be a reservoir of resistance genes that can be transferred to *S. aureus (141,142)*.

Because of extensive multiple resistance in coagulase-negative staphylococci, the glycopeptides vancomycin and teicoplanin are often used for therapy and prophylaxis in high-risk patients. Low-level resistance to glycopeptides has appeared in hospital isolates of coagulase-negative staphylococci, and such resistance can be produced by exposure to increasing drug concentrations *in vitro*. Teicoplanin resistance is easier to produce than vancomycin resistance, and MICs are higher *(143)*. Similar low-level teicoplanin-resistant, vancomycin-sensitive strains are being increasingly isolated from clinical specimens *(144–146)*. There is some evidence that *S. hemolyticus* is more likely to exhibit teicoplanin resistance than are other coagulase-negative species but not all studies have shown this.

Molecular methods have revealed clusters of hospital infection with indistinguishable strains of coagulase-negative staphylococci *(147–150)*. In most instances, however, the sources and routes of transmission of the outbreak strains are unclear. In general, however, infection with coagulase-negative staphylococci should be regarded as endogenous unless clustering of unusually resistant isolates is noted. Colonization and infection with resistant strains are more likely with prolonged hospitalization and multiple courses of antibiotic therapy. Eradication of bloodstream infection will usually require the removal of the colonized catheter or prosthesis (see also Chapter 30).

Enterococci Enterococci are found in the stools of most normal people and sometimes in other sites such as the mouth and vagina. *Enterococcus faecalis* and *Enterococcus faecium* predominate, with *E. faecalis* usually being the most common; other species are uncommon causes of human infection. The enterococci typically cause endogenous infections, most commonly of the urinary tract, but also of the abdomen and pelvis, where they are usually mixed with other bowel flora. They are relatively poor pathogens but may go on to cause invasive disease in compromised patients, causing cholangitis, septicemia, endocarditis, and meningitis *(151)*. Multiresistant strains of enterococci cause hospital outbreaks in which they colonize the bowels of asymptomatic patients and are transferred between patients on staff members' hands *(151,152)*.

The enterococci are typically susceptible to ampicillin/amoxicillin but intrinsically relatively resistant to benzylpenicillin and other β-lactams such as cloxacillin, the cephalosporins, and the carbapenems. They are also usually resistant to trimethoprim and the sulfonamides, the quinolones, low levels of aminoglycosides, and low levels of clindamycin. Furthermore, these microorganisms have a remarkable ability to acquire new resistances to ampicillin/amoxicillin and other drugs that might be used against gram-positive bacteria, including chloramphenicol, erythromycin, tetracycline, high levels of aminoglycosides and clindamycin, and now, the glycopeptides vancomycin and teicoplanin. *E. faecium* is inherently more resistant to penicillin and ampicillin than *E. faecalis*, probably due to changes in the affinity of the enterococcal PBPs.

Transferable β-lactamase–mediated ampicillin resistance has been reported in *E. faecalis,* but although such strains have caused several large hospital outbreaks *(153,154)*, they are usually rare in clinical material.

Because the enterococci are intrinsically resistant to the most commonly used antimicrobials, they have become increasingly important as causes of infection and superinfection in hospitalized patients. Enterococci are now the third most common cause of healthcare-associated infections, being responsible for 10% to 12% of all healthcare-associated infections, 10% to 20% of HA UTI, and 5% to 10% of HA bacteremias *(155)*. Because of their great ability to acquire multiple resistances, the enterococci are one of the few bacterial groups that can become resistant to most available antibiotics.

Glycopeptide-Resistant Enterococci Glycopeptides inhibit the synthesis of gram-positive cell walls by binding to the amide bond of the D-alanyl-D-alanine terminal sequences of the muramyl pentapeptide of the elongating peptidoglycan polymer. The large glycopeptide molecules then impede the action of both the polymerase that extends the peptidoglycan backbone and the transpeptidase that cross-links the growing chain to the existing cell wall *(156,157)*.

Most clinically important gram-positive bacteria are naturally susceptible to the glycopeptides vancomycin and teicoplanin. Vancomycin resistance can be divided into low-level (MICs of 8–32 μg/mL) and high-level (MICs > 64 μg/mL). Acquired glycopeptide resistance is rare but is most frequently seen in enterococci, which exhibit at least four resistance phenotypes *(158)*: (a) v*anA*, high-level transferable resistance to both vancomycin and teicoplanin, associated with the production of a 38- to 40-kDa membrane protein, (b) *vanB*, inducible low-level resistance

to vancomycin alone that, in some strains, is associated with a 39.5-kDa membrane protein, (c) v*anC*, constitutive low-level vancomycin resistance seen in some strains of *Enterococcus gallinarum*, and (d) *vanD*, described in only a few strains of *E. faecium*, with constitutive resistance to vancomycin (MICs ~64 μg/mL) and to low-levels of teicoplanin (MICs ~4 μg/mL). *Enterococcus casseliflavus/Enterococcus flavescens* appear to have intrinsic low-level resistance unrelated to that of the other phenotypes.

The v*anA* phenotype of high-level resistance to both vancomycin and teicoplanin is usually encoded on a transferable plasmid and is the most serious clinical problem. v*anA* strains have vancomycin MICs of 64 to more than 1,024 μg/mL and teicoplanin MICs that are usually one or two times lower than this. The *vanA* gene encodes an abnormal D-Ala-D-Ala ligase, which results in the replacement of the normal D-Ala-D-Ala termini of peptidoglycan precursors by D-Ala-D-Lactate, which cannot bind glycopeptides *(157,158)*. The successful production of the *vanA* glycopeptide resistance phenotype is dependent on the cooperative activity of the products of seven genes, which are usually contained in a transposon and usually encoded on a plasmid. The mechanisms and genetics of the other vancomycin resistance phenotypes have not been so well elucidated, but they all seem to result from the production of altered ligases. The *vanA* gene is variably transferable by conjugation or transformation *in vitro* to other gram-positive bacteria, including *S. aureus (120)*, but it has not, until recently, been passed to other genera naturally. However, as described above, there were reports from the United States in 2002 of two unrelated clinical isolates of MRSA that had acquired the *vanA* gene, presumably from enterococci *(121)*. Only a handful of similar events have since been reported and continuing surveillance will reveal whether such strains will increase in prevalence in the future.

Vancomycin has been used for several decades, but acquired resistance was rare until a multiple strain outbreak of vancomycin- and teicoplanin-resistant enterococci appeared in London in 1986 *(159)*. Since then, such strains have been seen throughout the world. They are common in the United States, where the NNIS survey found a 20-fold increase in healthcare-associated VRE isolates during the period 1989 to 1993 *(160)* and a 47% increase in ICU isolates from 1994 to 1998 and in 1999 *(23)*. In US ICUs, about 12% of hospital isolates of enterococci are VRE. They are much less common in Europe.

In the EARSS surveillance data for 2008 *(24)*, no invasive vancomycin-resistant *E. faecium* were seen in 10/33 countries. However, three countries reported vancomycin resistance rates in *E. faecium* isolates of more than 25%, namely, Greece (28%), Ireland (35%), and the United Kingdom (28%). In several European countries, VRE rates have been declining, possibly as the result of improved control measures. The worldwide emergence of VRE has been associated with the spread of a major hospital-adapted clonal lineage (clonal complex 17: CC17) of *E. faecium* with a background of high-level aminoglycoside resistance *(161)*.

Although the origin of the vancomycin-resistance transposons is obscure, the emergence of this resistance has occurred during a time when the glycopeptides have been increasingly used for the treatment of multiresistant staphylococci, enterococci, and *C. difficile*–associated diarrhea *(162)*. Furthermore, outbreaks of healthcare-associated VRE are most common in renal, liver, and hematology departments and in ICUs where glycopeptide therapy is common.

A further source of glycopeptide "pressure" is the use of the antibiotic avoparcin in animal husbandry. Avoparcin is a glycopeptide related to vancomycin that is not used in human therapy but is added in small amounts to animal feed in Europe. Several studies suggest that in farms where avoparcin additives are used animal and human bowels become colonized with *vanA* type VRE, and frozen chickens in supermarkets may be a source of VRE for people unexposed to hospitals or glycopeptides *(163,164)*. After admission to hospital, treatment with glycopeptides may select these microorganisms from the bowel with resulting healthcare-associated infection *(165)*. As a result of these studies, several European countries have now banned avoparcin feed supplements, but this issue remains controversial. Avoparcin is not used in the United States, which has the greatest incidence of VRE and where transmission appears to be mainly healthcare-associated. The reasons for the differences in the epidemiology of VRE between Europe and the United States have not been fully elucidated *(166,167)* (see also Chapter 33).

Multiply Resistant Pneumococci *Streptococcus pneumoniae* is the most common cause of bacterial pneumonia, the second most common cause of meningitis, the third most common cause of septicemia, and an important pathogen of otitis media. All of these are predominantly community-acquired infections. Until recently, the pneumococcus was fully sensitive to benzylpenicillin and not often considered an important hospital pathogen. However, the pneumococcus does cause hospital cross-infection *(168)*, and hospital outbreaks with multiply resistant strains (which are more readily recognized) are being reported with increasing frequency. Transmission is presumably by droplet spread, and ideally, infected patients should be nursed in side rooms.

S. pneumoniae frequently acquires resistance to tetracycline and sometimes to sulfonamides, erythromycin, lincomycin, or chloramphenicol. Pneumococci are normally relatively resistant to aminoglycosides (MICs of streptomycin 8 μg/mL), but some strains show high-level resistance (>2,000 μg/mL). Penicillin resistance was first reported in 1967 from Papua, New Guinea and, since then, has been seen with increasing frequency in many countries. Multiple resistance is an increasing problem, the most commonly seen patterns being resistance to penicillin and tetracycline and resistance to penicillin, tetracycline, and chloramphenicol.

Sensitive strains of pneumococci have penicillin MICs of 0.006 to 0.008 μg/mL. The first penicillin-resistant isolates showed low-level resistance with MICs of 0.1 to 1.0 μg/mL, but in 1977, pneumococci were isolated in South Africa showing high-level resistance with penicillin MICs of >1 μg/mL *(169)*. Penicillin resistance results from the stepwise acquisition of multiple genetic changes that produce various alterations in pneumococcal PBPs *(170)*. The variant sequences inserted into the PBP genes appear to have been derived by transformation from oral streptococcal species *(171)*. Although many penicillin-resistant isolates

of pneumococci are sensitive to newer β-lactams such as cefotaxime, some strains are resistant to these drugs by producing simultaneous changes in more than one penicillin-binding protein. Penicillin resistance in pneumococci may not be detected by routine sensitivity-testing methods, and for disc testing, a 1 mg oxacillin disk is recommended *(172)*.

The geographic variation in the distribution of resistant strains of pneumococci is considerable, even between different cities in the same country. In the EARSS surveillance data for 2008 *(24)*, 10% of all (>11,000) invasive *S. pneumoniae* isolates reported by 32 European countries were nonsusceptible to penicillin. Most northern countries had nonsusceptibility rates below 5%, but Finland (11%) and Ireland (23%) had relatively high rates. Rates of >25% were reported from southern and eastern Europe, including France (30%), Hungary (27%), and Turkey (34%). Other countries had even higher rates but with small numbers of isolates. In the US NNIS surveillance data up to 2004, penicillin resistance rates in healthcare-associated isolates were around 19% for both ICU and non-ICU patients (Table 86-2).

Since the early 1980s, many reports have appeared of hospital outbreaks of penicillin-resistant pneumococci *(173–176)*. These outbreaks often involve children or the elderly in day-care or chronic care centers. In these age groups, nasal carriage is common, and during outbreaks, other patients, staff members, and family members may become rapidly colonized by resistant pneumococci after casual contact with affected patients. Carriage may persist for several months, and the microorganisms may then disseminate further within the community.

Respiratory infections with strains of pneumococci showing low-level penicillin resistance can be treated with high doses of penicillin. Meningitis and infections with high-level resistant strains have been successfully treated with vancomycin or third-generation cephalosporins such as cefotaxime or ceftriaxone *(177,178)*. However, resistance to third-generation cephalosporins has increased dramatically in some areas *(179),* and there have been failures with these regimes in meningitis; a combination of vancomycin with cephalosporins, meropenem, or rifampin have been recommended *(180)*. Treatment with other antistaphylococcal agents such as erythromycin, chloramphenicol, lincomycin, or rifampin should be guided by the results of sensitivity testing.

Clostridium difficile *C. difficile is* a special type of antibiotic-resistant healthcare-associated pathogen. *C. difficile* is an anaerobic spore-forming bacillus that is widely distributed in the environment and colonizes the bowel asymptomatically in some people; it is resistant to several common antimicrobials. Antibiotic therapy tends to disrupt the normal sensitive bowel flora and allows antibiotic-resistant *C. difficile* to proliferate. Some classes of antibiotics, especially cephalosporins and quinolones, appear also to encourage the microorganism to sporulate and produce toxin. Toxigenic strains produce two toxins A and B *(181)* that act on the bowel mucosa to produce *C. difficile*–associated disease (CDAD). This ranges from mild, reversible diarrhea to pseudomembranous colitis, toxic megacolon, and fatal bowel perforation.

CDAD may occur as sporadic cases when carrier patients enter hospital and are started on broad-spectrum antibiotics. However, cross-infection from diarrheal CDAD patients to others may occur following contamination of staff hands or the hospital environment with spores. *C. difficile* is now the most common cause of healthcare-associated diarrhea *(181)*.

Since January 2004, English hospital trusts have been required to report cases of CDAD in inpatients older than 65 years. There was an increase in the numbers of reported cases of CDAD from 44,448 in 2004 to 51,690 in 2005 *(182)*. Increasing CDAD has been associated with significant and increasing mortality: the number of death certificates mentioning *C. difficile* in England and Wales increased from 975 in 1999 to 1,214 in 2001 and to 3,807 in 2005 *(183)*.

In addition to the continuing increase in endemic *C. difficile* infections, there have been recent reports from Canada, the United States, and Europe of large, often multicenter, hospital outbreaks of CDAD, associated with high rates of morbidity and mortality (20,*184,185,*186). These outbreaks have been caused by a new virulent and highly transmissible strain of *C. difficile*, referred to variously as toxinotype III, North American pulse field gel electrophoresis type 1, and PCR-ribotype 027 (NAP1/027) (186). This strain appears to be a hyperproducer of toxin and elaborates a binary toxin as well as toxins A and B. *C. difficile causing* CDAD is thus another environmental, opportunistic MDR pathogen that is encouraged by antimicrobial use, is spread by poor hygienic practice, and has increased dramatically in recent years (see also Chapter 37).

CONCLUDING REMARKS

Antimicrobial resistance, often multiple, has spared few healthcare-associated pathogens and is increasing inexorably. Even by the early 1990s, several authorities had warned that the emergence of essentially untreatable multiresistant healthcare-associated pathogens signified a crisis for antimicrobial therapy and heralded the end of the antibiotic era ((4): *The crisis in antibiotic resistance*; *(187)*: *Resistance to antimicrobial drugs — A worldwide calamity;* (1): *Epidemiology of drug resistance: implications for a post-antimicrobial era*). The situation has since deteriorated further and has been aggravated by the lack of new antimicrobials in the pharmaceutical pipeline *(188)*. The Infectious Diseases Society of America has produced a policy paper in response to this crisis entitled *Bad bugs, no drugs. As antibiotic discovery stagnates….a public health crisis brews* (189), and the European Academies Science Advisory Council and the European Society of Clinical Microbiology and Infectious Diseases have voiced similar concerns (*190,*191).

The lesson that should have been learned and taken to heart is that increasing antimicrobial use is associated with increasing antimicrobial resistance. The management and control of resistant infections in hospitals will depend more on the control of hospital infection and of unnecessary antimicrobial therapy than on the availability of yet more powerful antibiotics.

CHAPTER 87

Antimicrobial Stewardship

Dilip Nathwani

In the 20th century, the discovery of penicillin was regarded as one of the major medical advances that stimulated "the antibiotic revolution" (1). While transforming the prognosis of infections, by the middle of the last millennium, over 80% of patients diagnosed with acute bronchitis received antibiotics—a shift in public and professional behavior that was not supported by evidence of clinical benefit (2). Therefore, an increase in antimicrobial resistance was an inevitable, evolutionary consequence of the increased exposure of bacteria to antimicrobials *(3)*. Resistance is now a global public health problem that impacts clinical practice (1,2). Despite this problem, the perception among clinicians regarding the relevance of resistance to their clinical practice remains challenging. For example, a recent survey of 149 junior hospital doctors from France and Scotland showed that although 95% regarded resistance as a national problem, only 63% rated the problem as important in their own daily practice *(4)*. These results are consistent with other studies *(5–7)*, which show that only a minority of staff are aware of effective methods for reducing antimicrobial resistance.

Patients and the public have also an important role in reducing collateral damage from antibiotics *(8)*. In a large UK household survey, 79% of 7,120 respondents were aware that antibiotic resistance is a problem in British hospitals, but 38% of respondents did not know that antibiotics do not work against most coughs or colds, and 43% did not know that antibiotics can kill the bacteria that normally live on the skin and in the gut. Therefore, the education of clinicians and the public about resistance is important. The focus, however, should be on changing behavior rather than simply increasing knowledge about antibiotics or resistance. A recent analysis (9) of the value and outcomes of public campaigns aimed at improving the use of antibiotics in outpatients in high-income countries concluded that hard scientific evidence for a cause–effect relationship is lacking because of multiple potential confounders, their multifaceted nature, and relatively poor availability of data. However, despite this, the results of several campaigns suggest they had a positive effect on the use of antibiotics, although whether this was related to change in the behavior of physicians, patients, or both was not made clear (9). While we wait for better designed interventions, one European campaign is worthy of attention. The European Parliament initiated an annual European Antibiotic Awareness Campaign in 2008, targeted at increasing awareness of the general public about the prudent use of antibiotics in 2008 and improving antibiotic use in primary care in 2009. The campaign for 2010 will focus on hospital prescriptions. The campaign materials include a focus on key unequivocal messages, logos, slogans, and media-related material such as toolkits and television coverage. Key success factors were good cooperation and process for building the campaign, strong political and stakeholder support, and the development of campaign materials based on scientific evidence (10).

WHAT IS ANTIMICROBIAL STEWARDSHIP?

In Europe in 2008, 16 countries had developed a national strategy to contain antimicrobial resistance, and 9 countries had an action plan *(11)*. If we are to preserve antibiotics as a valuable and precious resource and extend their useful life, a core component of most of these strategies is antimicrobial stewardship (ABS), which has been defined as a set of measures or interventions delivered by a multidisciplinary team working in healthcare institutions to optimize antimicrobial use among patients in order to improve patient outcomes, ensure cost-effective therapy, and reduce adverse sequelae of antimicrobial use including ecological effects such as resistance and *Clostridium difficile* infections (CDI) (12–14). There are also formidable hospital and society costs associated with antimicrobial-resistant infections (ARI). In a recent study of 1391 hospitalised patients 188 (13.5%) had a antimicrobial resistant infection (ARI). The medical costs attributable to the ARI ranged from $18,588 to $29,069 and excess duration of hospital stay and attributable mortality of 6.4 to 12.7 days and 6.5% respectively. The total costs to this patient cohort were $13.35 million in 2008. This study eloquently identifies the potential beneficial fiscal impact of good ABS programs and their cost-effectiveness (15).

At the heart of any stewardship program is an antimicrobial management (AMT) or stewardship (AST) team—terms commonly used for the multidisciplinary team. In this program, each member is given specific roles, which collectively take responsibility for the implementation of local policies. The critical value and role of the pharmacist as part of this team has recently been reviewed (16).

To be effective, the team must have full support from hospital leadership, work closely with infection control teams, and provide regular feedback to individual clinicians and clinical teams about their compliance with policies.

Stewardship programs are composed of organizational structures and action plans for implementing ABS. While many such programs have a hospital focus, they are also of relevance and importance to primary care (17). Targets for ABS include appropriate antibiotic selection, dosing, route, and duration of therapy. ABS needs to be combined with infection prevention measures and environmental decontamination to limit the emergence and transmission of antimicrobial resistance; this trio of measures will address the so-called holy trinity of resistance development and spread (18). This trinity recognizes that to minimize the development of resistance there must be a collaboration between ABS, infection control programs, and environmental service departments.

BOX 87-1

National Antimicrobial Prescribing Indicators Introduced by Scottish Government in 2009

Hospital-based empirical prescribing: Antibiotic prescriptions are compliant with the local antimicrobial policy, **and** the rationale for treatment is recorded in the clinical case notes in ≥95% of sampled cases.

Surgical antibiotic prophylaxis: Duration of surgical antibiotic prophylaxis is ≥24 h%, **and** it is compliant with local antimicrobial prescribing policy in ≥95% of sampled cases.

Primary care empirical prescribing: Seasonal variation in quinolone use (winter months vs. summer months) is ≤5%, calculated from PRISMS data held by NHS Boards.

(From Scottish Antimicrobial Prescribing Group. Available at *http://www.scottishmedicines.org.uk/smc/6616.html* (cited May, 2010).)

PRIMARY CARE ANTIMICROBIAL STEWARDSHIP

The focus of this review is primarily hospital stewardship programs. However, one should not underestimate the need for similar programs in the community, particularly long-term care facilities and the veterinary sector. They need to be developed and implemented strategically in conjunction and collaboration with hospital programs. There are many emerging examples of successful stewardship programs addressing primary care. Programs from Belgium (19), France (20), and Sweden (21,*22*) among others, are worthy of note. In France, a sustained national reduction in antibiotic use has been associated with a reduction in the proportion of penicillin-nonsusceptible *Streptococcus pneumoniae* in France *(23)*. More recently, in Israel a national restriction of ciprofloxacin use was associated with an immediate, marked reduction in ciprofloxacin resistance in gram-negative bacteria isolated from urine by 1.16% for each decrease of 1,000 DDDs (defined daily doses) in ciprofloxacin use (24). Of these successful national initiatives, very few have been linked with improved patient clinical outcomes, which is a long-term ambition of these interventions.

One example of a more cohesive national stewardship program that integrates community and hospital stewardship and has a focus on CDI, an important adverse ecological outcome, is emerging from Scotland. Hospital-based studies have shown that the introduction of conservative antibiotic policies in hospitals aligned with strict infection control was associated with a reduction in CDI (25,26). In Scotland, this was one of the key factors that stimulated a national stewardship program with one aim: to reduce *C. difficile*–associated diarrhea (CDAD). In 2009, the Scottish government announced a new health efficiency and access to treatment target for *C. difficile*–associated disease by the National Health Service (NHS) Scotland. This was defined as being "to reduce the **rate** of CDAD among patients aged 65 and over by at least 30% by 31 March 2011." The target will measure the rate of CDAD reported from acute hospitals, nonacute hospitals, and community settings per 1,000 occupied bed days in Scotland (27). Recognizing the key relationship between poor-quality antibiotic prescription, particularly cephalosporins and quinolones, and CDAD, the Scottish government and Scottish Antimicrobial Prescribing Group (SAPG) have agreed upon and set three supporting antimicrobial prescribing targets, in addition to infection control measures, that support and encourage hospitals and communities to achieve this CDAD target. The target related to community prescribing is seasonal variation in quinolone use (summer months vs. winter months). This indicator is now a set target of <5% variation for all health regions (NHS Health Boards) within Scotland *(28)*. This is 1 of 12 quality indicators to evaluate the impact of primary care ABS interventions that have been developed by the European Surveillance of Antimicrobial Consumption Group *(29)*. The indicators are either measurable from routinely available data or can be measured sustainably by clinical teams. Other targets related to hospital prescribing have also been set and are summarized in Box 87-1. In Scotland, national data on the primary care quinolones indicator is currently being analyzed, but data from the author's region, NHS Tayside, one of the health regions in Scotland, show that consumption has fallen by 2 prescriptions per 1,000 residents per month in the past year (D. Nathwani, personal communication). Assuming seven DDDs per prescription, this equates to a decrease of at least 3,000 DDDs per month in NHS Tayside's population of 350,000 people, which should be enough to reduce ciprofloxacin resistance in *E. coli* by 1% (24). Analysis of trends in antibiotic resistance will follow the analysis of the national impact of the primary care quinolone prescribing indicator.

The models of the various stewardship programs employed in the community need to reflect not only the clear differences in community and hospital-care provision but also national and regional sociocultural and economic differences in healthcare provision (30).

HOSPITAL ANTIMICROBIAL STEWARDSHIP

In the United States and Europe, a variety of organizations have proposed a framework and governing principles for hospital antimicrobial stewardship (H-ABS)

(2,14,17). This will help to support the development, implementation, and evaluation of existing and new programs within North America and Europe. However, their value in other countries may be more limited due to resourcing and sociocultural differences. For example, in India and Sri Lanka, 66% of community prescriptions include an antimicrobial, and in Bangladesh and Egypt, antibiotic use accounts for 54% and 61%, respectively, of all hospital prescriptions *(31)*. The potential value of ABS in such countries and its current role have recently been reviewed *(32)*. Therefore, a more global perspective, including cost-effectiveness of stewardship in developing countries, is also urgently required in keeping with the World Health Organization's aspirations *(33)*.

HOSPITAL ANTIMICROBIAL STEWARDSHIP GUIDANCE

In 2005 and 2008, MacDougall and Polk (12) and Owens (18) have comprehensively reviewed ABS programs in healthcare systems. It is not the intention of this review to detail the key studies identified in these and subsequent studies but rather to highlight systematic evaluations of recent literature and summarize their key findings.

The first systematic review of the literature was undertaken by the Infectious Diseases Society of America (IDSA) and the Society for Healthcare Epidemiology of America (SHEA). The published guidelines (14) for developing an institutional program to enhance antimicrfobial stewardship provide a range of recommendations and the supporting evidence for the effectiveness of a range of strategies. Whilst the guidance is primarily from a US healthcare and hospital perspective, many of the recommendations are broadly applicable to most countries and settings. These recommendations are supported by the evidence base for the range of tools or interventions used in stewardship programs and are tabled (Table 87-1). These guidelines use the IDSA–United States Public Health Service grading system for ranking clinical guidelines *(34)*.

The Cochrane Effective Practice and Organization of Care (EPOC)Group acceptd three designs for the evaluation of interventions: clinical trials, controlled before-and-after studies, and interrupted time-series (ITS) analysis (35). Guidelines on the application of these designs to the evaluation of interventions to reduce infection have been published (36) together with guidance on statistical analysis (37,38). All of these sources agree that an uncontrolled before-and-after study is not a valid study design (35–38). Less than 50% of articles published in 2004 to 2006 about interventions to improve hospital antimicrobial prescribing (39) met these minimum standards set by the Cochrane EPOC Group, which is an issue that scientific journals need to address to improve the quality of their publications.

This Cochrane collaboration systematic review and meta-analysis of ABS interventions in the community (40) and hospital (39) is probably a more robust analysis since the quality of studies and evidence reviewed were subject to the strict criteria mentioned above. In these reviews, the most common method for the evaluation of interventions was an ITS in hospitals (55% of studies) compared with 28% randomized controlled trials. ITS design also had the lowest risk of bias compared with other study designs.

The design of the various inpatient-based studies, the type and target for the intervention, and the outcome measures are summarized in Table 87-2 (39). Eighty-one (76%) of one hundred and six interventions relating to prescriptions in hospital inpatients (39) were associated with statistically significant improvement in the primary outcome. Nineteen (18%) of the hospital interventions aimed at increasing the intensity of antibiotic treatment, and only eight (8%) studies targeted the decision to prescribe—often an important source of poor prescribing. The most common target for intervention was the choice of drug (80%).

Computerized decision support is a promising method for reducing the number of patients that receive unnecessary antibiotics (41), and one study has shown the potential for this approach in hospital care *(42)*. Forty-seven (44%) of the interventions included a restrictive component, which limited the choice of antibiotic to professionals. This supports one of the two key recommendations in the IDSA and SHEA guidelines (14): formulary restriction or a requirement for preapproval for a specific drug, or both. This is commonly called a "front-end program," where antimicrobials are made accessible through a formulary or approval process.

The two most common persuasive interventions used in hospitals were the distribution of educational materials and reminders. In the Cochrane review (39), only 10% of hospital interventions used audit and feedback—commonly called the "back-end" program where antimicrobial use is reviewed after therapy has been initiated and recommendations are made with regard to their appropriateness. The relatively small number of studies evaluating the impact of audits with intervention and feedback is interesting as this intervention is regarded as fundamental to effective ABS in the IDSA and SHEA guidance (14).

The conclusions from this and other Cochrane reviews (*43,44,*45) is that the most successful interventions are those that involve professionals who are catalysts for change in both the development and dissemination phases and who provide concurrent feedback about implementation. However, this approach requires a considerable investment of time by these professionals as well as a need for information systems that are capable of providing concurrent feedback. Simply providing prescribers with educational information may be relatively unsuccessful, but this approach also requires considerably fewer resources, and so it could be a more cost-effective method for achieving change. Relevant educational material is increasingly available but is of variable quality. A review (46) of the availability and quality of a range of Web-based educational material relating to ABSs in healthcare institutions revealed a wealth of material but also showed significant variability in terms of design and ease of navigation, the amount and scope of information, the availability of material in different languages, and the ability to download the material. The available resources had a US and European bias, but most included guidance, current news, and educational teaching material. The prudent antibiotic user website PAUSE (http//www.pause.online.org.uk) is particularly useful for undergraduate students but can be adapted for postgraduate use. It is

TABLE 87-1

Infectious Diseases Society of America's Recommendations for Specific Antimicrobial Stewardship Measures

Strategy	*Recommendation (Strength and Grade of Recommendation)*
1. Resourced multidisciplinary AMT or AST	A-111
2. Collaboration between AST, hospital infection control, pharmacy, and other relevant stakeholders	A-111
3. Hospital leadership support and engagement	A-111
4. Agreement between key stakeholders of authority, compensation and outcomes of program	A-111
5. Hospital organizational and administrative support	A-111
6A. Prospective audit with intervention and feedback	A1
6B. Formulary restriction and preauthorization to reduce use and cost	A11
Formulary restriction and preauthorization to reduce long-term resistance	B11-111
Education	A-111
Enhance knowledge	B-11
Education impact on changing prescribing behavior	
Guidelines and clinical pathways improve antibiotic use	A-1
Guidelines and clinical pathways implemented through education and feedback on antibiotic use and outcomes	A-111
Antibiotic cycling	C-11
Antimicrobial order forms	B-11
Combination therapy to prevent resistance	C-11
Combination therapy to increase breadth of cover	A-11
Streamlining or deescalation of therapy	A-11
Dose optimization	A-11
Intravenous (parenteral) to oral conversion to reduce length of hospital stay and costs	A-1
Healthcare information technology to improve the decision-making process:	A-111
Electroinic medical records	B-11
Computer physician order entry	B-11
Clinical decision support	
Effect of computer-based surveillance on tracking resistance patterns, identification of nosocomial infections and drug adverse events	B-11
Value of clinical microbiology to provide specific data on resistance and epidemiology of outbreaks	A-111
Value of process and outcome measures to determine impact of antimicrobial stewardship on antimicrobial use and resistance patterns	B-111

Note: Core strategies. A-1 means good evidence to support a recommendation for use based on evidence from one or more properly randomized controlled trials *(34)*. For a majority of the recommendations, the quality of evidence is not very high (i.e., A or B; 2 or 3). (Adapted from Dellit TH, Owens RC, McGowan JE Jr, et al. Infectious Diseases Society of America and the Society for Healthcare Epidemiology of America guidelines for developing an institutional program to enhance antimicrobial stewardship. *Clin Infect Dis* 2007;44:159–177.)

recommended by the European Society for Microbiology and Infectious Diseases [ESCMID].

The Cochrane reviews (39) also concluded that hospital-based restrictive interventions were associated with a greater immediate impact than persuasive interventions. However, the impact of persuasive and restrictive interventions was similar after 6 months, and after 12 months, there was a suggestion that persuasive interventions had greater impact (39). Despite this, a recent survey *(47)* of 190 junior and 250 specialist medical staff, of which 164 responded, 85% had a positive attitude to an antibiotic approval (restrictive) program as this approach made teams think carefully about antibiotic choice. 91% also believed the advice given was helpful and educational (88%). Only 10% believed this process undervalued their intuition and experience, and 19% believed it infringed upon their autonomy.

Whilst guidelines and systematic review evidence is helpful, they do not often help differentiate, for policymakers working in "real-world" settings, the most effective interventions to implement based on clinical and cost-effectiveness grounds. Perhaps the next logical step in guideline development for stewardship may be to use the GRADE approach *(48)*. This approach may help patients, clinicians and policymakers better understand the implications of adopting guideline recommendations of variable strength. The GRADE approach encompasses recommendations based on a balance between the desirable and undesirable effects of an intervention, the quality of evidence, the value and

TABLE 87-2

Comparison of Evaluations of Interventions to Improve Antimicrobial Prescribing for Hospital Inpatients[a]

Comparison	*Hospital Inpatients*	
Design	***Number***	***%[a]***

[a]Some studies had more than one target or outcome.
(From Davey P, Brown E, Fenelon L, et al. Interventions to improve antibiotic prescribing practices for hospital inpatients. *Cochrane Database Syst Rev (Online)* 2005:CD003543.)

preferences of key stakeholders, and cost (or resource) allocation. This makes the decision-making process of what intervention(s) to adopt more "real world"–informed and transparent but accepts that, ultimately, successful implementation of all or some of these measures will be dependent on local need, organization, available resources, and priorities. The Cochrane systematic reviews (39), for example, identified significant gaps in the evidence base relating to cost-effectiveness. Thirty-one percent of hospital-care studies estimated the financial savings from a reduction in the use of target drugs, but only twelve percent of studies included information about the cost of design and implementation of the intervention, which is essential to the overall assessment of cost-effectiveness.

Whilst these reviews do inform the development and implementation of a stewardship program, local involvement and planning with all key agencies to seek consensus and ownership at a provincial and/or regional level is crucial. A recent example of reaching local consensus for a particular region has been the Ontario, Canada, Antimicrobial Stewardship Project *(49)*. The recommendations of a consensus conference indentified priority intervention for Ontario hospitals. This group acknowledged key drivers for successful stewardship and identified the core elements of the program and the required marketing strategy to support the implementation of a program within their region. The consensus conference identified the following core generic messages that would be relevant for most programs globally:

1. ABS programs are, first and foremost, patient safety and quality of care initiatives. They are also cost-effective across healthcare systems. The World Health Organization recognizes antibiotic resistance as third in priority on a list of patient safety challenges.
2. ABS programs and interventions are needed at provincial, regional, and local levels and should require accreditation by a national relevant body.
3. Implementation of programs need organizational and clinical leadership, performance accountability, and should be supported by dedicated and sustained resources, a multidisciplinary team of experts, information technology, education and training, measurement capability, and marketing strategy.
4. Existing and new networks and resources should be used or developed to support the effective implementation of ABS programs.

For those seeking a more European perspective, a recent European Union workshop in 2009 developed a conceptual framework for the implementation of ABS in the European Union (17). It aims to define the structural and organizational requirements so as to optimize antibiotic use in hospitalized patients. This framework recognizes: (a) the relevance of community care, (b) the importance of further research on the comparative clinical and cost-effectiveness of a range of interventions, (c) the need to strengthen the legal basis and core funding of ABS programs, and (d) the need to ensure that ABS is a core component of quality improvement and patient safety promotion initiatives. In Scotland, for example, healthcare-associated infections (HAIs) and ABS are now key components of the Scottish Patient Safety Program, a national quality improvement health initiative *(50)*. This program is immersed in the Institute of Health Care Improvement Methodology *(51)* to support achieving safe and reliable healthcare (52). At the heart of achieving improvement in HAI is teamworking, organizational change, and an improvement model where change is driven and evaluated through rapid tests of change called the Plan-Do-Study-Act (PDSA) cycle. The PDSA cycle is shorthand for testing a change by developing a plan to test the change (plan), carrying out the test (do), observing and learning from the consequences (study), and determining what modifications should be made to the test (act) *(53)*. The Institute for Healthcare Improvement has also developed the concept of care bundles to help healthcare providers improve the reliability of delivery of essential healthcare processes *(54)*. This has emerged from the acknowledgement that healthcare delivery is too dependent on individual clinicians' knowledge, motivation, and skills, with the result that only approximately 50% of patients receive the recommended care *(55)*. One explanation is that processes in healthcare are rarely designed to meet specific, articulated reliability goals *(55,56)*. A care bundle is a small set of practices that have been

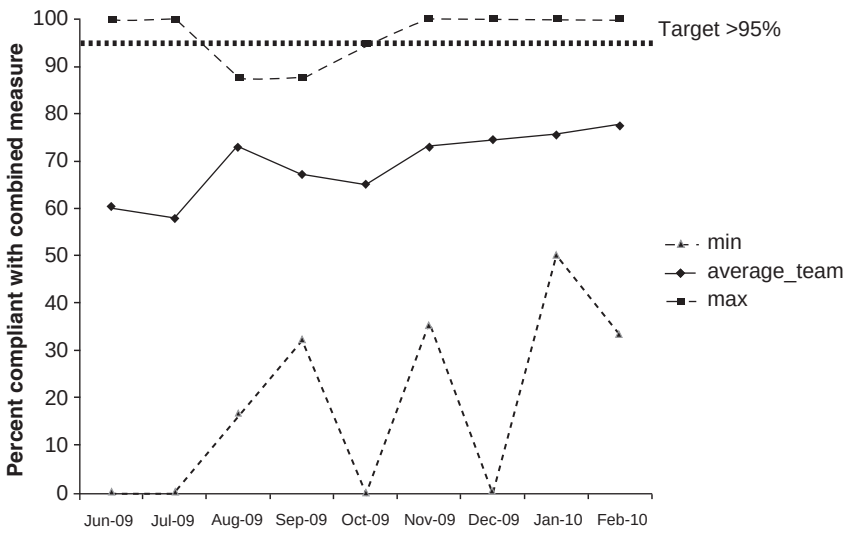
individually proven to improve patient outcomes and, when implemented together, are expected to result in a better outcome than when implemented individually *(54)*. The impact of a bundle depends both on the evidence that supports the recommended care processes and on the implementation and spread of its recommendations. Their value in infection prevention and management has recently been reviewed (57).

Implementation of Antimicrobial Stewardship Programs

Despite the publication of national ABS guidance, many surveys show that their recommendations have not been widely adopted or routinely implemented. For example, in the United Kingdom in 1994, only 62% of 427 UK hospitals had a policy for antibiotic therapy and 75% had an antibiotic formulary *(58)*. Following interventions by the Department of Health to pursue any hospitals that did not have a formal prescription policy, a further survey of acute healthcare trust in England in 2004 to 2005 revealed that an antimicrobial policy was in place in 89% of responding trusts (109/123) *(59)*. This is an improvement on the previous survey result, but it is disappointing that 11% of responding hospitals had not taken the essential first step of writing an antibiotic policy. In the United States, 100% of 47 hospitals surveyed in 2000 had an antibiotic formulary *(60)*. However, only 47% had written policies for surgical prophylaxis—a key area of antibiotic misuse *(61)*. On a more encouraging note, a recent 2010 nationwide self-reporting survey from Belgian hospitals (62) of the national implementation of AMTs in hospitals revealed >90% adoption of stewardship interventions such as a formulary, practice guidelines for antibiotic therapy and surgical prophylaxis, and analysis of consumption data. All hospitals had an active AMT and many had appropriate interactions with the infection control teams and hospital management. This study also emphasizes the key role of AMTs in H-ABS. The survey is available electronically on the JAC website (http://jac.oxfordjournals.org/) and may be useful for developed countries wishing to gauge the maturity of stewardship programs within their hospitals.

Efficacy of Antimicrobial Stewardship Programs

The reviews by MacDougall and Polk in 2006 (12) and Lesprit and Brun-Buisson in 2008 *(63)* have summarized the evidence base and flaws with studies that have aimed to measure the impact of stewardship programs. The Cochrane reviews (39) identified that 32 (30%) of the hospital-based studies included reliable data about clinical outcomes. In only 12 of these studies was the intervention either wholly ($n = 8$) or partially ($n = 4$) designed to increase the intensity of antibiotic treatment. Clinical outcomes were measured in only 20 (23%) of 87 studies that aimed solely to reduce the intensity of antibiotic treatment. These latter studies do provide some reassurance that there were no unintended



Boards involved	3	3	5	7	9	10	12	13	14

FIGURE 87-1 Compliance with a combined measure of empirical antimicrobial prescribing in 14 NHS Boards in Scotland. The combined measure has two components: is the indication for treatment in the notes and is the treatment compliant with hospital policy? Data are collected from medical, surgical, and care of the elderly admission units. Data shown are as posted on April 20, 2010.

adverse clinical consequences of this reduction. Thirty-one (29%) hospital studies provided reliable data about microbial outcomes, and 24 interventions were associated with significant improvement. Studies with microbial outcomes are subject to additional risks of bias (39).

How Should Compliance with Antibiotic Stewardship Programs be Monitored?

One of the key components of ABS programs is an antibiotic policy or guideline for empiric treatment of infection or sepsis, disease-specific guidelines, and surgical prophylaxis. Measuring compliance with these policies is a common target for measuring compliance with stewardship programs. Hospitals fortunate enough to have sophisticated information systems may be able to use these to monitor compliance with policies *(64)*. However, this remains the exception rather than the rule. Less sophisticated information systems can still provide valuable information, but there is often no substitute for the manual collection of data *(65)*. This is not necessarily as daunting as it may seem. A 1-day prevalence survey of an entire hospital can be achieved in a few hours and may be a useful tool to detect deviations from guidelines and to provide physicians with educational feedback. The European Surveillance of Antimicrobial Consumption project has adapted a Web-based tool developed in Sweden for antibiotic surveillance (66) and has successfully used it for comparative surveillance of hospitals in 20 European countries (67). A variety of staff can be involved in auditing policies, including trainee nurses, pharmacists, doctors, and medical students *(68)*. Participation in data collection is an educational experience, and the information can be used to agree upon care bundles of three or four essential processes of care that must be completed and documented for every patient to monitor antibiotic compliance and review infection management *(69)*.

A more target- or performance-driven approach is to set nationally agreed compliance targets for key components of antibiotic prescribing in hospitals. In Scotland, for example, the two hospital prescribing indicators for acute hospital admission, empirical prescribing and surgical prophylaxis, were chosen to measure compliance with local antimicrobial policies. The SAPG had previously recommended a review of all hospital antimicrobials to restrict agents associated with CDI *(70)*. Compliance with this policy would, therefore, provide an assurance that these agents were not being used. Data for the combined (compliance with policy and recording in the medical case notes) hospital empirical prescribing measures show steady improvement in the average from June 2009, despite the fact that the number of participating hospital units has increased from 15 to 42 (Fig. 87-1). In the data from December 2009 to March 2010, at least 10% of hospital units have achieved the target of 95% reliability for the recording of diagnoses in notes and compliance with the local antibiotic policy.

CONCLUSIONS

Antibiotic stewardship must be integrated with infection prevention and control and environmental decontamination. Pivotal to this is the regular collation, analysis, interpretation, and feedback of data about antibiotic use, resistance, and clinical outcomes of infection at a local and national level.

A review of current evidence suggests that the evidence base for antibiotic stewardship should be strengthened by supporting evaluations that meet the minimum method criteria for inclusion in a Cochrane systematic review. Similarly, the cost-effectiveness of these interventions require further study with methodological rigor.

AMTs need to be supported both legally and fiscally with strong local and national leadership and alignment with quality improvement and patient safety programs. There is also a growing evidence base for effective behavioral and structural interventions and modern educational interventions to support antibiotic stewardship.

ACKNOWLEDGMENTS

I would like to thank my colleague Peter Davey for his immense contributions to ABSs and his guidance and support in helping me write this review. I also acknowledge the contributions of members of the SAPG and have their permission to share some of their data.

SECTION XIV
The Literature in Healthcare Epidemiology and Infection Control

CHAPTER 88

A Methodologically Focused Review of the Literature in Healthcare Epidemiology and Infection Control

Matthew Samore and Stephan I. Harbarth

The use of appropriate epidemiologic methods in experimental design and data analysis is recognized as an important aspect of generating sound scientific evidence in healthcare research. This chapter discusses methodologies relevant to epidemiologic, outcome, and intervention studies, as they are applied to problems of healthcare-associated infections. We stress common pitfalls and focus particularly on limitations of the published literature in healthcare epidemiology. Although the quality of studies in this field has improved over the last decade, many study reports still remain inadequate and lack methodological rigor.

Although many of the basic ideas of healthcare epidemiology can be traced back to Semmelweis *(1)*, the formal application of epidemiologic methods in infection control received a substantial boost during the 1970s and 1980s, with the publication of a number of methodologically oriented articles that brought innovation to the field (*2,3*,4,*5*). These influential, seminal articles covered topics such as the relationship between prevalence and incidence, matched cohort study design, confounding, and effect modification. Based on the assumption that healthcare-associated infections have causal and preventive factors that can be identified through systematic investigation, these articles demonstrated convincingly that epidemiologic methods add important knowledge to reduce the rates of healthcare-associated infections. Thus, the conceptual framework was laid for many interventional and observational studies in the field.

This chapter is based on this seminal body of work and brings to the readers' attention newer methodologies and principles. Recent advances in the conceptual underpinnings of epidemiology and selection of statistical models that facilitate causal inference may not have garnered widespread attention by Infection Preventionists and healthcare epidemiologists. Using selected articles as examples, the quality of methods in the infection control literature is discussed and opportunities for improvement are highlighted. By necessity, our review of articles and choice of topics is selective. The criticisms and suggestions, which complement the information presented in Chapters 1 to 4, are intended to be constructive. Some of our arguments may even challenge conventional wisdom and, in the process, stimulate a fresh perspective on the literature in infection control and healthcare epidemiology.

The chapter is organized into five sections based on specific recommendations for improving the quality of observational research in infection control and translating that research into action:

1. Use terminology clearly and precisely.
2. Search for and destroy confounding (as much as possible).
3. Recognize selection bias in all of its guises.
4. Account for timing of exposures and time at risk.
5. Develop guidelines according to explicit rules.

Diligent adherence by authors to these recommendations will facilitate clarity, completeness, and transparency of reporting of observational research in our field. Note that this chapter does not include recommendations for designing, conducting, and analyzing clinical trials and intervention

studies with a quasi-experimental design. The limitations and challenges of the latter study design have been underscored in recent years (6,7). Several approaches may help optimize the design of such quasi-experimental studies (i.e., "before and after" intervention studies) *(8)*. The ORION Statement published in 2007 provides standards for the design of high-quality quasi-experimental studies and outbreak reports (9). In particular, univariate and multivariate time-series analyses may complement conventional analytical methods and could be useful to study intervention effects in quasi-experimental studies. For instance, time-series methods have been applied for quasi-experimental study designs in which rates of antibiotic-resistant infections are ascertained before and after an intervention *(10,11)*. However, uncertainties still remain regarding the use of time-series analysis as an appropriate research methodology for analyzing the effect of infection control interventions and antibiotic policies on the epidemiology of multidrug-resistant microorganisms *(12)*.

RECOMMENDATION 1: USE TERMINOLOGY CLEARLY AND PRECISELY

Fundamental to scientific reasoning is the correct use of terminology. Several expressions used in healthcare epidemiology are misnomers, well embedded in everyday use. Table 88-1 summarizes several commonly misused terms and suggests more accurate terms.

Confusion in Classification of Study Design and Use of Terms *Case* and *Control*

Misnomers regarding terminology appear to be particularly common in conjunction with studies that examine outcomes of infections and other adverse events. If patients with a healthcare-associated infection are being compared to patients without healthcare-associated infection with respect to an outcome such as length of stay, mortality, or medical costs, a *cohort study* is being conducted, assuming that patients are selected on the basis of the presence or absence of infection. The infection constitutes the exposure. Similarly, studies in which outcomes of patients with a resistant microorganism are compared with outcomes of patients with the susceptible form of the microorganism are following a cohort design. If exposed and nonexposed subjects are matched on other criteria, such as age and severity of illness, the study is a *matched cohort study*. The distinction between matched cohort and matched case–control studies is not just a semantic one. In a matched case–control study, it is necessary to perform a matched analysis if the matching factors are associated with exposure, even if they are not associated with the outcome, whereas in a matched cohort study, this requirement does not exist *(13)*.

Abundant examples exist in which the terms *case* and *control* are used in the context of a matched cohort study, leading to confusion about the study design *(14)*. For instance, a study *(15)* about the "attributable mortality rate" of bacteremia due to methicillin-resistant *Staphylococcus aureus* (MRSA) claimed to perform a "retrospective cohort analysis and two independent case–control analyses." As outlined above, this terminology is incorrect, since in all three analyses, outcomes were compared, and thus, the term *matched cohort studies* would have been more appropriate.

Multiple Meanings of the Term *Attributable*

Perhaps nowhere is terminology in healthcare epidemiology more confusing than in the use of the word *attributable* (*16,*17). This word is included in a myriad of epidemiologic

TABLE 88-1

Terminology: Commonly Used Problematic and Ambiguous Terms

Commonly Used Name	*More Appropriate Term*	*Explanation*
Prevalence rate	**Prevalence or prevalence proportion**	Prevalence is the proportion of a specified population with a condition or disease at a defined point in time. A rate is the magnitude of change of one entity divided by another entity. Rates have different units in the numerator and denominator. *Prevalence rate* is an example of a term in which the word "rate" is used inappropriately to mean proportion.
Matched case–control study	**Matched cohort study**	Retrospective studies assessing the impact of healthcare-associated infections are comparing outcomes (deaths, costs) as principle study measurement. Since the exposure is known (presence or absence of an infection) and the outcome unknown, it is a cohort study by definition.
Mortality rate	**Case–fatality proportion or fraction**	*Mortality rate* is often used as a synonym for the incidence proportion of deaths in a study cohort due to the disease of interest. Similar to the expression *prevalence rate*, it would be more accurate to use the terms *case–fatality proportion* or *case–fatality fraction*.
Attributable fraction	**Excess fraction**	If the term *attributable fraction* is taken to mean the fraction of disease (or deaths) in which exposure was a contributory cause of disease, strong biologic assumptions are required. In order to avoid this problem, the term *excess fraction* is preferred.

terms with meanings that vary widely. The dictionary definition of *attributable* is "ascribed to" and, in epidemiology, it is frequently taken to be synonymous with "caused by." However, there are two types of causation that are often not distinguished. During a defined follow-up period, an exposure may either shorten the interval to occurrence of disease or cause a disease case to occur that otherwise would not have occurred *(18)*. The former is an *accelerated disease case*, whereas the latter is an *excess case*. If exposure prevents disease, this may be restated to indicate that exposure either lengthens the interval to occurrence of disease or averts a case from happening that otherwise would have occurred.

The rationale for constructing formulas to measure the *attributable fraction* is that not all disease in exposed patients is necessarily due to exposure: some exposed individuals would have developed disease, even at the same time, if they had not been exposed. It is also evident that the ratio of exposed patients belonging to these two causal types, accelerated or excess cases, depends on the duration of the follow-up. It can be shown that, compared to the enumeration of excess cases, deriving an estimate of the number of accelerated cases relies on additional, more tenuous assumptions about the form of the causal relationship between exposure and disease. Hence, rather than attempting to estimate the fraction of exposed cases that are caused by exposure, it is generally preferred to restrict attention to excess cases. The occurrence of excess cases can be estimated by simply comparing the incidence proportion in exposed individuals to the incidence proportion in nonexposed individuals, assuming that confounding is absent. Due to these considerations, Greenland and Robins *(19,20)* recommend the use of the term *excess fraction* in place of *attributable fraction* when the objective is to quantify the fraction of exposed cases that are excess cases caused by exposure. They reserve the term *etiologic fraction* to indicate the proportion of exposed cases caused by exposure, including both types of causation. The *population excess fraction* is an estimate of the fraction of all cases in the population that are excess cases due to exposure. The set of terms that cover these concepts are referred to as the family of *attributable fractions (13,19)*.

In contrast to the rich literature available in the field of chronic disease epidemiology, controlled studies aiming to determine the proportion of hospital deaths attributable to healthcare-associated infection are both rare and insufficient for the calculation of stable estimates *(21)*. Furthermore, several methodological issues have to be considered, since the causal relationship between exposure to infection and death can be jeopardized by multiple confounders and biases (see example 3 below: *Excess Mortality Due to MRSA Bloodstream Infection*). Clearly, the choice of methods does matter when the excess burden of healthcare-associated infections needs to be assessed. For instance, in a recent cohort study by a French group investigating the outcome of 8,068 critically ill patients, the statistical association between intensive care unit (ICU)-acquired infection and mortality tended to be less pronounced in findings based on the population excess fraction than in study findings based on estimates of relative risk (17).

RECOMMENDATION 2: SEARCH FOR AND DESTROY CONFOUNDING

This section discusses the central challenge in epidemiology, namely, how to reduce confounding. Informative examples from the published literature in infection control that have relevance to key aspects of the problem of confounding have been selected for pedagogic purposes. Prior to evaluating the quality of the methods used in these investigations, we provide an in-depth explanation of why confounding is important and how it arises. There are four research questions covered by the chosen articles, reworded here to be as explicit as possible:

1. Does prolonged postoperative antimicrobial use increase the risk of healthcare-associated bloodstream infection (BSI) compared to short postoperative antimicrobial prophylaxis?
2. How much does inadequate antimicrobial treatment of BSI in critically ill patients heighten the risk of death compared with adequate antimicrobial treatment?
3. Among patients with BSIs due to *S. aureus*, does methicillin-resistance increase the risk of death compared to methicillin-susceptible infection?
4. Does perioperative antimicrobial prophylaxis decrease the risk of surgical site infection (SSI) after clean surgery compared to no prophylaxis?

Background

The surgeon who explains that the reason his or her patients have a higher infection rate is that he or she operates on sicker patients demonstrates an informal grasp of the concept of confounding. However, when it is necessary to conduct and analyze an epidemiologic investigation, this intuitive understanding of confounding reveals its limitations. We begin by offering two core principles that may run somewhat counter to conventional wisdom:

1. It is not possible to use *statistical criteria alone* to recognize confounding or to determine whether it has been removed.
2. Confounding is identifiable only in the context of a *causal model (22)*.

Confounding is present when there is discordance between the *true causal effect* of an exposure on the outcome in a target population and the *measured association* between exposure and disease *(23)*. Thus, an exploration of confounding starts with an exposition on causation. What is meant by *true causal effect*?

Causation is best understood in terms of the question: What would have happened if the exposure had not occurred? Stated another way, the causal effect of exposure in exposed individuals is represented by the difference between their actual disease status and what would have happened if everything else had been the same up until the time of exposure, but that they had then not been exposed or exposed to a different degree in the latter scenario *(23)*. Under this formulation, causation is defined on the basis of a comparison between outcomes under mutually exclusive conditions: exposed and unexposed or, alternatively, varied levels of exposure. However, in any single patient, only one of these conditions is observed. In the absence

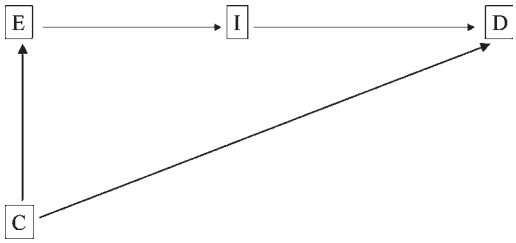

FIGURE 88-1 Graphical representation of causal relationships illustrated by *directed acyclic graphs*. An exposure (E) has both direct and indirect effects on disease (D). The indirect effects are mediated by an intermediate variable (I). A confounding factor (C) is a cause of both the exposure (E) and the disease (D).

of time machines to replay experience under dissimilar exposure conditions, a straightforward way to directly measure causal effects is not available. When exposure is randomly allocated, it is possible to derive an estimate of the unconfounded, average causal effect of exposure, with a random error correlated with sample size. In the absence of random allocation of exposure, causal inference relies on untestable beliefs regarding causal relationships and unmeasured confounders *(24)*.

It is useful to depict assumptions about causal relationships in a graphical format to identify potential sources of confounding. The causal effects of exposure on disease may be visualized as arrows aiming from exposure to disease (Fig. 88-1). These arrows represent the postulated causal mechanisms or pathways by which exposure affects the outcome or disease. Causal pathways that link exposure (E) and disease (D) may be direct or indirect. An indirect pathway is characterized by the presence of an "intermediate variable" (I) that mediates a causal effect, whereas a direct effect lacks an intermediate variable. The causal null hypothesis is the assumption that there are no indirect or direct causal pathways pointing from exposure to disease. Graphical representations of causal relationships are called *directed acyclic graphs* (25,*26*).

Confounding arises when direct or indirect causes of exposure are also direct or indirect causes of disease status. When exposure is a type of treatment and confounding is due to factors that influence treatment selection, the term *confounding by indication* is sometimes used *(27,28)*. Causes of exposure can be visualized as arrows pointing toward exposure. If these inputs into exposure also have outputs connecting to disease through paths that do not include exposure, noncausal pathways from exposure to disease exist. The labeling of a pathway as noncausal is done from the perspective of exposure and disease. If research questions pertain to multiple exposures, the postulated connections between each factor of interest and disease may, in turn, be divided into causal or noncausal pathways. Noncausal pathways create an association between exposure and disease, one that is not a consequence of exposure, hence the need to block the noncausal pathways if the goal is to estimate the true causal effects of exposure. Factors located within these noncausal pathways are usually associated both with exposure and disease, although in any given study these associations may themselves be obscured by confounding, and therefore, not manifested (*23,*29).

Successful randomization eliminates confounding by breaking the causal inputs into exposure or treatment. It makes the exposure or treatment actually received independent of what would have happened had exposure been absent or altered. This principle, which is surprisingly difficult to grasp, is another way to define the absence of confounding. The goal of epidemiology is to attempt to accomplish this feat with respect to measured confounders, using appropriate design and analytic strategies (29).

Perhaps what poses the most difficulty to individuals conducting epidemiologic research and readers of the literature is the myriad of statistical techniques available to analyze data. These statistical methods are not reviewed in detail here. Detailed recommendations for conducting methodologically sound multivariable analyses of observational studies have been summarized elsewhere (30,31). Rather, our goal is to emphasize the distinction between the statistical evaluation of association and the identification of confounding. Contrary to widespread belief, the *p*-value is not a useful test of confounding. Even the comparison of crude and adjusted measures of association is an inadequate approach by itself to detect confounding. Depending on the causal model, the adjusted measure of association may be more or less confounded than the crude measure. The judgment of whether an adjusted association is less confounded than a crude association relies on assumptions about the causal relationships between exposure, outcome, and the adjustment variables *(32)*.

Example 1: Prolonged Antimicrobial Prophylaxis

The first step toward reducing confounding in observational research on causal effects is to recognize its potential existence and to obtain measurements on potential confounders or to account for potential confounding during the design phase of the study. Sometimes these initial steps are omitted, as the following example illustrates.

Many investigators have examined the effect of antimicrobials on the subsequent occurrence of infection. Under certain conditions, systemic antibiotic use may decrease the risk of healthcare-associated infection. This has been demonstrated in clinical trials on ventilator-associated pneumonia (VAP) *(33,34)*. An opposite effect of antimicrobial prophylaxis was suggested in a study that found that the duration of antimicrobial prophylaxis after major surgery was associated with a significantly increased risk of healthcare-associated BSI *(35)*. The authors of this study observed six cases of BSI among 180 patients receiving short antibiotic prophylaxis, compared with 16 cases of BSI in 94 patients with extended antibiotic prophylaxis (crude odds ratio [OR], 5.9). These results were published without any consideration of the possibility of confounding.

In an observational study we conducted on the relationship between duration of antimicrobial prophylaxis and infections *(36)*, we found a strong association between prolonged antibiotic prophylaxis and subsequent healthcare-associated BSI in the crude analysis. A total of 2,641 patients undergoing cardiac surgery were included in the study, divided into those in whom antimicrobial prophylaxis was short (<48 hours) and those in whom antibiotic prophylaxis was prolonged (>48 hours) *(36)*. The unadjusted analysis revealed an OR of 3.3, based on the

occurrence of 27 cases of healthcare-associated BSI (1.8%) after 1,478 procedures using short antibiotic prophylaxis compared with 65 cases of healthcare-associated BSI (5.7%) after 1,139 operations with prolonged antibiotic prophylaxis. The problem with this crude analysis was that the length of follow-up and ICU stay affected the likelihood of receiving prolonged antimicrobial prophylaxis.

Using survival analysis methods removed confounding related to differences in the length of follow-up; the apparent association appeared smaller (hazard ratio [HR], 1.7) based on Cox proportional hazards regression. Seventy-seven percent of cases of healthcare-associated BSI occurred in patients who stayed longer than 4 days in the ICU. Similarly, extended antibiotic prophylaxis was correlated with longer ICU stay. After stratifying for length of ICU stay, prolonged antibiotic prophylaxis was not associated with a significantly increased risk of BSI (HR, 1.4). In an additional analysis, we showed that prolonged antibiotic prophylaxis did not decrease the incidence of SSI; however, it increased the risk of isolation of resistant gram-negative bacteria and vancomycin-resistant enterococci (VRE) (37). In summary, these results demonstrate confounding of the crude association between prolonged antibiotic prophylaxis and healthcare-associated BSI by differences in follow-up and length of ICU stay *(36)*.

Example 2: Inadequate Antimicrobial Therapy

Frequently, investigators do attempt to address confounding but use analytic methods that are suboptimal. A common error is to identify confounders primarily on the basis of the statistical significance of the association between the outcome and potential confounders. This strategy is inappropriate when the purpose of the regression model is to estimate the magnitude of the causal effect of an exposure on an outcome.

As an example, consider studies that have examined the impact of inadequate antimicrobial treatment of infection on patient outcomes *(38–41)*. This is a research question that is not amenable to direct testing in a randomized trial, since it would be unethical to willingly expose patients to inappropriate treatment. To answer the question, therefore, we have to rely on observational studies. On the face of it, it is highly likely that inadequate antimicrobial therapy does have some negative effect on outcome in critically ill patients. The key objective of an observational study, then, is to remove as much of the confounding as possible so as to obtain an unbiased estimate of the magnitude of effect of inadequate therapy. In one such widely cited study of patients in the ICU with BSI, therapy was defined as inadequate if the antimicrobials being given to the patient were ineffective against the causative pathogen at the time that identification and susceptibility results were reported by the clinical microbiologic laboratory *(42)*. The crude relative risk for mortality after inadequate therapy compared with adequate therapy equaled 2.2, corresponding to a crude OR of 4.1 *(42)*. The "adjusted" effect estimate of inadequate antimicrobial treatment of BSI on hospital mortality had an OR of 6.9, after including the use of vasopressors, age, organ dysfunctions, and severity of illness, along with inadequate therapy, in a multivariable logistic regression model.

A major limitation with this analysis was that the factors included in the logistic regression model were only those found to be significantly associated with mortality. A stepwise variable selection approach was used with a *p*-value of .05 as the limit for the acceptance or removal of new terms. The problem is that this method does not remove confounding by factors not selected in the model. Many characteristics were identified that distinguished patients with inappropriate and appropriate antimicrobial use, such as time in the hospital prior to BSI, prior use of antimicrobials, and serum albumin. Presumably, these were factors that directly or indirectly influenced the probability that treatment was inadequate or were proxies for such factors. Some of these factors were also associated with the outcome but not always to a statistically significant degree. Not including these factors in the model likely contributed to an exaggerated estimate of effect *(42)*.

All observational research is limited by the possibility of residual confounding due to unmeasured variables, but given a postulated causal model and a set of measured variables, some analytic strategies are less prone to confounding than others (25). The key point is that confounders do not have to be statistically significantly associated with the outcome to be confounders. As stated in the background section, the results of statistical hypothesis testing are tangential to the recognition of confounding. To some extent, the notion that confounders should be significantly associated with the outcome reflects the belief that the only "true" associations are ones that are statistically significant. Instead of focusing on statistical significance, the analysis should be directed toward a careful consideration of the potential sources of confounding and deriving the least-biased estimate of the true causal effect.

A frequently overlooked problem with conventional regression models is that they impose assumptions regarding the form of the relationship between the additional model factors and the outcome and between these additional factors and the exposure, which, if incorrect, may increase confounding *(43)*. The association parameter derived from the regression model provides an estimate of the unconfounded causal effect of exposure only when all of the assumptions of the multivariable model are correct. In addition, automated variable selection methods completely ignore the relationship between the putative confounders and the exposure. If the factors selected into the model are affected by exposure, their inclusion may also be deleterious with respect to confounding. This problem is discussed in more detail below.

Traditional stratification methods have an advantage over regression models because they involve fewer assumptions, but they lead to sparse numbers within strata when multiple confounders are present (44). Newer analytic strategies have been developed that overcome some of these types of problems and allow improved causal inference. These more robust methods start with a specification of the exposure of interest and build on an explicit structural model of causal relationships *(45)*. Another recent advance in epidemiology is the use of simulation to increase the flexibility of sensitivity analyses of confounding and other types of bias *(46,47)*.

One analytic method that has gained widespread application is the use of propensity scores, particularly for point exposures that are dichotomous or categorical *(28)*. The propensity score is the probability of exposure or treatment

based on factors that influence treatment, and thus, lies between 0 and 1 *(48)*. A multivariable logistic regression model is typically used to estimate this probability, and most commonly, the propensity score is used as either a matching or stratification variable to remove confounding by indication due to measured factors *(49)*. The propensity score method relies on assumptions about the form of the relationship between the confounder and exposure but is less susceptible than traditional models to bias by misspecification of the relationship between the confounders and the outcome *(50)*.

Example 3: Excess Mortality Due to MRSA Bloodstream Infection

Including a variable for adjustment sometimes increases confounding rather than reduces it. This happens when the adjuster is a consequence of the exposure of the interest and either lies on one of the causal paths between exposure and the outcome or is also an effect of the outcome *(51)*.

A number of investigators have compared outcomes in patients with resistant and susceptible infection *(40,52,53)*. In such studies, it is especially crucial to precisely specify the causal hypothesis of interest. Often, it pertains to the virulence of the microorganism: Do infections due to the resistant form of the microorganism have worse, similar, or better outcomes than infections due to the susceptible form of the microorganism? One such study measured mortality following BSI, comparing infections due to MRSA and to methicillin-susceptible *S. aureus (54)*. One of the control variables included in the logistic regression model was the presence of shock, presumably measured at the time of detection of BSI. The problem is that one path by which methicillin resistance may raise the mortality rate is in increasing the risk of shock. Controlling for shock produces bias toward the null in the estimate of the effect of methicillin resistance by blocking one of the causal pathways linking the exposure and outcome. More suitable adjusters would be measures of the severity of illness, such as an APACHE score, taken prior to the onset of symptoms and signs of infection *(55,56)*.

On the other hand, if the study goals were to address the question whether inadequate therapy of methicillin resistance caused an increase in mortality compared to adequate therapy of methicillin-resistant or methicillin-susceptible infection, shock at the time of detection of infection, prior to initiation of therapy, would be an appropriate adjuster. In this situation, shock is no longer causally downstream of the exposure of interest.

Example 4: Antimicrobial Prophylaxis in Clean Surgery

The final example is of a publication in which confounding was addressed in an appropriate fashion *(57)*. The purpose of the study was to evaluate the effect of antimicrobial prophylaxis on SSI after clean surgery. Control variables included in the analysis were factors that possibly influenced both the decision to prescribe antibiotic prophylaxis and the outcome of interest (SSI in clean surgery). The observational study, of patients undergoing herniorrhaphy or selected breast surgery procedures, was done in conjunction with a randomized clinical trial of perioperative antibiotic prophylaxis *(58)*. Patients were included in the observational cohort if they did not participate in the clinical trial. Thirty-four percent of patients (1,077/3,202) received prophylaxis at the discretion of the surgeon; 86 SSIs (2.7%) were identified. The unadjusted OR for infection comparing prophylaxis recipients with nonrecipients was 0.85 (26/1,077 vs. 60/2,125). The OR after adjustment for duration of surgery and type of procedure was substantially lower, at 0.59, indicating a 41% reduction in the odds of SSI following prophylaxis. Additional adjustment for age, body mass index, the presence of drains, diabetes, and exposure to corticosteroids did not change the magnitude of this effect meaningfully. The conclusion of the investigators was that the clinical criteria individual surgeons were using to decide which patients should receive prophylaxis were successfully targeting patients within the clean surgery group who were at higher risk for infection. Thus, this study confirmed results from the randomized study *(58)* and showed that, after correct adjustment for confounders, prophylactic antibiotics were beneficial in the nonrandomized patients.

RECOMMENDATION 3: RECOGNIZE SELECTION BIAS IN ALL OF ITS GUISES

Selection bias occurs when the selection of study subjects induces a noncausal association between exposure and disease. Thus, the end result is similar to confounding: it leads to distortion of the measured association between exposure and disease away from the true causal effect *(59,60)*.

For a variety of reasons, selection bias tends to be more common in case–control studies than cohort studies, although this need not be the case if the case–control study is rigorously conducted *(59,60)*. In the case–control study, subjects are chosen for inclusion according to case status (e.g., presence or absence of a resistant microorganism). The key principle is that controls should be an unbiased sample of the source population with respect to exposure. Just as in a cohort study, it is necessary to delineate the source population or study base—individuals who would be classified as cases if they developed the disease, or alternatively, the person–time experience during which there is eligibility to become a case. The failure to select subjects independently of exposure status distorts the causal relationship between exposure and disease. If subject selection is influenced by a factor that is associated with exposure, the consequence is selection bias. The result is that distribution of exposure in controls will differ in a systematic way from that of the entire study base. The sampled exposed and unexposed individuals will no longer be comparable with respect to disease incidence; a noncausal exposure–disease association is induced.

Antimicrobial Use and Risk of Infection with Resistant Microorganisms

Case–control studies on antibiotic-resistant microorganisms typically aim to determine risk factors (e.g., specific antimicrobial agents) causally related to colonization or infection with resistant pathogens *(61–63)*. The choice of appropriate controls is central to the validity of results in those studies (64,*65–67*).

We will look at studies of antimicrobial risk factors for infection with VRE, which have been plagued by suboptimal selection of controls (64). If the exposure of interest in a case–control study of VRE acquisition is vancomycin use, then controls should be selected that are representative of vancomycin exposure in the entire cohort of

hospitalized patients. Controls should not be intentionally limited to certain wards where vancomycin use is low since this would falsely overestimate the OR obtained for vancomycin. Often, for convenience reasons, patients with vancomycin-susceptible enterococci (VSE) are selected as the control group. The reason the choice of patients with susceptible microorganisms as the control group leads to a biased estimate of relative risk is that a distorted estimate of exposure frequency in the source population is obtained. The selection bias introduced by using control patients with susceptible microorganisms is likely to have the strongest impact on estimating the effect of exposure to antibiotics that are active against susceptible (but not resistant) microorganisms, which is often the exposure of greatest interest. The reason for this particular bias is that treatment with active antibiotics likely inhibits the growth of susceptible microorganisms, therefore making this exposure less frequent among patients who are culture-positive for susceptible microorganisms than among patients in the source population *(65)*.

Thus, vancomycin therapy may be identified as an individual risk factor not because it is a risk factor for the development of VRE but because fewer patients in the VSE comparison group received vancomycin. Vancomycin may be causal only with respect to its killing effect on VSE, not to its effect of enhancing the risk of VRE acquisition *(68)*. The selection bias associated with this type of control group selection was demonstrated in a meta-analysis that aimed to assess whether vancomycin therapy was a risk factor for the development of VRE *(69)*. Studies that used a control group of patients with VSE identified vancomycin therapy as a risk factor (pooled OR, 10.7), whereas studies that used a second control group (no patients with VRE and not limited to patients with VSE—therefore, similar to the base population of hospital admissions) revealed a far weaker association (OR, 2.7). This weaker association was then eliminated when the analysis was limited to studies that also controlled for time at risk prior to the outcome *(69)*.

Another situation in which selection bias may be a problem results from the use of clinical cultures to identify patients with a resistant microorganism. If the exposure influences the performance of the test used to identify the resistant microorganism or is itself influenced by a factor that affects culturing, the consequence is selection bias. In studies of resistant microorganisms, when the exposure of interest is antimicrobial use, factors that may influence both future culturing practices and prescribing of antimicrobials are the initial symptoms and signs of infection. Adjusting for the clinical manifestations of infection and other indications for antimicrobial use can remove this selection bias.

RECOMMENDATION 4: ACCOUNT FOR TIMING OF EXPOSURE AND TIME AT RISK

Time at Risk

There are two common ways that time is misunderstood or mishandled in epidemiology studies within the field of infection control. One pertains to the concept of *time at risk* and the other to time-varying exposures. The key role of time in the occurrence and detection of disease is worth emphasizing. First, time at risk serves as the stage on which other causes act. For instance, the longer the patient is hospitalized, the greater the opportunity for the patient to experience the use of invasive medical devices that are causes of healthcare-associated infection and the higher is the cumulative probability of occurrence of a healthcare-associated infection. Second, even for those causes that are experienced at a single point of time—for instance, ingestion of food contaminated by *Listeria*—time is important because of the induction period. If the follow-up time is shorter than the maximum interval from exposure to onset of symptoms (incubation period), the case may not be detected *(70)*. Third, time at risk itself may act as an intermediate variable, mediating the effects of other causes of disease. One of the indirect pathways by which high illness severity leads to higher infection risk is by increasing the length of hospital stay *(71)*. Fourth, exposures may not be constant during the period of risk; accounting for time-varying exposures poses additional problems discussed in more detail below.

Consider what actually constitutes the time at risk for healthcare-associated infections, using the situation in which only the initial infection is studied. An individual's time at risk for a healthcare-associated BSI begins when he or she is admitted to the hospital and ends at the time of occurrence of the first BSI or at discharge. More precisely, information about the presumed incubation period may be used to modify the start and stop times of this interval. The first 48 hours after hospitalization is "immortal time" in the sense that, by the usual case definition, events with onset during that interval are excluded. Conversely, infections detected up to a certain number of days after discharge may be included as cases, and so the follow-up time may extend for a brief period postdischarge *(72)*. Notwithstanding these subtleties, the time at risk is approximately the hospital length of stay for individuals who do not experience a BSI and the interval from admission to occurrence of the infection for those that do.

When the time at risk varies substantially from individual to individual, the incidence rate, denominated by person–time experience, is the appropriate measure of disease frequency. This concept is widely understood in infection control and forms the basis for measures of disease frequency such as number of catheter-related infections per 1,000 catheter days (*73,*74). However, the implication of variation in time at risk for the choice of the target measure of effect is less often recognized. Generally, if there is a need for adjustment on time-at-risk, the target parameter of an epidemiologic analysis should be person–time based, usually the incidence rate ratio or HR *(75,76)*. Analyses of data from case–control or cohort studies using logistic regression often neglect this issue *(77,78)*. Sometimes in such analyses, the time at risk is treated as a conventional risk factor *(79,80)*. Although this approach may be less biased than not accounting for time at risk at all, it neglects the distinction between time at risk and other types of confounders *(81)*. A related limitation is to use hospital length of stay for all patients, regardless of case status, as the adjustment variable *(82)*. A comparable type of inaccuracy is to calculate incidence densities using total person–time instead of person–time-at-risk *(83)*.

Time-Varying Exposures and Matched Cohort Studies

The analytic techniques that account for variation in time at risk are particularly valuable when exposures change over time. An exposure is considered time varying when its value changes in a meaningful way during follow-up. In outcome studies of healthcare-associated infections or other adverse events, in which the aim is to estimate the causal effect of infection on endpoints such as mortality or costs, the infection is a time-varying exposure (84). Infected patients are deemed exposed after onset of the infection. Prior to infection, patients are unexposed, as are patients who never experience infection. The interval from the start of follow-up to the onset of infection differs from patient to patient.

The most commonly used method to estimate excess morbidity and mortality caused by healthcare-associated infection or other adverse events is to perform a matched cohort study in which patients with the adverse event are matched to one or more reference patients who did not experience the adverse event *(52,85,86)*. Infected and uninfected patients are usually matched for age, the underlying disease, and additional variables that may have contributed to excess morbidity and extra length of hospital stay (Fig. 88-2).

This study design has several limitations because of the time-varying nature of the exposure. One source of bias occurs when infected and uninfected patients are compared with regard to *total* hospital costs or *total* hospital length of stay *(87–90)*. For infected patients, only those costs incurred after the occurrence of the healthcare-associated infection are possibly secondary to infection. Prior to the occurrence of infection, patients are unexposed. The association between preinfection outcome and infection is entirely noncausal from the perspective of measuring the excess burden of infection. Therefore, combining preinfection outcomes with postinfection outcomes dramatically amplifies confounding.

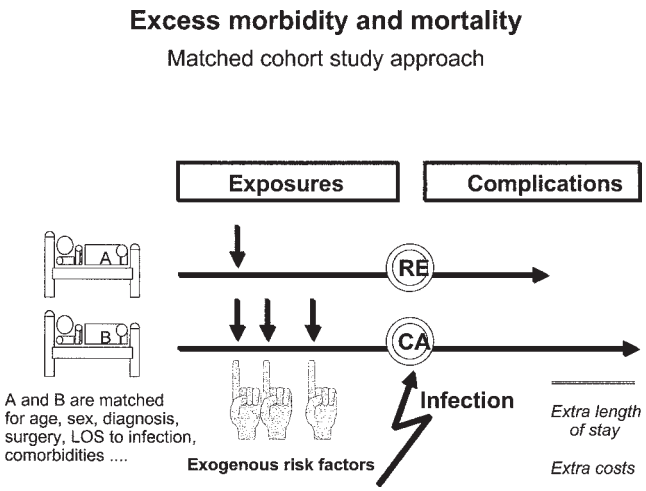

FIGURE 88-2 A schematic design of a matched cohort study. *Arrows* indicate exposure to risk factors for infection after admission. Patient A is considered an uninfected reference patient (RE) for "case" patient B (CA) who developed healthcare-associated infection indicated by the *broken arrow*. (Courtesy of Didier Pittet.)

Modifying the analysis such that average postinfection length of stay in infected patients is compared with average total length of stay in noninfected patients does not completely remove confounding by time *(91)*. Bias persists even in matched cohort studies in which noninfected patients are selected to have a hospital length of stay at least as long as the interval to infection in the corresponding infected patient, irrespective of differences in the severity of illness *(85)*. The reason for this bias is that conditioning on presence or absence of infection induces an association between the time to infection and time to discharge *(92)*.

Several recent studies have demonstrated the effect of this bias (*86,93–95,*96). Outcome analyses that did not account for the time prior to the occurrence of the infection or adverse event yielded different results than studies that did account for the time prior to the infection. As shown in Table 88-2, there is an important difference in excess length of stay between conventional matching approaches and methods that adequately model the timing of events. Schulgen et al. *(97)* tested different methods and showed that the use of unmatched or matched comparisons between noninfected and infected patients led to an overestimation of the excess length of stay due to SSI or healthcare-associated pneumonia compared to analyses based on a structural formulation of transitions between different states (Table 88-2). Similarly, Asensio and Torres *(98)* found that regression models yielded lower estimates of the excess length of stay and cost due to healthcare-associated infection than a matched-pair comparison. Likewise, Nguile-Makao et al. *(86)* observed that a multistate model that appropriately handled VAP as a time-dependent event produced lower values of the attributable mortality of VAP than a matched cohort analysis.

Another approach to estimating cost and length of stay effects of adverse events is to apply survival models, in which the adverse event is incorporated as a time-dependent variable *(99)*. This strategy can be applied to costs as well as length of stay *(91)*. Even when the time-varying nature of the exposure is accounted for, it is still necessary to adequately adjust for traditional confounders those factors that both increase the risk of infection and affect the outcome of interest. For instance, Soufir et al. *(100)* investigated the excess risk of death due to catheter-related bloodstream infection (CR-BSI) in a cohort of critically ill patients. The crude case–fatality ratio was 50% and 21% in patients with and without CR-BSI, respectively. The statistical method of adjustment was based on Cox proportional hazards regression, with the inclusion of matching variables and prognostic factors for mortality. CR-BSI remained associated with mortality following adjustment for prognostic factors at ICU admission (HR, 2.0; $p = .03$). However, after controlling for severity scores calculated 1 week before CR-BSI, the increased mortality was no longer significant in the Cox model (HR, 1.4; $p = .27$).

In summary, healthcare-associated infections unquestionably have substantial effects on morbidity and mortality. However, the matched cohort study design produces bias in the estimation of the effects of healthcare-associated infection on length of stay and costs. Cost effects or excess length of stay are likely to be overestimated if the interval to onset of healthcare-associated infection is not properly accounted for in the study design or analysis (84). Finally,

TABLE 88-2

Estimated Duration of Extra Stay in Days Per Infected Patient and 95% Confidence Interval for Two Studies on the Effect of Surgical Site Infection (Study I) and on Healthcare-Associated Pneumonia (Study II)

	Postoperative Wound Infection (Study I)		*Healthcare-Associated Pneumonia (Study II)*	
Approach	*Estimated Extra Hospital Stay*	95% CI	*Estimated Extra Stay in ICU*	95% CI
Two-group comparison	20.7	18.4–23.0	14.4	10.7–18.2
Confounder matching	16.9[a]	12.9–20.9	12.3	9.7–14.9
Confounder and time matching	11.4[b]	7.1–15.7	8.2	5.9–10.5
Method 1	9.8	5.7–13.8	3.4	0.8–6.0
Method 2	11.5	8.9–14.0	4.0	1.5–6.1

[a]Matching for age, sex, diagnosis, and degree of contamination of wound.
[b]Matching for age, sex, diagnosis, degree of contamination of wound, and time to infection.
Study I used a Markov transition state model and study II used a structural nested failure time model. Both studies account for the time from admission to healthcare-associated infection in the estimation of the effect of healthcare-associated infection on subsequent length of stay.
(Adapted from Schulgen G, Kropec A, Kappstein I, et al. Estimation of extra hospital stay attributable to nosocomial infections: heterogeneity and timing of events. *J Clin Epidemiol* 2000;53(4):409–417.)

appropriate statistical methods are important in analysis of excess costs associated with healthcare-associated infections, because informed decisions and policy developments may depend on them. Additionally, exaggeration of excess costs may lead to unintentional errors in the economic analysis of intervention programs (101).

RECOMMENDATION 5: DEVELOP GUIDELINES ACCORDING TO EXPLICIT RULES

Translating research in infection control into practice guidelines involves as the first step a rigorous review of evidence. Although expert opinion is a critical component of the development of recommendations and guidelines, it is important, whenever possible, to use results of the highest quality studies possible as the basis for infection control policy *(8)*. This is crucial, because many practices in infection prevention and control of multiresistant microorganisms have not been validated by controlled clinical trials. Unfortunately, there are many important questions in infection control for which we may never obtain data from randomized trials because of limitations in funding, lack of feasibility, and ethical dilemmas.

Methodological Quality of Guidelines in Infection Control

Guidelines are widely used and cited, because they attempt to summarize and critically appraise currently available evidence and give recommendations for daily practice *(102,103)*. By contrast, individual trials are often conflicting or nondefinitive because of their small sample size or other methodological limitations. Many guidelines rely on reviews that were either previously published or created by guideline developers. Systematic reviews can aid in guideline development because they involve selecting, critically appraising, and summarizing the results of primary research. The more rigorous the review method used and the higher the quality of the primary research that is synthesized, the more evidence-based the practice guideline is likely to be *(104)*. Conversely, the quality of a review is compromised if a comprehensive search is not made to ensure that all potentially relevant articles are considered for inclusion, if the selection of studies is not reproducible or is open to bias, if the methodological quality of the primary studies is not evaluated, or if possible reasons for the variability in results are not explored *(105)*. Table 88-3 summarizes the most commonly used levels of evidence of preventive or therapeutic interventions and the grading scale for recommendations made in practice guidelines.

Many guidelines in the infection control and clinical infectious disease literature are not following the highest possible methodological standards for the development of guidelines, as suggested by the Cochrane review group *(106)*. For instance, the draft of the new guideline on preventing catheter-related infections to be published in 2010 omitted eight category 1A recommendations that were listed in the old 2002 version of this document but were not mentioned anymore in the new version. The Center for Disease Control and Prevention's hand-hygiene guideline *(107)*, an otherwise exemplary appraisal of the evidence, also did not include a detailed description of the systematic review process. Finally, an analysis presented at the Infectious Diseases Society of America's 47th annual meeting revealed that most of the society's treatment guidelines are based on expert opinion, nonrandomized trials, and case studies. Only approximately 15% of the guidelines are supported by randomized controlled trials, considered the highest level of evidence. Nonetheless, more than 40% of the guidelines' recommendations were classified as class A, the strongest level of treatment recommendation (Dong Lee et al. from the Division of Infectious Diseases

TABLE 88-3

Levels of Evidence and Grades of Recommendations for Preventive or Therapeutic Interventions

Quality of evidence

I Evidence obtained from at least one properly randomized clinical trial with high power

II-1 Evidence obtained from clinical trials with low power or without randomization

II-2 Evidence obtained from well-designed cohort or case–control studies

II-3 Evidence obtained from studies using historical cohort comparisons

III Descriptive case series without controls or opinions of respected authorities

Strength of recommendation

A Good evidence to support a recommendation

B Fair evidence to support a recommendation

C Insufficient evidence to recommend for or against a recommendation

D Fair evidence to withhold a recommendation

E Good evidence to withhold a recommendation

at Drexel University College of Medicine in Philadelphia, Pennsylvania. Infectious Diseases Society of America's 47th annual meeting: Abstract 1324, presented November 1, 2009). Overall, many guidelines in this field leave uncertain the study selection criteria, data extraction process, and quality of the included studies. To improve the quality of evidence, investigators assembling consensus guidelines should add more systematic information about the search methods, data sources, study selection criteria, and details about study designs, interventions, settings, and the quality of studies included in their recommendations *(108)*.

CONCLUSION

We have critically assessed selected articles from the healthcare epidemiology and infection control literature to highlight methodological limitations and areas in need of improvement. We hope that this review will act as a stimulus to further research, based on sound methodological tools, and that the resulting body of work will advance new hypotheses for the prevention of healthcare-associated infections. Assuming that healthcare-associated infections have causal and preventive factors that can be identified through systematic investigation of different populations, epidemiology has the potential to contribute substantially to the understanding of the effectiveness of infection control measures and to act as a driver of practice change. As in any scientific endeavor, the fundamental challenge in healthcare epidemiology is to ask the important questions and then select the right methods to answer them. The availability of systematic epidemiologic methods for use in infection control provides an opportunity for more complete prevention of healthcare-associated infections in the next millennium.

SECTION XV

Organization and Implementation of Infection Control Programs

CHAPTER 89

Surveillance of Healthcare-Associated Infections

Katherine Allen-Bridson, Gloria C. Morrell, and Teresa C. Horan

Surveillance is the ongoing, systematic collection, analysis, and interpretation of health data essential to the planning, implementation, and evaluation of public health practice, closely integrated with the timely dissemination of these data to those who need to know. Surveillance of nosocomial or, as they are now known, healthcare-associated infections (HAIs) is a significant component of efforts to reduce and eventually eliminate HAIs in healthcare settings, including hospitals, long-term care facilities, and ambulatory surgical care centers *(1)*. In the 1970s, the Study on the Efficacy of Nosocomial Infection Control found that if hospitals adopted intensive surveillance and multifaceted prevention and control programs, nearly one-third of HAIs could be prevented (2). Later, the Centers for Disease Control and Prevention (CDC) recommended infection surveillance as a way to evaluate the success of control measures (*3,*4). In addition, surveillance of HAIs may provide data that are useful for recognizing emerging trends and contributing factors, such as procedures and new technologies that reduce HAIs. Increasingly, HAI surveillance data is being used by both regulatory agencies such as The Centers for Medicare and Medicaid Services (CMS) and The Joint Commission (JC), to assess the quality of care in the healthcare setting as well as by state health department HAI programs to assist in and to disseminate infection prevention activities.

NATIONAL HEALTHCARE SAFETY NETWORK

Throughout this chapter, CDC's National Healthcare Safety Network (NHSN) system is used to illustrate essential components of HAI surveillance. The NHSN is a secure, Internet-based surveillance system that integrates patient and healthcare personnel safety (HPS) surveillance systems. Three former CDC surveillance systems, including the National Nosocomial Infections Surveillance System (NNIS), National Surveillance System for Healthcare Workers, and the Dialysis Surveillance Network, were combined to form the NHSN.

The NHSN enables healthcare facilities to collect and use data about HAIs, adherence to clinical practices known to prevent HAIs, the incidence or prevalence of multidrug-resistant microorganisms (MDROs) within their organizations, trends and coverage of HPS and vaccination, and adverse events related to the transfusion of blood and blood products.

Since the inception of the NNIS system in 1970, CDC's primary goals for HAI surveillance have been to describe the epidemiology of HAI, provide national-level HAI comparative rates for hospitals and other healthcare systems, and promote methodologically sound surveillance in healthcare systems *(5,6)*. The NHSN includes four components, each concerned with an aspect of HAI control and prevention: patient safety, HPS, biovigilance, and e-surveillance.

The patient safety component of NHSN includes surveillance methods to identify and track device-associated infections, procedure-associated infections, antimicrobial use, MDROs, *Clostridium difficile* incidence and prevalence, and influenza vaccination of inpatient populations during the influenza season. Most of the modules require that a trained infection preventionist (IP) conduct active, patient-based, prospective surveillance of events and their corresponding denominator data.

The HPS component of NHSN includes methods to track and manage blood and body fluid exposures and influenza vaccinations of healthcare workers. The biovigilance component includes the collection of adverse event data to improve outcomes in the use of blood products, organs, tissues, and cellular therapies. The hemovigilance module is designed for monitoring adverse reactions and quality control incidents related to blood transfusion.

The e-surveillance component of NHSN is a work in progress and aims to make more extensive use of electronic data stored in healthcare application databases for the surveillance of HAIs and antimicrobial use and resistance (AUR). These efforts focus on standards-based solutions for conveying healthcare data and validation processes to confirm that the data received at CDC accurately reflect the data transmitted by healthcare facilities. Access to electronic information is of critical importance to healthcare as well as other segments such as science, business, and industry. Innovative methods of HAI surveillance require using new electronic tools to obtain healthcare information. The National Health Information Infrastructure (NHII) was created by executive order of President George W. Bush in April 2004 to develop a comprehensive network of interoperable systems to promote access to healthcare information and decision support *(7)*. Although the NHII supported ongoing research, adapting electronic data and new communication methods to acquire surveillance data of HAIs has been a slow and complex effort *(7)*. Increasing the use of electronic health record (EHR) systems and other tools will help automate data collection tasks previously performed manually *(8)*. Financial incentives up to $24 billion are available as a result of the U.S. Health Information Technology for Economic and Clinical Health Act (HITECH), a component of the American Recovery and Reinvestment Act of 2009. HITECH funding is expected to accelerate progress in EHRs deployment (9,10). Although new data-mining methods expedite surveillance efforts, until they are validated for sensitivity and specificity, they do not replace traditional practices of surveillance for infection that must continue to be conducted (11). However data are collected, surveillance measures must be accurate, comparable, and reflect the particular area of healthcare being monitored *(12,13)*. To ensure that data collected will support decision making, the healthcare facility should focus on its most critical and large-scale problems and use surveillance methodology that adheres to sound epidemiologic principles (11). A brief synopsis of the NHSN patient safety component modules follow (14). For complete and up-to-date information about the NHSN surveillance system components and criteria, access www.cdc.gov/nhsn/.

Procedure-Associated Module

Protocols in this module offer guidance relating to surgical site infection (SSI) and postprocedure pneumonia (PPP) monitoring. PPP events are monitored only for inpatient operative procedures and only during the patient's stay (i.e., postdischarge surveillance methods are not used for PPP).

Device-Associated Module

The use of medical instruments increases the risk of developing an HAI, and most patients admitted for care are exposed to a medical device in the course of their treatment. These devices include, but are not limited to, vascular and urinary catheters and respiratory ventilators. NHSN enables facilities to monitor infectious complications associated with the use of these devices and also related processes that might increase infection risk, such as central-line insertion practices (CLIPs).

Antimicrobial Use and Resistance Module

As part of their facility's antimicrobial stewardship efforts, the AUR module helps healthcare facilities electronically capture antimicrobial use and microorganism resistance to antimicrobials and analyze and report that data.

Multidrug-Resistant Microorganism and *Clostridium Difficile* Infection Module

The MDRO and *C. difficile* infection (CDI) module helps facilities meet criteria and metrics outlined in several organizational guidelines to control and measure the spread of MDROs and CDIs within their healthcare system. The module includes required and optional surveillance activities that can be tailored to the needs of the facility. In addition, process measures such as adherence to Contact Precautions when caring for patients known to be infected or colonized with an MDRO or *C. difficile,* as well as active surveillance testing for MDROs can be monitored. Finally, facilities may also measure the incidence and prevalence of positive cultures of these microorganisms in their patients.

Vaccination Module

Inpatient hospitalizations provide opportunities for routine influenza and infectious disease vaccinations in accordance with published recommendations. The vaccination module provides a means to monitor the success of efforts to capitalize on these opportunities.

PURPOSES OF SURVEILLANCE

A healthcare facility should have clear goals before implementing a program, and these goals must be reviewed and updated frequently using a tool such as an infection control annual risk assessment. This assessment should identify new infection risks resulting from evolving patient populations and facility priorities *(15)*. Examples include the introduction of new high-risk medical interventions, an increasingly immunocompromised patient population, and changing pathogens or antibiotic resistance. It is vital to identify and state goals or purposes of surveillance before designing a system and starting surveillance (11,*16,*17).

Establishing Endemic Rates to Inform Prevention Strategy

Most HAIs are endemic, that is, not part of recognized outbreaks *(18)*. A basic purpose of surveillance is to quantify endemic baseline HAI rates; 91% of hospitals reported using surveillance data for this purpose *(19)*. Baseline infection rates provide facilities with objective knowledge of the ongoing infection risks in their patients, and calculating these metrics is a first step toward infection prevention *(19)* (*see Data Analysis*). Determining endemic rates helps advance activities to improve quality of care. Failure to use surveillance data or evidence-based results to guide

prevention efforts is misguided and costly, compromising patient care and unduly burdening today's vulnerable healthcare system.

Identifying Outbreaks

Once endemic rates are established, focusing on deviations from the baseline may lead to identification of infectious outbreaks. The benefits of maintaining routine surveillance must be weighed against its heavy resource burdens. Outbreaks of HAIs are often identified more quickly by astute clinicians or laboratory personnel rather than by IP analysis of surveillance data. This lack of timeliness often limits infection prevention personnel's use of routine surveillance in identifying outbreaks in a hospital. Automatic computerized tracking mechanisms found in infection prevention and laboratory-based software and new, innovative surveillance techniques have the potential to quickly identify outbreaks and unusual or rare laboratory findings requiring immediate follow-up (*8,13,20,*21).

Evaluating Control Measures

After a problem has been identified through surveillance and control measures have been initiated, monitoring is needed to ensure that the problem has been controlled or eliminated. Alternatively, monitoring may show that some control measures are actually ineffective or unnecessary. For example, daily changing of respiratory ventilator breathing circuits was instituted and believed to help prevent ventilator-associated pneumonia (VAP). However, surveillance data have proven this intervention to be a costly and ineffective method of lowering VAP rates *(22,23)*. After the initial success of instituting control measures, it is also necessary to counteract complacency and not revert to preintervention routines. Monitoring efforts require vigilance and constancy in the collection and evaluation of surveillance data and the dissemination of findings to participants (24,*25*).

Collaborating with New and Existing Partners

During the past decade, individuals, consumer groups, legislative and regulatory agencies, and payors have heightened awareness of the problem of HAIs. Many state legislatures have instituted requirements for public disclosure of HAI rates, and many of these mandates require the use of the NHSN for facility reporting and state acquisition of HAI data. As a result, new state HAI programs have been developed and new relationships forged between these agencies, healthcare facilities, consumer groups, and federal HAI surveillance and prevention groups. States then have the information needed to inform the development of statewide initiatives to tackle HAI issues. Measures are also underway to link pay for performance with prevention of HAIs in acute care settings *(26)*, both of which require collection of HAI data. Because of this increased focus, the Healthcare Infection Control Practices Advisory Committee developed a guidance document on public reporting of HAIs *(27)*.

Many regulatory and accreditation organizations have interest in the measurement and prevention of HAIs. That interest has influenced how infection prevention programs develop policy and carry out their surveillance and infection reporting duties. Regulatory agencies within the U.S. Department of Health and Human Services, CMS, and the leading private sector accrediting body, the Joint Commission *(28,29)* are tasked with ensuring quality healthcare delivery to Medicare and Medicaid recipients. Since 1992, hospitals accredited by the Joint Commission have been required to use surveillance to bring about change in the risk of infection to patients *(30)*. There is renewed and heightened focus on patient safety related to prevention of infection and transparency of mechanisms. CMS changed the rules for the hospital Inpatient Prospective Payment System for fiscal year 2011, authorizing a higher annual payment for hospitals reporting central line–associated bloodstream infection (CLABSI) rates with the other measures required under the Inpatient Prospective Payment System *(31)*. SSI rate reporting will be required, beginning in 2012. This process gives hospitals a financial incentive to report the quality of their services and allows CMS access to data to help consumers make more informed decisions about their healthcare.

The CDC's Division of Healthcare Quality Promotion (DHQP) has been charged to collaborate in the healthcare, computer, business, and government sectors to create the expertise, information, and tools necessary to implement processes and prevention strategies to reduce and prevent HAIs. One of DHQP's partners, the National Quality Forum, is responsible for endorsing measures of healthcare quality—including HAI measures—that can be used for public reporting and quality improvement *(29)*. State agencies are also partnering with DHQP, and many agencies have instituted regulatory controls by enacting laws that mandate public reporting of HAIs *(32,33)*. In addition to participating in other infection prevention initiatives and research studies, healthcare facilities are also engaged with DHQP to implement strategies to reduce and prevent HAIs. The infrastructure needed by healthcare facilities to participate and report these prevention measures however, is sometimes not available (24,*34–36*).

Comparing Infection Rates among Healthcare Facilities and External Groups

Establishing the priorities of an infection control program is a difficult and ever-changing task. Surveillance allows a healthcare facility to compare their HAI rates with rates of other facilities. Interfacility rate comparison identifies outcomes that are most in need of improvement and identifies places where the finite resources of an infection control program should be directed. A healthcare facility's high infection rate, as compared with other facilities, may signal an investigation of a potential problem. In recent years, there has been a greater focus on external comparisons of facilities and groups to other facilities and groups as well as comparisons to aggregates such as the NHSN. Mandatory reporting systems that will be used for interfacility comparisons should be based on established public health science *(3,27)*. This type of comparison requires accurate data collection and appropriate risk adjustment of HAI outcomes. To adequately adjust infection data, patients' intrinsic and extrinsic risks for infection must be examined (*see Comparing Risk-Adjusted HAI Data*). Progress has been achieved in suitable risk adjustment, but more data on specific risk factors are still needed *(12)*. A facility's overall HAI rate is not a valid measure of the efficacy of the infection prevention program *(37–42)*, does not take underlying risk differences

into account, and should not be used for interhospital comparison. The standardized infection ratio (SIR) (*see Standardized Infection Ratio*), incorporating methodologically sound risk adjustment of HAI outcomes, is the preferred summary statistic to use for interhospital comparison.

Ensuring data accuracy is another challenge for healthcare facilities and the organizations responsible for aggregating their data. The independent determination of data accuracy or validation is an essential activity for organizations aggregating data from multiple collectors *(13)*. Aggregating organizations should examine a facility's data and screen for unusual patterns or other indications of inaccuracies. This should include reporting data back to the hospital to confirm that data received matches data sent. Determining the accuracy of the data includes confirming HAI case-finding methodology using three measures: sensitivity, positive predictive value (PPV), and specificity. Sensitivity is the percentage of all true infections that are reported. PPV is the percentage of reported infections deemed to be true infections. Specificity is the reported number of patients without HAI divided by the true number of patients without HAI *(43)*. Using an independently trained observer to ascertain the sensitivity, PPV, and specificity of HAI case-finding will strengthen the credibility of the surveillance system, help identify the means to adjust rates for facilities with rates that vary, and enhance the overall strength of the surveillance system.

Although determining the sensitivity, PPV, and specificity of all facilities validates the credibility of the multifacility surveillance system or aggregate group, determining the variation in sensitivity and specificity among facilities in a multifacility system may be an even more critical measure of credibility. Surveillance rarely achieves 100% accuracy. However, if one hospital finds HAIs among only 30% of its patients compared with a second hospital, which finds HAIs among 90% of its patients, the disparity in infection rates may be caused entirely by differences in case-finding sensitivity.

Determining sensitivity and specificity is difficult and resource-intensive. Fortunately, the NNIS evaluation study suggested that IPs generally report HAI data accurately. Low sensitivity (underreporting of infections), which ranged from 59% to 85% for the four major sites of HAI—bloodstream, pneumonia, urinary tract, and surgical—was a more serious problem compared with reporting of other measures. PPV ranged from 72% to 92% for these sites, and specificity ranged from 97.7% to 98.7% *(44)*. Because of the increase in state-based mandatory reporting of HAIs, there has been a corresponding increase in assessing data for inaccuracies and conducting formal validation studies *(45–49)*. Additionally, federal funds have been allocated for this purpose *(50)*.

ATTRIBUTES OF A SURVEILLANCE PROGRAM

A successful surveillance program uses thorough epidemiological principles in its planning. The data collected must be useful and complete. Attributes of a successful surveillance program are as follows:

- Accuracy
- Timeliness
- Usefulness
- Consistency
- Practicality

Accuracy

Effective surveillance must produce accurate data. Inaccurate data can result in wasted effort, resources, and personnel time, as well as the initiation of inappropriate, potentially harmful interventions. Using case definitions advances the accurate collection of HAI surveillance. A case definition is a "set of standard criteria for deciding whether or not a person has a particular disease or health-related event" *(51)*. The use of case definitions helps validate that patients identified as having an HAI do, in fact, have an HAI. The NHSN provides and requires the use of criteria (case defintions) for all types of HAIs.

Likewise, for surveillance data to be accurate, the denominator data, defined as the number of patients who are at risk for infection that is used to calculate infection rates, must also be accurate. For example, IPs must invest time to ensure that the identified number of central-line catheter days is correct to achieve an accurate CLABSI rate. Data collection can be time-consuming, and sampling methods offer a less time-consuming alternative *(52)*. Sampling methods however, including electronic capture, must be validated by a proven method before implementation.

Gathering accurate, highly sensitive numerator data is possible only if patients are monitored for the entire period of the case definition. For instance, NHSN case definitions for SSI specify a period of 30 days to 1 year postsurgery; the extended time period allows data to be gathered on surgeries that involve surgical impacts. Limiting surveillance to 1 week would result in inaccurately low SSI rates caused by a lack of sensitivity, because it would exclude patients who developed an SSI in weeks 2 to 4 (in a surgical procedure without implant).

Decreasing length of stay (LOS) within hospitals could directly affect the SSI rate. During 1970 to 2005, the average LOS in US hospitals decreased from 7.8 to 4.8 days *(53)*. This shortened LOS requires that surveillance be adapted to identify those patients whose infection develops in the postdischarge period (i.e., postdischarge surveillance). This adaptation is especially important for operative patients. Studies have shown that the percentage of SSIs that would be missed without postdischarge surveillance ranges from a low of 7% in trauma patients to a high of 85% to 95% in cesarean section patients *(54–59)*.

Postdischarge surveillance could use one of several techniques including contacting the patient or physician by telephone or mail; the surgeon, nurse, or IP observing the patient in the clinic; and detecting SSIs on readmission *(54–59)*. Significant methodological problems can exist, however, with postdischarge surveillance, such as physicians not responding in a timely manner to the IP; patients inaccurately diagnosing infection *(60)*, and uncertainty about how to account for patients lost to follow-up. These problems are not easily addressed, and studies have mixed findings on proposed solutions. For example, education on signs and symptoms of SSI would seem to improve a patient's ability to diagnose their own SSI. In one study, however, such education actually corresponded to a reduced sensitivity and significant reduction in specificity

of SSI identification (65.2%) compared with sensitivity and specificity of SSI identification in noneducated patients (83.3%) *(59)*.

Some studies had contradictory findings. One study successfully used antimicrobial administration in discharged surgical patients as a case-finding method. The same study also found that using other methods, such as mailed questionnaires to surgeons or patients, resulted in poor sensitivity data *(61)*. Yet in another study, the significant amounts of antibiotics dispensed following surgery, especially in breast surgeries (14%), led the authors to suspect preoperative prophylaxis extended into the postdischarge period may be a threat to the predictive value of postdischarge antimicrobial data as a case-finding tool *(62)*. Clearly, postdischarge surveillance methods need refinement. Research may reveal that a variety of procedure-specific data sources and methods are needed to identify the majority of postdischarge SSIs. Until a standard method is developed and validated, the Surgical Wound Infection Task Force recommended in 1992 that facilities use a method that accommodates their resources and data needs *(63)*.

Finally, accurate data also requires precise mathematical calculations. Many HAI software programs are currently available to assist with this, including the NHSN, which calculates risk-stratified rates, frequency tables, run charts, and SIRs.

Timeliness

A sound surveillance program produces useful and timely HAI data. There are two temporal methods of surveillance: prospective and retrospective. Prospective surveillance is monitoring patients during admission for symptoms and case-definition criteria so that the infection is identified as it develops. It involves reviewing patient records and visiting patient-care units during the patients' stay. Retrospective surveillance involves looking back to identify infections after they have occurred. An example of retrospective surveillance is to identify infections using only the review of a patient's chart following discharge.

Prospective surveillance can more quickly identify clusters of infection, and therefore, facilitate prompt investigation, analysis, and response activity and may prevent the development of more cases. It can also provide increased visibility of IPs on the wards, encourage staff reporting of suspected infections, and produce timely feedback of data for quality improvement purposes. One disadvantage is that it requires greater resources than retrospective surveillance, because multiple data sources need to be accessed rather than viewing all data gathered on a single completed patient chart. Retrospective surveillance "allows for a comprehensive review of sequential events in the closed record and avoids the often time-consuming efforts of locating and reviewing charts in busy patient care areas." Retrospective surveillance is best suited for issues that "have little opportunity or need for intervention" because the identification of HAI issues may be delayed (11). NHSN participation requires prospective surveillance.

Usefulness

Because infection prevention efforts have competing priorities, limited surveillance resources are best spent on actionable issues, including those that have validated methods of improvement (e.g., bolstered standards of practice, instituted prevention bundles, or uses new or enhanced technology). Monitoring issues with no opportunity for improvement produces wasted effort, frustration, and does not support the principles of quality improvement.

Consistency

Surveillance data must be collected in a consistent manner to be useful. First, individuals and facilities must be consistent in their collection and interpretation of data. Surveillance personnel must uniformly apply case definitions (e.g., all data collectors should identify a case of VAP the same way). Consistency is achieved with uniform case definitions, surveillance methods, and data sources, as well as with targeted education of IPs. Within facilities, new case-finding staff should be mentored in correct methods and the determination of cases validated by experienced IPs. Consistency of case determinations within an infection control department should be validated routinely by cross-checking. Sharing case studies among facilities in which subject matter experts have made HAI determinations *(64)* produces greater consistency. A stable infection prevention and control department that has low rates of staff turnover encourages data consistency.

The targets of surveillance should also maintain consistency over time. Longitudinal data must be available to successfully analyze the value of prevention efforts. This does not mean that newly identified issues must be set aside. Considering that a facility's high-risk procedures and patient populations will probably experience only incremental changes over time, ongoing monitoring and collecting longitudinal data can occur simultaneously with the monitoring of newly identified issues.

Practicality

Finally, the best surveillance plan is only as good as its execution. Although plans must be based on the needs of the facility, they must also reflect the actual resources available. According to a recent survey, 44% of an IP's time is spent on surveillance activities, and a facility of 500 beds has, on average, just over 0.5 fulltime equivalents in an IP role *(65)*. Facility-wide, active, prospective surveillance in such a setting is limited and cannot be completed accurately, comprehensively, or in a timely manner.

DEVELOPING A FACILITY SURVEILLANCE PLAN

Every facility should develop a formal surveillance plan, methodologically identifying the goals, types, approaches, and methods of surveillance to be undertaken. The essential steps involved in this process are listed in Table 89-1 and are explored further in this section.

Assessing the Population

The first step in developing a surveillance plan is to perform a facility-specific risk assessment, which identifies the facility's patient populations at greatest risk of acquiring HAIs and procedures posing the greatest risk of infectious complications (11). From this information, surveillance efforts can be prioritized and valuable resources used efficiently. Both assessment and plan should be reviewed

TABLE 89-1

Essential Elements of Surveillance

- Assess the population
- Select the outcome (event) or process to survey
- Choose the surveillance method(s) keeping in mind the need for risk adjustment of data
- Monitor for the event or process
- Apply surveillance definitions during monitoring
- Analyze surveillance data
- Report and use surveillance information

(Adapted with permission from Lee TB, Baker OG, Lee JT, et al. Recommended practices for surveillance. *Am J Infect Control* 2007;35(7):427–440.)

routinely to determine changing facility needs. The following variables should be identified in the assessment and used to determine HAI risks, surveillance capabilities, and how efforts should be prioritized:

- **Patient populations served by the facility that are at high risk of infection**, such as elderly, neonatal, or immunocompromised patients (e.g., those with autoimmune disorders; oncology, burn, or trauma patients; and those on medications or treatments suppressing the immune system).
- **High-volume or high-risk operative procedures that are performed.** High-volume procedures have the potential to harm large numbers of patients if deviations from high-quality care occur (e.g., a facility that performs a large number of laminectomies each month). Infections following high-risk procedures (e.g., hip arthroplasty) could result in severe or deadly infections or permanent loss of function or quality of life.
- **Types of invasive devices that are proven to be associated with HAI development** (e.g., intravascular or indwelling urinary catheters and respiratory ventilators).
- **Resources available for use in the surveillance.** The number, skills, and education level of fulltime staff available for surveillance and the types and scope of data sources will determine surveillance capacity.
- **The need to meet state and federal mandates.** Work with local, state, and federal health departments to ensure that required HAI reporting is completed.

The Focus of Surveillance

After the facility assessment has been completed, foci of surveillance must be determined. An HAI surveillance system may be sentinel event-based, population-based, or both. Each system type has a different focus. In sentinel event-based surveillance, the focus is on sentinel infections or those that clearly indicate a failure in the facility's efforts to prevent infections and require individual investigations *(66,67)* and root-cause analysis. Because of this, denominator data and infection rates are usually not collected or generated in sentinel event-based surveillance. Because sentinel surveillance identifies only the most serious problems, it should not be the only surveillance system employed in a facility. Population-based surveillance focuses on patients with similar risks for infection (e.g., patients undergoing endoscopy in a facility). It allows for the calculation of rates of HAI using both a numerator (the number of infections) and denominator (the number of exposures to the risk or patients at risk).

Regardless of the focus of surveillance selected, a successful surveillance plan needs to be well understood by and receive the support of facility management. It must be tailored to provide the information needed to identify and address the facility's HAI risks as well as to meet any external regulatory requirements.

Types of Surveillance

Once the foci of surveillance have been identified, the next decision is which type of surveillance to use. Two questions must be answered to determine the type of surveillance: Will the surveillance be passively or actively completed, and will the metrics used be outcomes or processes? Again, the facility risk assessment should inform both of these decisions. Each type of surveillance offers advantages. Factors including intended use of the data, resources available to complete the surveillance (including personnel, financial, data, and technical), and existing regulatory mandates will determine which type of surveillance to use.

Passive versus Active In passive surveillance, people who do not have a primary surveillance role (i.e., people other than IPs) provide the routine identification and reporting of infections. For example, when an HAI is suspected, clinical healthcare personnel complete the forms and send them to the IP. Because clinical personnel's skills and knowledge are related to patient care rather than surveillance, it is not surprising that problems associated with passive surveillance include misclassification, underreporting, and lack of timeliness. Negative reporting (i.e., confirming that no infections have occurred during the surveillance period) is usually not a part of passive reporting. Because negative reporting is not included in passive reporting, IPs may incorrectly conclude that no infections have developed, causing reported HAI rates to be falsely low.

Active surveillance is the process of vigorously looking for HAIs using trained personnel, most often including IPs. In this type of surveillance, IPs seek out HAIs using various data sources and methods, discussed later, to determine whether an HAI has occurred. IPs are likely to be current with changes in surveillance definitions and able to extend the search for the source of the infection beyond the walls of the healthcare facility. IPs can work with outpatient facilities affiliated with their facility when needed to address opportunities for infection prevention identified by surveillance. An IP at hospital A can also share HAI information with an IP at neighboring hospital B when B's patient presents to hospital A with an HAI. Active surveillance frequently will include visits to patient-care units and discussions with patient-care staff. Negative reporting is a required component of active surveillance.

Passive surveillance requires fewer resources than active surveillance, may not need a dedicated IP, and requires only minimal activities of those reporting. Active surveillance is

more accurate and provides complete identification of HAIs and an increased visibility of the IP within the facility. This allows the IP to develop relationships with the staff and may result in early identification of other infection prevention and control issues.

Outcome Versus Process The type of measurement must also be decided. Is the facility interested in measuring (a) the outcomes of care (e.g., SSI) or (b) the ways in which healthcare is delivered, also known as process measurement (e.g., preoperative hair clipping instead of shaving to prevent SSI)? Outcome measurements examine the results of healthcare interventions or activities. Process measurements examine the rate at which targeted actions, such as prevention measures, occur. There has been recent and renewed interest in using process measurements in HAI surveillance, because it evaluates a facility's compliance with bundles of prevention practices. Bundles, a combination of prevention activities aimed at producing the lowest rate of infection for a given intervention (e.g., VAP bundles, CLIPs), have been operationalized to produce checklists of actions *(68)*. These actions or processes can be monitored and compliance rates calculated. Process measures have also been used for monitoring traditional infection prevention activities, such as hand washing by healthcare personnel.

Mant provides a useful overview comparing outcome with process monitoring *(69)*. According to Mant, the advantage of outcome measurement is that it provides a direct measure of an important health outcome (e.g., a healthcare facility-associated CDI rate). They summarize important data in a manner that is clear and useful. The advantages of process measures are that they are easily interpreted and more sensitively and directly measure specific aspects of healthcare. Outcomes may be influenced by a variety of factors, some of which are not related at all to the delivery of healthcare (e.g., patient characteristics, measurement issues, and chance). Mant suggests that it is preferable to use outcome measures when healthcare seems to be the major determinant rather than for those issues that are socioeconomic or not related to healthcare. Process measures better monitor specific healthcare actions that have been proven to impact patient outcomes and are sometimes endorsed by national guidelines. Measuring process *and* outcomes for a single healthcare issue produces robust surveillance data that can lead to notable improvements in patient health. For example, CLIP and CLABSI data can be studied in tandem to inform and evaluate prevention efforts.

Perspectives of Surveillance

There are two perspectives to consider when performing surveillance: (a) scope and (b) approach. Each perspective has two choices. For the scope of surveillance, a facility may choose to perform facility-wide surveillance or to target surveillance of units or specific HAI events. For the approach of surveillance, a facility may decide to utilize a patient-based approach, or they may opt for a laboratory-based approach. Each perspective and approach has its advantages and disadvantages, and a facility must determine the best perspective and approach to meet its needs.

Scope: Facility-wide Versus Targeted Facility-wide HAI surveillance (also known as total, comprehensive, or house-wide) *(70)* involves monitoring all patient care areas for all types of HAIs (e.g., urinary-tract infections, SSIs, pneumonias, skin and soft-tissue infections, etc.). If properly collected, this data can be stratified by facility ward or service. Facility-wide monitoring can be a useful approach for very small facilities, but it is extremely labor-intensive, and is therefore, not feasible for most healthcare facilities.

Facility-wide surveillance can include two types of monitoring: incidence (new cases only) or prevalence (both new and existing cases). Prevalence surveillance can be performed on a single day (point prevalence) or over several days (period prevalence). In point prevalence, each patient is visited only once, and the surveillance is usually performed by a trained team using chart review, discussion with caregivers, and/or direct assessment of patients to identify infections. A facility may choose to utilize incidence surveillance on a routine, ongoing basis for targeted units or infections, to utilize prevalence surveillance to inform on specific infection concerns as they arise, and to determine the need for infection control or prevention activities. For instance, a facility may perform continuous-incidence surveillance for CLABSIs in those units that have the largest percentage of these devices. Additionally, the identification of the possible transmission of a resistant *Acinetobacter* species in a patient-care unit may warrant a prevalence survey to determine the infection and colonization burden of this microorganism, and therefore, one aspect of risk to patients. Follow-up prevalence surveys can be used to determine the success of transmission prevention efforts. Some studies have used prevalence surveillance to estimate antimicrobial use and adherence to isolation practices and to monitor practices related to high-risk devices such as intravascular catheters *(71,72)*. One group of investigators used sequential prevalence surveys to estimate the effectiveness of their infection control program on reducing the risks of HAI *(73)*. Prevalence surveillance data have also been used to heighten the awareness of HAI problems in institutions without other surveillance methods in place and have been influential in helping to establish ongoing prospective (incidence) surveillance. Using prevalence surveillance to establish a single overall rate for the purposes of interfacility comparison is not recommended for the same reasons that generating overall rates from incidence surveillance is not recommended *(41)*.

Prevalence methods have also been used to demonstrate long-term trends in the epidemiology of HAI in an institution. This method has met with varying success. One study demonstrated these trends may be estimated from repeated prevalence surveys *(72)*. However, the interpretation of the results was complicated by the small number of patients studied and variations in the types of prevalence rates calculated. Therefore, secular trends within a facility are best derived from ongoing prospective (incidence) surveillance methods.

Prevalence surveys also can be used to determine the approximate sensitivity of a facility's ongoing prospective surveillance, that is, how well true infections are being detected *(74)*. The assumption is made that the prevalence surveyors will detect and correctly identify 100%

of infections. An estimate reflects the percentage of true infections detected by routine surveillance; this has been termed the *efficiency-of-reporting score* or *efficiency factor (74)*. The efficiency factor, which was found in one national study to be 65%, can then be used to adjust incidence rate estimates for the magnitude of underascertainment, and thus, yield a more accurate rate *(75)*. This method and all incidence surveillance methods assume perfect specificity (1.0), that is, that patients without infection are identified as not having a true infection. However, one study found that IPs had more difficulty determining when an infection was not present than when one was present *(76)*, suggesting the need to adjust infection rates by the efficiency factor. Before ongoing prospective surveillance attained widespread use in the United States, some investigators used data from prevalence surveillance performed at regular intervals or from a single study to estimate the incidence of HAI *(77,78)*. This use has not been applied widely, partly because statistical conversion is necessary (*see Data Analysis)*.

There are two primary disadvantages of prevalence surveillance. First, the small number of patients surveyed in small facilities may not provide sufficient data for identifying important differences among patient populations, for example, the difference between pneumonia rates on medical and surgical services. Second, the prevalence rate overestimates the patients' risk of infection, which is calculated as the number of active infections on the day of the visit divided by the number of beds visited. This is because situations that result in extended patient stays (such as the complication of an HAI) can extend the hospital stay, increasing the prevalence rate when compared to the incidence rate (79) (*see Defining and Calculating Rates*). Most facilities perform incidence surveillance and utilize the data to calculate routine incidence rates (e.g., unit-specific monthly VAP rates).

Surveillance strategies that resulted in more efficient use of IPs began to emerge in the late 1970s. These strategies target efforts on certain areas in the facilities (e.g., intensive care units [ICUs]), patient groups (e.g., surgical patients), or infection sites (e.g., bloodstream infections), or a combination of both. This type of surveillance is, referred to as targeted surveillance. More recently, antibiotic-resistant microorganisms have been the subject of targeted surveillance. A variation on this approach, called surveillance by objective, was used by Haley in the mid-1980s (*80*,81). In this approach, infections are prioritized for prevention efforts—the more serious the infection, the more the effort expended. In ranking infections, Haley recommended using more than just the relative frequency of occurrence. Factors to assess included morbidity and mortality, extra costs associated with the infection, and preventability *(82–84)*.

Targeted surveillance (also known as objective- or priority-based) may be either site-directed or unit-directed. Site-directed targeted surveillance focuses on detecting one or more specific sites of infection (e.g., bloodstream infections or MDROs) occurring among all admitted patients. This approach would be useful, for example, in facilities that introduce prevention bundles and would allow the measurement of the success of these activities.

Unit-directed surveillance targets specific patient locations with the highest risks of HAI (e.g., ICU and bone-marrow transplant units). Within the NNIS system, unit-directed surveillance was aimed at ICUs and high-risk nurseries *(37)*. Beginning in 2005, the NHSN offered an opportunity for facilities to participate in HAI surveillance in patient-care areas outside the ICU including patient-care wards, freestanding dialysis centers, long-term acute-care areas, and outpatient areas *(85)*. In unit-directed surveillance, patients may be monitored for the presence of all types of infection or for only particular infections (e.g., VAP) or process measures (e.g., administration of antibiotics to emergency-room patients with pneumonia, within 4 hours of presentation). Because a geographically smaller area is covered during unit-directed surveillance, theoretically, less time is needed for this type of surveillance. However, ICU-targeted surveillance can be more time-consuming, because patients in these units may have extensive medical records.

Facility-wide surveillance has the advantage of providing a comprehensive view of the facility and detecting potential clusters of infection or antibiotic resistance throughout the facility. Weber et al. (86) found that this type of surveillance in their 700-bed acute-care hospital would have identified 60% more cases of all methicillin-resistant *Staphylococcus aureu*s and vancomycin-resistant enterococci, almost 70% more respiratory infections, and 80% more CLABSIs in the facility's medical–surgical areas than using targeted surveillance alone. However, using facility-wide surveillance for other than small facilities requires an inordinate amount of staff time and is probably not driven either by findings from the facility risk-assessment or prevention goals. Accordingly, the accuracy of facility-wide surveillance has been challenged, and it is not recommended to be used for interhospital comparisons *(87)*. Risk categories for data collected using facility-wide surveillance cannot be identified, which further limits its usefulness in infection prevention activities and is among the reasons that it is not a currently recommended method of surveillance for most institutions *(41)*.

Targeted surveillance has become increasingly common, because it requires fewer resources and has the potential for yielding more meaningful results than facility-wide surveillance. Targets or objectives are chosen as a result of the facility risk assessment. A disadvantage of targeted strategies is that clusters of infection in areas not under surveillance may be missed, although Haley recommended that the IP train other facility staff to be alert for and to report unusual clustering *(16)*. Using data that is available from other sources may also allow the identification of HAIs in areas not routinely targeted. This type of data mining answers some of the challenges posed by HAI surveillance. Many facilities customize their surveillance plan by combining unit- and site-directed targeted surveillance. This combination allows monitoring of high-risk populations located in special units, as well as those undergoing high-risk invasive procedures (e.g., central-line catheterization or total hip arthroplasty).

Patient-Based versus Laboratory-Based Case finding in patient-based surveillance involves assessing risk factors and monitoring patient-care procedures and practices.

It requires ward rounds and discussions with caregivers. Laboratory-based surveillance, on the other hand, involves detecting possible HAIs solely on the basis of laboratory reports from clinical specimens. The primary disadvantage of laboratory-based surveillance is that it will miss infections that are not cultured (e.g., clinical sepsis that only presents physical signs and symptoms and is treated empirically). Important infection issues that are not subject to culture may go unrecognized when only laboratory-based surveillance is used. Patient-based surveillance is, therefore, the recommended approach and is required for participation in most NHSN modules.

A summary of the advantages and disadvantages of types of, and approaches to, surveillance can be found in Table 89-2.

DATA COLLECTION

Numerator

Defining Healthcare-Associated Infection Data collectors must be able to accurately and quickly identify infections that are healthcare-associated and consistently apply definitions and criteria (88). Uniform definitions are critical for comparing data among healthcare facilities and comparing data with an aggregated database (e.g., state or national system) *(42,63,76,89)*. The NHSN system defines an HAI as "a localized or systemic condition that results from adverse reaction to the presence of an infectious agent(s) or its toxin(s) and that was not present or incubating at the time of admission to the healthcare system" (90). For most bacterial HAIs, this means that the infection usually becomes evident 48 hours

TABLE 89-2

Advantages and Disadvantages of HAI Surveillance Types and Approaches

Type/Approach	*Advantages*	*Disadvantages*
Passive	• Requires fewer dedicated resources	• Increased potential for misclassification and underreporting • Lack of timeliness
Active	• Increased visibility of the IP may lead to increased sensitivity of surveillance	• Requires dedicated resources, increased surveillance time
Outcome	• Outcomes (e.g., rates) are of most interest to patients/staff • Measures all aspects of care • Important to measure impacts of prevention efforts	• Can be influenced by nonhealthcare delivery issues that cannot be controlled by healthcare personnel • HAI rates and their limitations can be difficult to understand
Process	• Easy to interpret • More sensitively and directly measure aspects of care • Useful for measurement of adherence to bundles of care, proven to impact patient outcomes	• Do not measure the outcome of care that is often of most interest to patients and healthcare staff
Facility-wide	• Provides rapid, inexpensive estimate of HAI magnitude in facilities • Amenable to smaller facilities • Can be useful to identify and rationalize the need for ongoing prospective surveillance	• May not detect important HAI incidence differences between patient populations if denominators are small
Targeted (priority-based)	• Is directly responsive to the findings of the facility risk assessment, targeting unique surveillance needs • Directs limited IP resources to most important surveillance areas	• Unless combined with adjunct staff looking for HAIs or other data sources, may miss clusters of infection or emerging issues in locations/populations in which surveillance is not performed
Prevalence	• Can be useful to determine an estimate of HAI experience if incidence monitoring is not available (highlight a problem) • Periodic monitoring can provide an estimate of HAI trends within facility	• May fail to detect differences in rates between populations • May overestimate the HAI experience because of extended length of stays, when compared with incidence rates
Incidence	• Can be used to calculate meaningful rates for the time period of interest only (i.e., will not include HAIs from previous time period) • Comparative rates are available (e.g., NHSN)	• None
Patient-based	• More inclusive, accurate	• More labor-intensive
Laboratory-based	• Less labor-intensive	• Fails to identify HAIs that are not cultured, resulting in falsely low rates

(i.e., the typical incubation period) or more after admission. However, because the incubation period varies with the type of pathogen and, to some extent, with the patient's underlying condition, each infection must be assessed individually for evidence that links it to the healthcare event.

Several other important factors enter into HAI definitions and the use of those definitions for HAI surveillance *(89)*. A combination of clinical findings, diagnostic test results, and the type of patient determines the presence and classification of an infection. Clinical evidence comes from direct observation of the infection site and physical assessment or review of other pertinent sources of data, such as the patient's chart (detailed later in this chapter).

CDC/NHSN surveillance definitions of and criteria for specific types of HAIs can be found in the NHSN manual on the NHSN Web site at http://www.cdc.gov/nhsn/TOC_manual.html. Criteria for two HAIs require special consideration: infections acquired in the healthcare setting but not becoming evident until after discharge and infections in a neonate resulting from passage through the birth canal. The preventability or inevitability of an infection is not a consideration when determining whether it is healthcare-associated. For example, preventing the development of healthcare-associated *C. difficile* gastroenteritis after extensive antibiotic treatment may not be possible, but these infections are defined as HAIs because they would not have occurred in the absence of healthcare (i.e., antibiotic treatment). As another example, some would argue that neonatal infections acquired during vaginal delivery are inevitable and, therefore, should not be counted as healthcare-associated. However, as noted previously, these neonatal infections (e.g., group B streptococcal bacteremias with early onset) are considered healthcare-associated, even though they can be identified as maternally acquired. The analysis of their incidence can be disseminated to obstetricians for intervention and prevention strategies.

Three types of infections are *not* considered healthcare-associated: (a) infection associated with a complication or extension of infection already present on admission but not related to previous healthcare, unless a change in pathogen or symptoms strongly suggests the acquisition of a new infection, (b) infection in an infant that is known to have been acquired transplacentally (e.g., toxoplasmosis, rubella, cytomegalovirus, or syphilis) and becomes evident at or before 48 hours after birth, and (c) reactivation of a latent infection (e.g., herpes zoster [shingles], herpes simplex, syphilis, or tuberculosis). Finally, there are two conditions that are not infections at all but are important to consider in the surveillance for HAI: (a) colonization, which is the presence of microorganisms (on skin, mucous membranes, in open wounds, or in excretions or secretions) that are not causing adverse clinical signs or symptoms, and (b) inflammation resulting from a noninfectious cause such as injury or chemical exposure.

Surveillance definitions of HAIs are not intended to guide diagnostic or therapeutic decisions. Additionally, surveillance definitions at times may not accurately describe what is clinically observed or suspected. Physicians may, for instance, believe that a bloodstream infection is secondary to an unidentified infectious process occurring within the gut and should not be identified as a CLABSI because they believe the source is the gut and not the vascular catheter. Currently within NHSN, without an infection by surveillance definition for gastrointestinal infection or gastroenteritis along with microbiologic evidence suggesting that the two are related, CLABSI surveillance definitions will require the reporting of a CLABSI. HAI surveillance requires the consideration of multiple factors. As a result, a rigorous surveillance program can miss identifying true infections and erroneously count some noninfections as infections.

Identifying Data to Collect The data collected on a patient with a HAI include demographic, infection, laboratory, and other diagnostic test data. Table 89-3 shows the most essential data to collect. Additionally, information describing important risk factors for infection should also be collected but only if the information will be analyzed and used by the facility. For example, timing, dosage, and route of administration of preoperative antibiotics may be collected if such data will be used to help understand and guide the practice of surgical prophylaxis. Information on the use of indwelling urinary catheters, central intravascular or peripheral lines, or ventilators allow for surveillance of infections associated with these devices. Where feasible, corresponding denominator data should also be collected so that risk-adjusted infection rates can be calculated (e.g., VAP rates per 1,000 ventilator days in a specific type of ICU). In the NHSN system, information on adverse outcomes of HAI is also collected, such as development of a secondary bloodstream infection and the death of a patient. Determining the relationship between infection and death is essential in understanding an important outcome of HAI.

Identifying types of risk factors associated with the operation is useful when examining infections in surgical patients. Depending on the operative procedure, these may

TABLE 89-3

Essential Data on Healthcare-Associated Infections

include operative procedure category, duration and wound class of the operation, the American Society of Anesthesiologists score, use of general anesthesia, use of an endoscopic approach, whether the procedure was performed emergently or as a result of traumatic injury to the patient, and other variables. Data collected on all surgical patients being monitored, not just on patients who develop SSIs, provide a denominator for the calculation of specific rates.

Whenever possible, the data should be entered, analyzed, and stored on a secure computer. NHSN data collection forms can be accessed at http://www.cdc.gov/nhsn/dataCollectForms.html.

Finding Data The type of patients served by the healthcare facility and the methods of documentation determine which sources of data are used to perform surveillance. The IP should have ready access to every area of the facility and the full cooperation of facility staff to perform surveillance or conduct an outbreak investigation *(91)*. Case finding usually begins with the admission department, and also includes microbiology laboratory records, patient wards, sentinel reporting systems, and other areas, which could indicate the patients' charts that need to be reviewed *(92)*.

Capitalizing on Electronic Health Records Many healthcare facilities currently use some form of EHR. Electronic data used in the capture of information for the EHR, includes capture of both administrative data in electronic form (e.g., coded discharge data for claims processing) and clinical data in electronic form, such as EHRs used for clinical recordkeeping. This technology can influence how surveillance is conducted and can save time by accessing electronically available information. Electronic alerts obtained from clinical data may suggest the presence of an HAI and prompt further investigation. Microbiology data, radiologic data, and antimicrobial prescription data are some examples of clinically obtained electronic data. Chapter 16 contains a detailed discussion of the use of EHR, and specifically as used in surveillance for HAI.

The use of administrative coding data (e.g., ICD-9-CM discharge diagnosis coding or Medicare Provider Analysis and Review data) has often been suggested as a means to decrease the manual burden of HAI surveillance. However, this method of HAI identification has been shown to be very imprecise. One study cited a 0.23 PPV when comparing ICD-9-CM code-identified HAIs with HAIs identified using traditional methods (93). Another study using ICD-9-CM codes to identify urinary-tract infections (UTIs) showed a lack of discrimination between community-acquired and HAIs *(94)*. Surveillance for hospital onset *C. difficile* or methicillin-resistant *S. aureus* infection using these types of codes was found to be inaccurate as well *(95,96)*. Jhung and Banerjee (97) identify three primary limitations of using code data: (a) diagnosis code lists can be artificially abbreviated, (b) code lists do not correspond directly to clinical syndromes, and (c) clinicians and coders do not always speak the same language. Therefore, use of electronic data requires carefully piloted studies that include rigorous validation studies to confirm the accuracy.

When a potential infection case is identified through surveillance, the event must be confirmed. The most important source for confirmation is the patient's chart, which contains results of laboratory, radiology, and pathology studies; nursing and physician's notes and consults; admission notes with admission diagnoses; history and physical examination findings; records of diagnostic and surgical interventions; temperature charts; and reports of antibiotic administration. Patient care staff, including nurses, physicians, and respiratory therapists, are excellent additional data sources and can also be trained to complete forms alerting IPs to possible HAIs *(92)*. External sources of data, from health departments or CDC, can alert the IP about the need for active surveillance for newly emerging infections.

Collecting Data Healthcare workers who regularly interact with patients or review charts may be able to provide the IP with data collection assistance. However, due to their specialized training and experience using the case definitions, the IP or medical epidemiologist should be responsible for confirming the presence or absence of an HAI.

Usually, case-finding begins with the IP screening admission lists for patients admitted with infection (either community-acquired or readmission with an HAI) and those patients whose diagnoses (e.g., diabetes or severe immunosuppressive disorders) put them at risk of acquiring an HAI. Next, a visit to the laboratory or electronic review of culture reports can help better define the list of patients whose records require review. On the ward, a quick screening of nursing care reports, temperature charts, antibiotic administration sheets, Kardexes, and conversations with nurses and physicians can expand or focus the list. The IP's regular visits to the microbiology laboratory and patient wards provide opportunities to interact with staff members and gather clues on infected patients, identify unusual patterns of infection, and provide on-the-spot infection control education. Records are reviewed for evidence of infection, usually laboratory data followed by a review of the patient's record *(98,99)*. Physicians' progress notes and nurses' notes from the patient's record are particularly helpful and should be reviewed first. When access to computerized data sources exists, the IP can perform many case-finding activities at his or her desk. However, there is no substitute for frequent visits to the laboratory and patient-care areas to help accurately complete the infection data collection forms. These visits offer the chance for the IP to hear about observations that laboratorians or clinicians have made and may identify infection prevention opportunities not gleaned from electronic data review only.

Given the increasing demands for HAI data and the significant burden that manual collection of these data places on infection prevention and control resources, automated HAI surveillance using algorithmic case detection is an area of immense interest. In this type of surveillance, an algorithm developed from preexisting surveillance definitions, and using unique business logic, captures patient data from various electronic systems within a facility to determine the presence or absence of an HAI. While promising, this method of surveillance presents several challenges, including differences in the types and amounts of available harvestable

electronic data, variances in databases used within facilities and the need for standardization of algorithms for interfacility comparisons *(100)*. One of the biggest outstanding questions is whether these automated surveillance systems will produce data that are of a sufficient quality both from a sensitivity and specificity perspective. A small study comparing manual versus algorithmic detection of VAP applied against the determination of VAP by an infectious disease physician using CDC criteria found a slightly better PPV by algorithm (95%) than by clinician identification (81%) *(101)*. Another study used electronically captured data to compare an outcome called "ventilator-associated complications" to the CDC's VAP definition. Ventilator-associated complications were defined by increases in ventilator settings following a period of stable settings. This simpler system was better able to identify hospital mortality than manual application of the CDC VAP definition *(102)*. This type of surveillance may provide answers to the question of how to collect necessary HAI data when dealing with limited human resources. Validation studies will be key to moving this process along so that the data are accepted by those using it to institute and measure prevention efforts.

Identifying Denominator Data to Collect The denominators of infection rates are a tabulation of the cohorts of patients at risk of acquiring HAIs. For comparative purposes, the traditional denominators of patients admitted to or discharged from the facility, ward, or service have largely been replaced by denominators that better reflect the differences in risks among the monitored patients, such as number of days of exposure to a device. Examples of denominators currently used in NHSN are total number of patients and patient days in the unit and total number of ventilator days, central-line days, and urinary catheter days. Surveillance for antimicrobial resistant microorganisms requires the number of admissions to the unit of study or, in the case of outpatient surveillance, the number of patient healthcare episodes. As discussed in the section on numerators, NHSN has adopted a risk-modeling approach for procedure-specific SSI rates, in part, because it better enables fair inter- and intrafacility comparisons than previous universal risk-stratification systems (*see Comparing Risk-Adjusted Data*). For information on required denominator data for NHSN participation, see the specific NHSN module www.cdc.gov/nhsn.

Finding and Collecting Data The IP should enlist the help of others in the healthcare facility to collect denominator data. Operating room staff keep detailed logs of each procedure performed and can be encouraged to send daily reports to the IP. Alternatively, if the operating room records are computerized, these data can be downloaded directly into the infection control department's computer system. Similarly, a ward clerk can be trained to take daily counts of the number of patients admitted and a charge nurse can document the number of commonly used devices associated with HAI (e.g., urinary catheters). The midnight census can be used as the source of the number of patients in the unit, and respiratory therapy charge logs can also be used for ventilator days. As stated previously, all procedures must be validated by comparison with a proven method before they can be implemented.

DATA ANALYSIS

Defining and Calculating Rates

A rate expresses the probability of the occurrence of an event. It usually takes the form $(x/y)k$, in which the numerator x is the number of times an event has occurred in a population during a specified time period; the denominator y is the total population during the same time period, including those who did and did not experience the event; and k is the base or constant (e.g., 100, 1,000, or 10,000) that expresses the rate as a whole integer. The time period must be specified and identical for the numerator and denominator for the rate to be meaningful.

Three kinds of rates are used in HAI surveillance: incidence, prevalence, and incidence density. Incidence is the number of new cases of disease that occur in a defined population during a specified period of time. For HAI incidence, it is the number of new HAIs in a given time period divided by the number of patients at risk during that time period.

Prevalence is the total number of active (existing and new) cases of the disease in a defined population either during a specified period of time (period prevalence) or at a specified point in time (point prevalence). The point prevalence HAI rate is calculated by dividing the number of active HAIs in patients surveyed by the number of patients surveyed.

Rhame described the relationship between incidence and prevalence rates of HAI as follows: $I = P[LA/(LN - INTN)]$, where I is the incidence rate, P is the prevalence rate, LA is the mean length of facility stay for all patients, LN is the mean length of facility stay for patients with one or more HAI, and INTN is the mean interval from admission to the first HAI in those patients with one or more HAIs (79,*103*). In the hospital setting, prevalence rates almost always overestimate the infection risk because the LOS of uninfected patients is usually shorter than for those with infection. This can be seen more readily by rearranging the equation as $P = I(LN - INTN)/LA$, such that prevalence equals incidence times infection duration.

Incidence density is the instantaneous rate at which disease is occurring, relative to the size of the disease-free population. Incidence density is measured in units of the number of cases of disease per person per unit of time (e.g., 1.3 CLABSI per 1,000 central-line days). Incidence density is useful when the infection rate is a linear function of the length of time a patient is exposed to a risk factor (i.e., the longer the patient is exposed, the greater is the chance of acquiring infection). For example, rate 1—number of urinary catheter–associated UTIs divided by the number of indwelling urinary catheter days—is more useful than rate 2—number of urinary catheter–associated UTIs divided by the number of patients with urinary catheters. Rate 1 controls for the length of time a patient is exposed to the risk factor—the indwelling urinary catheter—which is linearly related to the infection risk.

One other rate that is often used is the attack rate, which is a special type of incidence rate. It is usually expressed as a percentage, where $k = 100$ and is used almost exclusively for describing outbreaks of infection in which particular populations are exposed for short periods of time.

Standardized Infection Ratio

Summarizing the HAI experience across groups of patients is desirable under certain circumstances, such as when a facility wants to describe its experience in a single metric that can take into account those risk factors that have been found to be associated with differences in infection rates (*see Comparing Risk-Adjusted HAI Data*). Based on the standardized mortality ratio, which is used widely in public health to analyze mortality data *(104)*, the SIR can be used for this purpose for HAI data. The SIR is an indirect adjustment technique that uses a standard population's risk-adjusted data to determine the number of HAIs that would be expected to occur if the facility's experiences were similar to those of the standard population's *(25)*. This expected number of HAIs (*E*) is then divided into the number of infections identified or observed (*O*), and the ratio is called the SIR (i.e., SIR = *O/E*). If the value of the SIR is equal to 1, then the HAI experience of the facility is the same as that of the standard population's. If the SIR is >1, there are more HAIs in the facility than expected, and further exploration of the data are needed to determine the causes and remedy them. If the SIR is <1, there are fewer HAIs than expected, and if case finding has been accurate and complete, this can be taken as evidence that HAIs are being prevented. The SIR is gaining acceptance as a useful metric, as evidenced by its use in hospital-specific HAI data reports in states with mandatory reporting laws *(45,105,106)*, by CDC in its state-specific HAI summary report *(107)*, and by the U.S. Department of Health and Human Services in its action plan to prevent HAIs *(108)*.

Device Utilization Ratio

Device utilization (DU) is defined as the number of device days divided by the number of patient days. In the device-associated Module of NHSN, device days consist of the total number of ventilator days, urinary-catheter days, and various types of central-line days. The DU of a critical-care unit or other patient-care location is one measure of the unit's invasive practices that constitute an extrinsic risk factor for certain HAIs. As such, DU may also serve as a marker for the severity of illness of patients in the unit. An IP's attention should not focus solely on infection rates in facilities. Those responsible for delivery of quality medical care must ask whether patients' exposures to interventions (e.g., devices or operative procedures) that increase risks of HAIs have been minimized wherever possible. For critical-care units, for example, the extent of DU may have to be examined. For surgical patients undergoing specific procedures, the distribution of patients by certain risk factors may provide valuable information *(37)*. Examining the appropriateness of an intervention also may aid in determining whether patient exposure was minimized.

Risk Adjustment of HAI Data

The denominator of a rate must reflect the population at risk. To compare a rate among patient groups within a facility, over time, or across facilities, the rate must be adjusted for the variations in *(91)* distribution of the major risk factor(s) that leads to the infection. The importance of risk adjustment was demonstrated when the federal agency then known as the Health Care Financing Administration failed to adjust for the major risk factor predicting mortality (i.e., severity of illness). Because of the absence of risk adjustment, most hospital administrators could not interpret or use these rates *(109,110)*.

A patient's predisposition for becoming infected is strongly influenced by certain risk factors such as personal characteristics and exposures. These risk factors are divided into two categories: intrinsic and extrinsic *(41,91)*. Intrinsic risk factors are those that are inherent in the patient, such as underlying disease conditions and advanced age *(91)*. Knowledge of the intrinsic risk factors is useful because separate risk-specific rates can be calculated, permitting the comparison of rates among patients with similar risks in different facilities or across different time periods. The Acute Physiologic and Chronic Health Evaluation (APACHE II) and diagnosis-related groups are two well-known indices for the severity of illness and are used to predict the risk of death and resource utilization, respectively, among ICU patients *(111)*. They are less useful when applied to HAIs because the factors associated with increased mortality and resource utilization apparently are not the same as the factors that increase the risk of infection. Patients with very high APACHE II scores probably do not survive long enough to acquire an HAI. One review suggests that no current severity of illness scoring system consistently adjusts risk for HAIs. Studies are needed to describe simple objective measures of severity of illness and/or underlying diseases that correlate with site-specific HAIs. These studies should also control for extrinsic risk factors for HAIs, such as exposure to devices.

Extrinsic risk factors may be healthcare worker–based (practices of an individual caregiver) or facility-based (practices in an entire facility). Although many extrinsic factors contribute to HAIs, the factors that have been implicated and studied most frequently are certain high-risk medical interventions, such as the use of invasive devices or surgical operations *(18,112–116)*. There are many reasons to explain the higher HAI rates among patients exposed to certain devices compared with HAI rates of patients not exposed to the devices *(40)*. Patients who require invasive devices may have more severe underlying disease conditions that increase their susceptibility to infections. These devices also provide a pathway for microorganisms from the environment to enter the body; facilitate the transfer of pathogens from one part of the patient's body to another; and act as inanimate foci where pathogens can proliferate, protected from the patient's immune defenses.

The risk of SSI is associated with a number of factors. Among the most important factors are the type and characteristics of the operative procedure performed, the degree of microbial contamination of the operative field, duration of operation, and the intrinsic risk of the patient *(115,117)*. Because infection control practices cannot alter or eliminate all of these risks, SSI rates must be adjusted for these risks before the rates can be used for comparative purposes. Two SSI risk indices—basic and modified—that effectively adjusted SSI rates for most operations were developed by the NNIS system *(117,118)*, and a variant of the basic risk index has been used in the NHSN *(119)*. However, NHSN is replacing this index with procedure-specific multivariable models to achieve even better risk adjustment *(107)*.

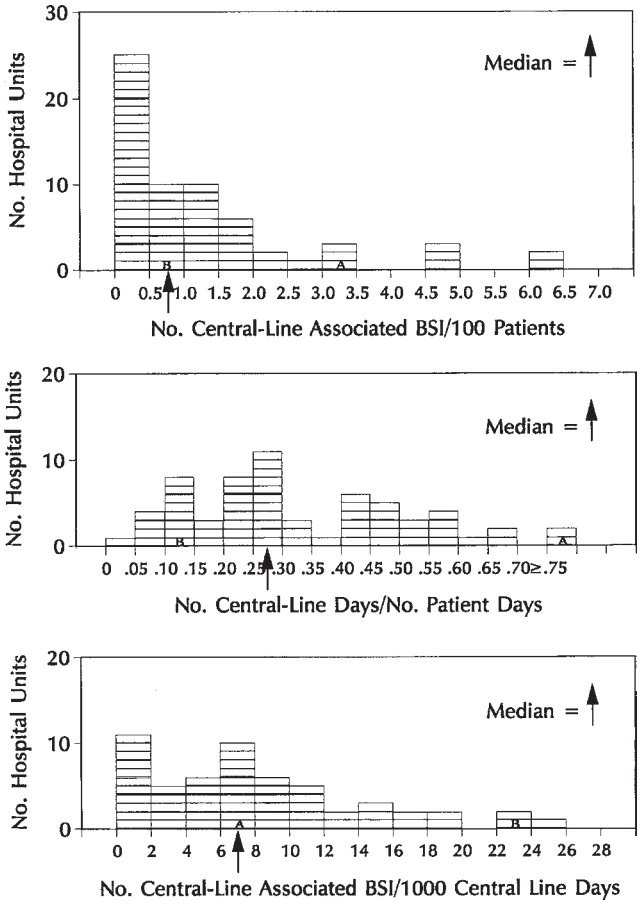

FIGURE 89-1 The effects of units of measure on CLABSI rates. (Adapted from Jarvis WR, Edwards JR, Culver DH, et al. Nosocomial infection rates in adult and pediatric intensive care units in the United States. National Nosocomial Infection Surveillance System. *Am J Med* 1991;91(suppl 3V):1855s–1915s.)

Figure 89-1 illustrates the effect of risk adjustment when comparing infection rates among various patient groups in hospital ICUs. The rate for hospital unit A, which uses the number of patients in the denominator, was nearly 5 times higher than the median for similar ICUs. However, hospital unit A had the greatest central-line use, that is, more than 80% of patient days were also central-line days. Using central-line days as the denominator of the rate helps to take into account this high use of central lines; thus, hospital unit A's device-associated device-day bloodstream infection rate was slightly lower than the median. Although using hospital unit A's device-associated, device-day bloodstream infection rate kept it from being designated a high outlier, unit A's high frequency of central-line use may need to be reviewed for appropriateness. On the other hand, hospital unit B's central line–associated bloodstream infection patient rate was near the median and its central-line use was low. When hospital unit B's rate was calculated using central-line days in the denominator, it was quite high, suggesting the potential need to review central-line insertion and maintenance practices.

Comparing Risk-Adjusted HAI Data

Facilities use surveillance data to assess their infection control program by comparing infection rates among similar patient populations within the facility (e.g., two separate medical ICUs), their rates with external benchmark rates, or changes in rates over time in their own facility. However, such comparisons can only be made if the rates control for variations in the distribution of the major risk factors associated with the infections. This process of developing comparable rates requires that the rates are site-specific, that uniform definitions and surveillance protocols are used to collect the data, that there is consistent and accurate case finding, and that the risks are similar or controlled for by risk-adjustment methods (such as stratification or standardization) *(120)*. The NHSN system, like the NNIS system before it, uses a population-based surveillance system that provides risk-adjusted rates that can be used for interfacility comparisons *(41,*121).

Testing for significance among infection rates is the subject of Chapter 3. However, the interpretation of those statistical tests should be carefully considered. Many facilities assume that any difference in the rates represents success or failure in the patient-care staff or institutional practices to prevent HAI. Although this may be true, there are other factors that could account for the differences in the rates.

First, surveillance definitions or techniques may not be uniform among the facilities, or they may be used inconsistently over time, causing variations to occur in sensitivity and specificity of infection case finding. Second, inaccurate or insufficient information about clinical and laboratory evidence of infections in the patient's medical record may compromise the validity and utility of the infection rate.

Third, the rates may not be adjusted for patients' intrinsic risks for infection. These risks are usually outside of the control of the facility and vary from facility to facility but are important factors in determining whether patients will develop infections. For example, a facility with a large proportion of immunocompromised patients would be expected to have a population at higher intrinsic risk for infection than a facility without such a population of patients. The unsuccessful attempts to compare unadjusted mortality rates *(109,110)* are reminders to those comparing infection rates that they must be certain to risk-adjust HAI rates. Finally, the size of the population at risk (e.g., number of patients, admissions and discharges, patient days, or operations) may not be large enough to calculate rates that adequately estimate the true rates for the facility. Although it may not be possible to fully correct for these factors, facilities should be aware of how they may affect the infection rate and take them into consideration when interpreting the data.

DATA DISSEMINATION

Surveillance is not complete until the data are disseminated to those who will use it to prevent and control infections. Because of its sensitive nature, information containing identifiers of patients or patient-care staff should be handled carefully. Data should not be used for punitive purposes but rather to augment quality improvement efforts.

It is customary for the IP to regularly provide a narrative summary and tabular and graphic reports of surveillance data to the facility's infection prevention or other oversight committee. The IP should include only those infection rates for which there are sufficient denominator data to

calculate meaningful estimates of risk. Therefore, monthly rate tabulation will not be practical in many small facilities or in larger institutions when small numbers of patients are at risk (e.g., for certain types of operative procedures that are performed infrequently). Infection rates for these instances may have to be calculated quarterly, semiannually, or annually, depending on the size of the denominator, or SIRs can be calculated. In addition, a thorough analysis of numerator data (i.e., the HAI) should be performed to gain insight into their epidemiology, including information on pathogens and risk factors.

Many state health departments are members of HAI prevention collaboratives with healthcare facilities within their borders. Complete data analysis and determination of the effectiveness of prevention efforts in these consortia require such data be shared with health department partners. Often, state health departments are responsible for posting HAI data on public websites, enabling consumer consideration and use in healthcare purchasing decisions.

APPLICATION OF THESE METHODS BEYOND HEALTHCARE-ASSOCIATED INFECTIONS

Nearly all of the best practices of HAI surveillance just described can be applied to monitoring other care processes, such as surgical preparation activities, and noninfectious outcomes of healthcare delivery, such as mortality or patient satisfaction. The characteristics of a successful monitoring and reporting system include the system being nonpunitive, confidential, independent, timely, systems-oriented, responsive, and providing expert analysis (122). IPs experienced in HAI surveillance can share their considerable expertise with colleagues monitoring other adverse events and attempting to improve the quality of care throughout the healthcare facility. Because the systematic collection of reliable data is essential to all successful evaluation efforts, HAI surveillance advances quality improvement and patient safety efforts across the entire healthcare facility.

CHAPTER 90

Isolation of Patients with Communicable Diseases

Jason E. Bowling, Jose Cadena, and Jan Evans Patterson

Despite advances in the control of infectious diseases in the last century, there is more interest than ever in the use of isolation precautions to control known and emerging diseases such as multidrug-resistant bacteria, multidrug-resistant tuberculosis (MDR-TB), pandemic influenza, and *Clostridium difficile* infection. These precautions are particularly important in the institutional setting due to the proximity and potential common exposures of patients who have communicable diseases with other patients. The terminology for isolation precautions has changed and developed over the years. Although the universal implementation of Standard Precautions simplified isolation policies to some degree, the terms used for isolation precautions varied among institutions, and some confusion ensued *(1,2)*. In addition, some of the situations outlined above may call for additional measures that are not in "Universal Precautions," as originally defined. The revision of the guidelines for isolation published in 1996 by the Centers for Disease Control and Prevention (CDC) approached isolation as transmission-based and clarified some confusing issues (3). Based on the positive results, this approach was reaffirmed in the most recent revision of the guidelines (4). Still, the infection preventionist (IP) is frequently called regarding the appropriate use of isolation precautions.

HISTORICAL PERSPECTIVE

The concept of isolating persons with communicable diseases was in practice even in ancient times according to biblical accounts of leper colonies, although the leprosy of biblical times may have been other skin diseases *(5)*. In modern times, hospital construction before 1850 featured crowded open wards *(6)*. As a consequence, cross-infection was common, and mortality rates were high in urban hospitals *(7)*. Florence Nightingale's observations from the Crimean War *(8)* led her to advocate small pavilion-type wards joined by open-air corridors. Nightingale emphasized the importance of asepsis and a clean environment. Her teachings were called "fever nursing" and varied from popular concepts of disease at the time, because fever nursing implicated transmission by contact with body substances rather than the environment *(9)*.

The germ theory of infection was accepted in US hospitals in the late 1800s, after the influence of Lister and Pasteur, and conditions began to improve as overcrowding decreased and antisepsis increased *(7)*. Communicable disease hospitals were using individual and group isolation as early as 1889 *(10)*. By the turn of the century, general hospitals were beginning to isolate patients with communicable diseases in an individual room with the use of separate utensils and disinfectants *(9,11)*. Grancher in Paris promoted the theory of communicability by contact rather than airborne spread for most diseases and allowed patients with communicable diseases to be housed in general wards but with separation by wire screens *(9)*. These screens separated the patient from other patients and served as a reminder for staff members to gown and wash their hands. Thus, began the trend in the United States from the isolation hospital to care of communicable diseases in a general hospital setting.

In the early 20th century, Charles V. Chapin of Providence City Hospital used individual isolation cubicles for patients with communicable diseases and documented that fumigation had no effect on secondary cases *(12)*. His work was very important in emphasizing the roles of persons rather than things as spreaders of disease and helped to end the miasmatic theory of transmission *(13)*. Richardson, the physician superintendent of Providence City Hospital, used the barrier method and the cubicle method for isolation of patients, allowing some patients with communicable diseases to be housed in the same room as other patients *(9)*. A card outlining the barrier technique needed was placed on the patient's bed.

The emergence of *Staphylococcus aureus* as a hospital pathogen in the 1950s and 1960s prompted the development of infection-control programs in US hospitals. In 1968, the first edition of the American Hospital Association's manual *(13)* presented a simple barrier precautions scheme for patients with communicable diseases, listing the need for gloves, gowns, masks, and visitor screening.

EARLY RECOMMENDATIONS FROM CENTERS FOR DISEASE CONTROL AND PREVENTION

While conducting healthcare-associated outbreak investigations in the 1960s, the CDC recognized that standardized

policies for isolating hospitalized patients with communicable diseases were lacking *(14)*. A group of experts convened in 1967 to develop the first CDC isolation recommendations, and first published five categories of isolation in 1970 *(15)*. Even in this initial manual, the philosophy behind the more recently developed Universal Precautions was expressed. By 1976, a survey showed that 93% of hospitals in the United States were using the category-specific approach to isolation *(16)*.

Substantial changes were made in the 1983 CDC recommendations (17). The updated category-specific guidelines for isolation published in 1983 (17) included seven categories of isolation: strict isolation, respiratory isolation, enteric precautions, contact isolation, tuberculosis (acid-fast bacillus [AFB]) isolation, drainage/secretion precautions, and blood and body fluid precautions. These isolation categories grouped diseases that require the same isolation precautions. After the more recent transmission-based guidelines from CDC, these categories are now of historical interest, but the terms are still commonly used and confused by some healthcare workers. IPs may be called on to clarify and compare these previous categories with the newer guidelines.

In addition, this 1983 guideline introduced disease-specific isolation as an alternative to category-specific isolation. Disease-specific isolation was offered as an alternative for hospitals wanting a more economic system that directed precautions at preventing transmission of a specific disease while avoiding unnecessary isolation precautions for some diseases. The guidelines stated that hospitals could choose the category-specific or the disease-specific system or design their own systems.

CATEGORY-SPECIFIC ISOLATION

Strict Isolation

Strict isolation was used to prevent transmission of diseases spread by both air and contact. Specifications for strict isolation include a private room with the door closed; masks, gowns, and gloves were indicated for all persons entering the room. This category has now been replaced with the use of Standard Precautions (for all patients) or Contact Precautions combined with Airborne Precautions in the new guidelines.

Contact Isolation

Contact isolation was a category designed to prevent the transmission of epidemiologically important microorganisms causing infection or colonization or highly transmissible microorganisms that do not warrant strict isolation. Conditions in this category are spread by direct or close contact. This category has been replaced by Contact Precautions in the new transmission-based guidelines.

Respiratory Isolation

Respiratory isolation was used to prevent droplet nuclei transmission, that is, transmission of diseases over long distances through the air. In the newer guidelines, this category has been replaced by Airborne Precautions.

Tuberculosis Isolation (Acid-Fast Bacillus Isolation)

Tuberculosis isolation was referred to as AFB isolation on the standard instruction card to protect patient confidentiality (17). Airborne Precautions have replaced this category in the new guideline. However, there are still many issues pertinent to tuberculosis that warrant special consideration regarding isolation, and these are discussed below (see Duration of Isolation in the "Tuberculosis Precautions: Special Considerations" section).

Enteric Precautions

Enteric precautions were used to prevent infections transmitted by feces. Examples would be hepatitis A or bacterial diarrhea. Enteric precautions are now included in Standard Precautions or, in the case of diapered or incontinent patients, Contact Precautions.

Drainage/Secretion Precautions

Drainage/secretion precautions were used to prevent the transmission of infection by direct or indirect contact with drainage from an infected body site or from purulent material. This isolation category was newly created for the 1983 guidelines and used for many infections isolated under wound and skin precautions or discharge and secretion precautions in the previous guideline. Minor skin, wound, or burn infections that can be adequately covered by a dressing previously included in this category are now covered by Standard Precautions. Major infections not covered or not adequately covered by a dressing are now covered under Standard Precautions or Contact Precautions, depending on the clinical setting.

Blood and Body Fluid Precautions

Blood and body fluid precautions were designed to prevent the transmission of blood-borne pathogens. This category is now only for historical reference because Universal Precautions superseded it. Precautions used for blood and body fluids are now recommended in Standard Precautions, which should be used for the care of all patients.

Comments

The advantage of category-specific isolation was that the grouping of diseases with similar routes of transmission was relatively easy to teach to personnel. It consisted of seven categories (six, if blood and body fluid precautions was excluded) that could be adopted, and the diseases grouped accordingly. A disadvantage of the system was that it was diagnosis- or disease recognition–driven and depended on the caregiver to identify the presence or suspected presence of a disease. In addition, drainage/secretion precautions could be confused with contact isolation and vice versa. Universal Precautions recommended barriers to prevent contact with blood and certain body fluids; body substance isolation (BSI) recommends barrier protection for contact with all body fluids or open skin lesions. Because Standard Precautions recommend both, many categories in category-specific isolation are superfluous. Strict isolation, respiratory isolation, and AFB isolation are exceptions but are categorized differently in the new guidelines.

DISEASE-SPECIFIC ISOLATION

Disease-specific isolation was one of two isolation systems recommended by the CDC in 1983 (17). In this system, communicable diseases were considered individually with regard to mode of transmission and infective material, and accordingly, precautions are specified for each disease. The purported advantage of this system is that because precautions are specific for each disease, there are no unnecessary barriers used, and this lowers the cost of isolation. It may also enhance compliance by physicians, who more readily understand the need for specific precautions for each disease. The disadvantage of this system is that because diseases are not grouped by category, it is more difficult to train staff that are not familiar with specific diseases. Another disadvantage is that, like category-specific isolation, this system is diagnosis-driven, and isolation precautions are often important early in the patient's hospital stay, before a diagnosis is made or even suspected.

IMPACT OF THE ACQUIRED IMMUNODEFICIENCY SYNDROME EPIDEMIC

The recognition of the acquired immunodeficiency syndrome (AIDS) epidemic in the mid-1980s affected isolation policies in healthcare institutions unlike any other event in modern medicine. Before 1987, most hospitals placed patients in isolation, based on diagnosis or suspected diagnosis, according to the category-specific or disease-specific precautions as outlined by the aforementioned CDC guideline (17). As it became apparent that transmission of human immunodeficiency virus (HIV) could occur from patient to healthcare worker, new guidelines were established to minimize exposure to blood-borne pathogens from all patients, not just patients with a diagnosis or suspected diagnosis of HIV infection (18). In contrast to the 1983 CDC guideline, the 1987 CDC document (18) recommended blood and body fluid precautions for all patients, regardless of known HIV status. The belief that such precautions were unnecessary in patients not known to have blood-borne pathogens was gone. Specifically, barrier precautions were recommended to prevent contact with blood, certain body fluids, and body fluids containing blood. The application of blood and body fluid precautions to all patients was referred to as "universal blood and body fluid precautions" or "Universal Precautions." In 1988, the CDC published an updated Universal Precautions for the prevention of transmission of HIV, hepatitis B virus (HBV), and other blood-borne pathogens to supplement the 1987 publication *(19)*. This document made it clear that transmission of other blood-borne pathogens, such as HBV, should be prevented as well as that of HIV. In a new precedent for the healthcare industry, the Occupational Safety and Health Administration (OSHA) became involved in regulating and enforcing these guidelines *(20)*. Now healthcare institutions were mandated to apply and enforce what was, in effect, blood and body fluid precautions as a minimum standard for protection of the healthcare worker.

Infection control programs recognized the potential benefit of this universal concept as a means of preventing cross-transmitted pathogens (blood-borne and non–blood-borne) among patients and healthcare workers. It became clear very quickly that an additional isolation system was needed to reduce the risk of transmitting non–blood-borne pathogens, because the CDC-defined Universal Precautions were primarily for preventing transmission of blood-borne pathogens. In the CDC 1988 update *(19)*, category-specific or disease-specific isolation precautions are recommended to fill this need, as described in the 1983 CDC guidelines. IPs at Harborview Medical Center in Seattle, Washington, recognized the problem early. They implemented a BSI system at Harborview in 1984 to control cross-transmission of non–blood-borne pathogens. This system designated all body fluids and tissue as potentially infectious *(21)*. In 1987 and 1990, Lynch et al. *(22,23)* described their system and its advantages in preventing the transmission of both blood-borne and non–blood-borne pathogens. This system provided an alternative to the category-specific or disease-specific systems. Some confusion ensued because the term Universal Precautions was sometimes used to apply to barrier precautions for all body fluids, not just blood and certain body fluids as originally defined *(1,2)*. Although the 1996 CDC guideline for isolation precautions in hospitals includes concepts of both Universal Precautions and BSI, these isolation systems are described briefly below because of their impact on current practices. Universal Precautions (now part of Standard Precautions) are also described in Chapters 73 and 74.

UNIVERSAL PRECAUTIONS

In 1985 and 1986, the CDC published recommendations to prevent the transmission of HIV in the workplace *(24,25)*. In 1987, a more comprehensive document (18) was published in response to increasing concern from healthcare workers about occupational exposure to HIV. These guidelines recommended the application of blood and body fluid precautions to all patients and designated this policy "Universal Precautions" or "universal blood and body fluid precautions."

Universal Precautions as presented by the CDC in 1987 (18) include the following concepts:

1. Healthcare workers should use appropriate barrier precautions to avoid skin and mucous membrane exposure when contact with blood or body fluids from any patient is anticipated. Gloves are to be worn for contact with blood and body fluids, mucous membranes, or nonintact skin; when handling surfaces or items soiled with blood or body fluids; or for venipuncture or other procedures involving vascular access. Gloves should be changed after each patient contact. Masks and protective eyewear or face shields should be worn when procedures are likely to generate aerosols or droplets of blood or other body fluids. Gowns should be worn for procedures that are likely to soil clothing.
2. Hands or skin contaminated with blood or body fluids should be washed immediately. Hands should be washed after removing gloves.

3. Precautions should be taken to prevent sharps or needlestick injuries. Needles should not be recapped, removed from disposable syringes, or manipulated by hand. After use, needles, disposable syringes, scalpels, and other disposable sharp instruments should immediately be placed in a designated puncture-resistant container.
4. Mouthpieces and resuscitation devices should be readily available for use in areas where resuscitation procedures may be anticipated.
5. Healthcare workers with exudative skin lesions should not be involved in direct patient care or handle patient-care equipment until the condition has resolved.

Precautions for Invasive Procedures

These were also outlined in the 1987 document and included routine surgical and obstetric procedures and outpatient physician and dentist office procedures. An invasive procedure was defined as surgical entry into tissues, cavities, or organs or repair of major traumatic injuries in an operating or delivery room, emergency department, or outpatient setting, including both physician and dentist offices; cardiac catheterization and angiographic procedures; vaginal or cesarean delivery or other invasive obstetric procedure during which bleeding may occur; or the manipulation, cutting, or removal of any oral or perioral tissues, including tooth structure, during which bleeding occurs or the potential for bleeding exists. Healthcare workers participating in such procedures should routinely use barrier precautions as needed to prevent skin and mucous membrane exposure to blood and body fluids from all patients. This includes not only gloves and surgical masks for invasive procedures but also protective eyewear or face shields for procedures that are anticipated to generate droplets or splashing of blood or body fluids. Effective barrier gowns should be worn when splashing is anticipated. Healthcare workers in obstetrics should use appropriate barrier precautions during deliveries. If a glove is torn or a sharps injury occurs, the glove should be replaced with a new glove. The needle or sharp instrument involved should also be removed from the sterile field.

Precautions for Dentistry

Blood, saliva, and gingival fluid from all dental patients should be considered potentially infective in both institutional and noninstitutional settings. Dental workers should wear gloves for contact with oral mucous membranes and, in addition, surgical masks and protective eyewear or face shields for procedures in which splashing of blood or body fluids is likely. Hand pieces should be sterilized after each patient use. Hand pieces that cannot be sterilized should at least be flushed, cleaned with a chemical germicide, and rinsed after each patient use. Contaminated dental materials (impressions, bite registration) should be cleaned and disinfected before being handled in the dental laboratory and before being placed in another patient's mouth. Infection control precautions for dentistry are more specifically outlined and updated in later recommendations *(26)* (see also Chapter 54).

Precautions for Autopsies or Mortician Services

Persons participating in postmortem procedures should wear appropriate barrier protective equipment. Equipment and surfaces contaminated during such procedures should be cleaned with an appropriate chemical germicide (see Chapter 80).

Precautions for Dialysis

Blood and body fluid precautions are to be used when dialyzing all hemodialysis patients, not just those identified as hepatitis B surface antigen positive or HIV positive. HIV-infected patients do not need to be isolated from other patients during hemodialysis. The dialyzer may be discarded after use. Institutions that reuse dialyzers may designate a specific single-use dialyzer to a specific patient for reuse after appropriate cleaning and disinfection on the same patient only. HIV-infected patients may be included in the reuse programs; individual dialyzers must never be used on more than one patient (see also Chapter 63).

Precautions for Laboratories

Blood and other body-fluid specimens from all patients are considered infective. Specimens should be placed in a well-constructed container with a secure lid to avoid leakage. Contamination of the outside of the container or the laboratory form should be avoided. Personnel who process specimens should wear gloves. Other barrier protection should be used as needed if splashing or aerosolization is anticipated. Biologic safety cabinets should be used for procedures that are likely to generate droplets or aerosols. After specimen processing, gloves should be changed and hands washed. Mechanical devices should be used for pipetting; mouth pipetting should never be done. Laboratory work surfaces and laboratory equipment should be decontaminated with an appropriate chemical germicide after blood or body fluid spills and when work is completed. Before leaving the laboratory, personnel should remove protective clothing and wash their hands (see also Chapter 77).

ENVIRONMENTAL CONSIDERATIONS FOR HUMAN IMMUNODEFICIENCY VIRUS TRANSMISSION

Disinfection and Sterilization

Environmental transmission of HIV in the clinical setting has not been documented; however, environmental considerations are reviewed, and the same precautions are recommended for all patients. Standard disinfection and sterilization procedures for equipment are recommended for inpatient and outpatient settings, as previously described in the CDC guidelines for environmental control *(27)*. Semicritical items, or items that contact mucous membranes such as endoscopes and bronchoscopes, should be sterilized or undergo high-level disinfection after each patient use. Chemical germicides registered with the U.S. Environmental Protection Agency (EPA) as sterilants may be used for high-level disinfection or sterilization depending on contact time (see Chapter 80). Under such guidelines, instruments used on HIV-positive patients do not require separate processing because high-level disinfection or sterilization should take place after use on any patient.

Housekeeping

Cleaning of environmental surfaces should be done after contamination by any patient; special cleaning is not required for patients with blood-borne pathogen infections. Horizontal surfaces should be cleaned when spills or soilage occurs and when patients are discharged. EPA-registered disinfectant–detergents should be used. Spills of blood or body fluids should be cleaned up immediately. Personnel should wear gloves. Broken glass and any other sharp objects should first be removed using tongs or forceps and placed in a sharps container. Then, visible fluid should be wiped up, the absorbent materials discarded as infectious waste, and the area decontaminated with a chemical germicide that is tuberculocidal and EPA-approved as a hospital disinfectant. For large spills, the contaminated area should be treated first with the chemical germicide and then cleaned and fresh germicide used for decontamination.

Laundry

Soiled linen should be handled in the same way for all patients with a minimum of agitation; linen should be bagged at the location where it was used. Linen with blood or body-fluid soilage should be transported in leak-proof bags. Linen should be laundered with detergent in hot water (71°C, 160°F) for 25 minutes. If a lower temperature is used, suitable chemicals for low-temperature washing must be used.

Infective Waste

Special precautions are recommended for handling certain hospital wastes that may be infective such as microbiology laboratory waste, pathology waste, and blood specimens or blood products. There has been disagreement on whether to classify communicable disease isolation waste as infectious waste. The CDC does not consider such waste as infectious, but before the Medical Waste Tracking Act of 1988, the EPA classified such waste as infectious waste. In the Medical Waste Tracking Act, however, the EPA modified its position and included only certain highly communicable disease waste from patients with infections due to biosafety level 4 etiologic agents (e.g., viral hemorrhagic fevers, such as Marburg, Lassa, and Ebola) as regulated medical waste *(28)*. Bulk blood, body fluids, or excretions may be disposed of through the sanitary sewer system.

Implementation

These recommendations also stated that employers should ensure that workers receive initial orientation and continuing education and training on the transmission and prevention of blood-borne infections and routine application of Universal Precautions in the care of all patients. Personal protective equipment should be provided by the employer, and monitoring of compliance to the recommended protective measures should be followed.

Other Isolation Categories

With regard to other isolation categories as outlined in the 1983 guideline, the implementation of Universal Precautions superseded the need for a separate category of blood and body fluid precautions. Other isolation precautions, however, were recommended as needed for conditions such as infectious diarrhea (enteric precautions) or tuberculosis (AFB precautions).

UPDATE: UNIVERSAL PRECAUTIONS, 1988

After the recommendations for Universal Precautions were published in 1987, hospitals scurried to write their own institutional policies and implement training for their personnel in the prevention of blood-borne diseases in the workplace. In 1988, the CDC published an update to Universal Precautions that indicated these precautions were also for the prevention of other blood-borne pathogens such as HBV and specified that only specific body fluids implicated in the transmission of blood-borne pathogens needed to be included under Universal Precautions. Many hospitals already had policies in place and employees trained by this time, which contributed to confusion in the use of the term Universal Precautions. A variety of different systems carried this term in individual institutions *(29)*. The 1988 update also included further clarification on the use of protective barriers, the use of gloves for phlebotomy, the selection of gloves, and waste management.

Body Fluids to Which Universal Precautions Apply

In terms of occupational exposures, blood is the most important source of HBV, HIV, and other blood-borne pathogens. Infection prevention efforts aimed at preventing occupationally acquired blood-borne infections must emphasize prevention of exposures to blood and promotion of HBV immunization. Universal Precautions apply to semen, vaginal secretions, cerebrospinal fluid, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, amniotic fluid, and any body fluid containing visible blood.

Body Fluids to Which Universal Precautions Do Not Apply

According to the 1988 update, Universal Precautions do not apply to feces, nasal secretions, sputum, sweat, tears, urine, and vomitus unless they contain visible blood. The risk of blood-borne pathogen transmission from these fluids is very low or nonexistent. The 1983 CDC guidelines (category-specific or disease-specific isolation) are cited for the prevention of non–blood-borne pathogen transmission. Universal Precautions do not routinely apply to saliva; however, special precautions are reiterated for dentistry because contamination of saliva with blood is predictable with dental procedures.

Use of Protective Barriers

The types of barriers needed for different procedures and clinical situations vary, so the healthcare worker must use appropriate judgment. Barrier precautions do not prevent sharps injuries; thus, caution in handling needles and sharps instruments, as previously outlined, is also necessary. Protective barriers should be used when exposure to blood or the above-named body fluids is anticipated. Hands or other surfaces contaminated with blood or the specified body fluids should be washed immediately.

Glove Use for Phlebotomy

Although gloves may reduce the amount of blood contaminating hands during venipuncture, they do not prevent needlestick injuries. The likelihood of exposure during phlebotomy depends on the skill of the personnel, the cumulative risk of the worker, whether the procedure is in a routine or emergency setting, and the prevalence of blood-borne pathogens in the patient population. Even though blood from all patients is considered infectious, the prevalence of HIV or HBV in volunteer blood donor centers is known to be low. Some centers, therefore, have not routinely recommended gloves for phlebotomy in these settings. Gloves should always be available for workers who choose to use them, however. Gloves should always be used for phlebotomy when the healthcare worker has scratches, cuts, or other breaks in the skin; when hand contamination with blood is anticipated, such as when phlebotomy is done on an uncooperative patient; for finger or heel sticks on infants or children; and when personnel are receiving phlebotomy training.

Glove Selection

The Center for Devices and Radiological Health, Food and Drug Administration (FDA), is responsible for the regulation of the medical glove industry. Medical gloves include sterile surgical or nonsterile examination gloves made of vinyl or latex. The gloves selected should be task appropriate, and the following are general guidelines. Sterile gloves should be used for contact with sterile body areas. Nonsterile examination gloves may be used for contact with nonsterile body areas or other procedures that do not require aseptic technique. Gloves should be changed between patient contacts. Gloves should not be washed or disinfected between patients. Exposing the gloves to surfactants used for washing may cause increased penetration of liquids through unseen holes in the glove (wicking). Disinfectants may damage the gloves. General-purpose utility gloves (rubber household gloves) should be used for housekeeping activities and instrument cleaning in which contact with blood or specified body fluids is anticipated. These gloves can be reused after decontamination but should be discarded if torn or visibly damaged. Since the publication of this 1988 update, there have been many studies published evaluating glove integrity (see below, "Are Gloves an Effective Barrier?").

Waste Management

Guidelines on waste management remain unchanged from the 1987 recommendations, but state and local regulations in many areas now supersede these recommendations, and this has been acknowledged.

Comment

Universal Precautions have the advantage of protecting the healthcare worker against unidentified blood-borne pathogen risks. Also, this system is simpler than traditional systems, because the blood and body fluid isolation category applies to all patients. However, the 1988 update, which was intended to clarify which body fluids are infectious, only served to confuse the issue because it is often difficult, at the bedside, to discern whether a body fluid contains blood. Furthermore, it is sometimes difficult to know the origin of a body fluid at the bedside and even more so when the specimen is removed from the bedside. BSI addresses some of these issues. Even so, the issue of cost and compliance in using Universal Precautions may also present a problem (see below, "Impact of Universal Precautions and Body Substance Isolation" section).

BODY SUBSTANCE ISOLATION

Jackson and Lynch *(21)* responded early on to the concern that unrecognized or undiagnosed cases resulted in unsafe exposures for healthcare workers. As early as 1984, these authors pointed out that many infectious agents are transmitted from patients who have only mild symptoms or no symptoms, and they recommended barrier precautions for anticipated contact with blood or any body fluids from all patients and reemphasized the important role of hand washing. Recognizing the limitations of the diagnosis-driven, category-specific, and disease-specific isolation systems, they systematically outlined an alternative system called BSI *(22)*. This approach was similar to the CDC Universal Precautions in that it presumed that all patients were potentially infectious, but it differed in that barrier precautions are used to prevent contact with all body fluids and tissue, not just certain body fluids and blood-tinged body fluids, as recommended in the 1988 CDC update. The term body substance rather than body fluid is used to emphasize that barrier precautions should be used to prevent contact with solids, such as tissue and feces, and body fluids. BSI contains six major components *(22)*:

1. Gloves should be used for anticipated contact with blood, mucous membranes, nonintact skin, secretions, and moist body substances of all patients. The 1987 article stated that hand washing is not necessary unless hands are visibly soiled from breaks in gloves. Gloves should be changed between patients.
2. After other types of patient contact without gloves, hand washing, which is effective in removing transient flora from the hands, should be done (10 seconds of soap and friction followed by a rinse with running water).
3. Other barriers such as gowns, plastic aprons, masks, or goggles should be worn as needed when soiling of clothing and/or skin or mucous membranes is anticipated.
4. Soiled reusable items, linen, and trash should be contained such that no leakage occurs. Double bagging is not needed unless the outside of the bag is soiled.
5. Needles and sharps should be placed in rigid puncture-resistant containers. Needles should not be recapped.
6. Private rooms are indicated for patients with diseases transmissible by the airborne route and for patients who may soil the environment with body substances.

Operational Issues

A single universal reminder sign—"Body substance isolation is for all patient care"—is placed in every patient room or at every bedside. This sign defines body substances and uses graphics and words to indicate when gloves, gowns, masks, or eye protection should be used. A stop sign alert is used on the door of patients with airborne diseases. This sign indicates that persons should check with

the floor nurse before entering the room. The floor nurse will determine if the person is immune and need not wear a mask (e.g., measles, chickenpox) or instruct the person to wear a mask (e.g., tuberculosis). Nonsterile gloves must be accessible near the bedside, and other barriers must be available on the nursing unit. As with Universal Precautions, some judgment by healthcare workers is required in determining when exposures may be anticipated.

Comment

BSI is like Universal Precautions in that it protects workers and patients against the transmission of blood-borne pathogens. BSI is easier to teach to staff and to apply at the bedside than Universal Precautions, as clarified in 1988, because barrier precautions apply to all body fluids not just certain body fluids. BSI has the advantage of protecting against non–blood-borne pathogens as well. Use of gloves has been shown to control cross-transmission of multidrug-resistant enteric gram-negative rods *(30)*. Appropriate use of BSI has indeed been documented to reduce colonization and infection with sentinel microorganisms such as *Pseudomonas aeruginosa*, *Serratia marcescens*, and aminoglycoside-resistant gram-negative bacilli *(23)*. In addition, BSI also has the advantage of lessening the psychological trauma of isolation by emphasizing the isolation of body substances rather than the isolation of people *(31)*. That is, because barrier precautions are used for all patients, additional restrictive isolation practices are not needed for most diseases, except those communicable by the respiratory route.

The system, as it was published in 1987, suggested that hand washing was unnecessary when gloves were used for barrier precautions *(22)*. This prompted criticism of the system by those stating that the wearing of gloves for contact with blood or body fluids did not eliminate the need for hand washing *(14,32)*. Studies have documented that hands can be contaminated with microorganisms even though gloves are worn *(33,34)*. When the system was described in later publications, gloving was not emphasized as a substitute for hand washing. In fact, hand washing is recommended when hands are soiled and between patient contacts *(23)*. Many institutions that have adopted BSI require hand washing after glove removal *(29)*.

ARE GLOVES AN EFFECTIVE BARRIER?

At the time of the publication of the 1988 CDC update, there were no published data on the preference of latex versus vinyl gloves. Since that time, there have been numerous studies addressing the integrity of gloves in general and latex versus vinyl gloves in particular. The standards for testing the integrity of latex gloves were established by the American Society for Testing and Materials (ASTM) of the FDA, and compliance with them is voluntary. In 1977, the standard allowed no more than 15 defects per 1,000 (1.5%) sterile unused latex surgical gloves, as determined by the watertight method of testing *(35)*, and 25 defects per 1,000 (2.5%) latex examination gloves *(35)*. In 1989, the FDA method for testing gloves improved, and the standards changed to an allowable defect rate of 2.5% for surgeon's gloves and 4.0% for examination gloves *(36)*. Due to the continued concern of potential transmission of blood-borne pathogens HIV, HBV, and hepatitis C, the FDA issued a final rule effective December 19, 2008, which further reduced the allowable defect rate for examination gloves to 2.5%. The FDA, using calculated projections based on available CDC data on HIV, HBV, and HCV infections, estimated that this modification in acceptable quality levels could potentially avoid seven cases of HIV infection and seven cases of chronic HBV infection transmitted to healthcare workers over a 10-year period *(37)*.

There are no standards for vinyl gloves. Concern regarding occupational exposure to HIV raised the issue of glove integrity in the clinical setting. In addition, some cases of herpetic whitlow in intensive care unit (ICU) nurses who used gloves focused more attention on this issue *(38)*. Scanning of gloves by electron microscopy has documented inapparent pits from 30 to 50 μm in size, suggesting the possibility that viruses could penetrate this barrier *(39)*.

In addition, several studies have documented leakage rates higher than the ASTM standard of 1.5% to 2.5%. DeGroot-Kosolcharoen and Jones *(40)* showed that although several brands of sterile latex surgical gloves were impermeable to water and blood, some brands showed leakage rates of up to 8%. Nonsterile latex and vinyl gloves showed leakage rates of 0% to 52%. Nonsterile packaging or packaging in suction kits increased leakage rates. Korniewicz et al. *(41)* studied gloves stressed by conditions mimicking those encountered in patient care and found that 63% of vinyl gloves leaked a stock solution of bacteriophage compared with 7% of latex gloves. Korniewicz et al. *(42)* also documented the penetration of 20% of latex gloves and 34% of vinyl gloves by *S marcescens*. These studies indicate that gloves reduce the risk of gross soilage from blood or body fluids but that they are not 100% effective.

Latex hypersensitivity due to repeated exposure and sensitization of the healthcare worker to latex antigens has led to the adoption of nonlatex gloves made out of various synthetic materials such as neoprene, polyurethane, and nitrile. Korniewicz et al. (43) examined both latex and nonlatex surgical gloves for defects after use by surgeons during surgical procedures and found overall glove defect rates of 5.6% and 7.5% for latex and nonlatex surgical gloves, respectively. Based on the data obtained during this review of surgical gloves, the authors recommended that surgeons change gloves within 2 to 3 hours to avoid exceeding defect rates >5%.

Doebbeling et al. *(33)* showed that washing gloved hands was not effective for decontamination, and in fact, 5% to 50% of hands were contaminated after gloves were removed. Washing gloves has also been shown to decrease their integrity *(44)*. Thus, gloves should not be washed and reused between patients. These studies affirm that although gloves can be used as a barrier to reduce gross contamination from blood and body fluids, antisepsis after glove removal remains very important because occult breaks in gloves can and do occur.

The surgical literature has long been concerned with perforations in gloves during surgical procedures. In 1899, Bovie *(45)* stated that careful hand washing was needed, because gloves could be punctured accidentally during an operation.

More recent studies have quantitated the number and location of inapparent perforations that may occur in gloves during surgical or dental procedures. Albin et al. *(46)* showed a 33% leak rate of latex gloves randomly studied after surgical procedures. These authors also documented a leak rate of up to 5.5% in unused gloves. Gloves studied sequentially showed a leak rate of 58.5% at the end of surgical procedures and 32% at the end of dental procedures. Double gloving decreased the leak rate to 25%. In the sequential surgical study, 52% of the leaks occurred in the first 75 minutes; in the sequential dental study, 75% of the leaks occurred in the first 30 minutes. Gloves used in cardiovascular, orthopedic, abdominal, and oral surgical procedures had leak rates of more than 50%. The frequency of occult glove perforation has been noted to be as high as 10% after interventional radiologic procedures *(47)*. In the Albin et al. study evaluating surgical and dental procedures, leak rates for gloves were evaluated for various members of the surgical team and were found to be highest for the surgeon (52%), followed by the first assistant (29%), and then the scrub nurse (25%) *(39)*. Most perforations (60%) occurred in the thumb or index finger of the glove. Other studies have also documented that the largest number of perforations occur in the thumb, index finger, and middle finger *(48,49)*.

IMPACT OF UNIVERSAL PRECAUTIONS AND BODY SUBSTANCE ISOLATION

Universal Precautions are now a minimum standard in US hospitals as a result of OSHA regulations. Many hospitals also have BSI or some modification of BSI in place because of increasing emphasis on the potential infectiousness of body fluids from all patients and the increasing rate of multidrug-resistant pathogens. To review the advantages of these systems over category-specific or disease-specific isolation, the latter systems may be inconsistently or incorrectly applied, whereas precautions that are used for all patients not only are easier to implement but also protect cross-transmission from patients who may lack signs or symptoms of a disease. Furthermore, there is less psychological trauma for individual patients identified as having a microorganism transmissible by blood or body fluids because all patients are treated in a standard manner. Because of healthcare worker concern about HIV in particular, this system at least theoretically eliminates the need for routine screening of all patients and personnel for HIV at periodic intervals—a process that would prove extremely costly *(50)*.

Some disadvantages of the Universal Precautions concept have been proposed. Because gloves were used more extensively for barrier precautions in BSI and in Universal Precautions, some healthcare workers have sometimes neglected to change gloves between patients *(30,32)*, and such practices have been associated with cross-transmission of microorganisms *(51,52)*. Education and reinforcement of appropriate use of gloves and changing gloves between patients can be successful in reducing such practices *(23,51)*.

The CDC has stated that each institution may design its own system of isolation (17). Indeed, as hospitals have tailored Universal Precautions or BSI to their own institutional needs, each system has incorporated elements of the other and the terms have been used interchangeably, even though there are real and philosophical differences between the two systems *(2)*. Consequently, confusion has ensued regarding the term Universal Precautions in particular *(1)*. The primary purpose of Universal Precautions is to reduce healthcare worker exposure to blood-borne pathogens, whereas the primary intent of BSI is to reduce cross-transmission of microorganisms between patients by transient carriage on the hands of personnel. An additional benefit is the protection of the healthcare worker from the patient's microorganisms *(2)*.

The effectiveness of Universal Precautions has been evaluated using the frequency of personnel nonparenteral exposures to blood and body fluids (including sputum, urine, feces) as a monitor. Fahey et al. *(53)* and Wong et al. *(54)* documented a significant decrease in nonparenteral exposures to blood and body substances after the implementation of Universal Precautions. Saghafi et al. *(55)* also documented a reduction in exposure of unprotected skin to blood, but the rate of needlestick exposures remained unchanged. So it appears that although Universal Precautions or BSI may significantly reduce nonparenteral exposures to blood or body fluids, other measures such as engineering controls are needed to reduce parenteral exposures such as needlesticks.

As Universal Precautions or BSI systems were implemented throughout the country, glove use increased substantially and cost became a concern. Doebbeling and Wenzel (56) evaluated the costs of using Universal Precautions, and McPherson et al. *(57)* evaluated the cost of BSI. Universal Precautions increased the total annual costs for isolation materials at a large university teaching hospital by $350,900—an increase, adjusted for inflation, from $13.70 to $22.89 (67%) per admission. Although BSI theoretically could be more costly, it caused an unadjusted increase in cost of 147% for isolation materials compared with an unadjusted increase in cost of 167% for Universal Precautions (56,57). There was an approximately 80% increase in the use of gloves for BSI compared with a 64% increase in glove use for Universal Precautions. Doebbeling and Wenzel (56). estimated that Universal Precautions cost approximately $269 million annually nationwide (using the dollar value from 1989) in hospitals alone and approximately $67 million in the outpatient setting, accounting for $336 million total per year nationwide.

Although these systems are expensive, the alternatives must be considered. The alternative of testing all patients admitted to US hospitals each year is estimated to be $2.6 billion or approximately eight times the cost of Universal Precautions *(58)*. Thus, Universal Precautions are less expensive than universal testing. In addition, a decrease in healthcare-associated infection rates has been documented after the implementation of Universal Precautions and BSI (2,56), providing further evidence for the cost–benefit of these systems in the United States.

Updated CDC Guidelines (1996–2007) and Recent Developments

The CDC's isolation guidelines were revised by the CDC's Healthcare Infection Control Practices Advisory Committee and were published in draft guideline format for public comment in 1994 *(59)* and in final form in 1996 (3).

The guideline contained three important changes from previous recommendations. First, "Standard Precautions" combine the major features of Universal Precautions and BSI. These precautions apply to all patients regardless of diagnosis or known infection status. This first tier of precautions is used to decrease the risk of transmission from recognized or unrecognized infection. Second, the previous categories of isolation (strict isolation, contact isolation, respiratory isolation, enteric precautions, drainage/secretion precautions) and the previous disease-specific precautions are superseded by the three types of transmission-based precautions. These precautions are based on routes of transmission for patients known or suspected to be infected or colonized with highly transmissible or epidemiologically significant pathogens. Third, the new guideline lists specific syndromes in adult and pediatric patients that are suspicious for infection and indicate which precautions to use on an empiric basis pending diagnosis. As with previous guidelines, the CDC recognized that no guideline adequately addresses each hospital's needs. Individual hospitals and healthcare systems are encouraged to review the recommendations and modify them according to their own needs and resources.

The 2007 guidelines expand the guidance from the 1996 guidelines to include settings outside acute care, such as long-term care and home-based care. In addition, the term healthcare-associated infections has taken the place of "nosocomial infections." After the 2003 severe acute respiratory syndrome (SARS) and concern for pandemic influenza, respiratory etiquette has been added to the guidelines. There is an update on protective precautions for severely immunocompromised patients and additional recommendations regarding the personal protective equipment necessary to perform certain procedures and environmental and administrative controls required for a safer healthcare environment (4). The 2007 guidelines reiterate Standard Precautions and transmission-based precautions as keystones of infection prevention in healthcare settings (4). Table 90-1 outlines the categorization of diseases by transmission-based precautions in accordance with these guidelines.

Transmission requires a source of infection, a susceptible host, and a mode of transmission. Transmission-based precautions intend to interrupt this cycle by interfering with the mode of transmission. Sources of infection may include patients, healthcare personnel, and visitors, as well as the environment (*60,61*,62).

The risk of acquiring healthcare-associated infections varies based on the setting where the patients are located. It is particularly high in the ICUs. In other settings, such as long-term care facilities (LTCFs), patients stay for prolonged periods of time. Patients at LTCFs are encouraged to participate in activities involving other residents, and this may result in increasing the risk of microorganism transmission. The isolation precautions used in acute care may not be practical in an LTCF, and prevention of transmission may be challenging.

What Elements May Help to Prevent Transmission in Healthcare Settings?

To improve the chance of success of any isolation-based precautions, some elements are necessary. These include the presence of healthcare system components that have an influence on the effectiveness of the transmission-based precautions, including adequate infection prevention staffing. A ratio of 1 IP per 250 patients was suggested during the study on the efficacy of nosocomial infection control project *(63)* and a ratio of 0.8 to 1 IPs per 100 patients on a more recent survey (64). Because of the increased complexity of patients and programs and the shift to ambulatory services, CDC does not recommend a specific ratio but recommends that there be adequate personnel for the complexity of the program. Designated unit nurses may function as infection prevention liaisons who serve as a contact between bedside nurses and IPs, the clinical microbiology laboratory, environmental services, etc. (4,*65,66*).

General Principles

Hand Hygiene Hand hygiene is the single most important method for preventing healthcare-associated transmission of infection. Despite its importance, compliance with hand hygiene is around 50% to 60% in non-ICU settings and may be even lower in ICUs (around 30%–40%) (67,*68–70*).

Such information must encourage, rather than discourage, IPs to continue to reinforce this basic control measure. Easy access to handwashing sinks or antiseptics may increase compliance and should be available, especially in high-risk areas *(71)*. Hands should be washed even when gloves are used, because small tears in the glove may be present and contamination can occur when the glove is removed (3). In addition, failing to change gloves between patients has been implicated in cross-transmission of hospital pathogens *(51)*. Several studies have shown reduced rates of healthcare-associated infections, including those due to resistant pathogens, with improved hand hygiene *(72)*. However, noncompliance with this simple measure has been documented repeatedly *(73,74)*. Risk factors for noncompliance with hand hygiene include being a physician, a nurse aide, male gender, working during the week, using gowns and gloves, automated sink, and performing activities with a high risk of cross-transmission and a high demand for hand washing (i.e., high workload) (75). High workload is a serious problem, particularly in an ICU, where there may be as many as 40 opportunities for hand hygiene in a 1-hour period *(76,77)*.

Hand washing at the sink is effective but is time-consuming compared to antiseptic hand rub, and frequent hand washing can also result in skin reactions *(78)*. These factors have led to the studies that have documented the efficacy of antiseptic hand rubs as a method for hand hygiene. Pittet et al. *(78)* documented an improvement in hand hygiene compliance from 48% to 66% with use of a hand rub and documented a consistent decrease in healthcare-associated infection rates hospital-wide, including decreased rates of methicillin-resistant *S. aureus* (MRSA) *(78)*. For these reasons, the antiseptic hand rub has been accepted, particularly in high-risk units such as the ICU. Exceptions to use include patients where spore-producing microorganisms are suspected (*C. difficile* infection), after going to the toilet, and when hands are visibly soiled (75) (see also Chapter 91).

Patient Placement and Transport A private room is recommended for patients with some infections that are highly transmissible or when patient hygiene is poor. There is evidence that patients colonized by infectious

TABLE 90-1

Types of Isolation Precautions

Standard Precautions

Use for the care of all patients

Airborne Precautions

In addition to Standard Precautions, use Airborne Precautions for patients known or suspected to have serious illnesses transmitted by airborne droplet nuclei; examples of such illnesses:

- Measles (rubeola)
- Monkeypox (until monkeypox confirmed and smallpox excluded—then Contact Precautions)
- Severe acute respiratory syndrome
- Smallpox (variola)
- Varicella (including disseminated zoster); also use Contact Precautions for patients with primary or disseminated zoster
- Tuberculosis; see specific guidelines *(116)*

Droplet Precautions

In addition to Standard Precautions, use Droplet Precautions for patients known or suspected to have serious illnesses transmitted by large-particle droplets; examples of such illnesses:

- Invasive *Haemophilus influenzae* type B disease, including meningitis, pneumonia, epiglottitis, and sepsis
- Invasive *Neisseria meningitides* disease, including meningitis, pneumonia, and sepsis
- Invasive multidrug-resistant *Streptococcus pneumoniae* disease, including meningitis, pneumonia, sinusitis, and otitis media
- Other serious bacterial respiratory infections spread by droplet transmission, including
- Diphtheria (pharyngeal)
- Mycoplasma pneumonia
- Pertussis
- Pneumonic plague
- Streptococcal disease (group A streptococcus): pharyngitis, pneumonia, scarlet fever in infants and young children, serious invasive disease, or major wound infection without dressing or inadequate containment of drainage by dressing
- Serious viral infections spread by droplet transmission:
- Adenovirus
- Influenza
- Mumps
- Parvovirus B19
- Rhinovirus
- Rubella
- Viral hemorrhagic fevers due to Lassa, Ebola, Marburg, Crimean–Congo fever viruses

Contact Precautions

In addition to Standard Precautions, use Contact Precautions for patients known or suspected to have serious illnesses easily transmitted by direct patient contact or by contact with items in the patient's environment. Examples of such illnesses:

- Gastrointestinal, respiratory, skin, or wound infections or colonization with multidrug-resistant bacteria judged by the infection control program, based on current state, regional, or national recommendations, to be of special clinical and epidemiologic significance
- Enteric infections with a low infectious dose or prolonged environmental survival:
- *Clostridium difficile*
- Rotavirus
- For diapered or incontinent patients: adenovirus, *Campylobacter* spp., cholera (*Vibrio cholerae)*, *Cryptosporidium* spp., enterohemorrhagic *Escherichia coli* O 157:H7, *Giardia lamblia*, Norovirus, *Salmonella* spp., *Shigella, Vibrio parahemolyticus*, *Yersinia enterocolitica*, hepatitis type A and E, or rotavirus
- Respiratory syncytial virus, parainfluenza virus, or enteroviral infections in infants and young children
- *Burkholderia cepacia* in patients with cystic fibrosis, including respiratory tract colonization
- Poliomyelitis
- Human metapneumovirus
- Congenital rubella
- Skin infections that are highly contagious or that may occur on dry skin:
- Diphtheria (cutaneous)
- Herpes simplex virus (neonatal or mucocutaneous)
- Impetigo
- Major (noncontained) abscesses, cellulitis, pressure ulcers, or wounds
- Pediculosis
- Scabies
- Staphylococcal furunculosis in infants and young children
- Staphylococcal scalded skin syndrome
- Zoster (disseminated or in the immunocompromised host)
- Vaccinia (*Eczema vaccinatum*, *Fetal vaccinia*, generalized vaccinia, progressive vaccinia)
- Viral/hemorrhagic conjunctivitis
- Viral hemorrhagic fevers (Lassa fever or Marburg virus)

(Compiled from Siegel JD, Rhinehart E, Jackson M, et al. Guideline for isolation precautions: preventing transmission of infectious agents in health care settings. Available at *www.cdc.gov/hicpac/2007IP/2007isolationPrecautions.html,* accessed October 25, 2010; Garner JS, the Hospital Infection Control Practices Advisory Committee. Guideline for isolation precautions in hospitals. *Infect Control Hosp Epidemiol* 1996;17:53–80.)

microorganisms can cause environmental contamination, which could theoretically lead to cross-transmission, such as MRSA, vancomycin-resistant enterococci (VRE), *C. difficile*, and norovirus *(79–82)*. The private room serves as a physical barrier and helps to reinforce antisepsis before exiting the room. Private rooms used for isolation should also contain bath and toilet facilities. If a private room is not available, patients infected or colonized with the same microorganisms may share a room. Grouping or cohorting with other infected or colonized patients is useful in an outbreak situation or when private rooms are scarce. There may be circumstances when a patient with a transmissible

infection must share a room with a noninfected patient. An appropriate roommate should be selected who is not likely to become infected or in whom consequences of infection would likely not be severe. In these cases, an IP should evaluate the situation to assist in selecting roommates carefully. Ensure that patients have appropriate distance separating them (≥3 ft) and close curtains between patients when available. Personnel caring for these patients should be aware of modes of transmission and take appropriate precautions to prevent spread of the microorganism.

Construction features and ventilation of isolation rooms are outlined in other publications (*83*,84,*85*). A private room with special ventilation (as outlined below) is necessary for those with diseases transmitted by the airborne route. An anteroom between the room and the hallway may be advantageous (although not required) for housing patients on Airborne Precautions by decreasing the possibility of the spread of airborne agents from the room into the hall (see also Chapter 84).

In the acute care setting, limiting the movement of the patient on isolation precautions limits the potential for spread of the transmissible epidemiologically significant pathogen. Thus, it is recommended that these patients leave their room only for medically necessary purposes. When transport is required, the appropriate barriers (dressings, masks, etc.) should be in place, and the personnel in the receiving department should be aware of the patient's isolation precautions and measures needed to reduce transmission. When possible, the patient should be educated about ways they can assist in minimizing spread of the microorganism. In the extended care or rehabilitation setting, residents or patients must leave their rooms for rehabilitation and socialization. There have been modified Contact Precautions recommended in this setting that are discussed below.

Indications and procedures to transport patients on isolation depend on the type of isolation that the patient requires. Patients on contact isolation precautions should have contaminated or colonized areas of the body covered during transport, and HCW should wear clean personal protective equipment (PPE) when handling the patient. Patients on Droplet Precautions should wear a surgical mask during the transport, but the HCW transporting the patient may not require a mask. Patients on Airborne Precautions should wear a surgical mask when they are being transported. Skin lesions should be covered during transport to avoid aerosolization of pathogens (i.e., varicella) (4).

Face Barrier Protection Besides gloves (discussed above) and gowns, barrier protection is also required to protect the face and mucous membranes when splashing of blood or body fluids is anticipated. Various kinds of mask protection, goggles, and face shields may be used as barriers to protect the eyes, nose, and mouth from exposures. This protection is required by the OSHA blood-borne pathogen final rule (3,*20*). A surgical mask can provide protection against large-particle droplets that are transmitted by close contact and travel short distances, as in those diseases covered by Droplet Precautions (see below). Recently, there was controversy over whether N95 respirators or surgical masks should be used to protect against 2009 H1N1 infection *(81)*. However, the current CDC recommendations for influenza recommend adherence to Droplet Precautions with the use of a surgical (or procedure) mask as per the most recent isolation precaution guidelines (4).

Gowns Gowns that are impermeable to liquids should be worn when splashing is anticipated. Leg coverings or shoe covers should be used when splashing is expected to be extensive. The wearing of gowns and protective apparel under such circumstances is mandated by the OSHA blood-borne pathogens final rule (3,*20*). Gowns are used with gloves for Contact Precautions and have been shown to decrease institutional spread of multidrug-resistant microorganisms *(86,87)*. Use of gowns and gloves together has been shown to be more effective to decrease transmission of VRE than using gloves alone (88). It has been shown that MRSA and VRE can contaminate the clothes of the HCW as well as hands *(89)*. In one study, 65% of nurses performing routine care on patients colonized by MRSA contaminated the front of their gowns or uniform with the microorganism *(60)*.

Equipment Whether special handling of equipment or articles is needed depends on the likelihood that the article is contaminated and the ability of the particular microorganism to survive in the environment *(90)*. Articles that are visibly contaminated or likely to be contaminated should be bagged. One bag is sufficient if it is sturdy and does not allow leakage and the outside of the bag is not contaminated when the article is placed in the bag *(91)*. Equipment may be disposable or reusable. Disposable equipment has the advantage of reducing the possibility of equipment becoming a vehicle for transmission of the agent, but use of disposable equipment may increase costs. Equipment that is reused between patients should be appropriately cleaned and disinfected (see also Chapter 80). Waste should be handled according to the institutional policy on waste disposal. Generally, double bagging is not indicated for waste or articles from isolation rooms. Equipment is usually classified using the Spaulding classification method, which defines the degree of disinfection and sterilization required, based on the risk of the equipment to transmit infection when used (92). Equipment is classified as critical items (those that pose a great risk of infection if the item is contaminated with any pathogen, including spores; they require sterilization [i.e., surgical instruments]), semicritical items (those that are in contact with mucous membranes or nonintact skin, and they require high level disinfection [i.e., colonoscopes]), and noncritical instruments (those that are in contact with intact skin [i.e., blood pressure cuffs]) (92).

Linen, Laundry, and Eating Utensils Soiled linen should be handled with a minimum of agitation and placed in a laundry bag in the patient's room or at the location where it was used. It should be transported in bags that prevent leakage. Disposable dishes and eating utensils are not required for patients on isolation. Reusable dishes may be used for patients in isolation, because the combination of dishwasher detergents and high water temperature adequately decontaminates dishes (3,*90*).

Housekeeping Routine daily cleaning procedures should be used in rooms with patients on most isolation precautions. Exceptions are those patients with microorganisms

known to be hardy in the environment (*C. difficile*, VRE). Special measures for these microorganisms include cleaning of the immediate patient environment (bed rails, bedside tables, commodes, doorknobs, horizontal surfaces) daily with an EPA-approved germicide. Terminal cleaning should include items that have been in direct contact with the patient or the patient's infective material. Housekeeping personnel use the same barrier precautions that would be indicated if the patient were still in the room. Horizontal surfaces and floors should be cleaned with a disinfectant–detergent solution. With the possible exception of the tuberculosis (AFB) isolation room, airing of a room or delay in admitting the next patient after an isolated patient's discharge is not needed (17,*90,93*).

Tiers to Prevent Transmission of Infectious Agents

There are two main tiers of the HICPAC/CDC guidelines to prevent transmission of infections in healthcare settings regardless of the presence of an infectious agent. The first tier is the most important strategy to prevent healthcare-associated transmission of infectious agents: Standard Precautions. The second tier is the institution of transmission-based isolation precautions.

Standard Precautions

Standard Precautions combine Universal Precautions and BSI and are based on the premise that "all blood, body fluids, secretions, excretions (except sweat), nonintact skin, and mucous membranes regardless of suspected or confirmed infectious status" may be infectious (4). Standard Precautions involve important interventions including hand hygiene, use of personal protective equipment (based on anticipated exposure), and safe injection practices, as well as appropriate management of environment and equipment.

The 2007 guidelines added to previous recommendations the use of respiratory hygiene/cough etiquette, safe injection guidelines, and use of a mask during certain procedures such as injection of material into spinal or epidural spaces or insertion of catheters into the epidural space (4).

Hand hygiene should be performed with soap and water if hands are visibly soiled. Alcohol-based hand sanitizers should be used after visible soil is removed with soap and water or if hands are not visibly soiled. Hand hygiene should be performed before direct contact with patients; after contact with blood, body fluids, excretions or mucous membranes, nonintact skin or wound dressings; after contact with intact skin if hands move from a contaminated to a noncontaminated body site; or after contact with objects close to the patient or after removing gloves (75).

For Standard Precautions, mask and eye protection or a face shield should be used to protect the eyes, nose, and mouth during activities that may generate splashing of blood or body fluids. A gown should be worn to protect skin and prevent soiling of clothing during such activities as well. Reusable equipment should be cleaned and reprocessed before being used on another patient. Ensure adequate cleaning of environmental surfaces. Handle soiled equipment and laundry in a manner that avoids exposures and transfer of microorganisms to other patients and the environment.

Care should be taken to avoid sharps injuries. Never recap used needles or use a technique that involves directing the point of the needle toward any part of the body. Place used sharps in a puncture-resistant container. Use mouthpieces or resuscitation bags instead of mouth-to-mouth resuscitation in areas where the need for cardiopulmonary resuscitation is predictable.

A patient who contaminates the environment or who cannot assist in using appropriate hygiene should be placed in a private room. If a private room is not available, seek consultation from an IP regarding placement.

Transmission-Based Precautions

The second tier of precautions is for patients with documented or suspected transmissible or epidemiologically significant pathogens that require more than Standard Precautions to prevent cross-transmission. Healthcare-associated pathogens may be transmitted by five major routes: contact, droplet, airborne, vector-borne, and common vehicle. The isolation guidelines are not generally relevant to vector-borne and common vehicle routes. Transmission-based precautions are of three types: Airborne Precautions, Droplet Precautions, and Contact Precautions. Types may be combined for diseases with multiple routes of transmission, and each type is used in addition to Standard Precautions. Another feature of the new guidelines is a list of specific syndromes in adult and pediatric patients that should be considered possibly infectious along with a listing of the type of transmission-based precautions that should be used empirically pending diagnosis.

Airborne Precautions

Airborne transmission usually occurs when a susceptible host inhales airborne droplet nuclei or small particles from an infection source containing microorganisms (i.e., tuberculosis) that may be dispersed over long distances. In addition to respiratory protection with N95 masks, prevention of airborne transmission requires use of special ventilation systems.

Airborne Precautions are used to prevent transmission of microorganisms that persist suspended in the air for long distances (i.e., tuberculosis). These patients should be placed in airborne infection isolation rooms. These rooms are negative pressure rooms with 12 air exchanges per hour in new construction and 6 exchanges per hour on existing buildings, with air exhausted to the exterior or recirculating through high-efficiency particulate air (HEPA) filters.

Healthcare workers should wear an N95 mask when entering the room. The mask should be fit-tested in all healthcare workers.

When airborne isolation rooms are not available, the patient should be placed in a private room with the door closed, and healthcare workers should wear N95 respirators. Patients should remain in their room as much as possible, and they should wear a surgical mask if they need to be transported to essential procedures.

Droplet Precautions

Droplet transmission occurs when an infectious agent is transmitted (usually) from the respiratory tract of a patient to the mucous membranes of another susceptible patient

by respiratory droplets that travel short distances though the air. The distance is usually 3 ft, but there are cases where it may travel up to 6 to 10 ft, especially in the setting of severe infections of SARS *(94)*. Some of these cases were due to lack of appropriate use of personal protective equipment *(94)*.

Droplets may be generated in the course of talking, coughing, or sneezing and during procedures involving the airway, such as intubation or bronchoscopy. Transmission via large droplets differs from airborne transmission in that the former requires close contact (within 3 ft) between the source and the recipient person and because large droplets do not remain suspended in the air and usually travel only short distances. Examples of diseases for which Droplet Precautions are recommended are meningococcal meningitis, multidrug-resistant pneumococcal meningitis or pneumonia, pertussis, streptococcal pharyngitis or pneumonia, influenza, and parvovirus B19 (for patients with aplastic crisis or chronic infection). Occasionally, pathogens not usually transmitted by way of droplets (such as *S. aureus* in the setting of pneumonia) can be transmitted through this route. The patient should be placed in a private room. If a private room is not available, patients with infection due to the same microorganism may be cared for in the same room (cohorted). If both private rooms and cohorting are unavailable, an IP should be consulted. There should be spatial separation of at least 3 ft between the infected patient and other patients and visitors. A mask should be worn when one is within 3 ft of the patient. It is most practical to wear a mask upon entering the room. The patient should leave the room only when necessary and should wear a surgical mask when doing so.

There are pathogens that are usually transmitted through droplets or contact but under special circumstances have been suspected to be transmitted through the airborne route such as SARS-associated coronavirus, influenza, and norovirus *(95,96,97)*. Droplet Precautions with a surgical mask is recommended for routine care of influenza patients. For procedures that will cause aerosolization of respiratory droplets, an N95 respirator should be used.

Contact Precautions

Contact transmission occurs when a microorganism is transmitted from one individual to another by a person or an object. Direct transmission occurs when the transmission happens without an intermediary object or person. Indirect contact transmission occurs when the bacteria is transmitted by healthcare workers or by instruments or devices.

Contact Precautions are designed to prevent direct or indirect transmission of microorganisms spread by contact. They are also indicated when there is fecal incontinence, abundant wound drainage, or other secretions or excretions of the body that lead to excessive environmental contamination. Ideally, patients on Contact Precautions should be placed in individual rooms. When individual rooms are not available, consultation with an IP should be obtained to decide whether cohorting or spatial separation of 3 ft or more (in multi-patient rooms) is indicated.

Healthcare workers entering the room or evaluating patients on Contact Precautions must wear a gown and gloves and perform hand hygiene before putting on PPE and after removing it. PPE should be donned before entering and leaving the room.

Gloves should be used as a barrier, as with Standard Precautions, for contact with blood and body substances. Also, under Contact Precautions, gloves should be changed after contacting infective material with high concentrations of microorganisms (e.g., feces and wound drainage). Gloves should be removed before one leaves the patient's room, and hands should immediately be cleansed with an antiseptic agent. A clean nonsterile gown should be worn if substantial contact with the patient is anticipated, the patient is incontinent of stool, or the patient has wound drainage that is not well contained by a dressing. The gown should be removed before one leaves the patient's environment. In the acute care setting, movement of the patient from the room should be for essential purposes only, and precautions should be maintained by the receiving department. When feasible, the use of noncritical equipment should be dedicated to a single patient or a cohort of patients. If equipment must be shared, it should be disinfected before use by another patient.

Examples of diseases for which Contact Precautions are recommended include infection or colonization with multidrug-resistant bacteria; *C. difficile* infection; respiratory syncytial virus (RSV) infection in children; and skin infections due to scabies, impetigo, and varicella zoster. Some diseases that are communicable by contact and by the respiratory route require Contact Precautions in combination with Droplet or Airborne Precautions; examples include viral hemorrhagic fevers such as Lassa fever or Marburg virus (Contact and Droplet Precautions), disseminated varicella (Contact and Airborne Precautions), and smallpox (Contact and Airborne Precautions).

Duration of Contact Precautions

The optimal duration of Contact Precautions for colonized or infected individuals remains controversial. In general, during outbreaks or clusters of infection, patients must remain in Contact Precautions during the duration of their hospital stay or the outbreak. In selected settings, especially among those patients that are detected during active surveillance outside the epidemic setting and are colonized or infected with microorganisms like MRSA or VRE, three negative cultures taken 1 week apart can reasonably be used to discontinue Contact Precautions (62). In other patients, resolution of symptoms that lead to the isolation (such as diarrhea in the case of *C. difficile* infection) may be a reasonable time to stop isolation (62).

Vancomycin-Resistant Enterococci

VRE have emerged and are quite prevalent in some areas of the United States and much less common in others. Patients colonized or infected with these microorganisms may be handled under Contact Precautions. Guidelines from the CDC for preventing transmission of VRE have also been published *(98)* and emphasize the principles of Contact Precautions. Environmental cleaning is also quite important for control of this microorganism because of its hardiness on environmental surfaces. For this reason, a daily cleaning of the patient's immediate environment (bed rails, bedside table, commode, doorknobs, horizontal surfaces) with an EPA-approved germicide is indicated.

A multifactorial approach in controlling this microorganism is recommended, such as antibiotic utilization efforts including appropriate vancomycin use by both the oral and the parenteral routes *(98)*. In some institutions, restriction of broad-spectrum cephalosporins has been helpful for control of VRE as well as other multidrug-resistant pathogens such as extended-spectrum β-lactamase-producing *Klebsiella pneumoniae (99)* (see also Chapter 33).

Vancomycin-Intermediate and Vancomycin-Resistant *Staphylococcus aureus*

Vancomycin-intermediate (or glycopeptide-intermediate) *S. aureus* (VISA; minimum inhibitory concentration [MIC], 8 μg/mL) was initially reported from Japan in 1996 and was subsequently reported from the United States *(100)*. Later, the Clinical Laboratory Standards Institute changed the vancomycin breakpoints for *S. aureus*. Isolates with a vancomycin MIC of >2 μg/mL are considered VISA *(101)*. Although these isolates showed reduced susceptibility to vancomycin rather than complete resistance, VISA was a concern because most reported patients required alternative therapy other than vancomycin *(100)*. VISA has been associated with a high mortality rate in ICU outbreaks in France *(102)*.

The CDC published guidelines for the prevention and control of staphylococcal infection associated with reduced susceptibility to vancomycin in 1997 *(100)*. These guidelines reiterate conservative use of vancomycin as a preventive measure. In addition, laboratory methods for susceptibility testing of these strains have been revised for more accurate detection. For preventing the spread of these microorganisms, the laboratory should immediately notify infection control personnel and the patient's attending physician. Infection control personnel, in conjunction with the state health department and the CDC, should initiate an epidemiologic investigation. Contact Precautions should be strictly enforced in the care of the patient. The number of personnel caring for the patient should be minimized, and specific healthcare workers should be assigned to the care of the colonized/infected patient or patients. Infection control personnel should inform healthcare workers regarding the epidemiologic significance of VISA and assist in monitoring compliance with Contact Precautions and other control measures. In coordination with public health officials as above, baseline surveillance cultures of the anterior nares and hands of those exposed to the patient, including healthcare workers and roommates, may be indicated to determine whether transmission has already occurred. Transfer of the patient within the facility or between facilities should be avoided. If transfer is necessary, the receiving unit or institution should be fully informed. Additional recommendations have been published by Wenzel and Edmond *(103)* that include excluding healthcare workers at risk for staphylococcal colonization from caring for patients with VISA and the use of mupirocin for eradication of nasal *S. aureus* colonization (see also Chapter 28).

In addition to VISA, the existence of hetero VISA (hVISA) makes isolation compliance even more compelling. This resistance, hVISA, is defined as the presence of small subpopulations of MRSA with intermediate resistance to vancomycin, which are difficult to detect and are present in only about 1 in 10^5 to 10^6 microorganisms *(104)*. They have been associated with increased rates of congestive heart failure and persistent bacteremia in patients with MRSA infective endocarditis *(104)*.

As of December 2007, there have been nine cases of fully vancomycin-resistant *S. aureus* (VRSA) in the United States: seven from Michigan, one from Pennsylvania, and one from New York (105). The concern with these isolates is not only the complete resistance to vancomycin but also genetic analysis suggests conjugative transfer of the *vanA* resistance gene from *Enterococcus* species to *S. aureus* and *in vitro* studies suggest that *vanA* can also be transferred from VRSA to MRSA (105). Thus, this may become a more significant problem than VISA. The CDC recommends the same guidelines for control of VRSA as for VISA, emphasizing strict Contact Precautions.

Multidrug-Resistant *Acinetobacter* spp.

Multidrug-resistant *Acinetobacter baumannii* has emerged as an important cause of healthcare-associated outbreaks, especially in the ICU setting *(106)*. This microorganism can be transmitted by contact with the hands of healthcare workers or by contamination of the environment (including linen and beds) or equipment (respiratory therapy, mechanical ventilation equipment, intravenous fluids, water humidifiers, other reusable medical equipment, wound care equipment, etc.) *(106–108)*. During a recently reported outbreak in an ICU, the recovery rate of *Acinetobacter* spp. from HCW hands was over 28% *(109)*. *A. baumannii* is one of the most difficult gram-negatives to control and eradicate in outbreak settings and has become a severe problem among injured soldiers returning from Afghanistan and Iraq (110).

Hand hygiene, strict Contact Precautions, aggressive environmental cleaning and disinfection, active surveillance and cohorting have been used to control outbreaks. However, interventions may fail, and closure of the units may be required for control *(107)* (see also Chapter 35).

Respiratory Hygiene/Cough Etiquette The SARS pandemic led to the development and implementation of certain precautions to prevent transmission of infections from patients with respiratory symptoms at the initial point of care. The elements of respiratory hygiene/cough etiquette are (a) education of HCWs, families, and visitors; (b) posted signs with easily understood instructions for patients and accompanying persons; (c) source control interventions (covering the mouth/nose with a tissue when coughing or sneezing, proper disposal of used tissues/appropriate use of masks by persons who are coughing); (d) hand hygiene when contact with respiratory secretions has occurred; and (e) maintaining a distance of ≥3 ft from persons who are coughing.

Protective Environment

This environment is used for the protection of allogeneic hematopoietic stem cell transplant patients. It minimizes the spore count in the air and is composed of environmental controls including HEPA filtration of incoming air, directed room air, positive pressure in the rooms when compared with the corridor, well-sealed rooms with no air entrance from the exterior, ventilation with 12 air exchanges per

hour or more, prevention of dust accumulation, and banning dried and fresh flowers and plants in the rooms.

Patients should remain in this protective environment and should wear N95 masks any time they leave the protected environment. Hand hygiene should be strictly enforced, but gowns and gloves are not routinely required. Rooms should be sealed and provided with HEPA filters, maintaining a positive pressure when compared with the corridor and at least 12 air exchanges per hour. In this setting, avoid carpets and perform regular cleaning with EPA-registered disinfectants, preventing dust dispersion. Furniture and furnishings with cloth upholstery that is difficult to clean should be avoided (see also Chapters 59, 83, and 84).

TUBERCULOSIS PRECAUTIONS: SPECIAL CONSIDERATIONS

There was a substantial increase in tuberculosis cases in the mid-1980s, primarily in association with the HIV epidemic. In 1990 and 1991, several healthcare-associated outbreaks of MDR-TB were documented *(111,112)*. In each outbreak, a delay or lapse in airborne infection isolation was a major factor in transmission. This resurgence of tuberculosis, emergence of strains of *Mycobacterium tuberculosis* resistant to isoniazid and rifampin, and documentation of healthcare-associated outbreaks of *M. tuberculosis* prompted the expansion and revision of CDC airborne infection isolation guidelines in 1990 *(113)*. In 1993, expanded updated guidelines were published in draft form in the Federal Register *(114)*, and more extensive guidelines were published in 1994 *(94)*. Due to enhanced containment and directly observed therapy, tuberculosis cases declined from 1993 to 2003, and the incidence of tuberculosis in the United States decreased by 44% to reach a historic low level in 2004 (115).

Major changes in airborne infection isolation included requirements for a high-efficiency filtration mask and duration of isolation based on clinical improvement and an emphasis on ventilation controls. Although special ventilation requirements were mentioned in the 1983 CDC guidelines for tuberculosis and certain diseases under strict isolation, the 1990 and subsequent guidelines emphasize these as particularly important control measures. Hospitals with older ventilation systems, which include many public hospitals with patients at risk for tuberculosis, have looked at ways to retrofit isolation rooms to meet the ventilation criteria outlined. In addition, the 1990 guidelines recommended special ventilation in bronchoscopy suites and areas where cough-inducing procedures, such as aerosolized pentamidine treatments, are performed. Infection control programs have also experienced OSHA involvement in this area because healthcare workers were involved in healthcare-associated outbreaks. Although the 1994 guidelines mentioned above focused on traditional hospital-based facilities, the 2005 guidelines expanded the range to include laboratories, outpatient areas, and other nontraditional healthcare settings *(116)* (see also Chapter 84).

Respiratory Protection

The 1983 guidelines for airborne isolation stated that a (surgical) mask should be worn if the patient is coughing and does not reliably cover his or her mouth (17). One report suggests that poorly fitting standard surgical masks are not protective *(117)*, but data on the efficacy of well-fitted masks (high-efficiency filtration or otherwise) in the clinical setting are lacking. The standard surgical masks used before the 1990 guidelines are adequate for barrier precautions but are not designed to seal tightly on the face and filter small particles. Disposable particulate respirators were originally designed for industrial use and filter particles that are 1 to 5 μm in size. They provide a better fit and filtration capability.

The 1990 guidelines stated that persons entering the room should wear a mask and specify that it should be a disposable, valveless, particulate respirator *(113)*. The 1993 draft guidelines called for a HEPA filtration mask *(114)*. The guidelines stated that the HEPA respirator mask is currently the only National Institute for Occupational Safety and Health (NIOSH)-certified mask meeting all suggested performance criteria regarding fit and filtration. NIOSH-certified dust–mist or dust, fume, and mist respirators had not been evaluated for these criteria. There was much controversy, discussion, and public comment regarding the need for these much more costly and uncomfortable masks in the clinical setting, particularly because the role of respiratory protection devices in preventing transmission of tuberculosis is not known. After a public comment period, guidelines were published in 1994 *(93)* with respirator criteria unchanged; however, in 1995, NIOSH subsequently revised the respirator certification to allow a broader range of respirator alternatives *(91)*. NIOSH indicated that the N95 (N category at 95% efficiency) meets CDC performance criteria for a tuberculosis respirator, and this respiratory protection is now widely used. This CDC/NIOSH-certified respirator continues to meet the minimum standards for respiratory protection in the usual areas where TB infection is encountered in the 2005 guidelines. These most recent guidelines suggest that further respiratory protection should be considered in situations where aerosol-producing or cough-inducing procedures are performed *(116)* (see also Chapter 38).

Duration of Isolation

Before 1990, the duration of isolation for tuberculosis patients was 2 to 3 weeks after beginning antituberculous therapy (17,*118,119*). However, even the 1983 guidelines state that isolation should be continued until there is a clinical response and a decrease in the number of microorganisms on smear (17). This qualification is further emphasized in recent guidelines because of failures of empiric therapy in MDR-TB cases in healthcare-associated outbreaks in the late 1980s *(113)*. The 2005 guidelines recommend that a hospitalized patient remain under airborne isolation precautions until certain criteria are met: three consecutive sputum samples obtained 8 to 24 hours apart (including one morning specimen) are AFB-smear negative, 2 weeks of an appropriate antituberculous medication regimen has been completed, and overall clinical improvement has been noted *(116)*. MDR-TB raises additional concerns due to the grave consequences of continued transmission and additional difficulty in treatment regimens. For patients with suspected or confirmed MDR-TB, many providers would continue Airborne Precautions throughout

hospitalization or until sputum cultures have converted to negative, regardless of sputum AFB smear status *(116)*.

Barrier Protection

Gowns are needed only if soiling of clothing is anticipated. Gloves are not indicated except, as dictated under Standard Precautions, for contact with blood or certain body fluids. As with other types of isolation, hands should be washed after touching the patient or potentially contaminated articles and before contact with another patient.

Decontamination

It is rare for inanimate articles to be involved in tuberculosis transmission. Procedures for cleaning, disinfecting, or sterilizing an item should be determined by its intended use. As for items used on any patient, critical items should be sterilized, semicritical items should undergo high-level disinfection or sterilization, and noncritical items should be cleaned (see also Chapter 80). Recent guidelines from the Association for Professionals in Infection Control and Epidemiology have recommended a 20-minute disinfection time for semicritical instruments such as bronchoscopes, to ensure tuberculocidal activity. Exceptional terminal cleaning to disinfect environmental surfaces is rarely needed. Routine cleaning with a hospital-grade EPA-approved germicide/disinfectant is recommended *(27)*. Routine daily cleaning procedures should be used to clean the rooms of patients on Airborne Precautions.

Ventilation

The American Society of Heating, Refrigerating, and Air Conditioning Engineers and the Federal Health Resources and Services Administration have published standard recommendations for indoor air quality in healthcare facilities (*83*,84,*85,120*). Special ventilation requirements for a patient on Airborne Precautions include negative pressure in relation to the hallway or anteroom; a minimum of 12 air changes per hour in new construction and renovation and six air changes per hour in existing facilities, including two outside air exchanges per hour; and direct exhaust to the outside. If direct exhaust to the outside is not feasible, then recirculation of air is permitted only through HEPA filtration to the air handler exclusively serving the isolation room *(116,120)*. The negative pressure room maintains airflow into the room from the hallway to minimize potential spread of tuberculosis bacilli into surrounding areas. The door must be kept closed to maintain negative pressure, and the direction of airflow should be monitored while the room is used for airborne infection isolation. A separate anteroom is not required but, if used, may serve as an airlock to minimize spread of droplet nuclei into the hallway. The anteroom should also have directional airflow. Direct exhaust to the outside must be away from intake vents, people, and animals in accordance with federal, state, and local regulations for environmental discharges.

The 2006 guidelines from the American Institute of Architects/Facility Guidelines Institute also address ventilation in patient waiting areas. Emergency room waiting areas should have at least 12 air changes per hour *(120)*. The guidelines also suggest that air from clinics with patients at high risk for tuberculosis should not be recirculated except through a HEPA filter. Because this may be very difficult to achieve in many clinic areas, early identification of patients with suspected tuberculosis followed by placement of the patient in a designated isolation room in the clinic or emergency room will assist prevention (see also Chapter 84).

Patient Management

Patient management issues arise for all types of isolation but may be particularly difficult for patients on Airborne Precautions. Patient and family education is particularly important when Airborne Precautions are implemented so that the patient understands the rationale for isolation and the psychological aspects and stigma of isolation can be minimized. The patient should be educated about coughing into a tissue and wearing a mask when it is necessary to leave the room. In general, the patient should not leave the room except for medically necessary procedures.

SPECIAL CONSIDERATIONS IN PEDIATRIC PATIENTS

Because pediatric hospitalizations are often due to communicable diseases, isolation guidelines are particularly relevant for this group of patients. Previous guidelines have stated that infants and very young children with pulmonary tuberculosis do not require isolation precautions because cough is rare and AFB in bronchial secretions is minimal. Exceptions could include pediatric patients with cavitary disease and patients with positive AFB smears. Concerns have also been raised recently about HIV-infected pediatric patients with tuberculosis. The 2005 guidelines for the prevention of tuberculosis transmission state that although children with tuberculosis are less likely to be infectious, transmission can still occur. It is recommended that children be screened for potential transmission risk using similar criteria as used for adult patients (i.e., cough >3 weeks, cavitation on chest radiograph, and/or respiratory tract or upper airway disease). Although gastric lavage is helpful in determining the presence of tuberculosis infection in the pediatric patient, the degree of AFB positivity cannot be correlated with tuberculosis transmission risk *(116)* (see also Chapter 38 for additional information on control of tuberculosis in healthcare facilities).

The psychosocial effects of isolation on hospitalized children have not been extensively studied, but a Swedish study suggests that isolation does not have a negative effect on a child as long as that child can observe the staff *(121)*. Another blinded, prospective study performed in Toronto evaluated isolated and nonisolated pediatric patients and found no significant difference in duration of interaction time between providers and patients or in parental satisfaction with quality of care *(122)*. As in adult patients, Standard Precautions are used, and thus, the category of blood and body fluid precautions is no longer necessary. Transmission-based precautions are currently recommended in addition, but disease-specific or category-specific isolation may be used, depending on the institution's choice. The Report of the Committee on Infectious Diseases (the Red Book) recommends transmission-based precautions, according to current CDC recommendations *(123)*. Some

institutions may choose BSI instead of transmission-based precautions. In the category-specific system, several pediatric diseases, which are grouped under Contact Precautions, include acute respiratory infections in infants and young children due to croup, bronchitis, adenovirus, and parainfluenza viruses. Under the new transmission-based guidelines, Droplet Precautions and Airborne Precautions are used more frequently on the pediatric ward because of the more common occurrence of airborne illnesses such as varicella, pertussis, measles, and erythema infectiosum.

Isolation Precautions for Newborns and Infants

The 1983 CDC guidelines outline modifications for the newborn or infant requiring isolation (17). Such modifications are needed because generally only a small number of private rooms are available for this group of patients, and because it is frequently necessary to cohort newborns and infants when outbreaks occur. Private rooms for isolation of newborns and infants are seldom indicated (or available), provided the following conditions are met: an adequate number of nursing and medical personnel are on duty and have sufficient time for appropriate hand washing, sufficient space is available for a 4- to 6-ft aisle or area between newborn stations, an adequate number of sinks for handwashing are available in each nursery room or area, and continuing instruction is given to personnel about the mode of transmission of infections. When these criteria are not met, a separate room with hand washing facilities may be indicated (17).

Forced-air incubators do not substitute for private rooms because they filter incoming air but not air being discharged into the nursery. In addition, the surfaces of incubators can become contaminated with healthcare-associated microorganisms and can colonize the hands and forearms of personnel caring for infants through portholes. Thus, forced-air incubators provide some protective isolation for the infants but do not prevent cross-transmission.

Cohorts of well newborns are also useful in minimizing cross-transmission of infection in a large nursery setting:

- A cohort usually consists of all well newborns from the same 24- or 48-hour birth period; these newborns are admitted to and kept in a single nursery room and ideally are taken care of by a single group of personnel who do not take care of any other cohort during the same shift. After the newborns in a cohort have been discharged, the room is thoroughly cleaned and prepared to accept the next cohort.
- Cohorting is not practical as a routine for small nurseries or in neonatal ICUs or graded in care nurseries. It is useful in these nurseries, however, as a control measure during outbreaks or for managing a group of infants or newborns colonized or infected with a multidrug-resistant or epidemiologically significant pathogen. Under these circumstances, having a separate room for each cohort is ideal but not mandatory for many kinds of infections if cohorts can be kept separate within a single large room and if personnel are assigned to take care of only those in the cohort.
- During outbreaks, newborns or infants with overt infection or colonization and personnel who are carriers, if indicated, should be identified rapidly and placed in cohorts; if rapid identification is not possible, exposed newborns or infants should be placed in a cohort separate from those with disease and separate from unexposed infants and newborns and new admissions. The success of cohorting depends largely on the willingness and ability of nursing and ancillary personnel to adhere strictly to the cohort system and to meticulously follow patient care practices (17).

Specific recommendations regarding the design of newborn nurseries are available *(124,125)* and specify the amount of floor space that should be allowed per bassinet for adequate separation of infants. Barrier precautions should be followed according to Standard Precautions for all patients and according to BSI in institutions that have this policy. The routine use of an overgown in the nursery has not been shown to decrease healthcare-associated infection rates or intravascular catheter colonization rates or to change hand washing practices *(126)*. Policies regarding gown use in nurseries vary between institutions, and nurseries should establish their own guidelines based on what is most appropriate for their personnel and problems. Gowns may be useful in decreasing the spread of microorganisms transmitted by droplets (see below, Respiratory Syncytial Virus) and should be used in those situations. A barrier such as a blanket or gown should be used when the infant comes into contact with staff, such as during a feeding *(126)*. Personnel do not need to wear masks, caps, and hairnets routinely.

Equipment shared by infants in a unit should be disinfected between uses with alcohol or a bleach solution. Nebulizers should be sterilized by autoclaving or gas sterilization at every shift. Soiled linens are handled as in other areas and removed from the nursery at every shift *(126)*.

Respiratory Syncytial Virus

Another special consideration in pediatric patients is RSV, a major lower respiratory tract pathogen causing community-acquired or healthcare-associated infection in infants and children. Large community epidemics occur characteristically from midwinter to early spring. Bronchiolitis due to RSV is included in Contact Precautions under the category-specific system, which recommends a gown when soiling of clothes is likely. The current CDC transmission-based guidelines recommend Contact Precautions for pediatric and adult RSV disease (4). Viruses such as RSV and rhinovirus can be transmitted by close person-to-person contact by large droplet spread, which occurs during coughing and sneezing *(127,128)*. In addition, respiratory secretions are also spread by hand-to-hand contact or by contaminated fomites *(127,129)*. Persistent shedding of RSV is common after infection, and RSV persists for a long period of time on environmental surfaces as well *(128)*. Thus, it is easy to see why RSV is transmitted easily in both the community and hospital settings and has been documented to cause symptomatic infections in 40% to 60% of infant contacts and 50% of hospital staff *(130)*. Control measures are particularly important in newborn nurseries that house premature infants and infants with pulmonary disease. In these high-risk hosts, mortality from RSV may be 35% to 50% *(131)*.

The CDC published surveillance data of RSV activity in the United States from 2005 to 2006, which revealed that 91% of the RSV infections detected occurred from November

2005 through April 2006. Given the risk of transmission and the potential severity of disease, RSV should be considered in the differential diagnosis of respiratory infections during its annual peak so that appropriate precautions can be taken *(132)*. A study performed in New York suggested that screening for the presence of RSV infection and cohorting patients with RSV effectively reduced the healthcare-associated transmission of RSV infection *(133)*.

Disposable eye–nose goggles decreased healthcare-associated RSV transmission in patients and staff during a 3-week period in one study *(129)*. When goggles were used, 5% of staff and 6% of infants acquired RSV disease compared with 34% of staff and 43% of infants when goggles were not used. Another study observed a 5% rate of disease in staff members using goggles versus 61% in those not using goggles *(134)*. Long-term efficacy, compliance, and cost-effectiveness of these goggles have not been evaluated.

The use of gowns and masks has not been effective in reducing cross-transmission *(135,136)*. The use of gowns and gloves has been effective as evaluated in a long-term interventional study in which compliance was also followed (137). The infection rate before intervention, when compliance with gown and glove isolation precautions was only 40%, was three times the rate of infection after intervention when compliance had increased to 80%. Glove and gown precautions have also been effective in other studies *(138)*.

Parvovirus

Human parvovirus B19 is the etiologic agent of erythema infectiosum (fifth disease), a common childhood exanthem resulting in a slapped-cheek appearance. It occurs in the community sporadically and in outbreaks. In addition to causing asymptomatic or mildly symptomatic disease in healthy adults, human parvovirus B19 may cause chronic anemia in immunodeficient patients and aplastic crisis in patients who have hematologic conditions with accelerated red blood cell turnover such as sickle cell anemia, hereditary spherocytosis, β-thalassemia, pyruvate kinase deficiency, and autoimmune hemolytic anemia *(139)*. This agent is transmitted by contact with respiratory secretions. Persons with erythema infectiosum—the most common form of infection due to this agent—do not require Droplet Precautions when admitted to the hospital because they are unlikely to transmit infection after the onset of the characteristic rash *(119,123)*. However, patients acutely infected with parvovirus B19 during aplastic crises can transmit the virus to patients and staff in the healthcare setting through contact with respiratory secretions, although this is uncommon *(138,139)*. Patients with chronic parvovirus B19 infection are probably less likely to transmit the virus in the healthcare-associated setting, perhaps because of lower levels of viremia *(140–142)*.

The following recommendations are suggested for the control of healthcare-associated transmission of parvovirus B19. Patients who have hereditary or acquired chronic hemolytic anemias presenting with aplastic crisis and immunosuppressed persons with aplastic crisis should be evaluated for parvovirus B19 infection *(143,144)*. Persons with suspected or proven acute or chronic infection (other than erythema infectiosum) should be on Droplet Precautions (3,*139,142,143*) (see also Chapter 51).

Burkholderia cepacia in Cystic Fibrosis Patients

Burkholderia cepacia is a multidrug-resistant gram-negative bacillus that chronically colonizes and may infect the respiratory tract of some cystic fibrosis patients. Colonization or infection with *B. cepacia* in cystic fibrosis patients is significant because colonization is difficult to eradicate and infection often results in rapid decline in pulmonary function and earlier death *(145)*. Several studies have suggested that person-to-person transmission is important *(146–148)* both inside and outside the hospital. In the hospital, *B. cepacia*–positive cystic fibrosis patients should not be housed in the same room as *B. cepacia*–negative cystic fibrosis patients. Contact Precautions or BSI should be used in the care of *B. cepacia*–positive cystic fibrosis patients.

PROTECTIVE ISOLATION

Although the technique for protective isolation was outlined in previous editions of the CDC isolation techniques for use in hospitals, the 1983 CDC guidelines eliminated this isolation category. Protective isolation requiring the use of gown, gloves, and mask for all persons entering the room of a patient immunocompromised by hematologic malignancy, chemotherapy-induced granulocytopenia, or solid organ transplant has not been shown to reduce infection risk (17,*149,150*). Nauseef and Maki *(143)* studied acute nonlymphocytic leukemia patients with chemotherapy-induced granulocytopenia and found that protective isolation did not decrease rates of infection, time of onset to first infection, or days with fever. In fact, there was a higher rate of bacteremia in isolated patients, perhaps because of neglected intravenous catheter care in this group. Walsh et al. *(150)* studied the value of protective isolation in cardiac transplant patients. There was no difference in isolated versus nonisolated patients in infection rate, infection-related deaths, types of infection, or overall outcome.

The lack of a demonstrable beneficial effect from protective isolation may result from the fact that infections in these patients are often due to their own endogenous flora; to transmission of microorganisms by unwashed hands of personnel; to the use of nonsterile items in routine protective isolation such as patient-care equipment, food, or water; and to the presence of nonsterile air (17). CDC guidelines state that, in general, compromised patients should be taken care of by using precautions that are no different from routine good patient care techniques, but for these patients, routine techniques must be emphasized and enforced. Healthcare workers involved in the care of these patients should be meticulous about hand hygiene before and after each patient contact. Such immunocompromised patients should be in a private room, when possible, and should be housed separately from infected patients or those likely to have an infection (17).

The total protected environment (TPE) has shown efficacy, however, in preventing infections in patients with prolonged granulocytopenia *(151)*. TPE includes a private room; HEPA air filtration; disinfection or sterilization of all objects coming in contact with the patient; the use of sterile gowns, masks, gloves, caps, and boots by hospital

personnel and visitors entering the room; the use of sterile water and semisterile or low microbial count food; and decontamination of the gastrointestinal tract *(151)*. This approach is expensive and may have poor patient acceptance *(151–155)*. Although TPE has been shown to lower the incidence of infection, the rate of survival may not differ in patients in TPE as compared with a standard hospital room *(155)*. This is largely due to improved management of infections and makes TPE a cost–benefit issue. Invasive aspergillosis is an infection that is often refractory to therapy and has a high mortality in these patients *(156)*. For this reason, the use of HEPA filtration and a private room is recommended for patients with prolonged granulocytopenia, such as bone-marrow transplant patients *(157)* (see also Chapter 59).

SPECIAL CONSIDERATIONS FOR PATIENTS IN EXTENDED CARE OR REHABILITATION

Long-Term Care and Home-Based Care

LTCFs are becoming more important as the population ages. Patients managed in LTCFs are being admitted with more acute diseases and are at increased risk of developing healthcare-associated infections *(158)*.

Consideration for transmission-based isolation precautions in long-term care is different than that of acute care hospitals. Isolation precautions should be individualized based on the likelihood of transmission and the mobility of the patients (4). Given prolonged stays and the need to maintain a "home-like environment," strict Contact Precautions cannot always be recommended, and adverse consequences of isolation should be considered *(158)*. Some institutions have adopted the use of gloves alone when in contact with patients on Contact Precautions, in addition to Standard Precautions and a hand hygiene program. This has been shown to contribute to increased compliance with isolation (among HCW using gloves alone vs. gloves and gowns during interactions) without increased transmission of microorganisms *(159)*. In patients with adequate mobility and multi-drug resistant organism (MDRO) infection, Standard Precautions may be adequate, but in those that require complete support and have uncontrolled secretions/excretions, Contact Precautions similar to those in the acute care setting may be needed. Airborne Precautions and Droplet Precautions may still need to be similar to those employed in acute care settings; however, the 2007 guidelines emphasize the need to individualize isolation decisions in this patient population.

Noncritical equipment should be assigned to each patient, but if this is not feasible, equipment should be appropriately disinfected between patients. Transportation and mobility of patients in isolation should be handled in a manner similar to that of acute-care settings.

The risk of infection during home-based care is reduced due to the limited contact with personnel and other patients. However, there is still a risk of transmitting infections from healthcare workers or family members to patients, such as influenza and scabies, or to transmit infections from patients to family members (e.g., tuberculosis). Noncritical items should remain at the home of the infected or colonized patient when possible and should be cleaned with a low to moderate level disinfectant before removing them from the patient environment (home) (see also Chapter 99).

In ambulatory settings, patients requiring isolation precautions should be moved to an individual room as soon as possible. When the patient requires Contact Precautions, they should be placed in an individual room and the HCW should wear appropriate PPE. If the patient requires Droplet Precautions, then he/she should be instructed on respiratory hygiene/cough etiquette as well.

In the ambulatory setting, patients requiring Airborne Precautions should be immediately identified and placed in a room with negative pressure and 6 to 12 air exchanges per hour with exhaust of the air to the exterior or through a HEPA filter. The patient should wear a surgical mask until he/she can be moved to a negative pressure room with the door closed. If a negative pressure room is not available, the patient should keep the mask on, and after the patient leaves, the room should remain empty for an adequate period of time (usually 1 hour).

As the number of elderly patients in extended care increases and as rehabilitation programs continue to proliferate, there will likely be an increasing number of patients with multidrug-resistant microorganisms in these settings. These patients have often been in the acute-care setting for extended periods of time or for frequent readmissions and have had multiple opportunities to acquire microorganisms such as MRSA, VRE, and multidrug-resistant *K. pneumoniae*. Rehabilitation and socialization in these settings are critical to maintaining or increasing functional status, and keeping patients restricted to their rooms on Contact Precautions, as outlined for acute care, may not be practical. Studies have documented that MRSA colonization is common in the nursing home, but infections are not frequent. This may also be the case with VRE as the data are accumulating *(160)*. The Long-Term-Care Committee of the Society for Healthcare Epidemiology of America has published guidelines recommending minor modifications of Contact Precautions in the long-term care setting *(160)*. This approach recommends education of personnel in these units regarding basic infection control measures. Surveillance cultures may be used in an outbreak of infection but are not cost-effective in the nonoutbreak setting. When a resident is transferred to another unit or facility, the receiving party should be made aware of that resident's colonization with a multidrug-resistant microorganism.

A private room is recommended when possible or if necessary. If this is not feasible, the patient who is colonized with VRE and is continent without diarrhea or has an open wound that is infected or colonized with VRE may be placed with another patient. The roommate should be selected with care and should not be severely immunocompromised, have open wounds, and preferably should not be receiving antibiotics or have an indwelling urinary catheter or drainage device. Gloves should be used for contact with the patients and their environment. Because soap may not adequately remove VRE from hands, chlorhexidine or an alcohol-containing antiseptic should be used after caring for VRE-infected or colonized patients. Gowns are recommended if contact is anticipated with the patient, the

patient's secretions, or the environment. VRE-infected or colonized residents may leave their room provided that they can understand and are compliant with basic personal hygiene, are continent of stool (or diapered to contain stool), and wear clean clothing. Resident education is particularly important, as much as is feasible, regarding good hygiene and hand washing. Patient-care equipment should be dedicated when possible, and the use of individual thermometers is recommended. In the rehabilitation unit, where equipment may be central, the patient may be scheduled at the end of the day and equipment disinfected after use. As with recommendations for VRE in acute care, daily environmental cleaning with a germicide is recommended. Vancomycin and cephalosporin use should be prudent.

Such modified Contact Precautions may be used as a model for other problematic multidrug-resistant microorganisms in the extended care setting. A similar protocol has been used in a unit with VRE and multidrug-resistant *K. pneumoniae*. Stool surveillance prevalence studies from 1 year compared with the next showed no significant increase in colonization with these microorganisms using these principles of modified precautions *(161)*.

CATEGORY A BIOTERRORISM AGENTS AND ISOLATION

Since potential bioterrorist diseases are not routinely seen, the healthcare epidemiologist and infection control department must be aware of whether and what type of isolation precautions are needed, particularly for category A agents—deemed the most likely bioterrorist agents.

Anthrax

Person-to-person transmission of anthrax is not a concern *(162)*. The natural life cycle is that hoofed animals inhale or ingest infective spore forms of *Bacillus anthracis* from soil or dust. The spore forms then germinate to become vegetative forms as they multiply, causing massive infection and toxin release associated with edema, hemorrhagic necrosis, and death. The carcass then decomposes; vegetative spores are exposed to oxygen; and the spore forms are regenerated. Humans can be an incidental host by skin contact with the spore forms; 95% of natural anthrax cases are cutaneous. Humans can also become an incidental host by inhalation of spores, occurring primarily by wool-sorting in endemic areas. Since the vegetative forms cause the disease in the body, anthrax is not transmissible person-to-person. The intentional anthrax attacks in October 2001 caused cutaneous cases from mail handling and inhalation cases from aerosolization of spores from mail-sorting equipment. There was no person-to-person transmission from these cases *(163)*. Standard Precautions is the only isolation category recommended for anthrax (see also Chapter 103).

Smallpox

Transmission of smallpox (variola) has generally occurred only in close contacts, but healthcare-associated spread has been reported. Droplet spread is the major mode of transmission, but airborne transmission through fine-particle aerosol can occur, particularly in severely ill patients *(164)*. The skin lesions of smallpox are also contagious and, unlike varicella, are contagious until the scabs separate. Contact Precautions and Airborne Precautions should be instituted immediately when there is high suspicion for smallpox, and public health officials should be notified. Masks of N95 quality or higher, disposable gloves, gowns, and shoe covers should be used for all contact with patients. Personnel should remove and dispose of protective garb before contact with others. Reusable bedding and clothing should be autoclaved or laundered in hot water with bleach to inactivate the virus. If smallpox is confirmed, these isolation precautions should continue until the scabs are separated. Clinical specimens should not be sent through the pneumatic tube system and should be carefully packaged for referral to a public health laboratory (see also Chapter 104).

Botulism

Botulism is a toxin-mediated disease due to botulinum toxin produced by *Clostridium botulinum*, and thus, is not transmitted person-to-person. Botulinum toxin can be detected in stool and serum and, if accidentally ingested or inhaled, could cause disease. Standard Precautions should be used in the handling of blood and body fluids *(164,165)* (see also Chapters 47 and 103).

Plague

Natural cases of plague, due to infection by *Yersinia pestis*, are usually bubonic, associated with the characteristic buboes as a result of transmission from the bites of infected fleas. Primary plague pneumonia is uncommon in natural disease but would be the expected form of intentional, or bioterrorist, plague. Person-to-person spread of pneumonic plague may occur by respiratory droplets. Therefore, Droplet Precautions are recommended for cases of pneumonic plague until at least 48 hours of appropriate antibiotic therapy is administered and the patient shows clinical improvement *(166)*. Patients with natural cases of bubonic plague without secondary pneumonic plague require only Standard Precautions (see also Chapters 47 and 103).

Viral Hemorrhagic Fevers

This diverse group of viruses, including Ebola, Marburg, and Lassa, are spread in a variety of ways but may be transmitted by the respiratory route or as a blood-borne pathogen. Droplet and Contact Precautions should be used *(59)* for these patients. Equipment should not be shared between patients, and materials contaminated with body fluids should be disinfected with a bleach solution or phenolics. Special laboratory handling is required, including a biosafety cabinet and barrier precautions. Laboratory personnel should be notified when this disease is suspected (see also Chapters 47 and 103).

Tularemia

The most common form of natural disease due to *Francisella tularensis* is ulceroglandular disease with associated lymphadenopathy; natural tularemic pneumonia is less common. Bioterrorist disease would be expected to be tularemic pneumonia, however, because of intentional aerosolization. Person-to-person transmission does not occur,

so only Standard Precautions are required. However, this disease is transmitted quite easily in the laboratory, and should be handled under a biosafety cabinet; therefore, the laboratory should be notified if tularemia is suspected *(167)* (see also Chapter 103).

CONCLUSION

Isolation guidelines have changed tremendously over the past couple of decades, largely because of the AIDS epidemic and the recognized risk of transmission of infection within the healthcare setting. The positive aspect of this change is that guidelines designed to protect against blood-borne pathogen transmission are standard for all patients. Precautions to prevent non–blood-borne pathogen transmission, including multidrug-resistant pathogens, are now more widely used and are standard in many institutions. The revision of CDC isolation guidelines has addressed some of the confusion in terminology that occurred with the implementation of Universal Precautions. Two tiers of precautions are used: Standard Precautions for the care of all patients, and a second tier of transmission-based precautions (Airborne Precautions, Droplet Precautions, and Contact Precautions) for patients with known or suspected diseases spread by these routes.

CHAPTER 91

Hand Washing and Hand Disinfection

Manfred L. Rotter

Although the importance of hands for the transmission of infectious diseases was not demonstrable before the 19th century when medicine began to adopt scientific ways of thinking, an idea of their role must have existed long before the Hungarian obstetrician Ignaz Philipp Semmelweis made his epidemiologic observations on the horrible spread of puerperal fever, which caused maternal mortality rates of up to 18% in some months at a Vienna, Austria, lying-in hospital during the years 1841 to 1847. At least from examples of the historical tradition, it may be concluded that hand washing is an old cultural heritage of human civilization. The idea has been handed down to us that this procedure not only served for the removal of dirt but also to deliver people symbolically from physical and moral evils, such as illness and sin. It is characteristic of the efficacy of modern scientific methodology that hands were identified as transmitters of disease even at a time when microorganisms were not yet recognized as a cause of infection. Semmelweis applied epidemiologic rather than microbiologic methods to test his hypothesis that preventing hands from introducing a fatal something into the maternal birth canal during vaginal examination would also end the hyperendemic situation of puerperal fever at his hospital. His attention was especially drawn to the markedly lower maternal mortality at the second obstetric department of the same hospital where, in contrast to his working place, where usually midwives conducted deliveries (Fig. 91-1) *(1)*. He identified the distinguishing moment in the incidence of puerperal fever by the fact that midwives had no contact with the autopsy room where, he postulated, hands were contaminated with the fatal etiologic agent.

Although the role of hands in the transmission of puerperal fever had been recognized as early as 1795 by Alexander Gordon and in 1843 by Oliver Wendell Holmes *(2)*, Semmelweis was the first to take appropriate action by introducing hand disinfection into clinical practice in May 1847. A little later and probably without knowledge of Semmelweis' findings, the Scottish surgeon Joseph Lister tested and proved Louis Pasteur's hypothesis that microorganisms not only cause fermentation and putrefaction but may also initiate suppuration in living tissues. By inactivating and keeping the causative microorganisms away from the surgical site, he prevented surgical site infection. Among other vehicles and sources, he also recognized the importance of the hands of the surgical team and consequently tried to eliminate their microbial flora before surgery.

MICROBIAL FLORA OF HANDS

Although it is not always feasible *(3,4)*, three groups of microorganisms may be distinguished on the skin: (a) microorganisms that reside on the skin, which the American surgeon Price (5) termed "resident" flora; (b) those that happen to be there as contaminants, which Price termed "transient" flora; and (c) pathogens that cause infections on the hands, such as panaritium digiti or paronychia, which can be called "infectious" flora.

Resident Flora

Except for the anaerobic propionibacteria that are located mainly at the ducts of sebaceous glands, most of these microorganisms reside on the uppermost part of the stratum corneum *(6,7)*, on corneocytes, and are embedded in a mass of lipids and cell detritus of the pars disjuncta *(8,9)*. They multiply in the upper regions of the hair follicle *(10)*. The deeper regions of the skin are, the ducts of eccrine and apocrine glands, not colonized *(11)*. The composition of skin flora has been described in several reviews *(12–19)*. Recently, molecular biologic diagnostic tools such as a novel pyrosequencing-based method, allowed characterizing a hitherto unknown diversity of skin bacteria on the palmar surfaces of the hands of young adults *(20)*. According to the findings of Fierer et al. *(20)* hands harbored, on average, 158 (in the range 46–401) unique species-level bacterial phylotypes, and among the 51 healthy volunteers, they identified a total of 4,742 unique phylotypes across the 102 hands examined. The bacterial diversity was more expressed in females than in males. The bacterial skin flora varies qualitatively and quantitatively by body site, gender, age, health condition, hospitalization, season *(6,11,21–23)*, handedness, and the time interval between last hand washing and skin sampling *(20)*. Except for areas with large numbers of sebaceous glands where propionibacteria prevail, the main portion of the skin flora is made up of *Micrococcaceae* such as staphylococcal species (*Staphylococcus epidermidis, Staphylococcus*

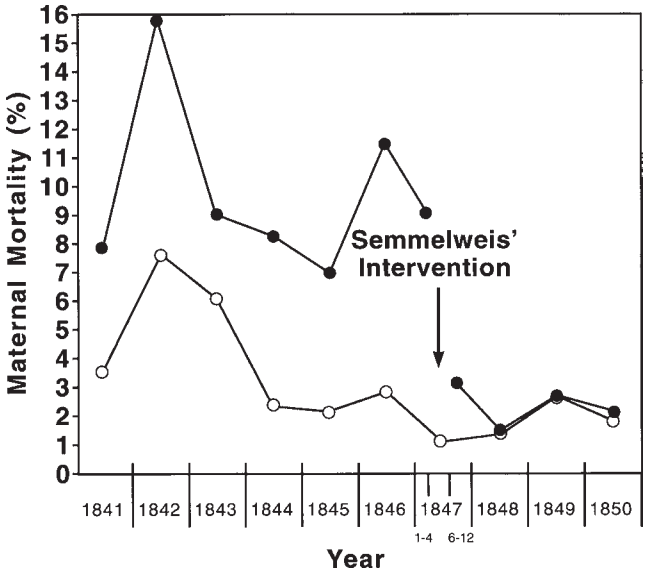

FIGURE 91-1 Maternal mortality at the First and Second Imperial-Royal Obstetric Department of the General Hospital in Vienna, Austria, 1841–1850. •, First Department; ○, Second Department. (From Rotter ML. Semmelweis' sesquicentennial: a little noted anniversary of hand washing. *Curr Opin Infect Dis* 1998;11:457–460, with permission.)

hominis, Staphylococcus capitis, etc.) and micrococci. Also, *Staphylococcus aureus* may temporarily colonize the skin, especially the perineal region, nose, hands, face, and neck. This occurs more often with children than with adults *(3)*, but healthcare personnel are especially prone to this colonization; the prevalence of colonization with *S. aureus* in healthcare personnel was reported by Larson et al. *(24)* to reach 18%. In the intensive care unit (ICU) of a German teaching hospital, Hofmann et al. *(25)* found *S. aureus* on 18.4% of nurses' hands and on 36% of doctors' hands. These data more likely reflect, however, a state of repeated contamination rather than true long-term carriage. Lipophilic and nonlipophilic corynebacteria are common inhabitants of the skin—the former usually in hairy regions, the latter more in bald regions *(6)*. The antibiotic-resistant *Corynebacterium jeikeium* may cause therapeutically difficult nosocomial infections in high-risk patients. Although the most common site of isolation is the perineum *(23)*, it may also occur on the hands. *Propionibacterium acnes* and *Propionibacterium granulosum*—the latter of which is less often isolated—multiply at sebaceous body sites *(11,26)*, but they can also be found in small numbers on the hands, although most likely as transients *(9)*. Fierer et al. *(20)*, however, identified them as the most abundant bacterial group on the palmar hand surfaces of their undergraduate student-volunteers who had, just prior to sampling, taken an examination. This may be because the students had often and intensely touched their sebum-rich forehead while thinking and, by this, contaminated their hands.

Gram-negative bacteria such as *Acinetobacter* and *Enterobacter* species may be isolated mainly from moist skin areas *(26–29)* but also regularly from the hands, where they may be regarded as residents *(30)*. Larson *(31)* found that 80% of persons outside the hospital and 21% of hospital personnel persistently carried *Acinetobacter* species and members of the *Klebsiella–Enterobacter* group. Males were significantly more likely to be carriers than females, and persons who washed their hands less than eight times per day were more likely to persistently carry the same gram-negative species than those who washed more than eight times. Well known is the report by Casewell and Phillips *(32)* of a hospital outbreak with *Klebsiella* colonizing the hands of hospital personnel. Attendants with close patient contact, as in ICUs, were especially likely to carry gram-negative bacteria on their hands *(33)*. A list on the contamination frequency with nosocomial pathogenic species on healthcare workers' hands and their persistence on hands and inanimate surfaces has been presented in a recent review by Kampf and Kramer *(34)*.

The population density of resident skin bacteria ranges somewhere between 10^6 colony-forming units (CFU)/cm^2 on the sebum-rich scalp and 10^2 to 10^4/cm^2 on the forearm *(35)*. Fingertip counts assessed by agar contact methods ranged from 0 to 300 *(36)*. The density remains remarkably stable for any given individual over long periods of time (5,*20,36–38*). Only diseases of the skin and agents interfering with the biocenosis, such as antibiotics or disinfectants, may cause long-term alterations *(6,14,26,39)*. The greatest short-term fluctuations (1–2 hours) are seen after intense contact with water *(40)*.

The normal microbial skin flora fulfills the important function of colonization resistance, thereby preventing colonization with other and potentially more pathogenic microorganisms. The influencing factors are the presence of free fatty acids liberated from skin lipids by bacterial metabolism, the presence of bacteriocins and other antibiotic-like bacterial secretions, and the low water content of the stratum corneum *(3,17,41,42)*. The pH value and osmotic conditions are less important *(21)*. Unless introduced into body tissue by trauma or in the presence of foreign bodies such as catheters or implants, the pathogenic potential of the resident flora is usually regarded as low *(43,44)*. Resident flora is difficult to remove by mechanical means. Washing hands with soap and water reduces the release of skin bacteria every 5 minutes by only 50% (5,*45,46,*47).

Transient Flora

Members of this group are characterized by their inability to multiply on the skin. They occur as skin contaminants. Among them, microorganisms with high pathogenic potential may also be found. Usually transient flora does not survive for very long, but sporadically multiply on the skin surface *(34)*. Besides the above-mentioned factor of colonization resistance, the inhospitable physicochemical environment may be another reason for the failure of transient flora to survive. Medical personnel, however, should never rely on this. In contrast to natural microbial skin flora, transient flora is easily removed by mechanical means such as hand washing. If hands are washed for 1 minute with soap and water, the reduction of bacterial release was measured to be two to three orders of magnitude (*48–53,*54). Even rubbing hands with water alone is effective *(52)*.

Infectious Flora

This group includes the etiologic agents of actual infections such as abscesses, panaritium, paronychia, and infected eczema on the hands. They are of proven pathogenicity.

S. aureus and β-hemolytic streptococci are the species most often encountered.

STRATEGIES OF HAND HYGIENE

Strategies for the prevention of hand-associated microbial transfer must take into consideration the fact that it is much easier to reduce the release of transient flora from the hands than that of resident flora and that, more than ever, infectious lesions must be healed before the hands may be regarded as safe. Therefore, the choice of preventive measures depends on which group of microbial flora is to be attacked. The precautions proposed in Table 91-1 are discussed below.

If microbial contamination is to be expected, the strategy is to *keep* hands clean, because this is much easier to do than to *make* them clean. If used intelligently, both the no-touch technique (use instruments rather than fingers) and protective gloves are suitable remedies against microbial transfer. This implies, of course, that instruments and gloves are changed after every patient. Although it was reported that transient bacteria were washed from gloves more easily than from hands *(49)* and that used gloves can be successfully cleaned of adhering microorganisms *(55,56)* and even of hepatitis B virus (HBV) antigen *(55)* by washing or disinfecting gloved hands for 30 to 120 seconds, this could not be confirmed by Doebbeling et al. *(57)* under conditions more appropriate to clinical practice with various treatments of only 10 seconds. The authors recultured the microorganisms used for artificial contamination not only from 4% to 100% of the gloves in counts between 0 and 4.7 log but also from the hands after the removal of the gloves *(57)*. They concluded that it may not be prudent to wash and reuse gloves between patients and that hand washing or disinfection should be strongly encouraged after removal of protective gloves *(57)*.

If hands are known to be or are suspected of being contaminated, the undesired transient microbial flora must be eliminated to render the hands safe for the next patient contact. This may be achieved by washing or disinfecting the hands. If, in contrast to an ordinary hand wash, a postcontamination treatment of hands involves the application of an antimicrobial preparation—either an antiseptic detergent (with water) or an antiseptic rub (without water)—it is termed "hygienic" ("hygienic hand wash" and "hygienic hand rub," respectively) in Europe to indicate that these measures aim only at the contaminating transient flora without consideration of the number and fate of the resident skin flora.

Recently, two excellent guidelines were published that delineate indications and details for hand hygiene (58,59). The WHO publication, in particular, offers an enormous amount of information with more than 1,100 references. Below, some additional perspectives are considered.

The decision of which of the above-mentioned measures to use in a particular situation depends on the probability that hands may have become contaminated with pathogens during a potential or known exposure. The higher the risk is, the more important it is to use a microbicidal postcontamination treatment that is effective and safe. In this context, "effective" means efficiently reducing the release of transients, and "safe" means that the treatment should not disseminate pathogens to be eliminated into the vicinity. It has been demonstrated that vigorous hand washing can disperse pathogenic microorganisms such as *Salmonella typhi* into the environment and onto the washing person *(60,61)*. Because hygienic hand rubs kill most transients still on the hands, rub-on techniques can avoid microbial dispersal and should therefore be used after every contagious contact, be it in the dissecting room, the microbiology laboratory, or in patient care, especially if the contact is to be ranked as "very dirty" on the Fulkerson scale *(62,63)* (Table 91-2) involving infected sites (ranks 13–15). Often, however, hygienic hand rubs are used not because of a specific indication but for purely practical reasons, such as availability and the simplicity of their application *(40)*. All other dirty contacts (ranks 8–12) may be followed by hand washing with unmedicated soap, but it should be realized that the complete procedure, including the journey to and from the washplace, makes an uneconomic use of time because it takes three to four times as long as a hygienic hand rub with an alcoholic solution delivered from a dispenser next to the patient's bed *(64)*. An additional advantage of the latter measure is that this method is less sensitive against poor performance

TABLE 91-1

Strategies for the Prevention of Microbial Transfer by Hands

Objective Situation	*Strategy*
To reduce the release of transient flora	*Keep hands clean (noncontamination)*
Hands are still clean	No-touch technique Gloves (protective)
Hands are contaminated	*Render hands clean (elimination of transients)*
After contacts without known or suspected "dangerous" contamination (Fulkerson scale 5–7)	Hand wash or Hygienic hand wash or Hygienic hand rub
After known or suspected contacts with patient secretions, excretions, blood, and infected sites (Fulkerson scale 8–15)	Hygienic hand rub
After working in a microbiology laboratory	Hygienic hand rub
To reduce or prevent the release of transient and resident flora	*Prevent microbial release*
Before surgical activity	Surgical hand disinfection and gloves (surgical)
Before patient care in protective isolation	Hygienic hand wash and gloves (sterile)
Colonization of hands with pathogens	*Treat the diseased skin* Chemotherapy (?) Antiseptic washings (?)
To avoid transmission of pathogens from infected lesions on the hands	*Refrain from activities involving infectious hazard* (e.g., surgery, handling foodstuffs and pharmaceuticals)

TABLE 91-2

Fulkerson Scale Ranking Contacts of Nursing Personnel from Clean to Dirty

Rank[a]	*Contact With*
1	Sterile or autoclaved materials
2	Thoroughly cleaned or washed materials
3	Materials not necessarily cleaned but free from patient contact (e.g., papers)
4	Objects contacted by patients either infrequently or not expected to be contaminated (e.g., patient furniture)
5	Objects intimately associated with patients but not known to be contaminated (e.g., patient gowns, linens, dishes, bedside rails)
6	Patient, but minimal and limited (e.g., shaking hands, taking pulse)
7	Objects in contact with patient secretions
8	Patient secretions or mouth, nose, genitoanal area, etc.
9	Materials contaminated by patient urine
10	Patient urine

[a]"Clean" activities, 1–7; "Dirty" activities, 8–15.
(Data from Fox MK, Langner SB, Wells RW. How good are hand washing practices? *Am J Nurs* 1974;74:1676–1678, and Larson E, Lusk E. Evaluating hand washing technique. *J Adv Nurs* 1985;10:547–552, with permission.)

of hand hygiene *(65)*. The necessary time expenditure may also be one of the reasons for poor compliance of healthcare workers with hand washing.

Hygienic hand washes with an antiseptic detergent are designed to rapidly wash off most of the transient flora by their mechanical detergent effect and to exert an additional microbicidal activity, with some agents accompanied by a sustained effect on the remaining hand flora. This latter effect may be useful in areas where microbiologically clean hands are desired during extended periods of time such as in protective isolation and in surgery, as well as in the food and pharmaceutical industries.

For these indications, hands play not only the role of a microbial vector, but they may also be an important source of undesired microorganisms multiplying in and being shed from the skin. The strategy to prevent this microflora from reaching sensitive areas such as surgical wounds, foodstuff, or pharmaceuticals is to reduce their release from the hands. This is best attained by using (sterile) gloves. Surgical hand disinfection can greatly reduce the release of transient and resident skin flora and is usually meant as an adjunct to surgical gloves in case they become punctured or torn. Scrubbing hands with unmedicated soap alone removes transient flora efficiently but has only a negligible effect on the resident skin bacteria (see below). For presurgical preparation of the surgeon's hands, prolonged scrubbing with unmedicated soap is, therefore, worth neither the effort nor the strain on the skin. Helpful recommendations for surgical hand scrubs have been provided by the Association of Operating Room Nurses (66), the new WHO guidelines (59), and most recently, by Widmer et al. (67).

Antiseptic hand washing may also be used therapeutically to clear carriers from pathogenic resident flora *(68)*.

Hands with infected purulent lesions are very dangerous sources of microbial flora with proven pathogenicity. Therefore, the only effective strategy is to prohibit any activity involving infectious risks such as engaging in surgery and other types of patient care or handling foodstuff and pharmaceuticals.

METHODS OF ELIMINATING MICROORGANISMS FROM THE HANDS

Mechanical and chemical methods for the reduction of microbial release from the hands are summarized in the following subsections.

Hand Washing

Although in German-speaking countries the term "hand washing" is exclusively reserved for the use of unmedicated soap and water (with or without a brush), in other parts of the world, it also implies the application of antiseptic soaps (disinfectant–detergents). In this chapter, the term is applied *sensu strictu* to washing hands with unmedicated detergent and water.

The objective of hand washing is to remove dirt (consisting of extraneous substances, sweat, skin lipids, epithelial debris, etc.) and loosely adhering microbial skin flora, which will include most of the transient but only a small part of the resident flora. In fields of application where the microbiologic aspect dominates, the aim is, of course, to reduce microbial release from hands to an extent that may be considered safe for the intended purpose. In the medical field, this purpose is usually to prevent hand-borne infection.

The efficacy of a hand wash depends on the time taken and the technique. Unfortunately, this period is usually rather (too?) short in normal hospital work. The average duration was reported by several authors to be between 8 and 20 seconds *(24,69,70)*. This period of time, however, does not include the additional time needed to approach and return from the washplace. Therefore, the complete process takes considerably longer. In fact, it has been measured to take 40 to 80 seconds *(64)*. Table 91-3 indicates how effectively the release of transient bacteria from artificially contaminated hands can be reduced by hand washing. The greatest reduction is achieved within the first 30 seconds; it ranges between 0.6 and 1.1 log after 15 seconds and between 1.8 and 2.8 log at the end of 30 seconds. Extending the washing time to 1 minute results in reductions of 2.7 to 3.0 log. A further prolongation of the procedure is not worth the effort, because after 2 minutes the reduction increases negligibly to only 3.3 log and after 4 minutes to only 3.7 log.

TABLE 91-3

Reduction of the Release of Test Bacteria from Artificially Contaminated Hands by Washing with Soap and Water

Duration	*Mean $\log_{10}$ Reduction*	*References*
15 s	0.6–1.1	*(71)*
30 s	1.8	*(50,75)*
	2.3–2.5	*(53)*
	2.5–2.8	*(48,49)*
1 min	2.7	*(49)*
	3.0	*(52,73)*
2 min	3.3	*(52)*
4 min	3.7	*(52)*

Although in most instances these reductions are probably sufficient to prevent infection-generating transmission of pathogens *(51,53,72,74–76)*, this is not always the case. Semmelweis, for instance, observed that normal hand washing did not always prevent the spread of fatal infection. Eleven parturient women died of puerperal fever after having been examined immediately after contact with a patient suffering from a foully discharging medullary carcinoma *(77)* by attendants who, in between, had washed their hands with only soap and water. After this experience, Semmelweis extended his order to disinfect hands in a solution of chlorinated lime from before entering the delivery or patient room to using it before each vaginal examination *(77–80)*. It is important to understand that some procedures of hand disinfection are significantly more efficient in reducing the bacterial release from hands than hand washing with soap and water.

Although highly sophisticated washrooms with fully automated functions have been shown to be even counterproductive rather than motivating healthcare personnel to adhere to hand washing rules *(81)*, certain requirements for washrooms must be fulfilled for minimal compliance. Wash basins should be conveniently located; no overflow or plug is necessary because hands should be washed only under running water. A mixer tap helps to provide water of comfortable temperature that, under the best conditions, is controlled thermostatically. Operating the water flow without using hands (elbow, knee, foot, sensor) may be desirable in certain critical areas. Suitable dispensers for soap, disinfectant (rub is better than detergent), hand lotion, and one-way towels are accepted requirements. There must also be a container furnished with a liner for used towels. If liquid soap is used, dispensers must either be easily removable and heat resistant for thermal reprocessing or they should be equipped with disposable bags. Liquid soap dispensed from refillable containers should be bacteriostatic to prevent microbial growth; topping of these containers is to be strictly prohibited.

An appropriate hand washing technique includes adjusting the water flow and the temperature (both activities can be accelerated by suitable technical devices), wetting hands, taking soap, rubbing hands to produce a lather without splashing, and performing wash movements that include rubbing palm to palm, rotational rubbing with clasped fingers of right hand in palm of left hand and vice versa, moving right palm over left dorsum and vice versa, palm to palm with fingers interlaced, backs of fingers to opposing palm with fingers interlocked, and rotational rubbing of right thumb clasped in left palm and vice versa. Each movement is to be repeated four times. This technique was proposed by Ayliffe et al. *(71)* as a standard technique when testing antiseptic hand washes. It could also represent a routine hand wash technique. Some authors demonstrated, however, that, after appropriate instruction, allowing each individual his or her own "responsible application" resulted in a better coverage of all hand surfaces *(82)*; and this is a prerequisite for a correct technique. Finally, hands are rinsed with fingertips up, and the water is cautiously shaken off. As concluded from the results of laboratory-based *in vivo* tests, the whole procedure should take not less than 30 seconds, a goal nearly impossible to attain during patient care. The subungual spaces harbor, by far, the main part of the bacterial hand flora *(83)*. The importance of this observation for the transmission of nosocomial infections by medical personnel is unknown, but Tanner et al. *(84)* found that, at least in presurgical hand preparation, nailbrushes and nail picks do not decrease bacterial numbers and are, therefore, unnecessary. After washing, the hands are dried with a disposable towel (paper or textile). Unless the water flow is discontinued by an automatic device, the water should be turned off by using the same towel rather than by the freshly washed hands *(73)*. The towel is then discarded into the appropriate container, and a hand lotion should be applied onto the hands. This latter step is extremely important to prevent chapping. Electric hand dryers are useless in hospitals because, with them, hand drying takes too long and because they lack the friction of towels to remove the remaining soap from the skin.

No matter how well and detailed hand washing techniques may be described, Larson and Kretzer *(85)* are probably right in suggesting that a subject of much greater concern is how to motivate personnel to wash their hands in the first place, because hand washing practices still remain suboptimal.

Hygienic Hand Rub

The objective of a hygienic hand rub is to reduce the release of transient pathogens with maximum efficacy and speed, so that hands can be rendered safe after known or suspected contamination. This should be done in a way that avoids microbial dispersal into the environment. A sustained effect is not required. The fate of the resident skin flora is disregarded in this procedure.

The technique of hygienic hand rubs includes rubbing small portions of 3 to 5 mL of a fast-acting antiseptic preparation onto both hands. This can be a very convenient way of treating hands after known or suspected contamination, because dispensers for hand rubs can easily be made available wherever necessary; for instance, they may be placed in the vicinity of every patient bed in high-risk areas. All areas of the hands must be covered by the disinfectant, but this is often not done *(70)*.

The antimicrobial spectrum necessary for hygienic hand rubs depends on the intended use. Commonly, the antimicrobial spectrum required includes only bacterial and fungal pathogens. Sporicidal activity is, if at all, only

needed in certain situations such as in *Clostridium difficile* outbreaks. But there are hardly any chemicals that are sufficiently strong and fast acting as well as skin-tolerable at the same time, so the mechanical action of a hand wash is usually used for spore reduction. "Hand washing with soap and water showed the greatest efficacy in removing *C. difficile* and should be performed preferentially over the use of alcohol-based hand rubs when contact with this pathogen is suspected or likely," concluded Oughton et al. *(86)* from the results of their laboratory-based experiments with artificially contaminated hands of volunteers. However, as the usually encountered nosocomial pathogens can still be around, it is recommended to first use an alcohol-based hand rub before washing hands. Activity against mycobacteria is required only at certain places such as in tuberculosis hospitals, wards for acquired immunodeficiency syndrome patients, and in pathology and microbiology laboratories. The antituberculous effect must be proven and stated on the label. Virucidal activity is not a general requirement and is only justified in special situations. Furthermore, it should only be claimed if the (proven) antiviral spectrum of a product also includes enteroviruses such as polio or hepatitis A virus together with an acceptable exposure time.

There is only a small range of possible agents for hand rubs, such as alcohols in high concentration, used alone or mixed with other antiseptics; aqueous solutions containing halogens such as chlorine or iodine; chlorhexidine; quaternary ammonium compounds; phenolics; triclosan; aldehydes; metallo-organic compounds; and oxidizing agents such as peracetic acid. Except for the alcohols, aqueous solutions of chlorine, povidone–iodine, and chlorhexidine, the other agents are usually used solely as adjuncts to alcohols (quaternary ammonium and ampholytic compounds, phenolics); are contained in antiseptic detergents (phenol derivatives, povidone–iodine, chlorhexidine, triclosan); or are not used at all because of poor efficacy, allergenicity, irritant or toxic potential, or ecologic considerations (aldehydes, metallo-organic, and peracetic acid). There is no doubt that alcohols are much more comfortable to rub onto the skin than aqueous solutions because of specific features such as excellent spreading and quick evaporation.

Table 91-4 summarizes examples of results from evaluations of commonly used active agents for their antibacterial efficacy, which was assessed in standardized tests simulating practical conditions on artificially contaminated hands of volunteers (*9,45,52,*54*,71,72,87,98,102–109*). As demonstrated, the alcohols *n*-propanol, isopropanol, and ethanol, and the halogen releasers sodium tosylchloramide and povidone–iodine appear superior to aqueous solutions of chlorhexidine diacetate, chlorocresol, and hydrogen peroxide. Among the results with the alcohols, there is a clear positive association between the extent of bacterial reduction and the concentration used. If mean log reductions obtained with the three alcohols are compared with each other at equal concentrations, *n*-propanol is the most effective and ethanol is the least effective alcohol. The efficacy of aqueous solutions of sodium tosylchloramide and povidone–iodine compares well with that of isopropanol at a concentration of 60% v/v.

Tuberculocidal activity has been demonstrated for the alcohols mentioned *(88–90,92,93,99)*, although with prolonged exposure *(89)*. Several recommendations suggest disinfection times of 1 to 5 minutes with 70% ethanol, 60% to 70% isopropanol, or 50% to 70% *n*-propanol *(87, 91,94)*. The halogen-based preparations are also regarded as active *(60,94)*.

The virucidal activity of alcohols is generally good with enveloped viruses *(54,95,96)*, including the human immunodeficiency virus (HIV). An exception is the rabies virus, which is reported to be ethanol-resistant *(97)*. Naked viruses, such as enteroviruses, are inactivated only by high concentrations of alcohols *(100)*, the most effective of which is reported to be ethanol *(96,101)*. Laboratory *in vivo* tests have shown that the effectiveness of alcohols against some difficult viruses such as entero- and rotavirus is significantly better than that of hand washing with unmedicated soap (*101,110–118*). Absolute ethanol reduced, for instance, the viral release from the hands by 3.2 log, 80% ethanol (v/v) by 2.2 log, and absolute *n*-propanol by 2.4 log (*110*). In contrast, individual hand washing for 10 to 55 seconds caused a reduction of only 1 log. Testing a commercial preparation containing a high-alcohol concentration, Schürmann and Eggers *(100)* concluded that this rub was effective against enteroviruses only under favorable environmental conditions such as high temperature, large disinfectant-to-virus volume ratio, and low protein load. In another study, the reduction in the release of human rotavirus strains from the hands by 70% (v/v) ethanol or isopropanol was approximately 100 times that of the reduction attainable with tap water or liquid soap *(111)*. A reduction of >3 log by a 60% ethanol preparation was demonstrated *in vivo* with the nonenveloped rota-, adeno-, and rhinoviruses *(112)*. Over the last several years, another nonenveloped virus, the norovirus (the former Norwalk-like virus), belonging to the family of caliciviruses, has been recognized as an important cause for epidemic and sporadic food-, water-, and airborne diarrheal disease. As, at present, the human norovirus cannot be grown in cell culture systems, related animal noroviruses have been and are used as surrogate viruses to evaluate the virucidal efficacy of antiseptic agents, especially alcohols. In fingertip experiments according to ASTM International E-1838-96 *(113)*, Gehrke et al. *(114)* found that a 70% (v/v) concentration of each of three tested alcohol species was more effective than their 90% counterpart. Ethanol turned out to be the most efficacious, followed by 1-propanol and 2-propanol, with the respective viral reductions being 3.78, 3.58, and 2.15 log.

In other fingerpad experiments, a combination of ethanol with 10% 1-propanol, 5.9% 1,2-propandiol, 5.7% 1,3-butandiol, and 0.7% phosphoric acid proved active at a much lower concentration of 55% against polio type 1 with a log reduction of 3.04 within 30 seconds, whereas with 2-propanol only 1.32 log were achieved. Within the same exposure time, feline calicivirus was reduced by 2.8 log *(115)*. (In quantitative suspension tests, with and without protein load, this formula reduced infectivity titers of seven enveloped and four nonenveloped viruses by $>10^3$ log within 30 seconds. Only ethanol at a concentration as high as 95% exerted a comparable activity.) Similarly, in another *in vivo* study using the then-amended fingerpad test method E 1838-02 of ASTM International *(119)*, it was also a combination of ethanol 70% (v/v), in this case, with polyquaternium-37 and citric acid that succeeded in

reducing the release of murine norovirus, which is nowadays regarded as a more relevant surrogate virus *(116)*, by 2.84 log within 30 seconds as compared to only 0.91 log achieved with pure ethanol 75% v/v *(117)*. (When tested in suspension, this test product reduced the infectivity of the nonenveloped viruses: human rotavirus, polio type 1, feline calicivirus, and murine norovirus by >3 log after a 30-second exposure.)

For years, HBV was thought to be extremely resistant to the action of chemical disinfectants. Dried or liquid human plasma containing high-titer HBV, however, did not cause hepatitis if the sera were treated before inoculation into susceptible chimpanzees with 70% isopropanol for 10 minutes, 80% ethanol for 2 minutes, 0.1% glutaraldehyde for 5 minutes, povidone–iodine with 0.8% available iodine for 10 minutes, or hypochlorite solution with 500 mg/L free chlorine for 10 minutes, whereas the control animals receiving untreated plasma developed the disease *(120,121)*. In another test system—the so-called morphology alteration and disintegration test—the HBV appeared significantly altered and disintegrated after exposure to 82% ethanol *(122)*. Ethanol was reported active against HBV at a concentration as low as 70% when in combination with agents such as hexachlorophene, quaternary ammonium compounds, octenidine, biphenylol, or hydrogen peroxide *(121–125)*.

Hepatitis C virus is likely to be inactivated by concentrations of 60% to 70% ethanol *(126)*.

As is evident from the above, alcoholic rubs are very well suited for hygienic hand disinfection, because their antimicrobial performance is excellent and fast, thus saving time; no wash basin is necessary for their use, and they can be positioned next to any patient bed; furthermore, their application does not cause microbial contamination of nurses' uniforms. However, one must bear in mind that the antimicrobial efficacy of alcohols is very sensitive to dilution with water and is, therefore, vulnerable to inactivation, especially with the small volumes of 3 to 6 mL, which, for hygienic hand rubs, are distributed all over both hands. If, for instance, 60% (v/v) isopropanol is rubbed onto wet hands in two portions, each of 3 mL, for 30 seconds, the mean log bacterial reduction achieved was measured to be 3.7, as opposed to 4.3 with dry hands *(107,127)*. Although being not as comfortable, an aqueous solution of povidone–iodine may be used as an alternative hand rub, if necessary, for any reason.

Mainly in North America, there is now a trend toward gel formulations. Comparative tests between liquid and gel formulations of alcohol-based hand rubs revealed, however, that the bactericidal efficacy of gels is significantly lower than that of rinses. Kramer et al. *(128)* compared the efficacy of 10 commercial gels and four rinses using the test method of the European standard EN 1500. No single gel met the requirements within 30 seconds of application, whereas all rinses did. From a report by Kampf et al. (129), it appears, however, that gels with a very high alcohol content can meet the requirement of EN 1500. A new gel containing 85% (by weight) ethanol proved to be bactericidal in suspension (when tested according to prEN 12054) and on volunteers' hands (EN 1500). Furthermore, in suspension tests, the gel was shown to be fungicidal (EN 1275), tuberculocidal (test according to the German Society of Hygiene and Microbiology with *Mycobacterium terrae* as a surrogate test bacterium for *Mycobacterium tuberculosis*), and virucidal (defined as a ≥4 log reduction, within different exposure times) for orthopox and herpes simplex 1 and 2 viruses (15 seconds); rotavirus and HIV (30 seconds); and adeno- (2 minutes), polio- (3 minutes), and papovavirus (15 minutes).

Also, in a prospective clinical trial, where immediately before and after direct contact with a patient pre- and postcontaminations were assessed, it was demonstrated that, on the hands of healthcare workers, equally good respective bacterial reductions of 1.28 and 1.29 log were achieved with both a rinse and a gel—the former containing a mixture of a high concentration of *n*-propanol (30% w/w) and isopropanol (45% w/w), the latter containing 85% (w/w) ethanol—whereas with another gel containing a mixture of 53% (w/w) ethanol plus 17% (w/w) isopropanol, a significantly inferior reduction of 0.51 log was seen *(130)*.

Despite the high alcohol concentration, the user acceptability was described as excellent, although it was even better with the gels. Owing to the ease of its performance, the hygienic hand rub not only offers the advantage of being fast and efficacious but also has the potential to improve the compliance of healthcare givers with hand hygiene.

For hygienic hand rubs, only a few clinical correlates with results from disinfectant testing exist. In one controlled study trying to relate the use of alcoholic rubs to infection rates *(131)*, isopropanol was used in a way that cannot be regarded as a real hygienic hand rub, namely, with average volumes of 0.9 mL per application, which is much too small to cover the surface of both hands and to remain there long enough to exert bactericidal effects. The study demonstrates, however, that a hygienic hand wash with chlorhexidine detergent, which was also tested, is clinically more effective than an individual hand wash with soap and water, which was followed by rubbing a bit of alcohol onto the hands; the study also demonstrated that, despite a preceding intensive education program, it seems very difficult to persuade and motivate medical personnel to observe the simplest rules for the most efficient procedure in the prevention of healthcare-associated infections.

Because hand rubs have a high antimicrobial potential, they can also be used in situations where direct contact with dangerous pathogens has occurred, such as after spillage in the microbiology laboratory or after touching infectious lesions. A high-level requirement for efficacy is, therefore, justified. With this perspective, a requirement for the performance of a reference hand rub was formulated by the Austrian and German Microbiological Societies *(132,133)* and, finally, by the European Committee for Standardization (134), choosing among the best-acting rubs available. From these, 60% (v/v) isopropanol was taken arbitrarily as an active agent to be used in two portions, each of 3 mL, during a total disinfection period of 60 seconds. The requirement of EN 1500 is that the reduction of transient flora assessed with a product for hand rubs shall not be significantly inferior to that with the reference rub, when tested in parallel, with the same volunteers, on the same day, in a crossover fashion.

Hygienic Hand Wash

The objective of the hygienic hand wash with antiseptic soaps is to reduce the release of transient flora by a washing procedure of significantly stronger efficacy than that of an ordinary hand wash with unmedicated soap. Even if the effect on the resident flora is usually disregarded in most indications, a residual effect may be desirable in some areas, such as in protective isolation, during hospital outbreaks *(69,71)*, and for handling foodstuffs as well as pharmaceutical preparations. The technique is similar to that of a normal hand wash but is performed according to the instructions of the manufacturer. As with the hygienic hand rub, the antimicrobial spectrum required depends on the area of intended use. But, in general, an antituberculous or antiviral activity is not necessarily expected from these antiseptics.

Active agents most often used in detergent preparations are iodophors, chlorhexidine gluconate, triclosan, biphenylol, and chloroxylenol. Hexachlorophene is not used anymore because of its neurotoxic activity *(135–137)* after transdermal absorption *(135,137)* and its poor activity against gram-negative bacteria *(49,52,138,139)*. Amphotensides and quaternary ammonium compounds are better suited to act as adjuncts to alcohols than to being used as active agents alone, because they are easily neutralized by anionic detergents and—at least quaternary ammonium compounds—by protein and hard water.

Table 91-5 summarizes examples of results on general antibacterial efficacy as assessed by the test method of the

European standard EN 1499 (54,140). It can be seen that among five antiseptic detergents tested concomitantly, only povidone–iodine liquid soap would have met the pass criterion to be significantly more efficacious than unmedicated soap. The activity of chlorhexidine gluconate detergent was stronger than that of soft soap, although not quite significantly, at least in this test (54). It is important to note that the hygienic hand rub with 60% isopropanol, tested concomitantly as a control in the same experiment, caused a significantly stronger bacterial reduction (4.0 log) than any of the tested hand washes (54). These results compare well with those of Ayliffe et al. *(71)*, who found that alcohol-based preparations, particularly *n*-propanol and isopropanol, were the most effective, followed by chlorhexidine and povidone–iodine detergent preparations, all of which were significantly more effective than nonmedicated soap. However, triclosan-containing soaps were no more effective than nonmedicated soap. In these experiments, the chlorhexidine detergent was found to be significantly more effective than the povidone–iodine preparation.

These results demonstrate clearly that compared with other methods of postcontamination hand treatment, alcoholic hand *rubs* are, at present, the most effective measure to quickly reduce the release of transient microbial flora from the hands. Consequently, it may be inferred that alcohol-treated hands are less likely to transfer bacteria than washed hands. Indeed, this has been shown by Ehrenkranz and Alfonso *(141)*, who demonstrated that after contact with heavily colonized patient groins, hand washing failed to prevent the transfer of aerobic gram-negative bacilli by healthcare workers' hands to urinary catheters in 11 of 12 experiments; after hand treatment with 70% (v/v) isopropanol, however, bacteria were transferred in only 2 of 12 experiments. Furthermore, soap failed to stop subsequent colonization in each of the 12 experiments, whereas alcohol failed in only five. The authors concluded that soap was generally ineffective in preventing hand transfer of gram-negative bacilli to catheters after contact with a heavy contamination source, whereas alcohol was generally effective.

In another clinical trial, it was shown that measures of hand hygiene prior to the insertion of peripheral venous catheters significantly influenced the relative risk of infectious complications, in that local reddening, swelling, pain, purulence, or fever of unknown origin occurred in only 51% or 61% of cases when gloves were worn or hands were rubbed with an alcoholic rinse, respectively, as compared to washing hands with plain soap or no hand hygiene at all *(142)*.

Unfortunately, definitions for the requirements of the efficacy of procedures for both hand rub and hand wash can hardly be based on sound epidemiologic data. Besides Semmelweis' experience that soap and water was not sufficient for some situations *(77,79)*, only a few more or less well-controlled field trials relate the use of certain hand washing procedures to the infection ratio *(143–145)*. Even if one or another detail in these studies may be criticized, they all indicate that the use of disinfectants results in a reduced infection frequency as compared with the use of unmedicated soap or with no hand washing. If this is translated into terms of disinfectant testing, which is easier to do *(71,127)*, one might be tempted to speculate that disinfectant–detergents, exerting an antimicrobial effect similar to that of chlorhexidine detergent or better, may have the potential to reduce the frequency of healthcare infections more efficiently than ordinary soap. With this in mind, the European Committee for Standardization has decided that, as a pass criterion for the hygienic hand wash, the bacterial reduction assessed in a test simulating practical conditions shall be significantly greater than that obtained with unmedicated soap. This shall be tested in parallel with the same volunteers, on the same day, and in a crossover design (140).

Surgical Hand Disinfection

The objective of surgical hand disinfection is to reduce the release of skin bacteria from the hands of the surgical team for the duration of an operation in case the surgical glove is punctured or torn. The intention is, thus, to bring down the amount of bioburden in the glove juice as much as possible to keep the inoculum at and in the surgical wound below the threshold for induction of infection. The infectious dose varies, however, and is unknown in the individual case, because it depends not only on the kind and virulence of bacteria entering the surgical site but also on the effectiveness of the host's defense mechanisms. These mechanisms, however, can be impaired by circumstances determined by the type of surgery (such as implantation of foreign bodies), by the need to operate on patients with an impaired immune system, or by the failure to completely remove necrotic tissue.

Although at least one outbreak of surgical site infections was reported when an antiseptic scrub was replaced by unmedicated soap (146), in contrast to hygienic hand disinfection, rub, or wash, surgical hand disinfection has never been proven in a controlled study to be necessary or clinically effective. Nevertheless, it is justified, because it is an integral part of the concept of aseptic surgery, the value of which can be regarded as having been proved by Lister's findings. Indeed, indirect evidence for the necessity

of a further precaution in addition to the surgical glove can be drawn from results compiled by Cruse and Foord *(147)*, who reported for clean surgical sites an infection ratio of 1.7% if gloves remained intact but of 5.7% for operations where gloves were punctured. To keep the bacterial load low on the skin of gloved hands is therefore an important goal. Because latex gloves are vulnerable, they cannot be relied on. Hoborn *(148)* reported in a study on glove perforation that 38% of all gloves used by the surgical team in orthopedic surgery were perforated. The following details are of interest: left-hand gloves were more often perforated (47%) than right-hand gloves (29%). The surgeons' gloves were most often damaged (53%), followed by those of the operating nurse (41%) and the assistant (19%). The index finger of the left hand was the most endangered site (29%), followed by the palm (24%). The left index finger was involved in 43% of all specifically surgeon-associated perforations. In soft tissue surgery, glove punctures were found at a significantly lower frequency. The overall ratio was 16%; left-hand gloves were involved in 22% and right-hand ones in 11%. The sequence of persons was the same as above: surgeon, 28%; operating nurse, 16%; assistant, 4%.

These data confirm those reported earlier by Furuhashi and Miyamae *(149)*. A later study by Palmer and Rickett *(150)* arrived at similar conclusions.

Recently, the incidence of microperforations in surgical gloves has been investigated *(151)* by employing the "watertight test" described in the European norm EN 455, part 1 *(151)*. Wearing gloves for 90 minutes or less resulted in microperforations in 15.4%, whereas wearing them for 91 to 150 minutes showed results in 18.1% and again in 23.7% if gloves were worn for longer. There were no significant differences in the frequency of microperforations between the surgeons', the first assistants', or the surgical nurses' gloves (23%, 19%, and 20.5%, respectively). Sixty-seven percent were found on the left (nondominant) hand glove, predominantly on the left index finger (32.3%). Concluding from these results, the authors recommended that the above-mentioned members of the surgical team change gloves regularly after 90 minutes of surgery *(151)*.

In another study *(152)*, this problem was investigated in a clinical setting where double-gloving was used during septic laparatomies. To measure bacterial passage through punctures to the outside of the inner glove, a modified Gaschen-bag method was used for sampling. For distinguishing bacteria coming from the surgical site as opposed to those coming through perforations of the outer glove, intraoperative swabs were taken. Depending on the duration of glove wear, the maximum proportion of perforated outer gloves was 15%. Approximately 82% of these perforations remained unnoticed by the surgical team. A proportion of 86% occurred in the nondominant hand glove, with the index finger punctured in 36%. Bacterial passage from the surgical site onto the outside of the inner glove was detected in 4.7% of the gloves. Here, too, the authors recommended changing gloves every 90 minutes *(152)*.

The bacterial leakage through pinholes in gloves has been experimentally found to range between 10^3 and 10^4 CFU *(147,148)*. In contrast, when hands were disinfected before donning gloves, the bacterial counts from leaking gloves did not exceed 100 CFU *(149)*. In fact, clinical indications show a causal link between hand preparation of the surgical team and the incidence of surgical site infections (146).

Although the aim of surgical hand disinfection is to render hands microbiologically clean with as little microbial release as possible, the antimicrobial spectrum need not include tuberculocidal, fungicidal, or virucidal activity, because pathogens belonging to these groups of microorganisms do not usually cause surgical site infections. Bacterial spores can only be mechanically removed by scrubbing hands—a procedure that should be carried out regularly before the first operation on a day. Surgical antiseptics must be active against the resident flora and against bacteria that are associated with surgical site infection.

With regard to antimicrobial effects, an *immediate* effect must be distinguished from *sustained, cumulative*, and *persistent* effects *(153)*, the occurrence of which depends also on the frequency and regularity of contacts with the antiseptic, as follows:

- The *immediate* effect immediately follows the antiseptic procedure.
- After a single contact, the *sustained* effect is defined as short-term antimicrobial activity retarding bacterial regrowth, maintaining the viable count, or even further reducing the bioburden under the glove.
- After multiple contacts, the *cumulative* effect is a microbial reduction that increases with every application of the antiseptic.
- With regular contacts, the *persistent* effect is a progressive reduction of skin flora during a longer period. This is, for instance, demonstrable after several days of regular application *(154)*.

As at the time of the first operation after the weekend or after a vacation, the surgeon's hands should be as safe as after several days' use of an antiseptic, neither cumulative nor persistent effects are really advantageous. Furthermore, in the interest of colonization resistance, it is not desirable to completely eliminate the resident skin flora by multiple or regular use of a highly active antiseptic. Admittedly, to attain this would be very difficult, anyway. In contrast, a sustained effect may be desirable to keep the bacterial numbers low under the glove during an operation, especially if preparations with only moderate immediate effect are used for surgical hand antisepsis. Because most operations are completed within 3 hours and because during long-lasting operations gloves should be changed anyway, 3 hours may be a reasonable time span to check on this feature when testing the efficacy of products.

Because the technique of surgical hand disinfection is of considerable influence on the release of skin flora, it is described here in detail. Useful guidelines for the surgical hand scrub have been published by the Association of Operating Room Nurses (66) and, most recently, in the WHO guidelines (59) and by Widmer et al. (67). On entering the operating suite, hands should first be treated as if they were contaminated, and transients should be removed with a social hand wash or, preferably, with an alcoholic hand rub. Then, the subungual spaces should be cleaned with soft wooden sticks, because most bacterial flora resides under the nails *(83)*. Long-lasting wash procedures with unmedicated soap and scrubbing are counterproductive, because they cause skin damage without significantly

reducing the release of resident skin bacteria (5,*45,46,*47). In fact, a preceding treatment with soap may even hamper the effect of an alcohol treatment *(155–157)*. For this reason, clean hands should not be washed before applying an alcohol-based rub excepting the first presurgical hand preparation of the day. A soft brush should be used only to brush nails and subungual spaces but not the skin as this may cause damage. Sterile disposable sponges may also be used. Fingertips should always point upward, with elbows down, to avoid recontamination of clean fingers and hands by water running down from contaminated proximal areas. If hands were (pre)washed, drying them is of great importance if an alcohol rub is to be used subsequently to avoid its dilution. In this case, the towels—paper or textile—need not be sterile but clean.

There are two principal techniques of surgical hand disinfection, both of which have advantages and drawbacks. If performed with a suitable antiseptic such as one containing an alcohol at high concentration, the *surgical hand rub* is very efficient in reducing the skin flora and, after antisepsis, hands need only be air-dried. It lacks, however, the cleaning function of a *surgical hand scrub*. This, in turn, requires hand drying and is much less efficient (see below).

The *surgical hand rub* is performed by pouring a small volume (~3 mL) of a suitable antiseptic, usually an alcohol preparation, into the cupped dry hands, rubbing it onto the entire surface of hands and forearms, keeping them wet for the scheduled time by adding further portions as necessary, and carrying out wash movements. Usually, total volumes of 9 to 12 mL are needed for a 3-minute period. However, the applied volume is not important as long as hands are kept wet during the scheduled duration of application *(158)*. All other techniques, such as bathing hands in a bowl with an antiseptic solution, are either wasteful and create an increased risk of skin damage and fire hazard or their antimicrobial effect is poor as with alcohol wipes and sprays. In contrast, smoothly brushing an alcoholic preparation into the subungual spaces increases the effect considerably *(156)*. Alcohol-wet hands should not be gloved but air-dried before donning gloves to avoid skin damage. During and between operations, surgical rubs can easily be performed after removal of gloves.

The *surgical scrub* is performed with antiseptic detergents according to the instructions of the manufacturer. Drying hands with fresh one-way towels or sterile drapes is usually necessary before donning surgical gloves.

A combined two-phase technique that includes a surgical hand wash followed by a surgical hand rub may also be used. If the antimicrobial agents are properly chosen, hands may be cleaned with an antiseptic detergent without reducing the antimicrobial efficacy of the subsequent hand rub, as is the case when an alcohol-based rub immediately follows a hand wash with unmedicated soap *(157,159)*. In contrast, a hand rub should never be followed by a hand wash, because this has been shown to considerably lessen the effect of the rub (*160,*161,162,*163–174*).

The duration of any preoperative treatment of the surgical team's hands should be kept as short as possible but as long as necessary to attain the goal of keeping the bioburden in the glove low. From the literature and from results of our own laboratory-based experiments with volunteers according to EN 12791, which has been found to be workable and the results of which are reproducible (161), it can be shown that the antimicrobial effectiveness of both surgical hand rub and scrub is significantly associated with the duration of the procedure (Tables 91-6 and 91-7). In a recent *in vivo* study, the immediate effects of 1-, 3-, or 5-minute hand rubs with *n*-propanol 60% (v/v) were found to result in respective bacterial reductions of 1.0, 2.0, and 2.3 log. With isopropanol 70% (v/v), they amounted to 0.7, 1.5, and 2.1 log, respectively. This trend was highly significant ($p < .001$). The same was true for the 3-hour effects when gloves had been worn for 3 hours (162).

A duration of 3 minutes for presurgical hand antisepsis is common nowadays, but with highly effective alcohol-based products, 1.5 minutes are effective, as demonstrated in laboratory-based *in vivo* experiments *(163–166)*.

Also, in a clinical setting, it could be shown that application of a highly efficacious alcohol-based product during 1.5 minutes was sufficiently active, which confirms the above-mentioned experimental data *(167)*.

As a rule, when choosing surgical hand antiseptics, one should never rely on results from suspension tests as they differ greatly from those obtained from *in vivo* trials *(168)*.

There is only a limited list of possible agents that can be used for the surgical hand rub. An indication of their antimicrobial efficacy is shown in Table 91-6, in which results obtained by comparable test methods are compiled from the literature. A clear association of the bacterial reduction with the nature and concentration of the antiseptic and with the duration of application can be seen (*45*,46,47,*51,* 91,*106,156,159–160*, 161,162,*165,166,169–174,176,179*). Similar data have been produced also by more recent studies *(177,178)*. As with the hygienic hand rub, *n*-propanol is the most active of the agents listed, followed by isopropanol, ethanol, povidone–iodine solution, and peracetic acid. An aqueous solution of chlorhexidine gluconate alone exerts only a mediocre immediate effect but is the only agent listed with a definite sustained activity *(154)*. In combination with alcohol (in this case), ethanol 61% w/w, however, the results are considerably more favorable *(177,178)*; although in one study *(177)*, the magnitude of an immediate reduction of 2.5 log within approximately 2.0 to 2.5 minutes raises the suspicion of incomplete neutralization of the chlorhexidine gluconate adjunct (Table 91-6). (It is important to realize that insufficient neutralization can result in false-positive efficacy assessment (181)). The immediate effect of an aqueous povidone–iodine solution compares well with that of 60% (v/v) isopropanol. Among the list of hand antiseptics, peracetic acid must be disregarded for toxicological reasons.

As with products for hygienic hand disinfection, the preparation of hand antiseptics in the form of gels is a new trend. And indeed, one gel containing 85% (w/w) ethanol was found to pass the strict requirement of EN 12791 (129).

The efficacy of frequently used antiseptic detergents is shown in Table 91-7 and compared with that of unmedicated soap (*45,46,*47,*106,149,153,170,176,182–186*). Here again, the association between bacterial reduction and duration of hand wash can be seen, although it is not as strong as that seen with the rubs. Unmedicated soap, used for 5 minutes, has only a poor immediate effect and no sustained effect, whereas povidone–iodine liquid soap causes a significantly stronger immediate reduction but also remains

without noticeable sustained action. The immediate effect of a chlorhexidine gluconate (4%) detergent was found to be comparable to that of the former, but the tested product demonstrated prolonged activity.

In another study mentioned above *(177)*, an initial (first day) preoperative scrub resulted in an unusually high immediate bacterial reduction of 1.6 log and a first-day 3-hour effect of 1.8 log, raising the suspicion of an incomplete neutralization (Table 91-7).

For toxicological reasons, hexachlorophene should no longer be used for surgical hand wash. In contrast to the immediate effect, which is similar to that of unmedicated soap, it possesses strong sustained activity. Quaternary ammonium compounds such as benzethonium chloride,

benzalkonium chloride, and cetrimide share comparable activity among each other. They are usually not used alone but, like chlorhexidine gluconate, are frequently added as supplements to alcohol rubs for synergistic and sustained effects that are, for instance, clearly demonstrable for chlorhexidine-alcohol preparations (Table 91-6). Triclosan shows some sustained activity, but even with five consecutive scrubs, each of 3 minutes, the bacterial reductions reported are rather disappointing *(185)*.

From the above results, it is evident that the antimicrobial efficacy of all antiseptic detergents currently available on the European market is significantly inferior to that of alcohol rubs or povidone–iodine aqueous solution. This is also depicted in Figure 91-2, which contains results that, except for hexachlorophene, were obtained by the same test method (*187*; updated 1993). From there, it can be seen that highly concentrated short-chain aliphatic alcohols, such as iso- and *n*-propanol, are up to 100 times more effective in reducing the release of skin bacteria. With this strong immediate effect, the question arises whether a sustained action, which is not demonstrable for alcohols, is needed and desired, as after such an extensive reduction, regrowth of the resident skin flora takes several hours for complete restoration (Fig. 91-2) *(188)*.

The consecutive use of a detergent and isopropanol, both containing chlorhexidine, results in a significant increase in effectiveness compared with unmedicated soap and alcohol (Table 91-8) *(149,159)*.

To develop a standard for the efficacy of surgical hand disinfection is difficult because epidemiologic information on the effectiveness of various procedures on the ratio of surgical site infections is not available. Therefore, it has been decided arbitrarily by the expert authorities in some European countries *(133,189)* to choose a reference

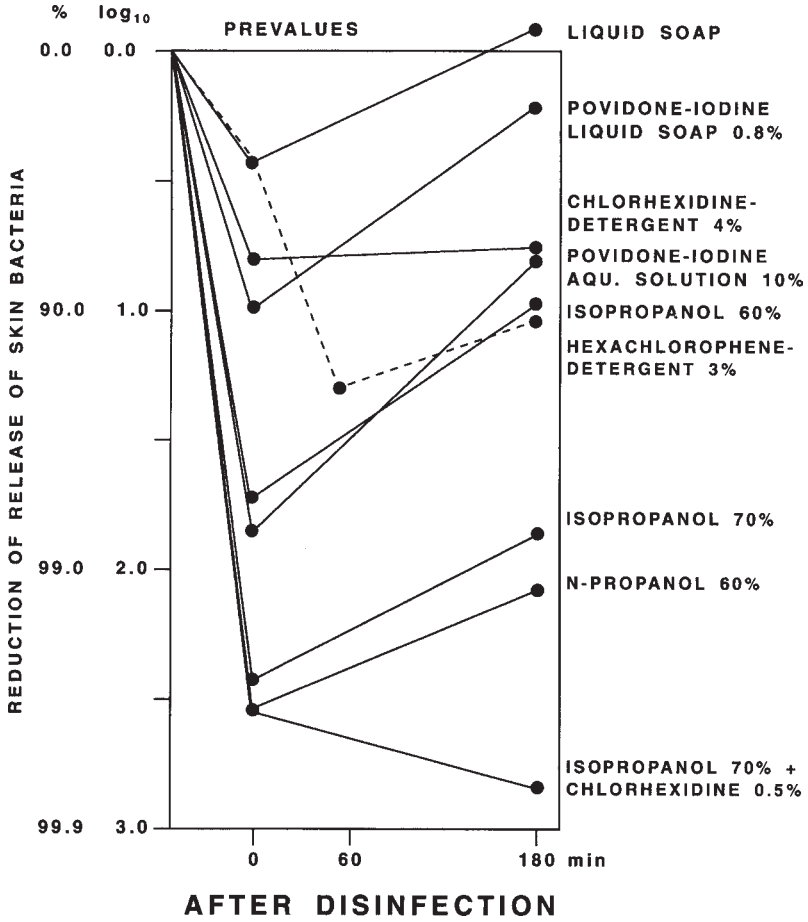

FIGURE 91-2 Killing curves showing the efficacy of various antiseptics for surgical hand disinfection (187; updated 1993) as assessed by the test model of the Austrian *(132)* and German *(133)* Societies for Hygiene and Microbiology and (for hexachlorophene, 4 minutes) according to the results of Michaud et al. *(153)*.

procedure for efficacy that ensures maximum reduction of skin flora at tolerable levels of skin strain and time expenditure. Efficacy, thus, is defined not by a numerically fixed measure of microbial reduction but by the mean reduction achieved by a reference disinfection procedure that is tested in parallel with a product to be evaluated with the same volunteers in two experiments that are carried out in a crossover design. Each volunteer acts as his or her own control. The requirement is then that the mean bacterial reduction assessed with the procedure under evaluation shall not be significantly inferior to that of the reference. This procedure involves rubbing and keeping hands wet with 60% (v/v) *n*-propanol (for details, see ref. *190*). For the European standard EN 12791 on surgical hand disinfection (180), a disinfection period of 3 minutes was chosen. With a well-trained team, the mean reduction in bacterial release will reach a magnitude of up to 2.9 log (Table 91-6). It is, however, unknown whether *in vivo* laboratory test results correlate with the ratio of surgical site infections. The results of one study comparing the clinical effect of a 75% alcoholic rub with that of surgical scrubs with either povidone–iodine or chlorhexidine (4%) gluconate detergents throw some doubts on this assumption: Although the bacterial reduction of skin flora achievable with the alcoholic rub was significantly superior to that assessed with the two scrubs, the clinical outcome of clean and clean–contaminated operations was virtually the same *(191)*. However, more data will have to be generated before a final conclusion will be possible.

COMPLIANCE WITH HAND HYGIENE

Compliance and Clinical Effectiveness of Hand Hygiene

As Elaine Larson *(192)* stressed more than a decade ago, even the most effective antiseptic procedure for removal of transient microbial flora from the hands is futile if it is ignored. Thus, compliance with the rules of hand hygiene is equally important for preventing the transmission of pathogens via hands and, by this, reducing the risk for the emergence of healthcare-associated infection.

By changing behavioral patterns of the staff and by creating an organizational climate in which hand hygiene was a definite goal, Larson et al. *(192)* succeeded, as a positive example, to reduce the incidence of infections due to methicillin-resistant *S. aureus* (MRSA) and vancomycin-resistant enterococci by considerably improving compliance to hand hygiene in two critical-care units of the intervention hospital as compared with the situation in comparable units of a control hospital.

In a similar attempt to promote hand hygiene by implementing a program with emphasis on alcohol-based hand rubs, Pittet et al. (193) improved the compliance of the

TABLE 91-8

staff from 48% to 66% within 3 years. As a consequence, the overall ratio of healthcare-associated infections decreased from 16.9% to 9.9%. Also, the transmission frequency of MRSA decreased from 2.16 to 0.93 episodes per 10,000 patient days.

Likewise, in five wards of a rehabilitation hospital, Girou et al. observed a strong negative association of the degree of hand hygiene compliance and MRSA prevalence *(194)*.

In another study, it was found that the carrier rate of rifampicin-resistant MRSA, being as high as 38.4 patients per 1,000 occupied beds—thought to result from bad hand hygiene practices—dropped to an average monthly rate of MRSA acquisition of 3.2 patients per 1,000 occupied beds during the period from October 2004 to October 2005. This was thought to be the consequence of implementing several hygiene measure interventions including the empowerment of the nurse at the bedside to be the patient's advocate *(195)*.

To cite another example of the beneficial effects of hand hygiene, in a neonatal unit, a three-phase intervention–observation study was conducted, comprising a multifaceted education program with hand hygiene compliance assessed during successive observational surveys and prospective monitoring of healthcare-associated infections. Across three study phases, the overall compliance improved from 42% to 55%, accompanied by an increase in hand rub consumption from 66.6 to 89.2 L per 1,000 patient days. This improved adherence to hand hygiene was independently associated with a reduction of the infection ratio among very low weight neonates from 15.5% over 10.7% to 8.8% per 1,000 patient days *(196)*.

Although the association of compliance with hand hygiene and infection ratio seems logical, the correlation is not that simple for various reasons: interventions to reduce the frequency of healthcare-associated infections are usually multimodal; hence, it is often difficult to ascribe a desired clinical effect to one measure alone, as, for instance, in the case of improving compliance *(197)*. Besides the degree of adherence to hand hygiene, other factors are equally important, such as the infection susceptibility of the patients, the number of potentially "dangerous" contacts (with respect to the transmission of pathogens), the effectiveness of a hand hygiene measure (with respect to its microbicidal efficacy and the quality of performance), the degree of nurse cohorting (number of patients one nurse has to care for), and the number of potential transmission pathways. The interaction of these factors has intelligently been laid down in a mathematical model by Austin et al. and by Beggs et al. *(198,199)*.

Considering these factors, it is not surprising that some authors have had the experience that compliance with hand hygiene is not necessarily associated with detectable changes in the incidence of healthcare-associated infection for whatever reasons *(69,200)*.

Monitoring the frequency of transmission episodes of nosocomial pathogens and the frequency of healthcare-associated infections in five ICUs, Eckmanns et al. *(201)* also found no correlation between the incidence of transmission episodes and hand hygiene compliance (as well as hand rub consumption). However, they noted that, in their study, the infection ratio was a relatively good indicator for the identification of pathogen transmission.

In a concise review, Allegranzi and Pittet *(202)* have recently summarized the most relevant studies assessing the impact of hand hygiene promotion on healthcare-associated infections and came to the conclusion that multimodal intervention strategies lead to improved hand hygiene and to a reduction in nosocomial infection; however, this could not be demonstrated in some studies.

Motives and Attitudes for Compliance

To understand motives and attitudes and to identify reasons for poor compliance, many studies have been carried out since the early 1980s. They were summarized by Pittet and Boyce *(203)*. An analysis of their own data by Pittet et al. (204) revealed that the average compliance was found to range below 50%, although it varied greatly. Doctors were less compliant than nurses, and the following risk factors for poor compliance were found: being a doctor (odds ratio [OR] 2.8 vs. nurse) or a nursing assistant (OR 1.3 vs. nurse), working during the week (OR 1.7 vs. weekend), activities with high-risk of cross-contamination (OR 1.8 vs. low risk), working in ICU (OR 2.0 vs. internal medicine units), and high intensity of patient care (OR up to 2.1 vs. low intensity).

In a study to elucidate behavioral determinants of hand washing among nurses, Whitby and McLaws *(205)* undertook an investigation, employing in focus-group

discussions supported by professional market researchers a semistructured interview technique and a questionnaire to explore attitudes, beliefs, and practices on hand washing. Responses from 754 nurses were analyzed by backward linear regression for hand washing intention. The authors reasoned that hand washing results in two behavioral practices, which they called "inherent" and "elective" hand washing. The former is an emotional driver and occurs when healthcare workers perceive themselves as "at risk" and cleanse their hands for self-protection, usually with water. The latter is acquired by education and is significantly predicted by nurses' belief in the benefits of hand hygiene, by peer pressure of seniors, and by role modeling but only to a minimal extent by the reduction in effort in changing from hand washing to a hand rub routine without having to use water. Therefore, the authors believe that the introduction of hand rubs alone without an accompanying behavioral modification program is unlikely to induce a sustained increase in hand hygiene compliance.

Another study, also based on structured interviews with nurses, physicians, medical residents, and medical students in five hospitals, led to the conclusion that beliefs about self-protection are the main reasons for performing hand hygiene and that a lack of positive role models and social norms may hinder compliance with hand hygiene *(206)*.

The importance of role models with respect to hand hygiene has also been found by others to be a significant factor for compliance, whereas increasing the number of hand-washing sinks, as a sole measure, had no positive effect in a newly built hospital *(207)*.

To quantify the behavioral determinants of healthcare workers' motivation to comply with hand hygiene, a cross-sectional study in a university hospital with a long history of hand hygiene campaigning revealed that perceptions that nosocomial infections are severe for the patients, that hand hygiene is effective at infection prevention, that pressure from superiors and from colleagues is important, and that hand hygiene is easy to perform was rated higher for motivation than reasoning about the impact of hand hygiene on patient safety *(208)*.

Other means of improving adherence with hand hygiene have been proposed, such as patient information and empowerment *(209)* or utilizing social marketing methods *(210)*. Also, certain logistic methods for planning hand hygiene campaigns have been proposed *(211)*.

ACCEPTABILITY OF HAND WASHING AND HAND DISINFECTION

To ensure compliance with hand washing rules, detergents and antiseptic preparations must be acceptable to the user *(212)*. Healthcare personnel often complain about dry skin, skin irritation, or even frank symptoms of acute irritant contact dermatitis, which increase the risk of colonization with potential pathogens from the hospital environment *(23,213)*. Therefore, suitable preparations should have minimal toxicity of any kind, including allergenic and irritant properties. However, only a few chemicals meet this requirement to an acceptable degree.

Frequent application of alcohol preparations may cause skin drying and, in some persons, irritant dermatitis *(175)*. Defatting of the skin is sometimes suspected as one of the possible reasons (47), but this seems more likely to occur with detergents that remove skin lipids, whereas evaporating alcohols leave dissolved fats behind. On the whole, skin dryness from frequent alcohol application is usually mild and may be easily prevented by the addition of suitable emollients to alcohol-based hand antiseptics. In a study evaluating the effect of emollients in alcohol-based hand rubs, even after extensive usage, a blinded dermatologist had difficulty identifying differences in the condition of hands treated with *n*-propanol with or without emollients *(175)*. Contrary to a general opinion in countries where alcohols are not much used for hand disinfection, they have been found well acceptable to healthcare personnel with less drying than, for instance, chlorhexidine-containing detergents *(177,178,191,203,214–217)*. Common mistakes in the use of alcohol-based hand rubs have been identified in applying them onto preirritated skin and washing hands before hand antisepsis *(218)*. Short-chain aliphatic alcohols are very rarely allergenic.

In contrast, it seems that many detergent antiseptics possess a certain allergenic potential. But reports on the acceptability of the various agents are contradictory, depending probably on the composition of the product with regard to emollients *(23,71)*. This may signify that variables other than the antiseptic agents may be involved in reported adverse reactions.

For chlorhexidine gluconate, the allergenic potential seems proven *(219)*. Reports on adverse reactions after application of chlorhexidine-containing preparations, however, do not always permit conclusions to be drawn as to whether they were the consequence of true allergies or other reactions *(220)*. In an ethanol-based preparation, it proved significantly more acceptable than in a detergent-based product *(215)*.

Povidone–iodine- and triclosan-containing products were judged differently, depending on the individual preparation *(23,71,221)*; therefore, a general judgment does not seem possible. In one report, the acceptability of triclosan detergents was comparable with that of soap and of a chlorhexidine detergent and better than that of ethanol and povidone–iodine liquid soap; the latter was considered especially harsh (47). In another report among 14 products, a triclosan preparation was noticed to be especially harsh, whereas two other triclosan detergents did not cause noticeable skin damage *(71)*.

Chloroxylenol is a proven allergen. The incidence of allergic reactions has been reported by the North American Contact Dermatitis group to be around 1% *(23)*.

A list of potentially allergenic agents used as hand antiseptics was published by Lautier et al. *(222)* in 1978. It contains relevant agents and indices for primary inflammation and surface irritancy according to dermatologic criteria.

Absorption of alcohols during frequent hand antisepsis with alcohol-based formulations also needs to be dealt with. With a view to the conditions in practice, there are two routes by which absorption can occur: dermal and pulmonary. A study by Turner et al. assessing blood alcohol levels in 10 healthy volunteers before and after applying an isopropanol-containing hand rub onto their hands every 10 minutes over a 4-hour period revealed that, after the final application, concentrations within a range of 0.5 to 1.8 mg/L

(corresponding to 0.0005–0.0018%) were measurable. From these results, the authors concluded that they had proved transdermal absorption (although they had not reported any preventive measures against pulmonary absorption, which, without protecting the breathable air, must inevitably have occurred!). These blood levels seem rather low, although it was reasoned that a 4-hour test is much shorter than a nurse's shift, so in real life under similar conditions, higher concentrations could accumulate *(223)*.

In a more recent study, the total dermal and pulmonary absorption of ethanol after excessive hand disinfection was studied by Kramer et al. (224). Twelve volunteers applied three hand rubs containing 95%, 85%, or 55% ethanol onto their hands. For hygienic hand disinfection, 4 mL were used 20 times for 30 seconds each time with a pause of 1 minute between applications. The highest median blood levels amounted to 20.95 mg/L, 11.45 mg/L, and 6.90 mg/L (equaling 0.02%, 0.011%, and 0.007%), respectively. The highest median acetaldehyde concentration was 0.57 mg/L after 30 minutes. For surgical hand antisepsis, 20 mL of each hand rub was applied to hands and forearms 10 times for 3 minutes each time with a break of 5 minutes between applications. The highest median of ethanol blood levels for the three products were 17.50 mg/L, 30.10 mg/L, and 8.80 mg/L, respectively (equaling 0.017%, 0.029%, and 0.008%). The highest median acetaldehyde level was assessed to be 3.99 mg/L. The dermal and pulmonary absorption of ethanol was rated to be below toxic levels in humans, and it was concluded that the use of the evaluated ethanol-based hand rubs is safe (224).

AGENTS USED FOR DISINFECTION OF HANDS

This section summarizes the agents most often used for hand disinfection. Hexachlorophene is not included, because it is no longer an accepted ingredient of hand and skin antiseptics.

Alcohols

Only short-chain aliphatic alcohols that are completely miscible with water are used as the main carriers of antimicrobial activity in hand rubs. These are ethanol and iso- and *n*-propanol. Although it is also a member of this group, methanol is seldom used. Low concentrations of higher alcohols such as butanol and aromatic alcohols such as benzylalcohol are sometimes contained in alcoholic preparations as synergistic supplements.

The antimicrobial effect of alcohols is based on protein denaturation. Alcohols have excellent, and the most rapid, bactericidal and fungicidal activity of all agents used in hand disinfection. They also possess good mycobactericidal activity. Enveloped viruses, including HIV, are readily inactivated, with rabies virus being the only exception. Inactivation of naked viruses such as picornavirus takes longer and requires higher concentrations (from 80% v/v upward), as does HBV. Dry bacterial spores may survive in alcohols for long periods of time *(225)*. Alcohols evaporate quickly from the skin and do not have a sustained activity. Because of their extraordinarily high bactericidal activity, including good activity against the resident skin flora, the latter property may, in fact, be needed only in surgical antisepsis or in special situations such as in protective isolation. After a 3- to 5-minute exposure to high concentrations of iso- or *n*-propanol, it takes the resident flora several hours to regrow to the original level (Fig. 91-2).

As shown in Tables 91-4 and 91-5, the bactericidal activity decreases in the order *n*-propanol > isopropanol > ethanol. From the available data *(226,227)*, it appears that identical bactericidal activity can be expected on the skin at the following concentrations (v/v): 42% *n*-propanol = 60% isopropanol = 77% ethanol. Methanol is infrequently used because of its toxicity and because of its relatively poor activity *(227)*.

The addition of some chemicals may increase the immediate effect of alcohols significantly and/or provide a sustained effect. With a supplement of 1% (v/v) hydrogen peroxide, the activity of ethanol was, for instance, increased by 0.26 log *(228)*, and with lower concentrations, the alcohol may even become sporicidal during storage *(229)*. This feature is used in the two WHO formulations, which contain final concentrations of 0.125% hydrogen peroxide (59). A combination with 1% to 2% iodine is classic and known as "iodine tincture." It must, however, be removed from the skin after drying because of possible skin irritation *(154)*. With low concentrations of iodophors as a supplement, no noticeable improvement was seen *(45)*. Additions of chlorhexidine, quaternary ammonium compounds, ampholytic and phenolic compounds, triclosan, and octenidine serve mainly to furnish the alcohol with sustained activity *(102)*. Organic matter slightly diminishes the antimicrobial activity of alcohols *(87)*. With blood, a bacterial reduction of 3.6 log resulting from a short-time rub (30 seconds) was diminished by 0.1 to 0.4 log, and after a longer rub (60 seconds), one of 3.8 to 4.4 log was diminished by 0.2 to 0.7 log *(228)*.

Short-chain alcohols are flammable. Because there exist strict fire regulations in most countries, which require special storage conditions for liquids with a flash point <21°C (easily flammable), it may be wise to shift the flash point of alcohol-based formulas above this critical temperature. Products such as these are categorized as "flammable," can be stored in larger volumes and at less stringent conditions, and meet these safety requirements at the following (or lower) concentrations (v/v), which have been assessed according to EN 22719: ethanol ≤68%, isopropanol ≤70%, and *n*-propanol ≤82%. Mixtures of ethanol or isopropanol with the latter alcohol increase both the flash point and the antimicrobial efficacy.

In the fields of application discussed above, alcohols are nontoxic; they also lack allergenic potential. Skin drying and irritant skin reactions may be avoided by adding suitable emollients such as glycerol, volatile silicone oils, refatting agents, and probably most importantly, rehydrating agents.

Iodophors

The use of elemental iodine as (alcoholic) tincture of iodine or as an aqueous solution of potassium iodine (Lugol's solution) has, nowadays, been replaced by preparations containing complexed iodine, usually with polyvinylpyrrolidone, polyether glycols, or polyoxyethanol derivatives, for better acceptability. The main mechanism of

microbicidal activity is based on the oxidizing potential of iodine. It is important to note that the strongest antimicrobial effect occurs with dilute rather than concentrated iodophor solutions *(230,231)*, the latter of which have sometimes been found to harbor live bacteria *(232)*. As can be noted from Tables 91-4, 91-5, and 91-6, an aqueous solution of povidone–iodine, the most commonly used iodophor, is approximately as effective in reducing skin flora as 60% (v/v) isopropanol, but preparations in liquid soap are much less active.

The antimicrobial spectrum of iodine preparations is wide, even including bacterial spores *(233)*. But in hand disinfection, this latter activity is too slow to be useful *(49,234)*. There are, however, important gaps in the spectrum, especially with enteroviruses *(235)*. If at all present, a claimed sustained effect is small and only short-lived (91,*236*). Organic matter reduces antimicrobial activity slightly *(231)*, but blood may abolish the antimicrobial effect altogether *(228,237)*. One gram of hemoglobin can inactivate 58 mg of iodine *(238)*. Unless special precautions are taken, the antimicrobial efficacy of povidone–iodine preparations wanes during storage *(231)*.

Because iodine is absorbed through the intact skin of neonates and across mucous membranes, the use of iodine-containing preparations may be associated with undesired side effects such as hypothyroidism and allergic reactions. But this is seldom a problem with iodophors in the field of application discussed here. In contrast, skin irritation and damage occur rather often, and may thus, adversely influence compliance with hand disinfection (47,*239*). However, acceptability may vary with the type of preparation and brand.

Chlorhexidine

Chemically, chlorhexidine is a cationic bisbiguanide compound. Its most commonly used water-soluble form is the digluconate salt, but the acetate and hydrochloride have also been used *(240,241)*, and hydrochloride is used in a powder preparation. There are aqueous and alcoholic solutions and detergent preparations. Chlorhexidine is incompatible with some nonionogenic chemicals, such as Tween 80, and with some anions, such as soap, phosphates, and nitrates. Some protein-containing solutions such as pus, blood, serum, or milk interfere slightly with the antimicrobial effect, which is best at pH 8 *(240,241)*. Chlorhexidine exerts its antimicrobial activity by increasing the permeability of the microbial cell, causing disruption of the cytoplasmic membrane and precipitation of the cellular contents. The antimicrobial spectrum is broad. There are, however, gaps that should be known. The activity against gram-positive is better than the activity against gram-negative bacteria and against fungi; activity against mycobacteria is poor. Chlorhexidine has no sporicidal activity. It is effective against lipophilic viruses *(242)* but hardly active against nonenveloped viruses such as entero-, rota-, and adenoviruses (58).

The immediate antibacterial activity is definitely slower than that of alcohols (91), but the residual effect of chlorhexidine, which is based on the strong affinity for surfaces, is regarded as being probably the best of any antiseptic available *(242,243)*. This feature has been and is still being used in surgical hand antisepsis to extend the antimicrobial activity of alcohols on the gloved hand (Table 91-6 and Fig. 91-2) and is thought to build up an antimicrobial layer when used permanently *(159)*. However, the question was raised whether this sustained effect is real or originates only from methodical difficulties in neutralizing its bacteriostatic activity in the various test models *(244)*. In a clinical study, the rate of central catheter–associated infections was significantly reduced by preparation and regular care of the site at the catheter entrance with chlorhexidine as compared with alcohol alone or povidone–iodine treatment *(245)*. When chlorhexidine was used for routine hygienic hand washes in ICUs as opposed to hand washing with unmedicated soap, a reduction of hospital infections was observed *(131,143–145,246)*.

Except for ototoxicity when instilled into the middle ear *(247)*, chlorhexidine is regarded as a safe antiseptic, even when used regularly on the skin of newborn infants *(248,249)*. There is no indication of absorption through the adult skin *(249,250)*, but low levels (up to 460 mg/L) were found in venous blood specimens of babies bathed with a chlorhexidine-containing detergent at the age of a few days *(251)*. Potential toxicity, however, was rated low *(252)*. Skin irritation is usually regarded as low *(233)* but not always *(220)*.

Triclosan

This trichlorinated dioxydiphenylether (Irgasan DP-300) is poorly soluble in water but dissolves well in alcohols and various detergents, such as anionic soaps. It is incompatible with lecithin and some nonionogenic detergents such as Tween 80 *(253)*. It probably acts on the cytoplasmic membrane of the microbial cell. Except for *Pseudomonas aeruginosa,* the antibacterial spectrum is broad, mainly bacteriostatic, with minimal inhibitory concentrations between 0.1 and 10 mg/L but with minimal bactericidal concentrations of 25 to 500 mg/L at 10 minutes of exposure *(253)*. Acceptable mycobactericidal activity has been reported *(219)*. Fungistatic (10 mg/L) and fungicidal (25 mg/L per 10 minutes) activities toward *Candida* species are good *(254)* but poor against molds such as *Aspergillus* species (minimal inhibitory concentration 100 mg/L). Triclosan is contained in detergents (0.4–2%); in alcohols (0.2–0.5%) used for hygienic and surgical hand or preoperative skin disinfection; and in many cosmetic products such as soaps, toothpaste, and deodorants. Compared with alcohols and even iodophors and chlorhexidine, its immediate effect is slow but more rapid than that of hexachlorophene. Although not as strong as that of chlorhexidine gluconate *(255)*, there is a definite sustained effect (Table 91-7) that is minimally affected by organic matter or blood *(256)*. There is no indication in the literature that triclosan has a toxic, allergenic, mutagenic, or carcinogenic potential for humans, although it is very toxic for aquatic organisms. Acceptability of use on the hands was rated differently.

Phenol Derivatives

Only a short synopsis is given here inasmuch as phenol derivatives are less used today than in past decades because of ecologic concerns.

2-Phenylphenol (2-Biphenylol, 2-Hydroxybiphenyl, 2-Phenyol) This agent is similar to chlorocresol and is incompatible with nonionogenic detergents, quaternary ammonium compounds, and proteins. It has a broad

antimicrobial spectrum, including mycobacteria, fungi, and viruses such as adenovirus, herpes, and influenza but not enteroviruses; in combination with propanols and detergents, 2-phenylphenol is active against HBV. Fields of application include hygienic hand wash (2%), skin antisepsis (0.2%), and preservation of cosmetics *(253)*. Rotter and Koller (54) did not observe activity significantly different from that of unmedicated soap when used for 1-minute hand washes. A sustained antimicrobial effect has been reported *(253)*. In appropriate concentration, it is well tolerated and nontoxic for humans.

Chlorocresol (4-Chloro-3-Methylphenol) This agent is poorly soluble (0.4%) in water but dissolves well in alcohols. It is incompatible with nonionogenic detergents and quaternary ammonium compounds. Chlorocresol is usually used in combination with other phenol derivatives in alcohols or soap for hygienic hand disinfection. It is a weak allergen, has low toxicity in appropriate concentrations, and is well tolerated *(253)*.

Chloroxylenol (Para-Chloro-Meta-Xylenol) This agent is similar to chlorocresol but has slightly better antimicrobial activity due to enzyme inactivation and cell wall alteration. It has a broad antimicrobial spectrum, including mycobacteria and some viruses (e.g., vaccinia). The bactericidal effect is less than that noted for chlorhexidine and iodophors *(257,258)*. It exerts some sustained effect. Organic matter has little impact on its effectiveness. It is used for hygienic hand washes in concentrations of 0.5% to 1%. The highest allowable concentration as a preservative in cosmetics in European countries of the Common Market is 0.5%, but in toilet and deodorant soaps, it may be used at a concentration of 2% *(238)*. It is less toxic than chlorocresol and has been documented to be a mild allergen.

Quaternary Ammonium Compounds

Common properties of this group of agents, which include benzalkonium chloride, benzethonium chloride, cetrimide, and cetylpyridinium chloride *(253)*, are as follows: They are mainly bacteriostatic and fungistatic, as well as microbicidal, but only at high concentrations, especially against gram-negative bacteria (*P. aeruginosa*); they have no activity against mycobacteria but are active against some viruses, especially in combination with alcohols (lipophilic viruses, rabies); they are incompatible with anionic detergents and have reduced effectiveness in the presence of organic matter and ion-rich water. Nowadays, these compounds are seldom used alone for skin and hand disinfection but are rather used in combination with other antiseptics, such as alcohols, to confer on them a sustained effect. Quaternary ammonium compounds have low allergenic and toxicity potentials, but these undesired effects are usually 3 to 10 times more frequent than observed with the substituted phenol derivatives discussed above *(253)*.

CHAPTER 92

Education of Healthcare Workers in the Prevention of Healthcare-Associated Infections

Karen K. Hoffmann and Eva P. Clontz

In the healthcare setting, ongoing education is required for several reasons. First, all healthcare providers need to participate in ongoing education to remain abreast of the scientific innovations in the field of infection control. Second, technological innovation demands learning new skills. Examples include the increasing use of computers in managing and analyzing healthcare-associated infection surveillance data and the increasing use of molecular epidemiology to evaluate healthcare-associated outbreaks. Third, regulatory bodies (e.g., Occupational Safety and Health Administration [OSHA] and The Joint Commission) require that workers receive ongoing training in a variety of areas depending on their job duties. Such training includes instruction on isolation techniques, aseptic practices, prevention of blood and body fluid exposure, and proper handling of hazardous chemicals.

The results of the national certification examination job analysis survey, administered to infection preventionists (IPs) between 1982 and 2010 by the Certification Board of Infection Control and Epidemiology (CBIC), consistently identified the task of education as one of the major areas of responsibility for IPs *(1)*. The 2010 analysis includes tasks in education and research (Table 92-1) *(2)*.

This chapter discusses education of healthcare personnel and patients/patient caregivers for the prevention of healthcare-associated infections and reviews educational requirements mandated by government and licensing agencies and research findings regarding education about specific areas in infection control. The chapter also includes a brief introduction to human factors engineering (HFE), learning theory, and the educational program planning process.

Practice competencies for infection prevention and control education were identified by a Delphi panel of experts in 2008. The final matrix of competencies may be a first step toward the development of a framework for standardized infection prevention education and training materials for hospital-based healthcare workers. The next step will be using the matrix to determine the validity of training materials (Table 92-2) *(3)*.

INFECTION CONTROL EDUCATION FOR HEALTHCARE WORKERS

Regulatory Educational Standards

The Joint Commission expects that new employees will receive orientation that covers the organization's infection control program and the individual's role in the prevention of infection. Another suggested activity is that continuing education be part of a problem-oriented or outbreak response. When infection rates are not reduced by the feedback of surveillance rates alone, The Joint Commission suggests using innovative educational approaches beyond the routine or standard in-services. Another expectation is for at least yearly education and training of all personnel to maintain or improve knowledge and skills based on findings from infection control activities such as healthcare-associated infection rates or outbreak investigations *(4)*.

The OSHA Occupational Exposure to Bloodborne Pathogens: Final Rule requires appropriate training for employees who are reasonably anticipated to come into contact with blood or other potentially infectious materials in the performance of their job duties. The standard mandates training initially upon an employee's assignment and annually thereafter *(5)*. The OSHA Compliance Directive CPL 2.106 Enforcement Procedures and Scheduling for Occupational Exposure to Tuberculosis (TB) requires worker training and information to ensure appropriate recognition and isolation of TB-infected patients *(6)*. Specific training elements must be included for each of these standards. Training records for blood-borne pathogens must be maintained for 3 years and must include dates, contents of the training program or a summary, the trainer's name and qualification, and names and job titles of all persons attending the sessions *(5)*.

Educational Offerings Designed for Infection Preventionists

Formal education specifically designed for the training of healthcare professionals in infection control began with a

TABLE 92-1

Association for Professionals in Infection Control and Epidemiology (APIC) Major Educational Tasks Cited by Infection Control Professionals

Education and Research

Education

1. Assess needs, develop goals and measurable objectives, and prepare lesson plans for educational offerings
2. Apply principles of adult learning to educational strategies and delivery of educational sessions
3. Prepare, present, or coordinate educational workshops, lectures, discussion, or one-on-one instruction on a variety of infection prevention and control topics
4. Evaluate the effectiveness of education and learner outcomes (e.g., behavior modification and compliance rate)
5. Instruct patients, families, and other visitors about methods to prevent and control infections

Research

1. Apply critical reading skills to evaluate research findings
2. Incorporate research findings into practice through education and consultation

(From Fabrey LJ. *A practice analysis of the infection preventionist: executive summary*. Applied Measurement Professionals, Inc. and CBIC. Milwaukee, WI, 2010.)

course offered by the Centers for Disease Control and Prevention (CDC) in 1968 *(7)*. This course plus additional training courses were offered by the CDC for many years but were discontinued in 1988 *(8)*. In 1989, the Association for Professionals in Infection Control and Epidemiology (APIC) assumed responsibility for offering training courses for infection control, and education remains the organization's top priority *(9)*. In addition to APIC, sponsors of infection control conferences, webinars, and workshops include APIC chapters in states and regions and specialized training programs, such as at the University of North Carolina at Chapel Hill. Graduate education in infection prevention was limited to master's degree programs in public health and nursing until 2010 when the Health Resources and Services Administration funded the Infection Prevention and Environmental Safety track within the Doctor of Nursing Practice Program at Loyola University Chicago Marcella Niehoff School of Nursing. The Study on the Efficacy of Nosocomial Infection Control Project findings emphasized the need for physician training in infection control. In response, the Society for Healthcare Epidemiology of America and the CDC provide a training course in healthcare epidemiology for physicians *(10)*.

TABLE 92-2

Infection Prevention and Control Competencies

- Basic microbiology: Describe the role of microorganisms in disease
- Modes/mechanisms of infection/disease transmission: Describe how microorganisms are transmitted in healthcare settings
- Standard and transmission-based precautions: Demonstrate standard and transmission-based precautions for patient contact in healthcare settings
- Occupational health: Describe occupational health practices that protect the healthcare worker from acquiring infection
- Patient safety: Describe occupational health practices that prevent the healthcare worker from transmitting infection to a patient
- Emergency preparedness: Define the importance of healthcare preparedness for natural or man-made infectious disease disasters

(From Carrico et al. Infection prevention and control competencies for hospital-based health care personnel. *Am J Infect Control* 2008; 36:691—701.)

A survey by the National APIC Education Committee investigated the use of outdated infection control practices or rituals. Outdated practices were more likely to be used by persons who were not certified by the CBIC and who worked in long-term–care facilities or in smaller hospitals rather than larger hospitals. However, certified respondents were no more likely than noncertified respondents to be interested in changing any rituals (11).

The CBIC administers the process for Certification in Infection Control (CIC). APIC founded CBIC in 1981, and the first examination was administered in 1983. CBIC is a voluntary, autonomous, multidisciplinary board that provides direction for professionals in infection control and applied epidemiology. The principal purpose of CBIC is to provide public protection by providing and measuring a standard of knowledge desirable for practicing professionals, to encourage professional growth and individual study, and to recognize individuals who fulfill the requirements for certification. Eligibility requirements include a current license or registration as a medical technologist, physician, or registered nurse, or a minimum of a baccalaureate degree. To use the designation CIC, the professional must meet the eligibility requirements and pass an examination. To maintain certification, professionals must recertify every 5 years *(12)*. In 1999, The Joint Commission required that individuals who oversee infection control activities be "qualified in infection control practices through education, training, experience, or certification" *(13)*. As The Joint Commission standards change, it continues to require specific education (Table 92-3).

APIC provides numerous educational resources, most importantly the curriculum manual, *APIC Text of Infection Control and Epidemiology*, and *Certification Study Guide*, continuously updated online. In addition, webinars, toolkits, and prevention guides are available.

Infection control education begins in college programs for healthcare workers; however, this subject is inadequately presented before clinical experience. Instruction in microbiology (the basis for understanding transmission of infectious diseases) is not required in many schools of nursing, and when infection control material is presented, it is frequently presented by someone lacking the expertise of an IP *(14)*. Education of house officers on infection control is determined by individual training programs.

TABLE 92-3

The Joint Commission Accreditation Program—Education

Hospital National Patient Safety Goals, Effective July 1, 2010—NPSG.07.05.01 Elements of Performance

- Educate staff and licensed independent practitioners involved in surgical procedures about surgical site infections and the importance of prevention. Education occurs upon hire, annually thereafter, and when involvement in surgical procedures is added to an individual's responsibilities
- Educate patients, and their families as needed, who are undergoing a surgical procedure and surgical site infection prevention

HR Standards, Effective January 1, 2009

- HR.01.04.01—EP1: The hospital determines the key safety content of orientation provided to staff. Note: key safety content may include specific processes and procedures related to the provision of care, the environment of care, and infection control
- HR.01.05.03—EP1: Staff participate in ongoing education and training to maintain or increase their competency. Staff participation is documented

(From The Joint Commission, http://www.jointcommission.org.)

Survey responses from 158 of 381 (41%) internal residency programs in the United States showed that 79% of survey respondents relegate infection prevention to a general lecture for all new employees. Seventy-seven percent dedicated a lecture on infection control to new house staff. Only 34% reported using an online module for infection prevention education. Infection prevention training is not an integral part of medical education and thus does not translate into daily clinical practice activities. A standardized curriculum for ongoing infection prevention education should be developed (15).

Although manufacturers are not routinely classified as sources of educational programs for healthcare professionals, they provide information in marketing their products. Such information must always be critically examined as to whether it is reliable and supported by scientific evidence. Manufacturers also provide training for use of their equipment, provide grants to support lectures, and produce products designed specifically for educational purposes such as videotapes and slides. These materials should be carefully evaluated for completeness of information and evidence of objectivity.

Targeted Infection Control Education

Standard Precautions Misinformation and confusion about the transmission of blood-borne pathogens have given impetus to infection control education. Studies of human immunodeficiency virus/hepatitis B virus blood-borne pathogens have emphasized the difficulty of changing behaviors and have shown that knowledge does not necessarily translate into changed behaviors. Several studies have recognized that the desired outcome has not been achieved through in-service educational programs that provide the standard information on risk behavior and ways to reduce that risk *(16–18)*. A 5-year study found a decrease in the number of needlesticks through a combination of more convenient placement of needle disposal containers, communication, and education, but this study did not single out effectiveness of education *(19)*. A variety of interventions, tested on personnel in an emergency department, improved compliance with universal precautions, including making gloves and eyewear more accessible, signage reminders, and hands-on training *(20,21)*.

Tavolacci et al. (22) tested medical and nursing students' knowledge. Medical students' scores were highest in knowledge of hand hygiene and Standard Precautions and worst scores were in knowledge of healthcare-associated infections. To increase compliance, students must learn essential behaviors in medical school. Sax et al.'s *(23)* study showed that specific training for all individuals increases adherence to standard and isolation precautions. Specialized training must be received before healthcare students undertake any patient procedure involving sharps devices. Elliott et al.'s *(24)* studies of medical students showed that training and increased awareness of sharp injuries resulted in a significant reduction in needlestick injuries.

Hand Hygiene Compliance Larson et al.'s (25) study of 40 US hospitals before and after the publication of the CDC Hand Hygiene Guideline included site visits and surveys to measure healthcare-associated infection rates 1 year before and 1 year after the publication of the CDC guidelines. Site visits used direct observation of hand hygiene compliance and determined if facilities changed policies and procedures in compliance with guideline recommendations. Results showed that 90% of 1,359 staff members surveyed anonymously reported that they were familiar with the guideline but 44% of hospitals found no evidence of multidisciplinary programs to improve compliance, and hand hygiene rates remained low at 56.6% compliance. Rates of central line-associated bloodstream infections were significantly lowered in hospitals with higher rates of hand hygiene ($p > .001$), and there was no reported impact on other healthcare-associated infection rates (25).

A lack of compliance with the CDC hand hygiene standards has plagued infection control efforts using traditional strategies for education. In a longitudinal study of hospital workers, it was found that, despite a comprehensive educational and promotional campaign, hand washing frequencies returned to precampaign levels in 6 months. The authors concluded that a lack of motivation (failure to change attitudes), rather than a lack of education, was the most important cause of poor compliance *(26)*. Similarly, Larson and Killien *(27)* found that current methods of focusing on the benefits of hand washing with a public relations approach (i.e., signs, lectures, or posters describing the importance of hand washing) missed the significant reasons given for infrequent handwashing, such as being too busy. Two sequential studies of intensive care unit (ICU) personnel found that education alone did not have a sustained effect, but that maintaining education and providing feedback on hand washing performance were critical to having a continuing effect on motivation *(28,29)*.

A 2006 multihospital study found that a lack of IP time to implement hand hygiene educational tools, even when

provided a multimodal prepackaged educational tool by CDC, was the primary barrier (30). Significant improvement in hand hygiene was observed when senior healthcare workers were present and when educational promotion and feedback were made available (31).

A hospital-wide education program demonstrated that adherence to hand hygiene recommendations improved significantly (48–66%). The program involved using posters and other visual displays that promoted the use of bedside hand rubs. The posters featured messages submitted by healthcare workers that were then graphically illustrated in cartoons. The creativity of this program may be one reason for its success, giving recognition and ownership to local healthcare workers (32).

An evaluation of a patient-empowering model for increasing healthcare worker hand washing compliance on a 24-bed in-patient unit effectively increased compliance 56% and was sustained over 3 months. Compliance was measured through soap usage per resident day. The intervention was that patients asked their healthcare workers if they had washed hands before providing care. Interestingly, patients reported asking nurses 65% of the time to only 35% for doctors *(33)*.

Noncompliance with the basic tenets of healthcare is evident in other areas of infection control practice, including aseptic technique, isolation, and Standard Precautions techniques. Ching and Seto *(34)* found that patient care practices for urinary catheter care were significantly improved when a nurse from the ward was chosen to act as an infection control liaison, promoting control measures and providing teaching, as compared to nurses receiving only in-service lectures. Two studies report successful outcomes in reducing either ventilator-associated pneumonia or central intravenous catheter infections. Both used a multidisciplinary task force to develop self-study modules, lectures, pre- and posttesting, and posted fact sheets as posters through the ICU. The studies using a multi-intervention approach showed significant reductions of 50% (35) to 66% (36) in hospital infection rates. These reports suggest a variety of educational methods may be needed to achieve and maintain adherence (32).

In summary, successful hand hygiene compliance is achieved through a combination of many strategies including observation and feedback, administrative support, senior staff modeling, product selection, and educational campaigns such as posters.

Human Factors Engineering Well-trained and educated healthcare workers continue not to comply with infection control mandates. Alvarado has stated that the educational methods themselves are at fault. "Search for the individual bad actor keeps us from looking at the design of the overall system" *(37)*. The traditional way of "simply telling them" assumes that the healthcare workers have the information, that learning has taken place, and that they will change to the desired behavior. It may be time to consider multifaceted approaches that will achieve good and sustained results, for example, HFE, which has its origins in the Industrial Revolution *(38)*. HFE looks at the causes and effects of human error and was originally applied to the design of increasingly complex airplane cockpits *(39)*. It has been applied to numerous diverse systems such as software and computer control. In healthcare, HFE has been applied to the problem that 70% to 80% of adverse anesthetic events in the operating room involve human error *(39)*. Evaluating the differences between visual and manual activities using the HFE model removed the problems and reduced the errors *(40)*.

The goal of HFE is a systematic approach to designing safer processes and products rather than relying on education alone. It relies on communication; training; fatigue and scheduling; environment and equipment; rules, policies, and procedures; barriers (safeguards); and tasks and technology tools *(41)*. The human factors model is to write down the characteristic of each aspect of performance expectations and then consider the effect of each characteristic on the individual whose behavior needs changing and alter the model so that the desired outcome is reached (42). Ultimately, it has been demonstrated to reduce the need for training and seeks to achieve optimum performance.

A continuing problem in infection control is that healthcare workers do not consistently comply with critical practices such as proper hand washing, administering preoperative antibiotics at the appropriate time, precleaning and disinfecting endoscopes correctly, following isolation precautions, using aseptic practices, and wearing appropriate personal protective equipment. HFE focuses on the user interface. Bagian et al. *(41)* state, "It is essential to design and implement a system that takes into account the concerns of the frontline personnel and is aimed at being a tool for learning, not accountability." The objective of HFE is to design devices or procedures that users accept willingly and operate safely in realistic conditions *(39)*. An example is the improved compliance of healthcare workers with hand hygiene policies with the use of waterless hand agents as an alternative to soap and water under certain conditions.

Alvarado (42) suggests comprehensive blame-free programs to analyze near misses as well as crashes. Lapses in infection control reflect system flaws rather than human incompetence.

Education for Specific Groups of Healthcare Workers

Effective programs must be customized to meet the needs of the group for which they are given. Studying a specific group of healthcare providers or targeting a learner population can assist the educator in developing programs that meet the unique interests of the group based on professional experience, intellectual maturity, and group readiness *(43)*. Factors to consider, regarding the participants, include the general educational background, reasons for attending, current level of knowledge on topic, and level in the decision-making structure of the institution (44).

Seto (45) found that the differing responses to "social power" by nurses and housekeepers have implications for their training. Social power is defined as "the potential ability of an influencing agent to affect the cognition, attitudes, or behavior of another person (the target) in infection control." Studies found that nurses respond best to informational and expert power. This finding suggests that effective education for nurses should include relevant references and convincing information (e.g., surveillance rates) given by a perceived "expert" in the field. Housekeepers were

responsive to legitimate power (the target's acceptance of a role relationship that obligates the target to comply with the agent's request) and coercive power (ability of the influencing agent to mediate punishment for the target), but less responsive to informational power. It therefore would be prudent for this group to have acknowledgment of the supervisor's endorsement of the educational content (45).

Hospital personnel with academic preparation in healthcare begin their employment with varying educational backgrounds in infection control. In addition to providing on-the-job training, the challenge is for IPs to advocate changes in basic education in the curricula of schools of nursing and medicine, so that healthcare personnel enter their professions with basic knowledge of infection control *(46)*. Dembry and Hierholzer *(47)* consider changes in the role of the hospital epidemiologist over the years, and recommend that infectious diseases programs in medical schools should include training in infection control.

Reports have demonstrated significant benefits by focusing on the physician-in-training for specific educational interventions *(48,49)*. An observation that few physicians were using a full-size drape during central venous line insertion led to a nonrandomized pre- and postobservational trial in six ICUs and a stepdown unit. A 1-day didactic course on infection control practices and procedures for third-year medical students and first-year residents resulted in a significant increase ($p < .001$) of full-size drape use and a significant reduction in catheter-related infections *(49)*. Another report using stations for training house staff on safety issues (needlesticks, back injuries, and TB exposures) resulted in the reduction or elimination of each adverse outcome *(48)*.

Mah and Meyers (50) summarized the effectiveness of educational modalities in changing healthcare worker behavior using Cochrane Database System Reviews. A small to moderate result came from audit and feedback (47 randomized controlled trials). Moderate to moderately large effectiveness was achieved through continuing education meetings—a combination of interactive and didactive workshops. Didactive workshops alone were less effective. Improved practice resulted from training opinion leaders (two of seven comparisons), Internet-based learning (in 3 of 16 randomized controlled trials), printed educational materials (2 of 14 comparisons), computer-based clinical decision support systems (43 of 65 comparisons), and academic detailing (combination of written materials, conferences, reminders, and audio/feedback) (18 of 18 comparisons) (50).

LEARNING THEORY AND BEHAVIORAL SCIENCES

Knowledge of learning theory and relevant fields in the behavioral sciences should guide the educator in planning educational activities for infection control. Learning theories have some elements in common including the idea that learning produces a relatively permanent behavior change and is an internal process that varies from person to person. Both biologic factors (e.g., heredity and sensory structures) and the intelligence that results from experience, education, and cultural background influence learning *(51)*.

Seto (45) has investigated social psychology, a field of study in behavioral sciences that is relevant for infection control education. The reasoned action model assumes that people's behavioral intent is a good predictor of actual behavior. A study testing this theory on the infection control policy to stop recapping of needles divided nurses into three groups of three wards each, using an initial survey to categorize those who would comply with practice as "agreeables" and those who would not as "nonagreeables." The authors then utilized three methods to introduce the policy: (a) by announcement only, (b) by announcement and passive education (posters and pamphlets), and (c) by passive plus active education (e.g., in-service lectures). Behavioral change was assessed by another survey. The results suggested that the agreeables had significant improvement in compliance (85%) using the announcement and passive education method compared with the nonagreeables (21% compliance). The nonagreeables reached 83% compliance when passive plus active education methods were used. Before the introduction of a new policy or procedure, a survey can be used to assess the proportion of staff already with behavioral intent to comply. If these are the majority, then an in-service program is not needed and the passive method would be sufficient (45).

Research in another social psychology theory, consumer behavior, has found that there are individuals called opinion leaders who can exert significant influence over others within their social/work groups. These opinion leaders can also influence how effectively new information is accepted by the group. Direct observation of practice before and after was made on two groups of ward nurses using new urinary catheter care guidelines as the infection control monitor. After both groups received the standard in-service education, opinion leaders provided tutorial demonstration to one group. There was a significant difference ($p < .01$) in compliance by the group receiving the opinion leaders' additional training (45,*52*). IPs should consider whether ward staff opinion leaders may promote or assist education.

Mah and Meyers (50) advocate a new socioethical approach to behavior change based on four tenets. First, a Learning Innovation Team was formed of people interested in promoting safe behaviors among healthcare workers. Team members brought their individual areas of interest and expertise to the group. The team created behavior change at the local level, which could then diffuse throughout the facility and region. Second, because personal experience outweighs scientific evidence in today's world, educators must appeal to their audience by appearing to have high moral character, respect for commonly held values, and create empathy with their cause. Third, since excellence of practice does not guarantee a positive outcome, the healthcare worker is to do his or her utmost to advance the welfare of patients. Infection prevention in healthcare should be built on improvement and behavior change (*praxis*), which the authors suggest should not be one at the expense of the other. Fourth, improved behavior occurs when there is conversation and communication. Most education occurs in the form of a monologue (computer-based training, lectures, and videos) and must be replaced with dialogue if culture change is to occur (50).

PLANNING EDUCATIONAL PROGRAMS

The IP and other healthcare professionals are engaged in education in informal settings such as responding to questions on the telephone or in the hallway; however, scheduled programs that meet institutional requirements or specific needs necessitate planning that is based on teaching-learning principles. Planning an educational program, activities, or displays includes the following steps: (a) assess learner needs; (b) define goals or purpose; (c) formulate objectives; (d) develop a plan—determine the setting, organize the content, choose the format, choose teaching materials, and establish a climate conducive to learning; (e) prepare an evaluation; and (f) implement, evaluate, and revise the program *(53)*.

Needs Assessment

Planning for educational programs begins with determining what knowledge is needed (e.g., what the discrepancy is between the present and required levels of competency). This needs assessment may be based on the needs of the individual learner (e.g., a hospital employee who fears catching a communicable disease) or on the needs of the institution (e.g., passing The Joint Commission survey or implementing decisions of the infection control committee).

Methods of determining the educational needs include interviews (both structured and informal, such as asking nurses and doctors what is perceived to be harming their patients), surveillance, environmental rounds, questionnaires, tests, observations, group meetings for problem analysis (e.g., discussion of isolation techniques), and medical/hospital records and reports (e.g., healthcare-associated infection rates). Seto et al. *(54)* used a written survey and found that the educational needs for nurses were not the same as those for the entire hospital, and identified the specific needs of nurses in various units. Long-term–care facility IPs responded to Leinbach and English's *(55)* statewide needs assessment indicating that training is needed, especially if it is comprehensive, accessible, and focused on long-term care. Weinstein et al.'s *(56)* study made use of observation in a hands-on exercise for needs assessment in basic infection control practice. Observation was also used in Fernsebner's *(57)* study for educational needs assessment through the use of mock surgery for operating room staff to identify breaks in aseptic technique. Another way to identify needs is to review new infection control guidelines to focus on only the practices that require change and to evaluate barriers for staff compliance (58).

Goals and Objectives

Needs assessment determines the goal or purpose of the learning activity and leads to formulation of objectives that assist the educator and the learner in planning, conducting, and evaluating the learning process. Goals tend to be descriptive global statements, whereas instructional objectives describe a performance the learners will be able to exhibit in order to be competent. An objective is the specific observable, measurable behavioral outcome of instruction. Mager *(59)* identifies three characteristics of an instructional objective: performance, conditions, and criterion. For performance, the objective describes what a learner is expected to be able to do using specific action words. Any conditions or constraints are described in the objective. Finally, the criterion states how well the learner must perform or what the criterion level is for mastery *(59)*.

Objectives may be classified into categories using classification systems such as one developed by Benjamin Bloom identifying three domains (affective, cognitive, and psychomotor). The affective domain includes interests, values, and attitudes. The cognitive domain includes knowledge, intellectual skills, and problem-solving abilities. The psychomotor domain includes manipulations and motor skills. The value of such a classification system for the educator is that it assists in communicating objectives clearly to the learner and in understanding the level of difficulty of the objectives *(60)*.

A learning objective clarifies what will be learned, gives guidance to choosing appropriate formats and teaching methods, and specifies what is to be assessed in the evaluation of the learner *(59)*.

Instructional Formats

The objectives guide the educator in choosing the most appropriate instructional format or combination of formats, including large groups, small groups and seminars, individualized instruction, or experiential learning, to facilitate student learning.

Another consideration in choosing the format is the preferred teaching style of the instructor/facilitator and the preferred learning style of the participant. Teachers have a preference for teaching styles, such as formal lecture, small-group discussion, or a mentor role working individually with learners, but they frequently adapt to a less-preferred style, because the objectives and educational needs influence the format. Kolb's classification system of learning styles combines two of four learning processes (concrete experience [feeling], active experimentation [doing], abstract conceptualization [thinking], and reflective observation [watching]) for each of the four learning styles in his system. Goldrick et al.'s *(61)* study of nurses in three specialized groups (critical care, operating room, and infection control) found that 64% of the respondents preferred the abstract, reflective, self-directed, discovery approach. Rakoczy and Money's *(62)* study of nursing students' preferred learning style produced similar results; students preferred abstract/reflective learning. Another study examining the cognitive style preferences of staff registered nurses found that the majority expressed agreement with making decisions by rule or policy, preferred focusing on learning one task at a time, and rated high a commitment to a group of principles or set of values *(63)*.

Large Groups The lecture–discussion method has been widely used and accepted by the educational community and is useful for groups larger than 15 people. It is an efficient way to transmit material to a large group in a short time and provides a specialist as a role model. However, this method is inconsistent with some principles of adult learning, and its disadvantages include the following: the student's role is passive, feedback is slow, individual differences cannot be accommodated, and attitude changes and reasoning skills are not developed *(64)*.

The qualities of a good lecturer/instructor include more than knowing the subject well. The speaker must organize the presentation logically with an introduction, body, and summary, and then communicate that information effectively. Personal characteristics of the speaker such as a sense of humor, spontaneity, and even dramatic ability help to maintain the attention of the learners. Butler *(65)* found that the students perceive the traditional didactic lecture as the least effective learning method. However, varying the lecture format with handouts or experiential tasks that involve active participation by students greatly enhances student learning. Cooper et al.'s *(66)* study of infection control training needs of medical students found that the 30-minute lecture–discussion was not effective in teaching about infection control guidelines in relationship to perceived risks of acquiring human immunodeficiency virus. A comparison of traditional classroom lecture with computer-managed instruction and keypad questions in a nursing course found no statistically significant difference in achievement between the two groups *(67)*.

Small Groups and Seminars The small-group instruction format is useful for groups of 15 or fewer participants. The small group is called a "seminar" when led by an instructor. When the group is student-centered, eight should be the maximum number of participants, and the instructor should serve as a resource person. Small groups and seminars are effective for attitude change, developing collaboration and problem-solving skills, applying concepts, and promoting peer interaction. The disadvantages of this method are that the groups require a great deal of time for careful management and planning by a competent facilitator and evaluating individual progress is difficult *(64)*.

IPs can maximize time and individualize educational offerings for specialized departmental needs by using departmental liaisons who learn from the IPs and take messages and programs back to their departments. To save travel and meeting time for distant locations, the Internet or teleconferences can be utilized *(68)*.

Individualized Instruction Individualized instruction designed to meet the exact needs of the individual student is ideal in that it accommodates individual differences, provides immediate feedback, and allows the learner to be an active participant. However, this method is difficult to use with large groups of people and with students who are not motivated, and is less effective for learning that involves changes in attitude. Developing materials for individualized instruction can be extremely time-consuming. Individualized instruction is applied through the use of such methods as independent study, correspondence study, manuals or syllabuses, videotapes, programmed instruction, and computer-assisted instruction *(64)*. Lieb et al. *(69)* developed self-paced learning stations for TB respirator training that was effective and time-efficient.

Programmed instruction consists of a series of frames that are carefully sequenced, so that learners will proceed at their own pace toward the desired behavior. This method is useful for teaching facts and skills but is less appropriate for teaching concepts and relationships *(70)*. Studies by Goldrick *(71)* concluded that the programmed instruction unit (PIU) is an effective alternative to classroom lectures for teaching basic infection control principles and resulted in cost savings. Application to infection control was tested on a randomized population of senior nursing students. A comparison was made of those receiving a PIU in the basic principles of infection control with those given tests only or those given tests and another PIU that did not cover infection control material. The study reported significantly improved scores for those given a PIU in infection control and an additional finding that 68% of students preferred this type of learning to a lecture *(67)*. In addition, a study of nurses and a study of third-year baccalaureate nursing students indicated that those who took a PIU covering the basic principles of infection control scored higher on posttests than those who attended a lecture, regardless of their pretest scores, educational level, and experience *(72,73)*.

Experiential Learning Experiential learning includes internships, student-initiated projects, and student participation in scholarship or research. This method is time-consuming for the educator and requires a supervisor for each student, but it offers effective individualized and specialized learning *(74)*.

Teaching Aids

Materials and Media Media and teaching materials can assist in achieving the objectives of an educational program but should be used only if they serve an educational purpose. Comprehension and retention can be dramatically increased with visual aids because as much as 83% of the data people gather may be from sight *(75)*. Available media include print (e.g., handout, manual, and textbook), chalkboards or flip charts, computer-assisted instruction, overhead transparencies, slides, audiotapes, videotapes, films, television, games and simulations, and manipulative materials.

When selecting teaching materials, the educator determines whether the quality and potential effectiveness will enhance learning. The selection of materials must also be based on the availability of equipment and money and compatibility with the educational setting (e.g., format, staff, space, and time). A study in a low-resource setting found that healthcare staff preferred flipcharts (low cost and easily available) over videotapes. In addition, the patients and their families preferred flipcharts (76).

Guidelines for evaluating media include the following: (a) Is the information appropriate for the level of the learners? (b) Is the information accurate and current? (c) Is there consistency between the learning objectives and the material? (d) Is the material organized and presented in a logical sequence? (e) Is the visual and verbal information simple? and (f) Is the technical quality good?

Slide presentations provide colored visual stimuli, are appropriate for large groups, and are easily transported. The following principles should be applied when designing or using slides: (a) clarity—address one point and present limited information so that it is clearly visible; (c) focus—select data that fit the objectives and synthesize the data; (c) appropriateness—present information that is appropriate to the level of understanding of the audience; do not present highly detailed and complex information to a general audience and do not oversimplify for an advanced-level audience; (d) accuracy—the slides should present correct

information, using correct spelling; (e) purpose—select only those slides that match the focus of the presentation; eliminate information that is not directly relevant *(77)*.

Technologic Resources Technology is a powerful tool that enables the educator to provide a dynamic learning environment. The creative educator can facilitate learning using technologic resources such as computers and telecommunications. Computers provide software for learners to explore and gain information using nonlinear, nonsequential searching techniques to link facts and ideas in a way best suited to that person's needs. Technologic advances such as virtual reality systems (a computer-based platform using a helmet-like apparatus to project a video image that gives the illusion of reality) have potential for useful application in education in healthcare.

Computer-assisted instruction and interactive video are useful aids for educating healthcare workers. In computer-assisted instruction, the learner interacts with a computer program that presents information in small steps. This method provides immediate feedback and allows learners to advance at their own pace. Interactive video (controlling a video by the computer) allows the learner to respond and interact. One study showed that computer-assisted instruction resulted in marked improvement in universal precautions—related behaviors in nurses *(78)*. Cohen and Dacanay *(79)* conducted a meta-analysis on computer-based instruction (CBI). The majority of the studies favored CBI over traditional methods of instruction, although few studies reported on retention, attitudes, and time to learn. The authors found large positive effects for interactive video applications of CBI that simulates clinical settings, requires involvement, and gives immediate feedback. Jamison and Brannigan *(80)* suggest that people with medical knowledge, as well as computer specialists, are needed for the process of implementing interactive video in medical education to make it most effective.

Establishing an Environment Conducive to Learning

Principles of adult learning applied to educational programs result in an environment that is conducive to learning. In addition to a comfortable physical environment, the interpersonal and organizational climate influence learning *(81)*. Some guidelines that facilitate a positive learning setting include the following: (a) adults are generally participating voluntarily in educational activities and do not respond well to coercive practices; (b) effective education is based on the mutual respect of instructors and learners; (c) collaboration, not competition, contributes to effective adult education; (d) active involvement followed by reflection is essential; and (e) adult learning is most effective when it is self-directed *(82)*.

Evaluation

Evaluation is essential in the educational process in that its purposes are to improve the learner's performance, the instructor/facilitator's performance, and the educational program itself. Evaluation is accomplished in informal ways as well as through the use of formal evaluation instruments to collect data. No single evaluation method is suitable for all purposes, but available methods include anecdotal records, self-evaluations, checklists, rating scales, tests, questionnaires, and interviews.

The first step in the evaluation is to determine the purpose of the evaluation. Questions to consider to guide the establishment of an evaluation process include the following: (a) Who is to be evaluated (e.g., learner, instructor, or program)? (b)When is the evaluation to occur? and (c) What is to be examined (e.g., learners, instructors, instructional formats, or materials and teaching aids)?

When learners are to be evaluated, they need to know what is expected of them. The objectives for an educational program state what is to be accomplished and are the guide for constructing an instrument to measure the extent of learning. A pretest may be administered to assess the learner's level of competence at the beginning of an educational program, and then a posttest indicates the progress made. When instructors are to be evaluated, constructive feedback results in improvement in teaching. Evaluation of an educational program may be formative or summative, depending on the purpose. Formative evaluation occurs during the program and provides for modification of the program while it is being conducted. Summative evaluation occurs after the program is completed and focuses on accountability, indicating whether a program should be continued, modified, or discontinued *(83)*.

> *I believe that education is the principal component of infection control. Without education, every other activity of our specialty is just so much meaningless busy work.—Sandra J. Pfaff (46), Third Annual Carole de Mille Lecture*

CHAPTER 93

Infection Control and the Employee Health Service

Pamela S. Falk

Hospitals, although traditionally a refuge for the sick and injured, not only are very dangerous environments for healthcare workers but also can be dangerous for patients. Hospital-based employee health programs are charged with diagnosing, treating, and preventing infectious diseases in healthcare workers. Because of this, a hospital-based employee health service plays an important role in the infection control program and is a key element in protecting patients from healthcare-associated infections.

Clear lines of communication need to be established between the employee health service and the infection control department. Infection control and employee health staff should meet on a routine basis and should communicate (telephone, notes, fax, e-mail) as needed for integration of activities. Protocols for triage, evaluation, prophylaxis, and follow-up after exposures should be developed and the roles and responsibilities of employee health and infection control should be carefully defined.

CONTROL AND PREVENTION OF SPECIFIC INFECTIOUS DISEASES IN THE HEALTHCARE SETTING

Varicella-Zoster Virus

The varicella-zoster virus (VZV) causes two diseases: varicella (chicken pox) and herpes zoster (shingles). Chicken pox is a common childhood disease. For the approximately 1% to 10% of adults who are susceptible to VZV *(1–7)*, exposure poses a significant risk of infection.

Assessment of Healthcare Workers' Immune Status A common goal of all infection control programs is to protect patients from healthcare workers who may be incubating infectious diseases after exposure in the community or in the hospital. All employees should, on their postoffer employee screening, be asked about a history of chicken pox. A healthcare worker with a positive history of chicken pox can be considered immune *(5–19)*. If the healthcare worker denies having had the disease or has an uncertain history for chicken pox, a serologic test, if deemed cost-effective by the institution, may be done to determine his or her immune status (see also Chapter 76).

Institutions should develop guidelines for managing healthcare personnel eligible for the varicella vaccine *(20)*. If the healthcare worker is not immune (either by history or serologic test), the varicella vaccine should be offered *(16–20)*. Serologic testing for postvaccination antibodies is not required *(16–19)*. Personnel who develop a rash after receiving the varicella vaccine must avoid contact with persons without evidence of immunity who are at risk for severe disease and complications until all lesions resolve (i.e., are crusted over or fade away) and no new lesions appear within a 24-hour period (*15*,21).

Nonimmune healthcare workers for whom the vaccine is contraindicated should be educated about the risk they pose to patients, should they be exposed to VZV and become infected. They should not be assigned to the care of any patient with chicken pox or herpes zoster.

Exposures to Varicella-Zoster Virus After a case of chicken pox has been confirmed in a patient or healthcare worker, infection preventionists should compile a list of personnel and patients exposed to the index case. The names of exposed employees are provided to the employee health service so that the immune status of those exposed can be determined. Exposed healthcare workers who are not immune should be furloughed. The period of contagiousness of infected persons is estimated to begin 1 to 2 days before the onset of the rash and to end when all lesions are crusted *(18)*. Thus, furlough should begin 8 days after the first day of exposure and extend through day 21 after the last day of exposure (*6*,*7*,*14*,*15*,*18*,*20*,21).

It is very important that nonimmune employees report chicken pox exposures whether they occur in the community or in the hospital. Employers should furlough healthcare workers with pay for exposures that occur within the institution. Without this policy, employees are reluctant to report their exposures. Although employees are strongly encouraged to report community exposures, few institutions furlough employees with pay after exposures in the community.

Although the risk of infection with VZV is less after exposure to a patient with herpes zoster than after exposure to a patient with chicken pox, the clinical manifestations

of chicken pox are the same after acquisition of infection by either type of exposure *(12)*. Nonimmune healthcare workers who have direct physical contact with draining vesicles of patients with herpes zoster should also be considered exposed and furloughed from work *(12)*. Nonimmune healthcare workers should refrain from working with patients with herpes zoster *(12)*.

Often, the source of exposure to VZV is a healthcare worker. One of the most important functions for the employee health service during the investigation of a VZV exposure episode is to confirm VZV infection in the index case. Once VZV infection has been confirmed, the employee must be furloughed until all lesions are crusted *(12)*. Although the furlough may be instituted by either the infection control department or the employee health service, the employee must return to the employee health service to be cleared before returning to work.

Prophylaxis using varicella-zoster immune globulin should be considered for nonimmune exposed healthcare workers who are at high risk for complications of varicella-zoster infection (pregnant and immunosuppressed employees) (*22*,23) (see also Chapters 43, 75, and 76).

Tuberculosis

The American Thoracic Society issued a statement in 1967 recommending that all hospitals have a "consistent program of tuberculin testing … of all employees who may be subject to exposure" *(24)*. By 1983, the Centers for Disease Control and Prevention (CDC) recognized that all healthcare workers were not at equal risk for acquiring tuberculosis (TB) and recommended skin testing based on individual classification of risk for a facility and the location and prevalence of untreated TB in the community, in the institution, and among personnel *(25,26)*.

Because of these recommendations, many hospitals in the late 1980s discontinued or restricted their purified protein derivative (PPD) skin testing program. However, since 1988, there has been a dramatic increase in TB in the United States that is largely related to the human immunodeficiency virus (HIV) epidemic *(26–28)*. Hospitals have had to reassess their TB surveillance plans and develop mandatory skin testing policies for healthcare workers. These programs should include baseline TB skin tests upon employment, periodic retesting for at-risk employees, postexposure evaluation, preventive therapy as indicated, and employee education (*26*,29) (see also Chapter 38).

Healthcare workers with a positive TB skin test on initial testing or with a skin test conversion after exposure should be evaluated for active TB by the employee health service. Persons with symptoms suggestive of TB should be evaluated regardless of skin test results. If TB is diagnosed, appropriate therapy should be instituted. Healthcare workers with a reactive skin test but without disease should be educated about the signs and symptoms of disease and instructed to report immediately to the employee health service for evaluation, should they develop any of these signs and symptoms.

Healthcare workers who have active pulmonary or laryngeal TB, endobronchial or tracheal disease, or a draining TB skin lesion pose a risk to patients and staff. Therefore, the CDC recommends that the healthcare worker be excluded from work until adequate treatment has been instituted, cough has resolved, and sputum has been found free of acid-fast bacilli on smears from three consecutive specimens collected at 8- to 24-hour intervals with at least one sample from an early morning specimen (because respiratory secretions pool overnight) (29).

Healthcare workers who cannot take or do not accept or complete a full course of preventive therapy should be counseled about the risk of reactivation of infection and development of disease and should be instructed to seek evaluation promptly if symptoms develop that may be due to TB.

Annual and postexposure tuberculin skin test results should be monitored routinely. Results of skin tests should be placed in the healthcare worker's medical records and recorded in an aggregate form for analysis of skin test conversion patterns in various areas of the hospital. The aggregate data set should include information about each skin test conversion such as job classification, work location, date of first PPD, and date of positive PPD. Analysis of the aggregate data set is done by the infection control department to determine whether personnel in any area or service in the hospital have an increased incidence of skin test conversions. An increased incidence of skin test conversions in a given area or service may indicate that the infection control procedures to prevent transmission of TB in that area or service need to be improved.

Seasonal Influenza

Since 1984, the recommendations of the Advisory Committee on Immunization Practices (ACIP) for immunization against influenza have included healthcare workers as a group because they may transmit influenza to patients *(30)*. The annual recommendations for adults were published in the 2008 ACIP guidelines. Annual vaccination against influenza is recommended for any adult who wants to reduce the risk for becoming ill with influenza or of transmitting it to others. Vaccination is also recommended for all adults in the following groups because these persons are either at high risk for influenza complications or are close contacts of persons at higher risk:

- Persons aged 50 years or older
- Women who will be pregnant during the influenza season
- Persons who have chronic pulmonary (including asthma), cardiovascular (except hypertension), renal, hepatic, hematological, or metabolic disorders (including diabetes mellitus)
- Persons who have immunosuppression (including immunosuppression caused by medications or by human immunodeficiency virus)
- Persons who have any condition (e.g., cognitive dysfunction, spinal cord injuries, seizure disorders, or other neuromuscular disorders) that can compromise respiratory function, or the handling of respiratory secretions or that can increase the risk for aspiration
- Residents of nursing homes and other chronic-care facilities
- Healthcare personnel
- Household contacts and caregivers of children younger than 5 years and adults older than 50 years, with

particular emphasis on vaccinating contacts of children younger than 6 months
- Household contacts and caregivers of persons with medical conditions that put them at high risk for severe complications from influenza (31)

All healthcare institutions should develop a policy to enhance the delivery of influenza vaccine to healthcare workers for the following reasons *(32)*: (a) healthcare-associated outbreaks occur during the influenza season, and a well-immunized workforce is less likely to transmit influenza to the patients under their care; (b) immunizations should minimize absenteeism during influenza outbreaks; and (c) influenza can be a serious disease and should not be confused with a cold or "intestinal flu." Immunization provides the best personal protection for each employee.

The vaccine should be offered beginning in October of each year. The employee health service and the infection control department need to collaborate in the education of healthcare workers about the importance of immunization against influenza. Measures should be taken to provide all healthcare workers, regardless of shift or work location, convenient access to influenza vaccinations at the work site, free of charge, as part of the employee health program *(20)*. The risk of introducing influenza into high-risk groups, such as those with compromised cardiopulmonary or immune systems or infants in the neonatal intensive care unit, should be reduced by targeted vaccination programs of these medical personnel.

In addition to a vaccination program, monitoring the community for influenza activity and monitoring healthcare workers for influenza may help prevent healthcare-associated transmission of influenza. When healthcare workers have signs and symptoms of influenza, they should be evaluated by the employee health service, and if possible, viral cultures and serologic tests for antibodies to influenza should be obtained.

To reduce the spread of virus to persons at high risk during community or institutional outbreaks, chemoprophylaxis during peak influenza activity can be considered for unvaccinated persons who have frequent contact with persons at high risk. Persons with frequent contact include employees of hospitals, clinics, and chronic-care facilities, household members, visiting nurses, and volunteer workers. If an outbreak is caused by a variant strain of influenza that might not be controlled by the vaccine, chemoprophylaxis should be considered for all such persons, regardless of their vaccination status *(32)* (see also Chapter 42). In addition, the employee health service would be responsible for education of healthcare workers about the side effects of the prophylactic drugs and for evaluation of healthcare workers for possible side effects of these medications. Healthcare workers with active disease should be relieved from duty because it is estimated that viral shedding in the nasal secretions usually continues up to 5 days after the onset of illness *(13,15)*. Healthcare workers should be cleared by the employee health service before returning to work.

Blood-Borne Diseases

All healthcare institutions should have a plan to follow-up all occupational exposures to blood-borne pathogens *(33)*. Healthcare workers must be educated about the importance of promptly reporting exposures. Ideally, each institution should have a triage system available by telephone 24 hours a day. Such a triage service could be provided by the infection control department, by the employee health service, or jointly by both services. This system provides immediate triage, initial evaluation, and early prophylaxis if needed. It also permits early counseling for anxious healthcare workers after exposure. If the exposed healthcare worker is seen in urgent care or the emergency department at night or on weekends or holidays, he or she should be instructed to report to the employee health service on the next business day (34).

The interval within which postexposure prophylaxis for HIV should be started for optimal efficacy is unknown. An occupational exposure should be regarded as an urgent medical concern and postexposure prophylaxis started as soon as possible after the exposure (i.e., within a few hours rather than days) (34,*35*). In the author's hospital, the policy is to start prophylaxis within 2 hours of exposure.

Prompt reporting of all exposures is necessary for the timely administration of postexposure prophylaxis. Source patients should be evaluated for a history of high-risk behavior and should have serologic tests performed for viral hepatitis and HIV as soon as possible after the exposure. Infection control personnel should conduct the risk assessment. Once the risk assessment has been completed, the information should be shared with the employee health service so that postexposure prophylaxis can be administered as soon as possible after exposure (*15*,34) (see also Chapters 73 and 74).

Measles, Mumps, and Rubella

Healthcare workers are considered at a higher risk of acquiring measles (rubeola), mumps, or rubella than are the general population because of their chance exposure to either ambulatory or hospitalized patients being treated for these diseases *(36)*. An effective immunization program for healthcare workers can markedly reduce this risk. In addition to protection for healthcare workers, such immunization programs can be expected to have institutional benefits, such as prevention of transmission of infectious diseases to patients and visitors, reduction of workers' sick days, and improved efficiency in the management of outbreaks and exposures.

When developing a measles, mumps, and rubella (MMR) vaccination program, the most accessible population for vaccination is the healthcare workers who are being seen for their postoffer evaluations. All healthcare workers who do not have documentation of physician-diagnosed measles, laboratory evidence of measles immunity, or contraindications to the MMR vaccine and who have not already received two doses should be vaccinated with MMR before starting work. All healthcare workers should be assessed during their annual physical visit to the employee health service. If a healthcare worker had a contraindication to MMR vaccine during the last employee health service visit, that healthcare worker should be reassessed and the vaccine given, if possible. If patients or personnel are exposed to measles, mumps, or rubella, the following should be considered (*36*,37):

1. If the index case is an employee, the infection should be confirmed by the employee health service. Serum

should be obtained for acute and convalescent antibody titers to help establish the diagnosis. However, results of serologic tests are usually not immediately available, and the response to most exposure incidents must be based on a clinical diagnosis. It must be remembered that MMR are no longer common childhood diseases, and each can be easily misdiagnosed by relying on clinical signs alone. Consultation with a physician experienced in the diagnosis of measles, mumps, or rubella, such as a dermatologist, pediatrician, or infectious diseases specialist, should be considered if the diagnosis is unclear.

2. The activities of the index case, such as contact with coworkers on his or her unit and social contact with other healthcare workers in areas in which the employee has worked (e.g., nursing units, various departments, clinics), should be documented. A list of exposed healthcare workers should be sent to the employee health service.
3. Exposed healthcare workers with documentation of immunity by vaccination or positive serologic tests should be considered immune and not at risk for clinical disease.
4. Those without documented immunity should be vaccinated as soon as possible, if there are no contraindications, and furloughed as necessary. Exposure to measles requires a furlough from 5 days after the date of first exposure to 21 days from the date of last exposure *(15–20,38,39)*. Those exposed to rubella should be furloughed from the 7th day after the first exposure to the 21st day after the last exposure *(15,20,40)*, and those exposed to mumps should be furloughed from the 12th day after the first exposure to the 26th day after the last exposure (*12*,*13*,*15*,21).
5. Exposure to measles or rubella is not a contraindication to vaccination. An emergency MMR vaccination program may be implemented if there is evidence that many employees are susceptible to the disease in question. Such an emergency program may be needed to prevent an outbreak of infections among employees.
6. During an outbreak of measles, all healthcare workers with direct patient contact who were born after 1957 should receive one dose of measles vaccine unless they can provide proof of immunity or document previous receipt of two doses of the measles vaccine *(39)* (see also Chapter 51).

Pertussis

Multiple outbreaks of pertussis in healthcare facilities have been reported in the literature. These outbreaks have resulted from failure to recognize and isolate infected infants and children and failure to recognize and treat the disease in staff members. Healthcare-associated acquisition of pertussis by healthcare workers has occurred during several outbreaks (41).

Investigation and control measures to prevent pertussis after unprotected exposure in healthcare settings are labor-intensive, disruptive, and costly, particularly when the number of exposed contacts is large. Such measures include identifying contacts among healthcare workers and patients, providing postexposure prophylaxis for asymptomatic close contacts, and evaluating, treating, and placing symptomatic healthcare workers on administrative leave until they have received effective treatment. Despite the effectiveness of control measures to prevent future transmission of pertussis, one or more cycles of transmission with exposures and secondary cases can occur before pertussis is recognized. This might occur regardless of whether the source case is a patient or healthcare worker, the age of the source case, or the setting (e.g., emergency department, nursery, or any other inpatient unit).

Infrastructure for screening, administering, and tracking vaccinations exists in occupational health or infection prevention and control departments in most hospitals, and hospitals should implement Tdap vaccination programs. New personnel can be screened and vaccinated with Tdap when they begin employment. As Tdap vaccination coverage in the general population increases, many new healthcare workers will have already received a dose of Tdap.

To achieve optimal Tdap coverage among personnel in healthcare settings, healthcare facilities are encouraged to use strategies that have enhanced healthcare worker participation in other hospital vaccination campaigns. Successful strategies for hospital influenza vaccine campaigns have included strong proactive educational programs designed at appropriate educational and language levels for the targeted healthcare worker, vaccination clinics in areas convenient to healthcare worker, vaccination at worksites, and provision of vaccine at no cost to the healthcare worker. Some healthcare institutions might favor a tiered approach to Tdap vaccination, with priority given to healthcare workers who have contact with infants aged 12 months or younger and other vulnerable groups of patients (41).

Therapy of infected patients and chemoprophylaxis of exposed healthcare workers has been successful in terminating outbreaks in healthcare institutions. Erythromycin has been the antibiotic of choice for both treatment and prophylaxis. More recently, the CDC has recommended that azithromycin be used for both treatment and postexposure prophylaxis for pertussis (42) (see also Chapters 75 and 76).

Meningococcal Exposure

Healthcare workers may be exposed to the meningococcus. Source patients with *Neisseria meningitidis* in their blood, spinal fluid, or respiratory secretions can be considered to be colonized with the microorganism in their oropharynx. Transmission is probably by way of large droplets. Exposure in a healthcare setting should be defined as an individual who has had close contact with the source patient with meningococcal disease. Close contact is defined as exposure to the patient's respiratory secretions (i.e., mouth-to-mouth resuscitation, endotracheal intubation or endotracheal tube management) but not as routine patient care activities (e.g., making beds and taking blood pressures) *(43)*.

In the microbiology laboratory, care should be taken whenever droplet formation or aerosolization is possible (subculturing and serogrouping). It is recommended that all work manipulations be done in a biologic safety cabinet. Some states are now requiring those who perform testing on this microorganism "to" receive the quadrivalent meningococcal polysaccharide vaccination for *N. meningitidis* types

A, C, Y, and W-135 (*44*,*45*,46). However, the meningococcal tetravalent conjugate vaccine is preferred for persons 11 to 55 years of age (46).

Infection control personnel should investigate every possible exposure, interview healthcare workers regarding possible exposure, and refer healthcare workers with exposures to the employee health service for prophylaxis (see also Chapters 47 and 76).

Herpes Simplex Virus

Personnel with active herpes simplex virus infections pose certain problems for infection control. Healthcare workers with draining oral lesions need to be educated about the importance of good hand washing, use of barrier protection for the infected site (e.g., mask), and avoiding care of high-risk patients (e.g., immunocompromised patients and newborns). Healthcare workers with herpetic whitlow may transmit the virus even when wearing gloves *(47)*. These healthcare workers should be excluded from patient care until the lesions are healed *(2,15)*. There is no evidence that healthcare workers with genital herpes need work restrictions.

All healthcare workers should be educated about the need to seek evaluation at the employee health service for diagnosis, treatment, and potential reassignment or furlough for herpetic lesions. It is the responsibility of the infection control department to educate healthcare workers about their risk of acquiring and transmitting the herpes simplex virus and the importance of hand washing after contact with herpetic lesions in patients (see also Chapter 44).

Ectoparasites

The most difficult part of dealing with healthcare workers who have been exposed, or presumably exposed, to an ectoparasite is contending with their hysteria. The employee health service and infection control department should work together and follow a consistent protocol for prophylaxis. In general, prophylaxis is not recommended for exposure to lice (sans bedmates). Healthcare workers who have had prolonged skin-to-skin contact with patients with scabies may benefit from prophylactic treatment (i.e., permethrin 5%, lindane 1%, or crotamiton) *(15)*. All healthcare workers must be made aware of the signs and symptoms of infestation, regardless of source of exposure, and should be instructed to report to the employee health service for treatment if such manifestations appear.

SYNDROMES THAT MAY BE DUE TO INFECTIOUS DISEASES

Diarrhea

An employee health policy should be developed that requires all employees with diarrhea to report to the employee health service for evaluation and clearance before reporting for work. Any employee with acute diarrhea should be relieved from work until it is determined whether there is an infectious etiology. The elements of good hand washing, especially after using the restroom, must be stressed.

Diarrhea in a food handler may be cause for concern. Because of the fecal-oral route of transmission for many bacterial and viral pathogens, the food handler may be the source of a hospital outbreak. It is very important that all food handlers report to the employee health service when they have diarrhea. They should comply with the hand washing policy after using the restroom and before handling food. They should also understand the proper use of gloves.

Skin Eruptions of Undetermined Cause

Many viral diseases such as chicken pox, measles, and rubella present with the sudden onset of a rash. Healthcare workers with a new-onset skin eruption should be instructed to report to the employee health service for diagnosis and clearance before reporting for work. Hospital-based outbreaks may be caused by a healthcare worker who does not report an eruption to the employee health service and continues to work, exposing patients and other healthcare workers.

The employee health service should play a pivotal role in the triage of all healthcare workers who have a rash. Healthcare workers should be seen in the employee health service in a timely manner and evaluated by an experienced practitioner. Employees who have a communicable disease should be furloughed from work. All employees who have a rash that may be a manifestation of a communicable disease should be reported to the infection control department so that postexposure control measures may be instituted. Employees with skin eruptions may be sources of exposure for diseases associated with significant morbidity and mortality in hospitalized patients.

DERMATITIS

Frequent hand washing is stressed extensively in infection control educational programs. One consequence of this is development of dermatitis of the hands. It is probably more risky to provide patient care with weeping dermatitis than it is to forgo hand washing all together. Furthermore, transient microbial flora on the hands acquired by contact with patients and environmental surfaces cannot be removed by hand washing when healthcare workers have dermatitis of their hands.

Dermatitis can be caused by a variety of factors, but in healthcare workers it is most commonly caused by excessive hand washing, harsh hand soaps, and use of gloves. Healthcare workers who scrub for operative procedures often react to the harshness of the scrub brushes. In addition, the unavailability of moisturizing lotion can lead to dry and cracked skin, especially during the cooler winter season.

Infection preventionists should encourage not only good hand washing but also good hand maintenance. When employees develop hand dermatitis, they should be instructed to report to the employee health service. Protecting the hands of healthcare workers from dermatitis is important for the health of the healthcare worker and for patients. The employee health service can help prevent healthcare-associated infections by consulting with the infection control department regarding reported cases of hand dermatitis and offering healthcare workers education and alternatives regarding daily hand maintenance.

Latex Allergy

Latex is liquid sap from the commercial rubber tree. Latex contains naturally occurring impurities (e.g., plant proteins and peptides), which are believed to be responsible for allergic reactions. Latex is processed to form natural rubber latex (NRL) and dry natural rubber. Dry natural rubber and NRL might contain the same plant impurities as latex but in lesser amounts. NRL is used to produce medical gloves, catheters, and other products. Dry natural rubber is used in syringe plungers, vial stoppers, and injection ports on intravascular tubing. Synthetic rubber and synthetic latex also are used in medical gloves, syringe plungers, and vial stoppers. Synthetic rubber and synthetic latex do not contain natural rubber or natural latex and therefore do not contain the impurities linked to allergic reactions *(48)*.

Reactions Associated with Latex Exposure

1. *Contact irritant dermatitis:* This is the most common type of reaction. It is not an allergic reaction that involves the immune system. Symptoms often present as skin irritations (e.g., dry, itchy, cracked, and reddened). Latex allergens may be absorbed through the openings in the skin and could progress to a true allergy *(49)*.
2. *Type IV delayed hypersensitivity (allergic contact dermatitis):* This is the second most common type of reaction reported due to latex exposure. This type of allergic reaction is mediated by T cells and is typically characterized by swelling, burning, itching, and rashes on hands when using gloves containing NRL. The reaction can occur in as little as 6 hours and up to 48 hours after an exposure to the offensive allergens. Allergic contact dermatitis associated with poison ivy exposure is an example of a type IV reaction. Generally, allergic contact dermatitis may spread beyond the area that has been exposed to the offensive allergen. Conversely, irritant contact dermatitis generally does not extend beyond the area of contact. Type IV reactions can progress to type I reactions with repeated exposure *(49)*.
3. *Type I immediate hypersensitivity:* This is the least common type of reaction but is the most serious and potentially life-threatening. It is an immune response to a foreign substance (latex protein) and produces such symptoms as edema of the exposed site(s), nausea, vomiting, sneezing, nasal congestion, or systemic reactions. Reactions typically begin within minutes, but may take several hours to manifest. The airways can close down, which may result in respiratory arrest. If not handled properly by medical personnel during such a reaction, anaphylactic type reactions can be fatal. Fatal reactions have been reported from exposure to NRL even when patients have no history of latex allergy *(49)*.

Recognized Routes of Latex Exposure

1. *Cutaneous* exposure can occur while wearing latex gloves or touching other latex products.
2. *Percutaneous* exposure can occur if the latex protein gets under the skin as with dry, irritated, and cracked skin.
3. *Mucosal* exposure occurs when touching a latex balloon to one's lips and mouth while blowing it up or having a dental procedure with a rubber dental dam.
4. *Parenteral* exposure occurs when medications are injected through a latex IV port or with a syringe with a dry rubber latex–tipped plunger. In this way, allergens are injected into the body or bloodstream.
5. *Aerosol* exposure may occur when an individual enters a room in which someone has donned powered latex gloves (causing proteins to be airborne) and protein particles are inhaled into the lungs.

At-Risk Healthcare Workers

Healthcare workers may be at increased risk of developing a latex allergy if they work in a clinical environment where latex products are frequently used. Healthcare workers with a history of multiple allergies, especially foods such as bananas, chestnuts, kiwi, avocados, or other tropical fruits, are also at risk. Asthma, allergic rhinitis, and hand dermatitis in a latex glove wearer also raises the risk of developing latex allergy.

The American Academy of Allergy and Immunology (AAAI) determined that because there is no known cure for this allergy, it would be beneficial to implement regulations early to prevent the allergy from becoming widespread. On September 30, 1997, the Food and Drug Administration ruled that "[a]ll medical devices containing latex [must] be labeled as such and [must] carry a caution that latex can cause allergic reactions" *(50)*.

The National Institute of Occupational Safety and Health issued comprehensive recommendations regarding latex in 1997. The recommendation was aimed at the employer and the employee. The healthcare facility was encouraged to use nonlatex gloves when latex was not absolutely necessary. It also encouraged education about latex allergies and periodic screening of high-risk employees. It was recommended that the employees take the initiative to rid the work environment of latex containing dust *(50)*.

In studies of healthcare workers, self-reported hypersensitivity is fairly common and closely associated with the use of medical gloves. There are no diagnostic tests or standardized criteria to diagnosis latex allergy. It is recommended that each institution assess the use of latex products and try to minimize it. Also, education is recommended for all healthcare workers about their personal risk and the risk they pose to their patients.

SPECIAL EMPLOYEE POPULATIONS

Day-Care Centers Associated with Hospitals

As competition among healthcare institutions grows, more institutions are offering on-site day-care centers for the children of healthcare workers. Employees in day-care centers may be exposed to a greater variety of infections compared with their counterparts in the main healthcare facility (see also Chapter 53). Infection control departments and employee health services are frequently charged with providing services for associated day-care facilities.

Diseases Commonly Encountered in Day Care

Enteric Diseases Fecal-oral transmission of pathogens such as *Salmonella*, *Shigella*, *Escherichia coli*, *Campylobacter*, hepatitis A, rotavirus, and a variety of parasites is common in day-care centers. It is imperative that the infection

control department educate the staff frequently on proper hygienic practices such as hand washing, diapering, and infant feeding. Employees in this area must understand the importance of reporting to the employee health service for any gastrointestinal signs and symptoms and/or diarrhea to avoid spread of disease in this highly susceptible population.

Respiratory Infections Children with respiratory infections may shed viruses before the onset of symptoms, making control of infections due to respiratory syncytial virus, parainfluenza virus, adenovirus, and other respiratory viruses difficult. Although infection preventionists need to educate the employees on hand washing, the employee health service can also help prevent the spread of diseases by diagnosing communicable diseases in employees and furloughing them during the infectious stage of their illness. Because the day-care center employees are asked to report to the employee health service for symptoms of any respiratory infection, the employee health service should document each case and share data on respiratory infections with infection control. In the event a higher than expected rate of disease is discovered in the day-care center, infection preventionists can investigate and implement control measures.

Skin and Cutaneous Infections As in the hospitalized population, lice and scabies pose a unique problem to employees in the day-care center. Employees or day-care center attendees may also contract and expose others to herpes simplex virus or bacterial pathogens such as group A β-hemolytic streptococci. It is important that both the infection control department and the employee health service are notified in the event of a case of cutaneous infection. The infection control department should investigate the exposure, and the employee health service should evaluate employees, provide treatment, and determine whether employees can continue to work or should be furloughed.

Day-Care Center Employee Health Policies Policies for the prevention of infections in the day-care setting and adherence to these policies are important for effective infection control in day-care centers. The policies must be in compliance with the appropriate regulatory agency guidelines. The policies relating to employee health should require (a) documented evidence of immunity to tetanus, measles, mumps, rubella, diphtheria, and poliomyelitis in caregivers by either immunization or serologic evidence of prior infection; (b) TB screening within 1 month of starting work and then annually, and appropriate follow-up protocols for PPD skin test converters; (c) annual updating for immunizations; and (d) guidelines for work restrictions if an employee has a communicable disease (i.e., furloughed from direct child care or excluded from work until the disease is no longer contagious).

Prehospital Healthcare Workers

Today, firefighters, emergency medical technicians, police officers, and others often are exposed to infectious diseases during patient care and transport to the hospital. The receiving hospital is often called on to triage and treat these prehospital healthcare workers or at least to ensure that their exposures are managed appropriately.

For the most part, prehospital healthcare workers transport patients with undiagnosed diseases. Therefore, when a patient has a disease transmitted by the airborne route, such as TB or chicken pox, or by large droplets, such as meningococcal disease, prehospital healthcare workers may be inadvertently exposed. It is important that infection preventionists include prehospital healthcare workers in investigations of exposures. Prehospital healthcare workers may be evaluated, prophylaxed, and followed up by the hospital employee health service just as the hospital's healthcare workers are evaluated, prophylaxed, and followed up after exposures to communicable diseases. If a separate healthcare provider has been established for the prehospital healthcare workers, the infection control department should communicate directly with that provider.

Prehospital healthcare workers are most at risk for exposures to blood and body fluids via needlesticks and splashes to mucous membranes. A system of reporting such exposures must be developed and included either in the hospital employee health program or by the outside healthcare provider. Education of the prehospital healthcare workers about reporting all exposures is important to the success of such programs. All prehospital healthcare workers need to know the mechanism for reporting exposures and fully understand the importance of postexposure evaluation, prophylaxis, and follow-up (see also Chapter 78).

Emergency Department: An After-Hours Employee Health Service

Traditionally, employee health services operate during the day Monday through Friday. However, employees who sustain an exposure after hours, on weekends, or on holidays usually report to the emergency department. Thus, the emergency department is often an extension of the employee health service, and communication between the emergency department and the employee health service and interaction with the infection control department is important to provide continuity of care for exposed employees.

Protocols for meningococcal exposure prophylaxis, hepatitis B vaccination and hepatitis B immune globulin administration, prophylaxis for exposure to HIV, and diagnosis of diseases such as chicken pox and measles are extremely helpful to emergency room doctors and nurses who are triaging an employee. Consistency in delivering care is the goal. Although the initial diagnosis or prophylaxis may occur in the emergency department, employees receive their follow-up care at the employee health service and their records are permanently filed in that location.

Although protocols outline the various interventions that are needed postexposure, it is important that emergency department physicians document the following: (a) complete description of the exposure; (b) completed employee occurrence report; (c) type of prophylaxis administered (e.g., hepatitis B vaccine and hepatitis B immune globulin) and schedule of additional doses if required; (d) clear communication to the employee regarding furlough status (after communication with the infection control department); and (e) referral to the employee health service, as soon as possible, to arrange follow-up care for any exposed or ill employee.

CHAPTER 94

Epidemiology and Prevention of Healthcare-Associated Infections Related to Animals in the Hospital

David J. Weber and William A. Rutala

Americans keep a wide variety of animals as household pets. Common pets include cats, dogs, birds, and fish; however, increasingly more exotic animals are being kept as pets, including other felines, ferrets, monkeys and other primates, rabbits, reptiles, rodents, and wolves. In addition, a variety of farm animals may be kept as pets, such as cattle, chickens, horses, pigs, and sheep. In 2006, 37.2% of households owned a dog, 32.4% owned a cat, 3.9% owned a pet bird, and 1.8% owned a horse *(1)*. The total number of animals owned was 72.1 million dogs, 81.7 million cats, 11.2 million birds, and 7.3 million horses. An estimated 9 million American homes had an aquarium. The average veterinary expenditures per household for all pets was $366 *(1)*. Retail trade in pet food alone totaled $41.2 billion in 2007 *(2)*.

Hospitalized patients may come into contact with animals for two main reasons: the use of animals for animal-assisted interventions (also known as pet therapy or pet-assisted therapy) and the use of service animals, such as guide dogs for the blind and primates for persons with impaired motion. This chapter focuses on the benefits and potential risks of animal use in the hospital, especially pet therapy. This chapter covers only the most common animals kept as pets and the major zoonotic diseases. Readers interested in a comprehensive review of zoonotic diseases or in rare and exotic zoonotic diseases are referred to several comprehensive monographs (*3,4*,5, *6–9*,10,*11*,12,*13,14*,15) and review articles *(16–18)*. Several excellent reviews of infections associated with pets have appeared in the general medical literature (19,*20–32*,33). The frequency of type of allergic reactions to pets has also been reviewed *(26,27,34–36)*. Finally, the infectious hazards associated with the use of animals in medical research have also been reviewed *(37–39)*. The clinical diseases associated with specific zoonotic agents and their therapy are well covered in infectious diseases textbooks *(40,41)*.

Multiple recent outbreaks of zoonotic diseases that have occurred as a result of petting zoos have called attention to the risks of human–animal contact, especially for young children (42,*43–45*). Recommendations to prevent such outbreaks have recently been published (46). In recent years, there has been a growing appreciation that most emerging infectious diseases are of zoonotic origin (*47–50*,51,52). Finally, with the exception of smallpox, virtually all potential bioterrorist agents are zoonotic pathogens including *Bacillus anthracis* (anthrax), *Coxiella burnetii* (Q fever), *Francisella tularensis* (tularemia), and *Yersinia pestis* (plague) *(53–62)*. Bioterrorist agents are discussed in Section XVII Bioterrorism. In the future, zoonotic pathogens may be introduced into humans via the use of xenotransplantation (*63–66*,67,*68*).

POTENTIAL HAZARDS OF ANIMALS IN THE HOSPITAL

A comprehensive literature survey of human pathogens listed more than 1,400 infectious agents capable of causing human infection *(47)*. Of these, more than half are known to be zoonotic (i.e., able to infect other host species). However, strictly speaking, zoonoses refer only to those diseases that are transmitted from vertebrate animals to humans. In most cases, humans are accidentally infected and are dead-end hosts. Other pathogens also share maintenance of their life cycle with both animals and humans. In addition, the ectoparasites of some domestic animals carry pathogenic microorganisms, which may spread to humans through close association with infested animals.

Humans may come into contact with animals through many activities, including pet ownership; leisure pursuits such as camping, hunting, and hiking; travel to remote regions; and via occupations such as animal husbandry, medical research, veterinary medicine, animal control, and handling of agricultural products or animal hides. This chapter reviews only the diseases most likely to be transmitted by domesticated animals that serve as pets or service animals, because these animals are most likely to be encountered in the hospital (Table 94-1). These common pets include birds; cats; dogs; rodents such as mice, rats, gerbils, and hamsters; and fish, turtles, snakes, and rabbits. Nonhuman primates that may be used to aid disabled persons are also discussed.

Potential Pathogens

Animals commonly used as pets can serve as the reservoir or source for a significant number of diseases that potentially could be transmitted to humans in the healthcare

TABLE 94-1

Diseases Potentially Transmitted by Pets in the Healthcare Setting

Infectious Disease	*Cats*	*Dogs*	*Fish*	*Fowl/Birds*	*Primates*	*Rabbits*	*Reptiles*[a]	*Rodents*[b]

[a]Reptiles include lizards, snakes, and turtles.
[b]Rodents include hamsters, mice, and rats.
+, rare zoonoses; ++, occasional zoonoses; +++, most common zoonoses.
(Adapted from references *4,16,18*,19,*20*.)

setting (Table 94-2). These animals are also involved in the life cycles of an even wider variety of diseases in which healthcare-associated transmission is either rare or impossible (e.g., echinococcosis, leishmaniasis, schistosomiasis, and trypanosomiasis). New zoonotic pathogens continue to be recognized either because the microbial agent is newly isolated or because its potential to cause human disease is newly recognized *(47–52)*. Newly discovered zoonotic pathogens discovered outside the United States include Nipah virus *(69)*, Hendra virus *(70)*, and SARS-coV *(71)*, whereas newly discovered pathogens in the United States include Sin Nombre virus *(72)* and Southern Tick–Associated Rash Illness *(73)*. Zoonotic diseases endemic outside the United States may spread to the United States,

TABLE 94-2

Medically Important Zoonotic Diseases

Pathogen	*Disease*	*Medical Illness(es)*
Viral		
Coronavirus	SARS	Pneumonia (mortality 10–15%)
Herpesvirus simiae (B virus)	B virus infection	Erythema, vescicles, ulcers, and local pain at site of inoculation Rapidly progressive ascending neuropathy and encephalitis
Lymphocytic choriomeningitis (LCM)	LCM meningitis	Influenza-like illness and occasional meningitis
Orbivirus	Colorado tick fever	Biphasic disease: sudden onset of fever, prostration, headache, photophobia, muscle and joint pains; followed by 2- to 3-d remission; then second episode of fever and rash (10%)
Orthopoxvirus	Monkeypox	Variola-like skin eruption with lymphyadenopathy (mortality ~10%)
Rhabdovirus	Rabies	Encephalitis (mortality ~100%)
Rotavirus	Rotavirus	Enteritis
Bacterial		
Aeromonas spp.	Aeromonas	Gangrenous wound infection, gastroenteritis, and pneumonia
Bacillus anthracis	Woolsorter's disease	Localized skin lesions; mediastinal or intestinal infection (rare) leading to sepsis
Borrelia burgdorferi	Lyme arthritis	Three stages: (a) localized characterized by skin rash (erythema chronicum migrans); (b) disseminated characterized by musculoskeletal symptoms, neurological, or cardiac abnormalities, arthritis; (c) persistent infection with chronic skin, nervous system, or joint involvement
Borrelia spp.	Relapsing fever	Systemic disease marked by periods of fever alternating with afebrile episodes; erythema, petechia, jaundice may occur
Brucella spp.	Brucellosis	Systemic disease with acute or insidious onset, characterized by fever, headache, weakness, sweating, chills, arthralgia, and weight loss
Campylobacter jejuni	Campylobacteriosis	Gastroenteritis
Capnocytophaga canimorsus	Septicemia	Sepsis with multiorgan failure and cutaneous gangrene
Rochalimaea henselae	Cat scratch disease	Lymphadenitis, Parinaud's syndrome, meningo-encephalitis, and bacillary angiomatosis in HIV-infected patients
Chlamydia psittaci	Psittacosis	"Atypical" pneumonia
Ehrlichia spp.	Ehrlichiosis	Multisystem disease; may have rash
Erysipelothrix insidiosa	Erysipeloid	Skin infection (localized pain, erythema, edema surrounding wound); arthritis; and sepsis (rare)
Francisella tularensis	Tularemia	Indolent ulcer and adenopathy (ulceroglandular); pneumonia; systemic symptoms (typhoidal); pharyngitis, abdominal pain, diarrhea, and vomiting (gastrointestinal); conjunctivitis; and adenopathy (oculoglandular)
Leptospira interrogans	Leptospirosis	Variable disease; biphasic illness—sudden onset with fever, headache, severe myalgias, conjunctival suffusion, rash, meningitis, hepatorenal failure, and CNS involvement
Listeria monocytogenes	Listeriosis	Variable disease, meningitis, and abortion
Mycobacterium marinum	Skin granulomas	Local ulcerative disease
Mycobacterium tuberculosis	Tuberculosis	Pneumonia, disseminated infection, and meningitis
Pasteurella multocida	Pasteurellosis	Cellulitis, septic arthritis, osteomyelitis; pneumonia; meningitis; endocarditis; sepsis; and intra-abdominal infection
Pseudomonas pseudomallei	Melioidosis	Fever, pneumonia, gastroenteritis; chronic cases may have necrotic and granulomatous soft tissue or bone lesions
Coxiella burnetti	Q fever	Variation in severity and duration; onset may be sudden with chills, headache, weakness, and malaise; pneumonitis and endocarditis may occur
Rickettsia rickettsii	Rocky Mountain spotted fever	Systemic illness with fever, headache, rash, meningitis, multiorgan failure
Salmonella enteriditis	Salmonellosis	Gastroenteritis, sepsis (occasionally), and osteomyelitis
Staphylococcus aureus	Staphylococcal infection	Skin and soft tissue infections, osteomyelitis, endocarditis, toxic shock syndrome, and gastroenteritis (toxin mediated)

(*Continued*)

TABLE 94-2

Medically Important Zoonotic Diseases (*Continued*)

Pathogen	*Disease*	*Medical Illness(es)*
Streptococcus pyogenes	Streptococcal infection	Pharyngitis and cellulitis; streptococcal toxic shock syndrome
Streptobacillus moniliformis	Haverhill or rat bite fever	Systemic illness characterized by sudden onset fever and chills, headache and muscle pain, followed by rash, polyarthritis, and rarely endocarditis
Vibrio parahemolyticus	Vibriosis	Acute gastroenteritis
Yersinia enterocolitica	Yersiniosis	Acute ileitis; peritonitis may occur; rarely septicemia, reactive arthritis
Yersinia pestis	Plague	Systemic disease with multiple manifestations: lymphadenitis (bubonic), pneumonia (pneumonic), and sepsis
Fungal		
Dermatophytes	Ringworm	Skin disease (ringworm)
Parasitic		
Babesia microti	Babesiosis	Sepsis with fever, shaking chills, headache, gastrointestinal symptoms, and arthralgias; hemolytic anemia
Cryptosporidia spp.	Cryptosporidiosis	Gastroenteritis (self-limited in normal host, may become chronic in immunocompromised host)
Ehrlichia risticii	Ehrlichiosis	Systemic illness similar to Rocky Mt. spotted fever without rash
Giardia lamblia	Giardiasis	Chronic diarrhea
Toxoplasma gondii	Toxoplasmosis	Usually asymptomatic, lymphadenopathy, chorioretinitis, and encephalitis (immunocompromised host)

(Adapted from references *4-6,8,9,27,28.*)

leading to sporadic infections or outbreaks such as dengue *(74)*, monkeypox *(75)*, and West Nile disease *(76)*.

Healthcare-Associated Hazards of Animals in the Hospital

Zoonotic diseases can be transmitted to humans through animal trauma (bites, scratches, and stings); direct contact; arthropod vectors; aerosols; and contamination of food, water, or milk *(4,77)* (Table 94-3). Physicians should be aware of the major clinical syndromes associated with zoonotic diseases and their potential to cause healthcare-associated infection (*78*,79,80) (Table 94-2).

Hospitalized patients often have altered host defenses that may increase their susceptibility to a zoonotic infection and/or increase the severity of clinical disease *(81–86)* (Table 94-4).

In addition to direct transmission from animal to human, healthcare epidemiologists and infection preventionists should be aware that some zoonotic diseases may be transmitted from human to human, whereas others may represent a hazard in the microbiology laboratory (Table 94-4) (see Chapter 77). Several recent papers have provided recommendations for the management of animals in public settings and healthcare facilities (46,*87–89*,90).

Unfortunately, few scientific studies have addressed the potential risks of animal-to-human transmission in the healthcare setting. Furthermore, because animals have, in general, been excluded from hospitals, experience gained by means of case reports and outbreak investigations is minimal. However, Lefebvre et al. *(91)* assessed 102 healthy visitation dogs for the presence of zoonotic pathogens. Zoonotic agents were isolated from 80% of animals including toxigenic *Clostridium difficile* (40.1%), *Salmonella* spp. (3%), extended spectrum β-lactamase (ESBL)- or cephaloporinase-producing *Escherichia coli* (4%), *Pasteurella* spp. (29%), *Malassezia pachydermatis* (8%), *Toxocaria canis* (2%), and *Ancylostoma caninum* (2%). Scott et al. *(92)* described an epidemic of methicillin-resistant *Staphylococcus aureus* (MRSA) on a rehabilitation geriatric ward. The paws and fur of a cat that roamed the ward were heavily colonized by MRSA, and the cat was considered to be a possible vector for the transmission of MRSA. Lyons et al. *(93)* described an outbreak of *Salmonella heidelberg* in a hospital nursery that was traced to infected calves on a dairy farm where the mother of the index patient lived. An outbreak of *Rhodococcus (Gordona) bronchialis* sternal surgical site infections after coronary artery bypass surgery was linked to a nurse whose hands, scalp, and vagina were colonized with the epidemic pathogen *(94)*. Although cultures of neck-scruff skin of two of her three dogs were also positive, whether the animals were the source for colonizing the nurse or whether both the animals and nurse were colonized from an environmental reservoir could not be determined. An evaluation of a large outbreak of *M. pachydermatis* in an intensive care nursery discovered that the isolates from all 15 case patients, 9 additional colonized infants, 1 healthcare worker, and 3 pet dogs owned by healthcare workers had identical patterns of restriction fragment length polymorphisms *(95)*. The authors believed that *M. pachydermatis* was likely introduced into the intensive care nursery from the healthcare worker's hands after being colonized from pet dogs at home and then persisted in the nursery through patient-to-patient transmission. Patient infections were not benign and included eight bloodstream infections, two urinary tract infections, one case of meningitis, and four asymptomatic colonizations. Multiple healthcare-associated outbreaks of

TABLE 94-3

Transmission of Important Zoonotic Diseases

Disease	*Aerosol*	*Ingestion*	*Contact*	*Animal Trauma*	*Arthropod-Vector*
Viral					
B virus infection		Saliva		Primate bite	
LCM meningitis	Infected aerosols	Food, water			
Colorado tick fever					Tick
Rabies	Probably bat caves, laboratory		Secretions, corneal tranplant	Wild animals, dog, cat	
Bacterial					
Aeromonas spp.	Fresh water drowning	Food, water	Water	Fish, reptile	
Anthrax	Spores in hides, spores in raw wool	Spores in contaminated meat	Spores in hides or environment	Contact with lesions on animals	
Brucellosis	Inhalation while handling animals or products	Goat cheese and milk products	Animal and food products		
Campylobacteriosis		Meat, poultry, milk, water	Puppies with diarrhea		
C. canimorsus sepsis				Dog bite	
Cat scratch disease				Cat scratch	
Ehrlichiosis					Tick
Erysipeloid			Fish slime, shellfish	Lobster or crab pinch	
Leptospirosis	Secretions, wild and domestic animals	Water, milk	Contaminated water		
Listeriosis		Vegetables, water, cheese			
Lyme arthritis					Tick
Melioidosis				Rodents	
Monkeypox	From infected animals		Primates, rodents		
Mycobacteriosis *(M. marinum)*			Water, fish tanks		
Pasteurellosis	Respiratory secretions		Cat, dog secretions	Feline bites and scratches, dog bites	
Plague	Inhalation-infected material		Infected animals	Cat scratch	Rodent flea
Psittacosis	Dried excreta from birds				
Q fever	Endospores from animal-contaminated soil, cat afterbirth		Infected animals		
Rat bite fever		Water, milk contaminated by infected urine		Lab and wild rodents	
Rocky Mountain spotted fever	Laboratory accident		Engorged tick		Tick
Relapsing fever					Tick
Salmonellosis		Food esp. poultry, eggs, shellfish, water	Fecal material reptile/amphibians		Cockroaches, bed bugs

(*Continued*)

TABLE 94-3

Transmission of Important Zoonotic Diseases (*Continued*)

Disease	*Aerosol*	*Ingestion*	*Contact*	*Animal Trauma*	*Arthropod-Vector*
Tuberculosis	Respiratory secretions	Milk (*M. bovis*)			
Tularemia	Droplet particles, dead birds, animals	Food including meat	Dressing squirrels, muskrats, etc.	Cat bite (rare)	Tick
Vibriosis		Shellfish			
Yersiniosis		Milk, water	Farm animals		
Fungal					
Dermatophytes			Dogs, cats		
Parasitic					
Babesiosis					Tick
Cryptosporidiosis		Cysts in water, ice			
Ehrlichiosis					Tick
Giardiasis		Cysts in water			
Toxoplasmosis		Oocysts from cat feces, tissue cysts from uncooked meat			

(Adapted from references *4,30,37,41*.)

Microsporum canis (ringworm) with person-to-person transmission have been described in newborn nurseries *(96,97)* or neonatal intensive care units *(98)*. In the latter case, the source of infection was a nurse, likely infected from her pet cat.

Outbreaks of Q fever have been described in a secondary school in which infected goats were maintained for teaching purposes *(99)*, in a psychiatric institution in which patients and staff worked with goats on a farm *(100)*, and in a university department in which sheep placentas were used for fetal respiratory studies *(101)*. There are two reports of postmortem examinations that lead to the transmission of *C. burnetii* to pathologists, mortuary technicians, doctors, and a medical student *(102,103)*. Person-to-person transmission of Q fever within a family that affected five members has been reported *(104)*. Healthcare-associated transmission has also been reported. There have been several reports of hospital staff who acquired Q fever via exposure to infected patients *(102,105,106)*. In the latter case, Q fever developed in an obstetrician 7 days after he cared for a woman undergoing a spontaneous abortion at 24 weeks. *C. burnetii* was identified in the fetal spleen and kidney, and the placenta, but not the lung. Probable patient-to-patient transmission has also been described *(107)*.

ANIMAL USE IN THE HOSPITAL

Service Animals as Aids for Disabled Persons

The Americans with Disabilities Act (ADA) of 1990 is a federal civil rights law that protects persons with disabilities from discrimination in areas of employment, public services, public accommodations, services operated by private entities, and telecommunications *(78)*. Title III of the ADA mandates that persons with disabilities accompanied by service animals generally must be allowed access with their service animals into places of public accommodation, including restaurants, public transportation, and healthcare facilities. The responsibilities of healthcare institutions under the Act have been extensively reviewed in a guidance document by the Association for Professionals in Infection Control and Epidemiology *(78)*. *Disability*, as defined in the ADA, is any physical or mental impairment that substantially limits one or more major life activities such as breathing, hearing, or caring for oneself. *Service animal* is a legal term defined in the ADA. A service animal is a dog individually trained to do work or perform tasks for the benefit of a person with a disability. A service animal is not considered a "pet," because it is specially trained to help a person overcome the limitations caused by his or her disability *(78)*.

Dogs are most often trained for service work *(78)*. In the United States, an estimated 5,000 working dogs guide the visually impaired, more than 2,500 working dogs assist the hearing impaired, and more than 2,500 working dogs aid the physically challenged persons *(108)*. Service animals provide several valuable services, including enhanced mobility, dignity, decreased anxiety, improved confidence, and independence *(109)*. Not surprisingly, visually challenged persons have a close relationship with their dogs. The importance of guide dogs is well recognized, and they are often exempt from public health regulations governing dogs in general. Animals may also be used to aid the hearing disabled and physically disabled patient; however, these uses are less well described than those of guide dogs.

TABLE 94-4

Zoonotic Diseases with Special Healthcare-Associated Concern

			Compromised Hosts with Increased Susceptibility[a]	
Disease	*Human-to-Human Transmission*	*Important Laboratory Hazard*	*At-Risk Population*	*Disease*

Ehrlichiosis	Not described	No	Not described	
Giardiasis	Yes (fecal–oral)	No	Not described	
Toxoplasmosis	Yes (transfusion)	Yes	Organ transplant	Pneumonia
			HIV infection	Encephalitis

[a]Lack of a described risk should not be taken to imply that immunocompromised patients are not in fact at higher risk for disease acquisition or progression.

Healthcare facilities as places of public accommodation are required to permit the use of service animals by a person with a disability as defined by the ADA, unless doing so would create a fundamental alteration or a direct threat to the safety of others or the facility *(78)*. It is not permissible to require that a service animal wear special equipment or tag nor is it permissible to require "certification" or proof of an animal's training or a person's disability.

To ensure compliance with the ADA, healthcare facilities should have a written policy regarding the use of service animals by employees, patients, and visitors. This policy should ensure that service dogs and their owners have general access to the institution. The service animal policy should include the following topics *(78,110)*. First, the locations in the hospital from which the service animal is prohibited. Such areas would include those that pose a risk to patients, especially areas that require the use of sterile or clean precautions such as operating rooms, pharmacy, and kitchens. Also, the service animal should be prohibited from areas that pose a risk to the animal such as pathology and radiology. Second, facilities should not permit handlers with service animals to act as self-appointed animal-assisted therapy (AAT) ("pet therapy") providers. Third, employees, visitors, and patients should be educated to understand that service animals should not be allowed to come in contact with any patient's nonintact skin (e.g., surgical wounds and drainage tube). Fourth, there should be a mechanism to screen persons other than the handler (e.g., roommate) who may come into contact with the service animal for allergies or fears regarding the service animal. Fifth, the policy should define conditions on which the service animal may be removed, restricted, or denied access to an area. Such conditions might include aggressive behavior (i.e., biting), inability to contain excretions, or apparent illness. Evaluation of a potentially ill animal should be made by a veterinarian. Sixth, care and feeding of the service animal should be the responsibility of the owner or the handler or their designee rather than healthcare personnel. The facility may elect to provide temporary care such as during a short operative procedure but would need to have available trained personnel. Legal services should be consulted regarding any formal consent needed when the handler transfers responsibility for service animal stewardship to a facility representative. Finally, a mechanism should be in place for determining the appropriate use of a service animal on a case-by-case basis.

Differences Between Service Animals and Therapy Animals

Therapy animals and their handlers are trained to provide specific human populations with appropriate contact with animals *(111)*. They are usually personal pets of the handlers and accompany their handlers to the sites they visit, but they may also reside at a facility. Animals must meet specific criteria for health, grooming, and behavior. Therapy animals are usually not service animals. Federal law, which protects the rights of qualified persons with disabilities, has no provision for people to be accompanied by therapy animals in places of public accommodation that have "no pets" policies. AAT is a goal-directed intervention in which an animal is incorporated as an integral part of the clinical healthcare treatment process. Animal-assisted activities (AAAs) provide opportunities for motivational, educational, and/or recreational benefits to enhance a person's quality of life. Both AAT and AAA are delivered by a trained person.

Animal-Assisted Therapy

AAT is designed to promote improvement in the physical, psychosocial, and/or cognitive function of people who are being medically treated *(112)*. Other terms used in the literature for AAT are "pet therapy" or "pet-facilitated therapy." In a review of pet-facilitated therapy as an aid to psychotherapy, Draper et al. *(113)* noted that a literature review conducted in 1987 revealed more than 1,000 articles on the human–animal bond. As of 1983, however, only six studies of the therapeutic value of pets in which controls were used had been reported. They concluded that the benefits of pet therapy rely heavily on anecdotal reports and the widespread attachment of persons with animals. More recently, Allen *(114)* performed a critical appraisal of the literature from 1986 through 1997 and concluded that most reports describing the effects of human–canine interactions fell into the lowest category of scientific studies (i.e., descriptive studies and expert opinion). Newer research, sometimes using controlled trials, has provided evidence that companion animals provide health benefits in the home setting *(115)*. However, there continues to be a paucity of well-designed clinical trials evaluating the benefits of AAT in the hospital.

The benefits of AAT have been reviewed *(116–122)*. AAT has been most commonly reported to be beneficial among the chronically mentally ill *(118,123–125)*, geriatric patients *(126–130)*, patients with hypertension or coronary artery disease *(131,132)*, and human immunodeficiency virus–infected persons *(133)*.

Several recent articles have reviewed the potential risks associated with AAT in healthcare facilities *(87,134–136)*. Risks fall into four general areas: reservoir of multidrug-resistant human pathogens, animal bites or scratches, allergies, and transmission of a zoonotic infection. The potential risks of bites or acquisition of a zoonotic disease are reviewed later. However, to date, there have been no reports of illness or disease among hospitalized patients associated with a well-designed program that provides AAT.

ANIMALS USED IN HOSPITALS AS RESERVOIRS OF MULTIDRUG-RESISTANT PATHOGENS

Since the last revision of this chapter, there has been a growing literature that animals commonly used as pets or for AAT may be colonized with multidrug-resistant pathogens and that these animals may transmit such pathogens to human contacts (*137*,138,139). Of particular concern are MRSA, *C. difficile*, and ESBL-producing gram-negative bacilli *(140)*.

MRSA first emerged as a serious pathogen in human medicine in the late-1970s and has been increasingly reported in animals in the last 10 years *(141)*. Human strains of MRSA have increasingly been described in cats, dogs,

horses, and pigs. A cross-sectional study demonstrated a high prevalence of concurrent MRSA colonization as well as identification of indistinguishable strains in humans and pet dogs and cats in the same household *(142)*. Owners of MRSA-colonized dogs are more likely than owners of non-MRSA-colonized pets to be colonized with MRSA *(143)*. A positive correlation has been demonstrated between the presence of a cat in the home and isolation of MRSA from surfaces *(144,145)*. Recently, 2 of 11 resident cats of a long-term care facility were found to be colonized with MRSA *(146)*. It appears that humans are generally the vector for animal colonization *(141)*. For example, a pet therapy dog appears to have been colonized by MRSA after visiting the geriatric wards *(147)*. In a longitudinal study of dogs involved in AAT in healthcare facilities, Lefebvre et al. *(148)* demonstrated a rate of MRSA acquisition that was 4.7 times higher than in dogs involved in other animal-assisted interventions. However, animal-to-human transmission has been suggested. For example, Manian reported recurrent MRSA infection in a patient with diabetes and in his wife. The nares of the family dog were colonized with an identical strain of MRSA. Recurrence of MRSA infection and nasal colonization in the couple was halted only following successful eradication of MRSA from the dog's nares *(149)*. Similarly, Cefai et al. described a colonized dog that was implicated as reservoir for reinfection of two nurses after their treatment to eliminate MRSA carriage *(150)*. To date, the available data on MRSA transmission between humans and companion animals are limited, and the public health impact of such transmission needs to be the subject of more detailed epidemiologic investigations *(151)*.

The incidence of *C. difficile* infection in the United States has been noted to be increasing over the last decade in association with the emergence of a new, hypervirulent stain (NAP1/BI/O267) *(152)*. *C. difficile* is both a commensal microorganism and a pathogen in domestic and food animals *(153)*. Recent studies have found considerable overlap among bovine, equine, porcine, canine, and human isolates *(153,154)*. Toxigenic strains of *C. difficile* have been isolated from companion dogs, and dog colonization with *C. difficile* was associated with living with an immunocompromised individual *(155)*. Human strains of *C. difficile* have been isolated from the stool *(156)* and paws *(157)* of pet therapy dogs.

ESBL-producing gram-negative bacilli have been isolated from animals *(140)*. Recently, acquisition of a multidrug-resistant *E. coli* from a dog bite was reported *(158)*.

DISEASES TRANSMITTED BY ANIMAL BITES

Animal bites are a major public health problem *(159,160)*. National estimates based on a 1994 national telephone survey of randomly selected households revealed 4.7 million dog bites, of which approximately 799,700 necessitated medical attention *(161)*. These numbers corresponded to an annual incidence rate of 18 per 1,000 and bites requiring medical attention 3 per 1,000 (adults 2 per 1,000 vs. children 6.4 per 1,000). A follow-up survey from 2001 to 2003 revealed that an estimated 4.5 million people were bitten each year *(162)*. Compared with 1994, the incidence of dog bites among adults remained relatively unchanged whereas the incidence among children declined by 47%. Overall, 19% of dog bites required medical attention. Although most bite wounds are trivial and most victims do not seek medical attention *(162)*, bite wounds have been reported to account for approximately 1% to 2% of all emergency department visits in the United States *(162–167)*. More precise population-based estimates are available from a 1992 to 1994 National Center for Health Statistics survey, which reported that 334,000 dog-related injuries were seen in US emergency departments for a rate of 129 per 100,000 persons *(164)*. More recent data from the National Electronic Surveillance System-All Injury Program for the year 2001 revealed that an estimated 368,245 persons were treated in US emergency departments for dog bite–related injuries (rate: 129.3 per 10,000 population) *(168)*. This is slightly lower than the rate of 158 per 10,000 population reported from the 2001 to 2003 national cross-sectional telephone survey *(162)*. Although most bites produce only minor injury, at least 10% require suturing *(169)*, and 1% to 5% required hospitalization *(164,167,169–173)*. An estimated 5,991 hospitalizations resulted from dog bites in 1994 *(173)*. Between 1991 and 1998, 6,676 hospitalizations in California resulted from dog bites *(174)*. Attacks by dogs resulted in at least 25 deaths between 1995 and 1996 *(175)* and 27 deaths between 1997 and 1998 *(176)*. Between 1979 and 2005, an average of 19 deaths were reported annually from dog bites *(177)*. In summary, dog bites result annually in an estimated 17 to 19 deaths, 6,000 to 13,000 hospitalizations, and more than 330,000 emergency department visits, with the total costs of treating these injuries being $235,600,000 to $253,700,000 *(173,177)*. Because of its medical importance, the epidemiology, clinical management, and prevention of bite wounds have been extensively reviewed *(165,171,178–190)*.

Epidemiology

Only the epidemiology of bites relevant to risks associated with the use of animals in the hospital is reviewed here. Dog bites account for 70% to 93% of animal bites, and cat bites account for 3% to 15% *(165,171,191–193)*. Dog bites more commonly involve the lower extremities, followed by the hands, arms, face, and trunk *(165,171,179,193)*. A survey of dog bite wounds treated in the emergency department in 2001 revealed that 45% of injuries occurred to the arm and hand but that injuries to the extremity increased with age and accounted for 86.2% of injuries treated in persons 15 years of age *(168)*. Cat bites more commonly involve the hands, followed by the arms, lower extremities, face, and trunk *(165,179,194)*. The peak incidence of bites occurs in persons 5 to 9 years of age *(164,168–170,193)*. Compared with older children and adults, young children have a higher risk of being bitten and of suffering fatal injuries from bites *(172,175,195–197)*; bites are more likely to involve the face, head, or neck *(164,168,195,198,199)*; bites are more likely to occur at home and to be caused by the child's pet *(164,172,196)*; and the attacking dog is less likely to have a history of biting *(172)*.

About two-thirds of bites occur when interacting with a dog (e.g., petting, feeding, and playing) or when on the dog owner's property *(193,200)*. Only about 25% of victims, however, report direct interaction with the dog, such as

feeding, playing, or petting *(193)*. Only a small proportion of bites occur when the dog has been teased or abused. Large dogs are more commonly involved than small dogs in attacks. Shepherds and mixed breeds are most commonly named as the biting animal *(165,198,199,200)*. During 1995 to 1996 and 1997 to 1998, Rottweilers were the most commonly reported breed involved in fatal attacks *(175,176)*.

Etiologic Agents of Infection

The infection rate from penetrating dog bites has generally been reported in the range of 5% to 15% *(165,166,181,201)*. Cat bites are more likely to become infected than dog bites *(165,202)*. Factors that increase the risk of infection after a dog or cat bite include (a) full-thickness puncture; (b) hand or lower extremity wounds; (c) wounds requiring surgical debridement; (d) wounds involving joints, tendons, ligaments, or fractures; and (e) wounds in patients who are high-risk hosts *(181)*.

A large number of aerobes and anaerobes have been isolated from the gingival flora of cats and dogs *(203,204)*. Pathogenic microorganisms derived from the normal oral flora of cats and dogs can be isolated from approximately 90% of clinically infected wounds *(205,206)*. Most infections that develop after a cat or dog bite are polymicrobial *(206–208)*. Goldstein, Talan, and associates *(207–211)* have studied the microbial agents associated with animal bite infections. The most common aerobic microorganisms isolated from infected dog bites were *Pasteurella* species 50%, *Streptococcus* species 46%, *Staphylococcus* species 46%, and *Neisseria* species 16% *(208)*. The most common aerobic microorganisms isolated from infected cat bites were *Pasteurella* species 75%, *Streptococcus* species 46%, *Moraxella* species 35%, *Staphylococcus* species 35%, and *Cornyebacterium* species 28% *(208)*. Anaerobic microorganisms are commonly isolated from both cat bite and dog bite wounds. In addition to these microorganisms, others included *Enterococcus* species, *Eikenella corrodens*, EF-4a and 4b, *Micrococcus* species, *Acinetobacter actinomycetemcomitans*, and *Haemophilus aphrophilus*. Rarely, gram-negative bacilli, such as *Proteus mirabilis*, *Enterobacter cloacae*, and *Pseudomonas fluorescens*, have been isolated from infected wounds. Of particular importance is *Capnocytophaga canimorsus*, which has been associated with severe sepsis and a high case–fatality rate. Unusual infections following dog bites have included blastomycosis *(212)*, leptospirosis *(213)*, brucellosis *(214)*, and salmonellosis *(215)*. Unusual infections transmitted by cat bites or scratches have included tularemia *(216–228)* and plague *(229–232)*.

The anaerobic bacteria isolated from dog bite wounds may include species of *Actinomyces*, *Bacteroides*, *Fusobacterium*, *Peptostreptococcus*, *Eubacterium*, *Veillonella*, and *Leptotrichia*. The constituents of the oral flora of animals may occasionally be β-lactamase producers *(205)*.

A large number of pathogens may occur in infections that complicate the bites of animals other than dogs and cats *(178)*; however, a few generalizations may be made. All felines, including lions, cougars, panthers, and tigers, may transmit *Pasteurella multocida. P. multocida* may also be transmitted by other animals, including pigs, rabbits, rats, opossums, and wolves. The agents of rat bite fever, *Streptobacillus moniliformis* and *Spirillum minor*, may be transmitted by several small rodents, such as the rat, mouse, and gerbil *(233)*. Bites inflicted in the water or by aquatic animals or reptiles (alligators, snakes, and piranhas) may become infected with *Aeromonas hydrophila*, *Vibrio* species, or *Edwardsiella tarda*. Although most cases of tularemia follow the handling of rabbits, infection may be transmitted by bites from other animals, such as the cat, coyote, pig, and squirrel. Ferrets have become a popular pet in recent years. Ferret attacks are common and may lead to severe injury and even death, especially among young infants *(234,235)*. Ferrets have been the source of viral influenza *(236)* and *Mycobacterium bovis* chronic wound infection *(237)*. Potential zoonotic diseases include leptospirosis, listeriosis, salmonellosis, campylobacteriosis, tuberculosis, rabies, cryptosporidiosis, dermatophytosis, scabies, and various helminth infections (visceral larva migrans, cutaneous larva migrans, dipylidiasis, and dirofilariasis) *(238)*.

More than 80 strains of aerobic bacteria have been isolated from the mouths of rhesus monkeys *(239,240)*. Nonhuman primate bites can result in infection with herpes B virus, *E. corrodens*, *Corynebacterium* species, α-hemolytic streptococci, and occasionally *Enterobacteriaceae (241)*. Nonhuman primates may become infected with bunyaviruses (Marituba fever, Caraparu fever, and Oropouche virus), poxviruses (tanapox and monkeypox), rhabdoviruses (Marburg disease), togaviruses (Kyasanur forest virus, yellow fever, and Zika fever), hepatitis A, hepatitis B, *Campylobacter*, *Salmonella*, *Shigella*, *Mycobacterium tuberculosis*, *Yersinia* species, *Giardia*, *Cryptosporidia*, filaria (*Brugei malayi*), flukes (*Paragonimus westermani*), and flatworms (*Schistosoma japonicum*). Transmission to humans for some pathogens (e.g., *B. malayi*) may require the presence of specific arthropod vectors. Other agents may be transmitted by the respiratory route (e.g., *M. tuberculosis*) or the fecal–oral route (e.g., hepatitis A). Of these pathogens, laboratory personnel have acquired Marburg virus, Ebola virus, monkeypox, hepatitis A, *Shigella*, tuberculosis, and herpes B virus infection. To date, more than 25 cases of herpes B virus infection in humans have been reported *(242–246)*, with a case–fatality rate of >50%. A guideline designed to prevent herpes B virus infection in monkey handlers has been published *(247)*.

PATHOGENS OF SPECIAL IMPORTANCE

Pasteurella Species

Epidemiology and Microbiology *Pasteurella* spp. are small, nonmotile, nonspore-forming, gram-negative coccobacilli. On gram-stained smear, the microorganisms generally appear as a single bacillus but may occur in pairs or chains. They frequently show bipolar staining. The microorganisms are aerobic, facultatively anaerobic, and grow well at 37°C on blood, chocolate, and Mueller–Hinton agar but not on MacConkey's agar. Growth is facilitated by enriched media and increased CO_2. More than 17 species of *Pasteurella* are known; *P. multocida* subspecies *multocida*, *P. multocida* subspecies *septica*, *P. canis*, *P. stomatis*, and *P. dogmatis* are the most common pathogens in humans *(248)*. One author noted that *P. multocida* subspecies *septica* was more likely to be isolated from wounds and

P. multocida subspecies *multocida* from the respiratory tract *(248)*. However, a larger study reported that for both cat- and dog-associated bite wounds, *P. multocida* subspecies *multocida* was more commonly isolated than *P. multocida* subspecies *septica (208)*.

P. multocida has been isolated from the digestive system or respiratory tract of domestic cats and dogs, rats, mice, rabbits, cattle, sheep, swine, horses, and monkeys. Carriage rates of *P. multocida* in the oral or nasal secretions of various apparently well animals are high: 70% to 90% in cats, 50% to 66% in dogs, 51% in pigs, and 14% in Norway rats.

Most human infections result from direct inoculation by bites or scratches. Infections following animal exposure in the absence of bites or scratches probably stem from contact with animal secretions. *P. multocida* infections are frequently associated with impaired host defenses and include the following localized infections (host defense defects): septic arthritis (prosthetic joints or joints damaged by degenerative or rheumatoid arthritis), meningitis (infants younger than 1 year of age or elderly persons), spontaneous bacterial peritonitis (cirrhosis), sepsis (alcoholism and diabetes mellitus), lower respiratory tract infections (chronic obstructive pulmonary disease and bronchiectasis), urinary tract infections (underlying structural and/or functional alterations), and endocarditis (prosthetic valve). Human-to-human spread of infection has not been documented, and contaminated food or water has not been implicated as a source of infection.

Clinical Features of Disease and Diagnosis Infections with *P. multocida* may be divided into three categories *(249)*. First, soft tissue infections may follow animal bites or scratches *(250–253)*. Rapidly spreading cellulitis is the most common presentation. Joint or bone penetration may lead to septic arthritis or osteomyelitis *(254)*. Prosthetic joints may be seeded by more distal injury with infection *(255,256)*. Second, *P. multocida* may cause respiratory tract colonization or infections such as acute pneumonia, chronic pneumonitis, or empyemas *(250,252,257–259)*. Most infected patients have underlying pulmonary diseases, including bronchitis, chronic obstructive pulmonary disease, or bronchiectasis. A history of animal contact is common, but actual bites or scratches are rare. Finally, *P. multocida* may cause serious systemic diseases such as endocarditis *(260,261)*, meningitis *(262–264)*, intra-abdominal infection *(252,265,266)*, urinary tract infection *(267)*, and sepsis *(268–270)*.

Definitive diagnosis requires isolation of the microorganism. However, *P. multocida* should be considered a potential pathogen in any skin or soft tissue infection after an animal bite, especially that of a cat or a dog.

Capnocytophaga Canimorsus

Epidemiology and Microbiology *C. canimorsus* (dysgonic fermentor-2 [DF-2]) is a fastidious, gram-negative, opportunistic pathogen that can cause serious multiorgan disease in humans. More than 100 cases have been described in recent reviews *(270–280)*.

C. canimorsus is a thin nonspore-forming rod 1 to 3 μm long. The microorganism exhibits gliding motility and is oxidase- and catalase-positive but negative for nitrate reduction, urease, and indole. It is a fastidious, slow-growing microorganism that, depending on the culture method used, may take from 3 to 11 days to form mature colonies.

C. canimorsus has a worldwide distribution. Studies suggest that it is part of the normal gingival flora of cats and dogs. Although infected patients have ranged from infants to persons older than 75 years, 60% of infections have been reported in adults older than 50 years.

Approximately 80% of patients reported in the literature have a predisposing condition, most commonly splenectomy. Other predisposing conditions have included Hodgkin's disease, trauma, idiopathic thrombocytopenic purpura, alcohol abuse, steroid therapy, and chronic lung disease. Forty percent of the cases of sepsis, however, have occurred in persons with no predisposing condition. Sepsis is the most common clinical infection. *C. canimorsus* infections range from mild to fulminant, with shock, respiratory distress, and disseminated intravascular coagulation. Meningitis may occur *(281,282)*. Dermatological lesions (maculopapular rash and purpura) or gangrene are common. The overall mortality is approximately 30%.

Infection is strongly associated with dog bites. More than 50% of patients have reported dog bites before clinical infection. Infections have also followed cat bites or scratches *(278,283,284)*, scratches from dogs, and contact with wild animals. An additional 20% of patients have reported exposure to dogs without a history of an actual bite or scratch.

Clinical Features of Disease and Diagnosis The clinical syndrome in humans is characterized by disseminated intravascular coagulation, cellular necrosis in certain organs such as kidneys and adrenal glands, cutaneous gangrene, thrombocytopenia, hypotension, hemorrhagic diathesis with purpuric skin lesions and petechiae, and renal failure with oliguria and anuria. The case–fatality rate is approximately 25%. Death has not been confined to immunocompromised patients.

Infection with *C. canimorsus* should be considered in patients who have a compatible clinical syndrome with a history of a dog bite or animal exposure. Definitive diagnosis requires isolation of the microorganism from blood or other body fluids or tissues. Empiric therapy should be instituted based on the clinical presentation. In patients who show high-grade bacteremia, the microorganism has been demonstrated in peripheral blood smears *(285,286)*. Therefore, all patients suspected of having *C. canimorsus* sepsis, especially splenectomized patients, should have a Gram stain of their buffy coat.

Cat Scratch Disease

Epidemiology and Microbiology Multiple species of *Bartonella* have now been demonstrated to be pathogenic for humans *(287,288)*. Clinical syndromes caused by these bacteria (etiologic agents) include the following: Oroya fever and verruga peruana (*B. bacilliformis*), bacteremia and endocarditis (*B. quintana* and *B. henselae*), bacillary angiomatosis (BA) and peliosis (*B. quintana* and *B. henselae*), HIV-associated neurologic syndromes (*B. quintana*), and cat scratch disease (CSD) (*B. henselae*, *B. clarridgeiae*, and *Afipia felis*) *(289–296)*. *B. henselae* is considered the primary agent of CSD *(297)*.

The syndrome of regional lymphadenopathy after a cat scratch was first described in 1932 by Lee Foshay in the United States and Robert Debre in France. Debre and Lamy provided the definitive description of CSD in 1950. A clinical diagnosis of CSD was established by the presence of three of four criteria including (a) a history of animal (in 99% of cases, a cat or dog) contact with an abrasion, scratch, or ocular lesion; (b) a positive cat scratch skin test result; (c) negative results of laboratory studies for other causes of lymphadenopathy; and (d) characteristic histopathology of the lymph node.

Infection with *Bartonella* species results in disease syndromes of variable severity, ranging from lymphadenopathy only (CSD) to systemic disease. As noted by Anderson and Neuman *(294)*, the severity and presentation of disease are related to immune status. In general (excluding *B. bacilliformis*), immunocompetent patients who are otherwise healthy tend to present with classic CSD when infected with *B. henselae*. Patients who are immunocompromised by having AIDS, chronic alcoholism, immunosuppression, or other serious health problems tend to have systemic disease; however, there have been rare reports of systemic disease, including BA, in immunocompetent persons *(298)*.

Clinical Features of Disease and Diagnosis CSD most commonly occurs among children and adolescents. Typically, it begins 4 to 6 days after animal contact (most commonly a scratch by a cat, especially a kitten) with the formation of a 2- to 3-mm macule at the site of inoculation, which progresses to a papule or pustule. Inoculation papules are described in 50% to 76% of reports *(299)*. Approximately 3 weeks after inoculation, regional adenopathy develops (range 5–50 days). About 80% of involved nodes are located in the head, neck, or upper extremities. The node is tender in 80% of patients and suppurates in 15% of patients. Fever and malaise each accompany the illness in about 30% of patients. Resolution occurs spontaneously in 2 to 6 months. Less common clinical findings include rash, hepatosplenomegaly, lytic bone lesions, granulomatous conjunctivitis, pneumonitis, endocarditis, and central nervous system involvement *(300)*. *B. henselae* has been shown to be the third most common cause of fever of unknown origin in children, accounting for approximately 55% of cases.

Manifestations of *Bartonella* infection in the immunocompromised patient include cutaneous BA, extracutaneous lesions, bacillary peliosis hepatitis, and fever with bacteremia *(301–303)*. BA is the most common clinical manifestation of *Bartonella* infection in the immunocompromised person. Clinical findings associated with BA include elevated, friable, firm, bright red papules (67% of cases); subcutaneous nodules (50%); and cellulitis plaques (5–10%). Extracutaneous manifestations may be present and include visceral lesions in the respiratory or gastrointestinal mucosa, heart, liver, spleen, bone marrow, muscles, or lymph nodes.

CSD is diagnosed by its distinctive clinical picture and the characteristic histology of lymph node biopsies. Similarly, BA is diagnosed by its clinical syndrome and characteristic histology of skin or liver biopsies. Serologic tests (indirect fluorescence assay and enzyme immunosorbent assay) for the diagnosis of *B. henselae* are now widely available. In addition, polymerase chain reaction tests are now commercially available using tissue or blood.

Prevention of Animal Bites in the Hospital

Hospital personnel and owners of seeing-eye dogs should be notified to discourage the petting of such dogs. Petting and playing with dogs distracts them from their primary responsibility and might lead to injury.

Animals used for pet therapy should be carefully screened, and all encounters should be carefully supervised. Patients who might benefit from pet therapy should be carefully screened as well. Toddlers, patients with psychiatric difficulties, and active children are probably at higher risk for bites and should either be excluded from pet therapy or carefully supervised. Guidelines for the prevention of animal bites have been published *(304,305)*. Immunocompromised patients, including functionally asplenic patients and HIV-infected patients, also should not interact directly with animals. All patients bitten or scratched in the hospital should be appropriately evaluated.

DISEASES TRANSMITTED BY DIRECT CONTACT

Ectoparasites

Animals may be infested with ectoparasites, which harbor microorganisms potentially pathogenic for humans, either transiently or chronically. Animals that are allowed outdoors, such as cats and dogs, are at special risk for becoming infested. Once infested, close contact with humans may allow transmission of infection. Of most concern are tick-borne diseases, which in the United States include babesiosis, Colorado tick fever, ehrlichiosis, anaplasmosis, Lyme disease, relapsing fever, Rocky Mountain spotted fever, southern tick–associated rash illness, and tularemia *(306–312)*. In general, the reservoirs for these diseases are small animals, such as rodents or rabbits. Only in the case of ehrlichiosis is the dog believed to be a possible reservoir. In other cases, the dog acts as a passive carrier of the infected tick. Pets may become ill with leptospirosis, Rocky Mountain spotted fever, and tularemia.

As with humans, pets should be inspected twice daily for ticks. Removal is best accomplished by grasping the head of the tick with a forceps and gently pulling until it is removed *(313)*. Care should be taken to avoid crushing attached ticks, spraying blood from engorged ticks, and excoriating the area. After removal, the area should be cleansed with soap and water or a disinfectant.

Cats and dogs could also be agents for transmitting plague to humans via its rodent flea vector. Plague causes a self-limited disease in dogs, but cats are susceptible to severe and often fatal infection. Animal fleas are best eradicated by flea dips. Pets should not be allowed to forage in areas where *Y. pestis* is prevalent.

Scabies is caused by a subspecies of the mite *Sarcoptes scabiei (314)*. The subspecies that infects cats and dogs can occasionally be transmitted to humans. These mites can cause intensely pruritic, papular, excoriated lesions but do not cause burrows, because the animal subspecies cannot complete its life cycle in humans. Hence, disease

is a manifestation of hypersensitivity in the human host. Diagnosis is by clinical presentation because skin scrapings are negative. Multiple healthcare-associated outbreaks of scabies have been reported *(315–317)*. Control measures have been described *(316,317)*.

Fleas from infested animals, as well as those in the environment, will feed on humans *(314)*. They also carry the intermediate stage of the tapeworm, *Dipylidium caninum* (human infestation occurs via ingestion of infected fleas).

Pathogenic Bacteria

In addition to harboring *Staphylococcus* spp. *(318)*, animals may rarely harbor pathogenic *Streptococcus* species in their eyes *(319)*, on their fur, or in their pharynx. Occasionally, humans may become infected as a result of animal contact. For example, a household cat or dog has occasionally served as the reservoir for household infections with the group A *Streptococcus (320)*.

Dermatomycoses

Zoophilic dermatophytes occasionally cause disease in humans. *M. canis* (less commonly *M. gypseum* and *Trichophyton mentagrophytes*) produces most superficial fungus infections of dogs and cats and may cause tinea capitis or ringworm in humans *(19,321)*; however, cats, the major reservoir for *M. canis*, often have inconspicuous or subclinical infections. These infections may not be suspected until lesions appear on human contacts. Ten percent to 30% of cases of human dermatophytoses in urban settings are estimated to be of animal origin.

The spectrum of disease is variable and can include circular alopecia, scaling and crusting lesions, or ulcers and nodules. Ringworm is characterized by an annular, expanding, erythematous area with central scaling, crusting or healing, and surrounding follicular papules. An exudative secondary bacterial infection may occur. Wood's light examination of hairs demonstrates *Microsporum* infection by showing blue-green fluorescence. Zoophilic fungal infections may also be demonstrated by scraping the lesions followed by examination with 20% potassium hydroxide. Exact identification of pathogens requires culture on fungal media.

Aquariums and Water-Related Diseases

A large number of bacterial infections may be acquired by trauma sustained in water or by injuries caused by water-dwelling animals *(322–324)*. The most important of these pathogens are *A. hydrophila*, *E. tarda*, *Erysipelothrix rhusiopathiae*, *Mycobacterium marinum*, *Vibrio cholerae* non-O1, *V. parahaemolyticus*, and *V. vulnificus*. Aquarium-acquired *Plesiomonas shigelloides* infection has been reported in a 14-month-old girl *(325)*. Cercarial dermatitis occurred in a 33-year-old man who stocked his aquarium with local snails *(326)*.

M. marinum causes granulomatous, papular cutaneous lesions in humans. Deep tissue infections may also occur and include tenosynovitis, septic arthritis, and osteomyelitis. Many cases result from injuries sustained while cleaning fish tanks *(327–336)*. Rarely, infections due to other *Mycobacterium* spp. have been associated with care of an aquarium *(337)*. A public aquarium was reported to be the source of an outbreak of Legionnaires' disease *(338)*. Pet turtles *(339)* and frogs *(340)* that are often maintained in home aquariums have been responsible for multistate outbreaks of salmonellosis.

Other potential infections that could be acquired by maintaining an aquarium include erysipeloid and gangrenous soft tissue infections. Erysipeloid is a skin infection of pig handlers, abattoir workers, and fish workers worldwide. Infection usually results when the microorganism contaminates cuts and abrasions. Infection is characterized by erythema with pain and edema of skin spreading peripherally. Septic arthritis may develop. Severe cellulitis, including gangrenous soft tissue infection, may result from infection with *A. hydrophila* or *V. vulnificus. Aeromonas* infection has also followed the use of medicinal leeches (see following section).

A large number of marine animals may injure humans via bites or stings or when humans ingest them *(341–346)*.

Because aquariums may harbor the aforementioned pathogens, aquariums, if present in a medical facility, should be cleaned only by trained medical personnel. In addition, because water may serve as a reservoir for multiple antibiotic-resistant gram-negative bacilli, aquariums should not be maintained in areas frequented by immunocompromised or intensive care patients.

Francisella tularensis

Epidemiology and Microbiology *F. tularensis* is capable of infecting more than 100 species of wild and domestic animals and more than 100 species of invertebrates *(347)*. The diversity of both biological and mechanical vectors is also high (>15 ticks, >10 mosquitoe species, tabanid flies, mites, fleas, and lice) *(348,349)*. Natural foci of infection are found in the Northern Hemisphere. Both sporadic *(350)* and epidemic cases occur *(351)*.

Tularemia may be acquired via multiple routes including (a) direct contact with infected animals, including bites, scratches, and contact with nonintact skin or mucous membranes; (b) arthropod bite (most commonly an infected tick); (c) inhalation of contaminated animal products in the laboratory; and (d) ingestion of contaminated food or water *(348,349,352–361)*. Crushing of infected ticks living on dogs may also lead to infection *(362)*.

Clinical Features of Disease and Diagnosis The incubation period is 3 to 5 days (range 1–21 days). Multiple clinical forms have been described; they are determined principally by the agent's route of entry *(348,349,356–362)*. Tularemia usually starts abruptly, with onset of fever, chills, headache, anorexia, malaise, and fatigue. Other symptoms include myalgia, cough, vomiting, pharyngitis, abdominal pain, and diarrhea. Fever typically lasts several days, remits for a brief period, and then recurs *(363,364)*. Presentations of tularemia include the following:

1. Ulceroglandular (21–78% of cases)—The most common presentation of tularemia is the ulceroglandular form, which accounts for about 85% of cases in the Western Hemisphere. A local lesion is seen at the site of entry (an arthropod bite or an injury inflicted by a contaminated sharp), which progresses to a necrotic ulceration accompanied by swelling of the nearby lymph node. The node frequently suppurates, ulcerates, and becomes sclerotic.
2. Oculoglandular (0–5% of cases)—This form develops when infective material comes into contact with the

conjunctiva. The primary lesion consists of an ulcerated papule on the lower eyelid that is associated with regional adenopathy *(365)*.

3. Glandular (3–20% of cases)—Occasionally, lymphadenopathy may occur in the absence of an ulcerative local lesion. The course is similar to ulceroglandular fever.
4. Pulmonary (7–20% of cases)—Pneumonia may result from inhalation of an infected aerosol from handling dead animals or examining pets that are ill with respiratory infections and when laboratory workers attempt to isolate the pathogen on agar plates *(366–370)*. During septicemia, the microorganisms can lodge in pulmonary tissues and give rise to secondary tularemic pneumonia. Symptoms include cough and high fever, occasional pleurisy, and rarely dyspnea. The chest radiograph may demonstrate disproportionately extensive disease compared with the physical examination.
5. Typhoidal (5–30% of cases)—The typhoidal form, which is uncommon, results from ingestion of contaminated food (usually rabbit meat) or water. Symptoms include fever, prostration, and gastroenteritis. Ulcerative lesions are found in the mucosa of the gastrointestinal tract.
6. Miscellaneous—Uncommon forms of tularemia include oropharyngeal (0–12% of cases), caused by ingestion of contaminated food or water, and meningitis (rare) *(371)*. Infection of a central nervous system shunt has been reported *(372)*.

Tularemia may be a serious disease. The case–fatality rate in untreated patients for the pneumonic and typhoidal forms is between 40% and 60%.

The diagnosis is often suspected on the basis of an appropriate exposure history or with an eschar at the site of an arthropod bite; it may be confirmed by serologic testing. Since the microorganism is fastidious, routine cultures of blood, lymph nodes, sputum or pharynx, and skin lesions are usually negative.

RESPIRATORY INFECTIONS TRANSMITTED FROM ANIMALS

The diagnosis of a lower respiratory tract infection is relatively simple in most cases. The major symptoms are fever, productive or nonproductive cough, chest pain that may be pleuritic, and shortness of breath. Headache and myalgias are common. Physical examination and chest radiography can confirm the diagnosis. Despite the relative ease of diagnosis, defining the etiologic agent of pneumonia remains difficult. Etiologic agents are commonly grouped into "typical" and "atypical" agents. Typical agents include *S. pneumoniae*, *Streptococcus* species, *S. aureus*, and *H. influenzae*. Atypical agents most commonly include respiratory viruses, mycoplasma, *Chlamydia pneumoniae*, and *Legionella pneumophila*; however, a variety of zoonotic pneumonias that are community acquired must be considered in the differential diagnosis of "atypical pneumonia" *(373,374)*.

Etiologic Agents and Epidemiology

Several zoonotic agents transmitted from pets may produce significant respiratory symptoms. Diseases transmitted by the aerosol route include anthrax, brucellosis, plague, psittacosis, Q fever, and tularemia. Other zoonotic agents that may involve the lungs include CSD, dirofilariasis, echinococcosis, ehrlichiosis, leptospirosis, melioidosis, pasteurellosis, Rocky Mountain spotted fever, toxocariasis, and toxoplasmosis. Of these, the pathogens most likely to be transmitted during pet therapy would be *Chlamydia psittaci* from infected birds, *C. burnetii* by infected cats, and *P. multocida* by close animal contact.

Pets, especially dogs, can develop fungal pneumonia following exposure to an environmental source with *Blastomyces dermatitidis*, *Coccidioides immitis*, *Histoplasma capsulatum*, and *Cryptococcus neoformans*. Common-source outbreaks involving humans and dogs of histoplasmosis and blastomycosis have been described. In general, animal-to-human transmission does not occur; however, animal-to-human transmission of blastomycosis has been reported after dog bites.

The etiologic agents of mammalian tuberculosis (*M. tuberculosis*, *M. Bovis*, and *M. africanum*) can infect animals, and, rarely, animal-to-human transmission has been described. The main reservoir of *M. bovis* infection in mammals is cattle, but badgers, foxes, nonhuman primates, bison, and opossums have been found to be infected *(375–377)*. Transmission to humans is usually via milk from infected cattle. In developed countries, such as the United States, the pasteurization of milk and the testing and culling of infected cattle have resulted in steep decreases in *M. bovis* infection *(378)*. For example, a recent analysis revealed that 1.4% of US cases of tuberculosis were due to *M. bovis (378)*. The main reservoir for *M. tuberculosis* is the human, but other animals including monkeys, large apes, elephants, and dogs can become infected. Rarely, animal (e.g., elephant)-to-human transmission of *M. tuberculosis* has been documented *(379)*.

M. avium complexes are of most consequence for birds, but are also pathogenic for swine, cattle, sheep, dogs, cats, and humans. Other mycobacterial species, such as *M. fortuitum*, *M. chelonae*, *M. kansasii*, and *M. marinum*, have been only infrequently isolated from exotic and cold-blooded animals.

Prevention Of the zoonotic agents that may cause pneumonia, only plague *(380)*, *M. bovis (381)*, Q fever, and possibly psittacosis *(382)* may be transmitted between humans. Patients with respiratory infections with these agents, therefore, should be placed on Airborne Precautions. Birds, especially psittacine birds, should be excluded from the hospital. Patients with respiratory infections consistent with tuberculosis should be maintained on Airborne Precautions and be prohibited from interacting with animals.

Q Fever

Epidemiology and Microbiology Q fever is the only rickettsial microorganism spread primarily by the aerosol route rather than by an arthropod intermediate *(383–404)*. In the United States, a variety of domestic farm animals may be infected, including goats, sheep, and cattle. Microorganisms are shed with placental tissues, feces, urine, and uterine discharges. Domestic animals may become infected from contact with contaminated tissues during parturition *(409)*. Parturient cats have been the source of

multiple outbreaks *(405–407)*. A parturient dog has also been reported as the source of an outbreak *(408)*. Person-to-person transmission of *C. burnetii* is rare but has been reported from patients to hospital staff and to attendants during autopsies *(388)*. It has also been transmitted via bone marrow transplantation and via blood transfusion *(384)*. As noted previously, an obstetrician was infected while attending a pregnant woman, with vertical transmission also occurring in that case. Sexual transmission probably occurs.

Clinical Features of Disease and Diagnosis Most patients with Q fever are asymptomatic, and disease is usually self-limited. The spectrum of Q fever includes isolated fever, flulike illness, atypical pneumonia, hepatitis, fever and rash, pericarditis, myocarditis, meningoencephalitis, and infection during pregnancy *(409)*. Pneumonia is highly variable, occurring in up to 90% of cases *(410,411)*. Acute disease typically manifests as a pneumonitis with malaise, anorexia, muscular pain, and usually an intense preorbital headache and fever; defervescence usually occurs within 1 or 2 weeks. Extrapulmonary complications include granulomatous hepatitis, pericarditis, myocarditis, uveitis, meningitis, and subacute bacterial endocarditis. Of these, endocarditis is the most common complication *(412)*. Infection of vascular grafts has been reported *(413)*. Chronic infection in patients with cancer has been described *(414)*. As in animals, infection in pregnant women may result in maternal illness, prematurity, or abortion *(415,416)*. Epidemiologic clues and serologic testing are the keys for proper diagnosis *(417)*. Polymerase chain reaction has been successfully used for clinical diagnosis.

Prevention Immunization with inactivated vaccine prepared from *C. burnetii* (phase I)-infected yolk sac is available in Australia and Eastern European countries. It has proven useful in protecting laboratory workers and should also be considered for use by abattoir workers and others in hazardous occupations. An acellular vaccine is available in the United States for persons conducting research with pregnant sheep or viable *C. burnetii*.

Chlamydophila psittaci

Epidemiology and Microbiology *C. psittaci* is pathogenic for most avian species and is capable of widespread dissemination to humans who have pet birds, who visit pet shops, or who care for birds *(418–422)*. During the 1980s, approximately 70% of the psittacosis cases with a known source of infection resulted from human exposure to caged pet birds *(423)*. Other persons at risk include employees in poultry slaughtering and processing plants, veterinarians, laboratory workers, farmers, and zoo workers. Spread to humans occurs by inhalation of microorganisms persisting in dried feces, contact with bird feather dust, and exposure to birds flapping their wings for exercise. Outbreak investigations suggest that human-to-human transmission occurs in addition to animal-to-human transmission *(424)*. Healthcare-associated outbreaks have been reported *(282,425)*, but the accurate identification of the causative agent as *C. psittaci* has been questioned, because serologic tests may cross-react with *C. pneumoniae (426)*. Infection with feline *C. psittaci* has been reported in a man with a cat *(427)*.

Clinical Features of Disease and Diagnosis

C. psittaci causes infections in humans ranging from a severe systemic illness to an asymptomatic infection *(428–436)*. Symptomatic psittacosis is characterized by high fever, chills, headache, myalgias, dry cough, and, sometimes, respiratory compromise. Extrapulmonary manifestations are common and include cardiac, neurological, hematologic, hepatic, and renal changes. Case–fatality rates as high as 40% have been reported, but with treatment mortality is usually <1%.

As in Q fever, the diagnosis is suggested by an epidemiologic exposure and compatible disease course and is confirmed by serology.

Yersinia pestis

Epidemiology and Microbiology Most cases of plague result from humans coming into contact with sylvatic sources of disease and being bitten by an infected flea. Pneumonic plague may occur following hematogenous spread of bacteria during bacteremia in patients with bubonic or septicemic plague, or by inhalation of bacteria after coming into contact with a person or animal (most commonly a cat) with plague pneumonia. Acquisition of pneumonic plague via droplet transmission from an infected cat has been reported *(437–441)*. Pneumonic plague in humans is believed to be highly contagious via droplet transmission. However, the last case of secondary pneumonic plague in the United States was reported in 1925 *(442)*.

Clinical Features of Disease and Diagnosis Inhalation plague pneumonia begins with a painless cough and shortness of breath *(443–449)*. Pathologically, plague pneumonia is a bronchiolitis and alveolitis causing lobar consolidation and evolves into lobar consolidation with areas of hemorrhage. Patients with hematogenous plague pneumonia present with fever, lymphadenopathy, cough, hemoptysis, and chest pain. Diagnosis is via isolation of the causative pathogen from sputum.

GASTROINTESTINAL INFECTIONS ACQUIRED FROM ANIMAL RESERVOIRS

Many gastrointestinal pathogens of humans have animal reservoirs. These pathogens may then be acquired by humans via ingestion of contaminated surface waters, raw milk, and uncooked or undercooked foods, such as shellfish, fish, poultry, and meat. Enteric bacterial pathogens acquired from pets include *A. hydrophila*, *P. shigelloides*, *Campylobacter jejuni*, *E. tarda*, *Salmonella*, *Y. enterocolitica*, and *Y. pseudotuberculosis (450)*. Parasites include *Cryptospordium*, *D. caninum*, *Giardia*, *Isospora belli*, and *Strongyloides* species *(450)*.

Of the zoonotic infections, *Salmonella* is the greatest public health concern. Nontyphoidal *Salmonella* have been isolated from many domestic animals, including cats, dogs, birds, reptiles, hamsters, and monkeys. In the recent past, turtles were recognized as an important source of human

salmonellosis *(451)*. Pet turtles caused an estimated 14% of all cases of *Salmonella* infections in the United States for a total of 2,000,000 cases per year. Reptiles continue to be a source of human salmonellosis *(452,453)*. Multiple outbreaks of *Salmonella* have been reported in hospitals involving person-to-person transmission, common-source outbreaks (e.g., food), and the use of contaminated instruments (e.g., gastrointestinal endoscopes) *(454)*.

Bacterial gastroenteritis linked to pets has been demonstrated for *A. hydrophila*, *P. shigelloides*, *Y. enterocolitica (455)*, and *C. jejuni (456–458)*. All these pathogens have been isolated from many animals, including dogs, cats, reptiles, hamsters, and monkeys. In humans, all these pathogens may cause gastroenteritis characterized by fever, chills, nausea, vomiting, and diarrhea.

Cryptosporidia is now recognized as an important gastrointestinal pathogen. In normal hosts, it generally causes an episode of self-limited diarrhea. However, in patients immunocompromised by HIV infection, it may cause chronic diarrhea with severe fluid losses and malnutrition. Multiple outbreaks among veterinarians have been described. Hospital *(459–462)* and veterinary school outbreaks *(463)* have also been described. Cats and dogs can likely transmit infective oocysts to humans.

Although most dogs and cats harbor *D. caninum*, human infections are uncommon. Infections are acquired by ingestion of an infected flea, which acts as an intermediate host. Infection may be asymptomatic or associated with abdominal pain, diarrhea, irritability, and anal pruritus. Passage of proglottids that resemble grains of rice in the stool may lead to presentation to a physician *(464)*.

Toxocara canis and *Toxocara cati* are helminth parasites that affect dogs and cats, respectively. Animals may be infected *in utero* and transplacentally or may become infected by ingestion of infested feces. Once passed in animal feces, the ova take several weeks to mature but can remain viable for months. Humans are infected by ingestion of the ova. This situation usually occurs in children younger than 6 years who play in areas where cats and dogs defecate. Contamination of sandboxes used by daycare centers has been demonstrated. In humans, most infections are asymptomatic but may present as cough and wheezing from pulmonary migration, or with abdominal pain, hepatomegaly, and peripheral eosinophilia.

The reservoir for *Giardia* is wild animals. The role of pets in the transmission of giardiasis to humans has not been well defined; however, there have been isolated reports of giardiasis related to dog or cat exposure.

Fang et al. *(450)* have summarized several rules to help prevent the acquisition of enteric infections from pets. These rules include (a) wash hands after handling an animal, (b) keep cages and pens clean to avoid attracting fleas, (c) do not use waste material from pets as fertilizer, (d) cover children's sandboxes when not in use, (e) consult a veterinarian regarding illness in a pet, (f) deworm dogs and cats regularly and do not allow them to defecate on playgrounds, (g) remove animal feces from a lawn frequently, (h) dispose off cat litter daily, (i) treat affected pets and their areas with powders and sprays on alternate weeks for effective flea control, and (j) do not keep turtles as pets.

GUIDELINES FOR THE PREVENTION OF TRANSMISSION OF ZOONOTIC DISEASES

Service Animals

Service animals such as guide dogs provide an important health service for the disabled. Prohibiting service animal's access to a public facility violates the ADA. Recommendations for the use of guide dogs in hospitals have been published *(88,465)*.

Pet-Facilitated Therapy

An extensive literature supports the use of pet-facilitated therapy. Benefits cited by advocates include improved self-esteem, increased knowledge and practice of caring from pets, increased socialization by sharing animal experiences, increased empathy, production of feelings of being liked unconditionally, enhanced nurturing behaviors, increased feelings of control, increased independence, and increased ability to follow directions. Unfortunately, these reported benefits are almost entirely based on anecdotal reports rather than on controlled clinical trials. Additional research is required to determine scientifically which patients would benefit from pet-facilitated therapy and the best form of animal–human interaction.

Animals within the hospital pose a potential risk; however, with the use of a carefully developed and implemented policy, animals can probably be used with minimal risk, provided current recommendations are followed *(89,90)*. Infection control guidelines for AAAs and AAT are also available from the Delta Society *(111,120)*. Similar to the perceived benefits of pet therapy, the risks have been incompletely assessed. However, one study of 2,361 visits to 1,158 patients by dogs under "strict guidelines" reported no incidents of zoonotic infections or evidence that the dogs acted as fomites in the transmission of microorganisms from patient to patient *(466)*. Additional studies are warranted, especially before immunocompromised patients are allowed contact with animals. The Delta Society provides a directory listing of AAT and AAA programs in hospitals (*www.deltasociety.org*).

More detailed guidelines regarding the evaluation of patients suitable for AAT, medical clearance procedures for animals considered for pet therapy, and protocols for the management of pet therapy in healthcare facilities have been published *(88–90)*.

OTHER USES OF ANIMALS IN HOSPITALS

Medicinal Leeches

Leeches have been used in medicine for centuries. The word *leech* is likely derived from the Old English *laece* meaning physician (*467*,468). Medicinal leeches (hirudotherapy) were introduced by Avicenna in "Canon of Medicine" in 1020. They were reintroduced by Abd-el-latifal-Baghdadi in the 12th century (468). Leeches continue to be used in modern medicine in the management of acute problems related to vascular congestion in patients with reimplantation of digits and ears and in reconstruction using cutaneous or muscle flaps *(469–473)*. Leeches are

useful in reducing vascular congestion because they are capable of ingesting up to 10 times their body weight in blood. The process of absorbing blood is aided by the production of hirudin, which inhibits the thrombin-catalyzed conversion of fibrinogen to fibrin, hyaluronidase, proteinase inhibitors, and a vasodilator.

The most common leech used is *Hirudo medicinalis*. Wound infections are an important hazard with the use of medicinal leeches. The most common pathogen is *A. hydrophila (474–477)*, but infection with *V. fluvialis* has also been reported *(478)*. The incidence of wound infections has been reported to be 7% *(474)* and 20% *(479)*. Multiple potential pathogens have been isolated from *H. medicinalis*, including *A. hydrophila*, *Staphylococcus* species, *Alcaligenes* species, *Pseudomonas putida*, and *Fusobacterium varium (480)*. *A. hydrophila* obtained from the gut of *H. medicinalis* has been found to be susceptible to third-generation cephalosporins and tetracycline *(481)*. Treatment of leeches with ciprofloxacin has been reported to eliminate carriage of *Aeromonas* spp. *(482)*. Systemic antibiotics administered to patients have been found to penetrate into leeches and to significantly reduce the rate of *A. hydrophila* isolation compared with controls (i.e., 12% vs. 100%) *(483)*. For this reason, suppression of leech enteric bacteria by antibiotic administration has been recommended as possibly an effective strategy to prevent invasive infection with *A. hydrophila*. Additional clinical trials have been recommended, however, to assess the efficacy of prophylactic antibiotic administration *(483)*.

Medicinal leeches should not be reused between patients because of the risk of cross-infection. Syphilis, puerperal fever, and erysipelas have occurred from the reuse of medicinal leeches *(467)*. Furthermore, laboratory studies have indicated that many parasites, such as *Toxoplasma gondii* and *Trypanosoma brucei*, not only survive but also multiply inside the gut of the leech *(484)*. Once used, medicinal leeches are a biohazard and should be discarded in a manner consistent with Occupational Safety and Health Administration guidelines.

CONCLUSIONS

The use of service animals provides a valuable function for the disabled. Adherence to the ADA with regard to service animals can be safely managed in the hospital setting. The benefits of a well-managed AAT program remain inadequately demonstrated by scientific studies. However, the risks have proved largely theoretical. Pets have been associated with healthcare-associated infections and should be prohibited from hospitals. All healthcare facilities should have policies regarding service animals and the visitation by personal pets.

CHAPTER 95

Role of the Microbiology Laboratory and Molecular Epidemiology in Healthcare Epidemiology and Infection Control

Charles W. Stratton IV and John N. Greene

In the late 19th century, early microbiologists such as Pasteur and Koch demonstrated that infections were due to specific microorganisms and that these microbes could be isolated by appropriate cultures. Another early microbiologist, Lister, recognized the principle that certain chemicals antagonized microbes. Lister then applied this principle to infection control by using phenol to sterilize surgical instruments and dressings to reduce the morbidity and mortality associated at that time with surgery *(1)*. Thus began the association of microbiology with antibiosis and infection control.

The relationship of microbiology with infection control was formally recognized in the early 1970s by the Centers for Disease Control and Prevention (CDC), which developed standard definitions for nosocomial infections and methods for infection surveillance (2). Infection control committees incorporated these CDC recommendations into practice at that time. The result was a shift from unproductive environmental sampling *(3)* to more directed surveillance and intervention when established baseline endemic rates of infection were exceeded. However, unless these baseline endemic rates of infection were exceeded, the surveillance process was, for the most part, passive.

As humans and medicine complete the first decade of the 21st century, infection control strategies continue to evolve. First, microbiologic surveillance has shifted away from general categories of medical service, infection site, and hospital-wide infection rates and is focusing instead on problem categories (4,5). These focused categories include high-risk areas such as intensive care units (ICUs) (*6,7*), preventable high-risk infections such as intravascular device–related infections *(8,9)*, the surveillance and control of microbial resistance (10,11,*12–14*,15,*16*), and emerging pathogens (10,17,*18*). Second, infection control strategies today are more proactive, which simply means that active intervention for prevention of infections and control of resistance has an equal priority to simply monitoring for changes in these parameters *(6*,*8*,*19–21)*. Third, it is now recognized that a key component in this proactive strategy is the need for ongoing and constant education of healthcare and infection control personnel as well as education of residents, pathologists, infectious disease fellows, and clinical microbiology fellows *(22–26)*. Such educational efforts are becoming important functions of an infection control committee with the assistance of the microbiology laboratory. Fourth, implementation of efficient infection control requires the construction of a computerized information network that ideally includes the hospital, the community, the state, the nation, and other countries (27,*28–33*). Such networks that eventually would include guidelines, microbiologic surveillance data, and full-text references (i.e., PDFs) available on the Internet ultimately will become the cornerstone of infection control.

The interaction of the microbiology laboratory with healthcare epidemiology and infection control continues to evolve as an integral part of a nationwide concerted effort to develop and improve infection control practices and programs. This process began with the National Nosocomial Infections Surveillance (now the National Healthcare Safety Network) system developed by the CDC. This system provides risk-specific infection rates for use by hospitals and national healthcare planners to set priorities for their infection control programs and to evaluate the effectiveness of their effort *(31)*. The Division of Healthcare Quality Promotion at the CDC through National Healthcare Safety Network continues to provide relevant surveillance information on healthcare-associated infections *(34,35)*. In addition, the Division of Healthcare Quality Promotion is expanding to provide relevant information for other healthcare facilities such as dialysis centers *(29)*. The Study on the Efficacy of Nosocomial Infection Control conducted by the CDC in the 1970s found that hospitals had lower rates of healthcare-associated infections if levels of surveillance activities were increased *(36)*. Thus, many infection control programs received additional support to increase the number of infection preventionists (IPs).

Meanwhile, the focus and procedures of microbiology laboratories were changing because of multiple factors that included increasing resistance, emerging pathogens, and new technology (10,17,37). For example, the need for clinical microbiology laboratories to detect emerging antimicrobial resistance (*38*,39,40,41) has resulted in new approaches and technology for this purpose *(42–44)*. All of these factors have resulted in important changes in the role of the microbiology laboratory in healthcare epidemiology and infection control.

The microbiology laboratory has always been recognized as an essential element in the control of healthcare-associated infection *(3)* and has long served as an early warning system for healthcare-associated infections by identifying clusters of microbes with unique phenotypic characteristics and communicating this information to IPs (*45*,46). In the past, such healthcare epidemiology and infection control activities did not place a great demand on the microbiology laboratory.

Today, however, the work done by the microbiology laboratory is increasingly complex and demanding. Much of this has direct implications on healthcare epidemiology and infection control. Microbiology laboratories now must be able to detect, identify, and characterize an expanded array of microbes, including newly emerging pathogens (10,40). Some of these pathogens, such as fungal microorganisms, may be important causes of healthcare-associated infections but difficult to detect *(47–49)*. Fortunately, traditional methods using cultures for isolation, identification, and susceptibility testing of pathogens have been supplemented by highly sensitive, rapid, and specific molecular biologic techniques in which unique DNA or RNA sequences can be directly detected (10,*12*,17,*18*,*43*,*44*,*50*,*51*,52,*53*,*54*,55,56,*57*,*58*). These and other molecular techniques have enabled microbiology laboratories to "fingerprint" microbes, thereby facilitating studies of healthcare-associated transmission *(58,59)*. Finally, the microbiology laboratory's role in monitoring and controlling resistance has become critical because of the increasing frequency with which resistant pathogens are causing healthcare-associated infections (10,*12–14*,*21*,*38*,*42*,*60*). This role today may include not only the accurate detection of resistance *per se* but also the determination of the molecular epidemiology of the resistant isolates. The amount of work by the microbiology laboratory to support healthcare epidemiology and infection control has greatly increased.

The role of the microbiology laboratory in healthcare epidemiology and infection control continues to expand. For example, IPs today often augment their surveillance efforts by the use of computer-generated focused microbiologic surveillance reports from the microbiology laboratory. Problems thus detected may require molecular methods as a part of their evaluation. If the problems involve resistance, additional susceptibility testing and molecular methods may be required. Finally, the microbiology laboratory has become recognized as an important resource for the microbiologic training and education of healthcare and infection control personnel. Indeed, the interactions of infection control committees with the microbiology laboratory are now so complex and important that most committees require that a representative of the microbiology laboratory serve as an active member to ensure the appropriate advice, education, coordination, and technical support. This chapter examines these various facets of the changing and increasingly critical role of the microbiology laboratory in healthcare epidemiology and infection control.

SURVEILLANCE

The key to an effective infection control program continues to be effective surveillance, which the Study on the Efficacy of Nosocomial Infection Control has defined as an IP using basic epidemiologic techniques to perform surveillance on clinical ward rounds, to analyze rates of infection, and to incorporate the data generated in decision making *(31)*. Such surveillance for healthcare-associated infections involves identifying patients who are colonized or infected, assessing the risk of transmission of infection between patients, proving transmission of a given strain from one patient to another, and, more generally, detecting healthcare outbreaks *(61)*. However, to recognize the existence of an outbreak, baseline endemic rates of infection must be determined for each type of infection within a given institution.

Defining endemic rates (the number of infections divided by the number of patient-days or patients at risk) for services, sites of infection, microorganisms, and procedures can be accomplished in each hospital by an active surveillance system coordinated by the IP and the microbiology laboratory. Clusters and epidemics can be investigated when endemic threshold rates are exceeded, when unusual or new microorganisms are isolated, and when new sites of infection are identified. Collection of surveillance data, usually by the IP, consists of reviewing microbiology reports generated by the laboratory. If trends of increasing or unusual infection rates are discovered, then chart review and discussion with personnel involved in patient care should follow to determine the significance of these isolates. The importance of active surveillance is seen with the recent outbreak of the pandemic H1N1 influenza *(62)*. Pandemic influenza is an example of emerging and reemerging infectious diseases that must be monitored with ongoing surveillance strategies and new diagnostic methods (40,*43*,55,56,57,*63*,*64*) (see also Chapters 101 and 102).

With increasing resistance and the fact that many healthcare-associated infections are caused by resistant microbes, surveillance and control of resistance have become critical (10,*12–14*,*21*,*38*,*42*,*60*). Susceptibility patterns can be monitored for emergence of resistant microorganisms; when resistant microorganisms are identified, appropriate isolation precautions should be instituted. Moreover, control of antimicrobial use has become important for controlling resistance (10,*12–16*). For this reason, the antibiotic subcommittee of the pharmacy and therapeutics committee should be included as a part of the infection control program for preventing resistance. One practical way to do this is for a representative of the microbiology laboratory to be a voting member of both the infection control committee and the antibiotic subcommittee. In addition, one or more members of the antibiotic subcommittee should be a member(s) of the infection control committee.

Today, all microbiology laboratories have a computerized reporting system known as the laboratory information system *(65)*. Computer-generated microbiology reports are usually sorted by site of isolation, type of microorganism, and location of the patient, but they can be programmed to focus on any particular problem. Reports are generated daily and cumulatively. These reports are used to detect trends of increasing infection rates or increasing resistance and are reviewed daily by the IP. In addition, the IP often participates in daily clinical microbiology rounds in which new positive cultures at each bench station are reviewed.

The microbiology laboratory receives appropriate hospital demographic information on any culture request and often is able to use this information to recognize clusters of similar isolates. In addition, the availability of laboratory computer systems allows specific types of patients (e.g., transplant patients) or specific locations (e.g., ICUs) to be easily grouped and reviewed. When such focused microbiologic surveillance is desired, the microbiology laboratory should have the capability to provide such reports. In the past, a computerized reporting system did not necessarily mean that focused surveillance reports could be easily obtained. Often, some degree of computer programming was needed; therefore, this programming capability should be readily available. Once obtained, these focused surveillance reports for specific units should be incorporated as a routine surveillance method with these reports also provided to the medical director of the specific unit(s) (5,*6–8*).

Once the microbiology reports have been reviewed and prioritized, charts of the patients with the microorganisms of interest should be analyzed to evaluate the significance of the isolates as potential causes of healthcare-associated colonization and infection. Susceptibility trends should be analyzed. By defining baseline endemic rates for various infections and resistance problems through effective surveillance, unusual disease and resistance activity will trigger disease control and prevention efforts (10,*12–14*,*21*,*38*,*42*,*60*). In summary, an active surveillance system assists the clinician in making an accurate diagnosis and prescribing therapy by providing the knowledge of disease occurrence and antibiotic resistance patterns.

IDENTIFICATION OF OUTBREAKS

An investigation of a potential outbreak of healthcare-associated infections must first determine if these infections are related in any way (*31*,41,46). Most often, this determination involves recognition of the microbial pathogen causing the outbreak and differentiation from those microorganisms of the same genus or species that, although isolated from some patients, are not involved in the outbreak (*31*,41,46,55,*59*,*66*). However, an outbreak may involve resistance rather than an increased incidence of infections. For example, an outbreak might actually consist of only one strain of vancomycin-resistant *Staphylococcus aureus* because of the implications of such an isolate *(67)*. If the outbreak can be linked to infection by a single strain (also called a clone), exposure to a common source or reservoir or transmission from patient to patient would be inferred.

Traditionally, the epidemic strain has been defined with phenotypic methods, which include genus, species, biotype, serotype, phage type, bacteriocin production, and antimicrobial susceptibility patterns *(68)*. Phenotypic methods reflect genetic traits and may be quite specific. When a given phenotype is rarely found in a microbial strain, that phenotype alone may provide convincing evidence of transmission between patients (e.g., *Escherichia coli* O157:H7). However, microorganisms with commonly expressed phenotypic characteristics may require additional subtyping (37). Sometimes, isolates share phenotypic markers but are actually genotypically different; this implies the presence of two separate strains and infection from two different sources. The limitations of phenotypic techniques are presented in Table 95-1.

TABLE 95-1

Limitations of Phenotypic Methods

Influenced by environmental selective pressure
Unstable antigenic traits may be altered by random mutation
Resistance patterns are strongly influenced by the selective pressure of antibiotic use
Bacteria predictably alter the expression of the characteristic being assessed
Necessary reagents may not be commercially available, which limits the number of tests available for phenotypic testing
Phenotypic traits may not have sufficient discriminatory power to distinguish each strain of a species

When microbial pathogens are nontypeable by phenotypic methods or have only a few types, the poor discriminatory power precludes the use of these typing methods. This has led to the use of genotypic methods for typing. This approach has been extremely successful and is now termed *molecular epidemiology* (37,46,55,56,57,*58*,*59*,*66*,69). These molecular epidemiologic methods most often involve genotyping of microbial plasmid or chromosomal DNA and go far beyond the current limitations of phenotyping and provide more accurate data during outbreak investigation (37). Moreover, outbreaks of viruses *(70)* and free-living microorganisms can now be adequately studied with current molecular epidemiologic methods.

However, combining methods of microorganism identification provides stronger evidence for the presumed relationship between isolates. Such was the case with an outbreak of neonatal meningitis caused by *Enterobacter sakazakii (71)*. Biotypes, plasmid DNA profiles, and antibiograms of isolates from patients and the environment were identical,

establishing the means of transmission from a powdered milk preparation. On the other hand, multiple typing systems may show dissimilarity among strains, casting uncertainty on the relatedness of isolates. This was illustrated when widespread colonization of personnel with methicillin-resistant coagulase-negative staphylococci (MRCNS) at a Veterans Affairs hospital was investigated *(72)*. Antimicrobial susceptibility profiles, biotyping, phage typing, plasmid profiles, restriction fragment length polymorphism (RFLP), and plasmid hybridization with a DNA probe showed dissimilarity among strains. Because of the absence of strain similarity that has been found using the various methods, the role of human reservoirs of MRCNS as a source for infections in hospitalized patients remains obscure *(72)*.

Identification of a microorganism by any means requires thorough knowledge of the unique attributes of the microorganism to distinguish it from the large background of nonepidemic, nonpathogenic strains (55,56,57,*58*,*59*,69). Specific strain identification can be critical in identifying outbreaks of infection (55,56,57,*58*,*59*,69). This can be seen with the speciation of coagulase-negative staphylococci. *S. schleiferi* is a species of coagulase-negative staphylococci that is pathogenic in animals and humans, causes pyoderma and abscesses, and has been described in an outbreak of wound infections *(73)*. Isolation and speciation of this pathogen from a cluster of surgical site infections would have far greater impact than the isolation and report of coagulase-negative staphylococci from the same cluster, as the latter would be interpreted as likely representing various coagulase-negative species and thus skin contaminants. As the ability to characterize strains improves, the number of differences detected between strains will likely increase. This will allow better characterization of the pathogenesis of coagulase-negative staphylococci *(74)*.

An important feature of an epidemiologic evaluation is the determination of clonality of the suspected pathogen regardless of the mode of transmission. A clone is a set of isolates that have been recovered independently from different sources, in different locations, and possibly at different times but that show so many identical phenotypic and genetic traits that the most likely explanation for this identity is a common origin (69,*75*). Clonality among isolates in an outbreak must be established before it can be concluded that the outbreak originated from a common source (69). Successful clone identification requires knowledge of the genetic stability of the microorganism, the selective pressure of the environment, and the discriminatory power of the given procedure used to characterize the isolate (69). The judgment of nonclonality eliminates an isolate from consideration as one involved in a particular chain of transmission (69). A judgment of probable clonality strengthens the case for either a common-source outbreak or an outbreak resulting from person-to-person transmission in proportion to the rareness of that clone in the environment (69). Following a given clone throughout its travels by surveillance methods has documented the worldwide spread of multiresistant strains of penicillin-resistant *Streptococcus pneumoniae (76)*, methicillin-resistant *S. aureus* (MRSA) *(77)*, and community-acquired MRSA *(78)*.

Host responses to invading microorganisms may also be used to identify and track infections that are difficult to investigate using current phenotypic and genotypic methods. For instance, serology may be used to determine infection rates during outbreaks, particularly when cultures have not been obtained or are obtained after initiating treatment or when routine cultures may not detect infection (e.g., pneumonia). This was seen with group A *Streptococcus* (GAS) infections in a nursing home *(79)*. Nine (56%) of the 16 cases of GAS disease or infection in residents were confirmed by serologic testing (anti-DNase B titers) alone *(79)*. The identification of a single serotype (M-1, T-1) from the four available isolates and epidemiologic correlation suggested that a single strain of GAS was introduced into the nursing home by the index patient, with subsequent person-to-person transmission. Similarly, pulsed-field gel electrophoresis (PFGE) has been used to document a community outbreak of invasive GAS infection in Minnesota *(80)*. Field inversion gel electrophoresis is another electrophoretic typing method similar to PFGE that has been developed for GAS *(81)*. These electrophoretic methods are able to identify differences between and within M types of GAS. Another molecular method for distinguishing GAS is fluorescent amplified fragment length polymorphism (AFLP) analysis *(82)*. Finally, the *emm* gene for the M protein has proven useful for typing GAS *(83)*.

When investigating a possible outbreak, the healthcare epidemiologist or IP, who formulates a hypothesis based on clinical and epidemiologic evidence, must collaborate with a microbiology laboratory to provide microbiologic data to either support or refute the hypothesis (27,*45*,46,*59*). Isolates from multiple patients are examined to determine whether the infections are related. Establishing similarities or differences among epidemic isolates is not always sufficient to determine the source or the mode of dissemination *(84)*. Data derived from epidemiologic studies are also needed. Cultures and molecular typing without an epidemiologic study often lead to uninterpretable results. However, when molecular typing is combined with an epidemiologic study, the two methods are complementary in confirming transmission of a single or multiple strains *(85)*.

EPIDEMIOLOGIC TYPING

Currently, there are a vast number of epidemiologic typing systems available (37,55,56,57,*58*,*59*,69,*86–88*,89,90,*91*,92). These include molecular methods that are clearly useful for the epidemiologic analysis of infectious disease outbreaks (52,89,*90*,*91*,92). However, to gain acceptance and be routinely applied in clinical situations, molecular epidemiologic methods must be easy to perform, rapid, reproducible, and cost-effective and provide additional information not obtained from traditional typing techniques (*84*,*85*,*87*,89,*90*,*91*,92). Also, it is important with high-resolution typing systems to distinguish between comparative epidemiologic typing systems that are used in outbreak investigations and library epidemiologic typing systems that are used in surveillance systems *(87)*. Most of the currently available molecular typing systems are comparative methods that are reproducible in single assay, have high discrimination ($D > .95$), and are used to compare isolates from a suspected outbreak and distinguish them from sporadic isolates. Such comparative methods include RFLP, PFGE, and arbitrarily primed and randomly

amplified polymorphic polymerase chain reaction (PCR) analysis. Library typing systems, in contrast, are reproducible over time and between laboratories, have discrimination power balanced against evolutionary stability, and are used for long-term surveillance. Library methods include serotyping, insertion sequence fingerprinting, ribotyping, PFGE, AFLP, infrequent-restriction-site amplification PCR, interrepetitive element PCR typing (rep-PCR), and PCR-RFLP of polymorphic loci. Finally, a typing method cannot be considered valid unless it is capable of discriminating among randomly chosen isolates (*84–91*,92).

The basic premise inherent in any typing system is that epidemiologically related isolates are derived from the clonal expression of a single precursor and share characteristics that differ from epidemiologically unrelated isolates (52). The utility of a particular characteristic for typing is related to its stability within a strain and its diversity within the species *(93)*. The most clinically relevant isolates are those with characteristics that provide for increased virulence or resistance and are often the most difficult to differentiate *(93)*. The strength of typing depends on the discriminatory power of the method used *(93)*. When strains are nontypeable or have only a few serotypes, such poor discriminatory power precludes the use of certain typing methods. Ideally, a typing method will recognize each unrelated isolate as unique. In practice, the technique is considered useful if the most common type it detects occurs in <5% of the population *(93)*. There is currently no gold standard or definitive typing system or even an authoritatively validated collection of isolates against which a new method can be evaluated *(93)*. Nevertheless, bacterial typing systems are applied clinically to address one fundamental question: Are two isolates the same or different? *(93)*

One of the earliest phenotypic methods used in hospitals for outbreak investigations was biotyping. Biotyping refers to establishing the pattern of activity of cellular enzymes. Most microbiology laboratories identify bacteria with an automated biotype system *(94)*. The ability of biotyping to differentiate among unrelated strains (discriminatory power) is poor. However, Maki et al. *(95)* successfully used biotyping to implicate contaminated intravenous fluid preparations as the means of transmitting *E. agglomerans* to patients. However, if the same strain differs in one or more biochemical reactions because of mutations in gene expression or a random mutation, then the strains may be mistakenly reported as unrelated *(93)*. Also, specific testing reagents are often difficult and expensive to develop and characterize or are not available in most microbiology laboratories *(93)*. Because of these limitations, new methods to characterize epidemic strains were developed. The different but complementary epidemiologic typing techniques are reviewed in the chronologic order of their development.

ANTIMICROBIAL SUSCEPTIBILITY TESTING

Antimicrobial susceptibility testing (AST) is an inexpensive, easy to use, and readily available means that often is used to characterize microorganisms. The IP frequently reviews daily and cumulative antimicrobial susceptibility reports (antibiograms) for emerging patterns of resistance *(96–99)*. A new or unusual trend of antibiotic resistance from isolates from different patients may raise the suspicion of an outbreak. For example, the rate of ampicillin resistance in *Haemophilus influenzae* isolates from adults was higher than expected in a Georgia community when all isolates were analyzed over a given time, alerting local physicians to the possibility of treatment failure *(100)*.

AST has been used successfully in the investigation of several outbreaks. For example, review of antimicrobial susceptibility patterns implicated vancomycin-resistant *Enterococcus faecium* as the cause of an outbreak in a cardiothoracic surgery ICU *(101)*. AST is frequently all that is required in the investigation of an outbreak of MRSA in a hospital where the microorganism is not endemic. However, this has become the exception rather than the rule. In an era of multidrug-resistant pathogens, AST has become less sensitive. The shortcomings of AST for epidemic typing are well known. The use of AST is limited in epidemiologic studies because of phenotypic variations and because changes in antibiotic resistance occur frequently under the extraordinary selective pressure caused by the extensive use of antimicrobials in hospitals today.

BACTERIOPHAGE AND BACTERIOCIN TYPING

Bacteriophages are viruses capable of infecting and lysing bacterial cells. When used in epidemiologic investigations, their susceptibility or resistance to lysis characterizes isolates by each member of a panel of bacteriophages *(102)*. For *S. aureus* and *Salmonella* species, phage typing was the mainstay of strain discrimination in the past *(102)*. The problem with this method is that it is very demanding, subject to biologic variability, and available only at reference laboratories because of the need to maintain stocks of phages and control strains *(102)*. Phage typing is still used for *Salmonella* surveillance *(103)*. However, DNA-based techniques have, for the most part, replaced bacteriophage typing as the authoritative system.

Bacteriocin typing depends on the susceptibility of the test microorganism to toxins produced by other bacteria. This method has limitations similar to those of phage typing and is rarely used today.

PLASMID PROFILE ANALYSIS

The first genotypic method applied to epidemiologic study involved the analysis of plasmids. Plasmid profile analysis (PPA) or plasmid fingerprinting involves the extraction of plasmid DNA followed by the separation of plasmid molecules by agarose gel electrophoresis *(104)*. Initially, the isolation of plasmid DNA required liters of bacterial broth cultures and relied on sophisticated ultracentrifugation techniques *(105)*. Currently, PPA is simple to perform, requires a minimum of equipment and expense, and is well suited for the study of outbreaks of infection (37). This technique has been used successfully for the isolation of plasmid DNA from most *Enterobacteriaceae*, *Streptococcus* species, *Staphylococcus* species, *Legionella*, *Vibrio* species, *Plesiomonas*, *Pseudomonas* species, and *Campylobacter* species (37,*105*).

Plasmid fingerprinting by agarose gel electrophoresis is a useful means of identifying epidemic strains in outbreaks of healthcare-associated infections and following endemic antibiotic resistance patterns and the spread of specific resistance genes *(104)*. PPA has been used to identify epidemic strains of gram-negative bacilli In one study, PPA for all epidemic isolates of gram-negative bacilli was the same, whereas coisolates (controls) showed different DNA patterns, although the antibiograms failed to show a difference (106). Plasmid profiles were found to be better than antibiograms in identifying epidemic strains of *Salmonella typhimurium* and slightly better than phage typing *(105)*. An epidemic of *Pseudomonas aeruginosa* causing wound and peritoneal infections in hemodialysis patients was traced with PPA to an iodophor solution *(107)*. Two outbreaks of infection resulting from *Enterobacter cloacae* that occurred 6 years apart in the same burn unit were attributed to two different strains by plasmid fingerprinting *(108)*. An outbreak of infections caused by an aminoglycoside-resistant strain of *Acinetobacter calcoaceticus* in an intensive care setting was investigated with plasmid fingerprinting *(109)*. All isolates from patients and the environment were identical, thus suggesting a common means of transmission *(109)*.

Because plasmids can spread from one bacterial species or strain to another by conjugation, it is occasionally the plasmid rather than the bacterial strain that is epidemic *(110)*. An epidemic plasmid may be found in several different bacterial species or serotypes *(110)*. These epidemic plasmids can enter a hospital in one or a few strains and subsequently spread by conjugation to other strains present in the flora of hospitalized patients *(110)*. Whenever possible, it is extremely important for one to compare epidemic strains with nonepidemic control strains (37,*105*). However, the presence of one or more plasmids may be unique to a particular strain of a pathogen and, therefore, be used to incriminate that microorganism in an epidemic, especially if the plasmid is stable through time and environmental stress *(23,105)*.

PPA has significant limitations inherent in the fact that plasmids are mobile, extrachromosomal elements rather than the chromosomal genotype that defines the host microorganism. Moreover, plasmids can exist in different molecular forms such as supercoiled (closed circle), nicked (open circle), and linear; each form migrates differently during gel electrophoresis. Both the reproducibility and discriminatory power of plasmid analysis can be greatly improved by digesting the plasmids with restriction endonuclease enzymes. The resulting restriction fragments are then analyzed by electrophoresis. Restriction enzyme analysis (see later discussion) *(111)* of plasmids is now the method of choice when plasmid analysis is desired. Tables 95-2 and 95-3 show the advantages and limitations of PPA, respectively. Usually, PPA is most effective in studies that are restricted in time and place (e.g., an acute outbreak at one institution) *(112)*.

TABLE 95-2

Advantages of PPA

Applicable to many bacterial strains
Entire analysis can be completed in 1 d
Twenty-four or more cultures can be processed at one time
Gene expression (i.e., production of surface antigen or specific protein) is not necessary
Cultures too "rough" to serotype are easily analyzed
Microtechniques conserve reagents and space
Rapid, inexpensive, and reproducible

(Data from Soll DR, Pujol C, Lockhart S. Laboratory procedures for the epidemiological analysis of microorganisms. In: Murray PR, Baron EJ, Jorgensen JH, et al., eds. *Manual of clinical microbiology*. 9th ed. Washington, DC: American Society for Microbiology, 2007:129–151; and Eisenstein BI, Engleberg NC. Applied molecular genetics: new tools for microbiologists and clinicians. *J Infect Dis* 1986;153:416–430.)

RESTRICTION ENDONUCLEASE ANALYSIS

Restriction endonuclease analysis (REA) relies on enzymes that recognize unique plasmid or chromosomal DNA sequences and cleaves the double-stranded DNA at specific sites within the target (37,*113*). The separation of these fragments by size in agarose gel produces a restriction endonuclease profile *(114)*. Unlike PPA, small differences in bacterial strains with identical profiles can be detected with REA, as can acquisition of a new plasmid. If two plasmids are of the same size and yield identical fragment patterns on REA, especially if two or more restriction enzymes are used, they may be assumed to be identical or nearly so *(110)*. Thus, two plasmids may be of the same size but produce different patterns of fragments, identifying two different strains. Such was the case when large plasmids of similar size were found in both strains of *Klebsiella pneumoniae* causing infection in an intensive care nursery a year apart, suggesting they were similar strains *(114)*. However,

TABLE 95-3

Limitations of PPA

The epidemic strain may contain no plasmid DNA or a plasmid that is difficult to isolate
Strains unrelated to the outbreak may contain the epidemic profile
The presence of a plasmid does not provide evidence that it codes for a specific factor (i.e., toxin, antigen, or resistance)
Many plasmids (especially R-plasmids) are readily lost or acquired
Plasmids are subject to rearrangements
As extrachromosomal elements, plasmids do not reflect the stable genotype of the microorganism

(Data from Soll DR, Pujol C, Lockhart S. Laboratory procedures for the epidemiological analysis of microorganisms. In: Murray PR, Baron EJ, Jorgensen JH, et al., eds. *Manual of clinical microbiology*. 9th ed. Washington, DC: American Society for Microbiology, 2007:129–151; Eisenstein BI. New molecular techniques for microbial epidemiology and the diagnosis of infectious diseases. *J Infect Dis* 1990;161:595–602; Lupski JR. Applied molecular genetics: new tools for microbiologists and clinicians. *J Infect Dis* 1986;153:416–430.)

REA showed that the two plasmids were from two different strains causing two separate outbreaks *(114)*.

REA of plasmid DNA was used to implicate rectal probes of electronic thermometers in the transmission of vancomycin-resistant *E. faecium* between patients during an outbreak *(115)*. In another study using REA, spread of MRSA in a hospital was traced to a healthcare worker (HCW) with chronic sinusitis *(116)*. The plasmid DNA of isolates from affected patients and a respiratory therapist yielded the same pattern on restriction endonuclease digestion. Epidemiologic methods led to the control of the outbreak without extensive culturing of specimens from patients, personnel, or environmental surfaces or requiring other expensive and labor-intensive resources.

The role of asymptomatic fecal excretors treated with antibiotics in the epidemiology of healthcare-associated *Clostridium difficile* diarrhea was clarified with REA typing of the strains cultured from stool specimens. Johnson et al. *(117)* found that asymptomatic fecal excretion of *C. difficile* was transient in most patients. Treatment with metronidazole was not effective. Although treatment with vancomycin was temporarily effective, it was associated with a significantly higher rate of *C. difficile* carriage 2 months after treatment. In five instances, the recurrent *C. difficile* excretion represented acquisition of new strains (reinfection) based on REA typing of the isolates, and three patients began excreting the same REA strain after initial eradication with vancomycin. In another study, the epidemiology and relatedness of *C. difficile* isolates in two geographically separated hospitals in a large city were studied using REA *(118)*. A high degree of similarity among isolates from these different hospitals suggested the possibility of an extended outbreak with subsequent genetic drift at the two different institutions. Comparisons of REA typing with other methods such as immunoblot, bacteriophage and bacteriocin, ribotyping, protein profile analysis, arbitrarily primed polymerase chain reaction (AP-PCR), and toxinotyping for *C. difficile* have noted that REA (along with AP-PCR and toxinotyping) is among the most discriminating of the techniques in establishing strain differences *(119–121)*. The REA for *C. difficile* strains is among the most reliable typing methods for current use by clinical laboratories.

Molecular epidemiology can also be used to study resistance patterns resulting from selective pressure from antibiotics. REA of chromosomal DNA has been used to demonstrate that resistance to ciprofloxacin in strains of *Serratia marcescens* and *Proteus mirabilis (122)* and to imipenem in strains of *E. aerogenes (123)* arose from endemic susceptible strains.

REA can be combined with other methods to strengthen the association between isolates during outbreak investigations. PPA and REA were used to trace an outbreak of multiresistant *Salmonella newport* infections to animals fed subtherapeutic doses of antibiotics *(124)*. Another example involved the use of plasmid profiles and restriction endonuclease digestion to show that an MRSA outbreak was caused by a single strain introduced by an employee 15 months before an outbreak on a vascular surgery service *(104)*. Strains from patients and employees were found to be identical with this technique.

In addition to plasmid DNA, reproducible REA patterns of chromosomal DNA can be detected. REA is especially useful for examining viruses, protozoans, and bacterial strains that lack plasmids *(125)*. REA recognizes specific sites on the chromosome, and the pattern is unique for each isolate *(125)*. Different strains of the same bacterial species can be shown to have different REA profiles. Despite phenotypic dissimilarity, REA of chromosomal DNA of group B *Neisseria meningitidis* identified isolates from the throat that were genetically similar to an epidemic strain *(126)*. However, if, genotypically, all strains appear similar, including the random endemic isolates (controls), then additional restriction digestions with at least two other enzymes that are able to discriminate outbreak strains from endemic strains are likely to be useful in typing isolates *(84)*. The outbreak strains can be considered to belong to the same clone if a second enzyme shows identity among the outbreak strains *(84)*.

RFLP produced by restriction endonucleases has proved useful for strain identification of mycobacteria, for detecting cross-contamination, and for tracing epidemics *(127,128)*. For example, RFLP was used effectively to study an outbreak of tuberculosis with accelerated progression among human immunodeficiency virus (HIV)-infected patients *(129)*. An outbreak of 60 cases of tuberculosis in the Netherlands associated with one physician's office was successfully investigated using RFLP *(130)*. Ongoing uses of RFLP include determining whether the emergence of a multidrug-resistant tuberculosis isolate is clonal or whether reinfection occurs with different RFLP types and analyzing strains on a geographic basis *(131)*. The results of such studies are changing the traditional concepts of tuberculosis transmission. For example, tuberculosis in elderly persons has been generally thought to be the result of reactivation. However, two recent studies have found that a high proportion (30% or more) of tuberculosis cases in elderly people appear to be due to recent infection rather than reactivation *(132,133)*. This has important implications for control of tuberculosis.

The limitation of having enough DNA to analyze (which requires 6 or more weeks of growth of the isolate) can now be overcome by combining RFLP with PCR (which requires short periods of growth by amplifying small quantities of DNA) *(131)*. However, the expense and the labor-intensive and time-consuming requirements of RFLP limit its use to research facilities.

Invasive aspergillosis is a well-known infection with a high mortality that affects immunosuppressed patients. Healthcare-associated outbreaks have been associated with contaminated ventilation systems and construction within or near hospitals that have immunosuppressed patients *(134)*. Although airborne transmission has been suggested by epidemiologic studies, an accurate typing system, until recently, has not existed to confirm this hypothesis. Biotyping methods are unreliable in differentiating strains because of variable phenotypic expression under different environmental conditions. RFLP of total DNA, digested by particular restriction enzymes, is able to discriminate strains of *Aspergillus fumigatus* to some degree *(135)*. Girardin et al. *(136)* used Southern blot hybridization of moderately repeated DNA sequences to fingerprint strains of *A. fumigatus* isolated from patients with invasive aspergillosis and from their hospital environment. They

demonstrated that some strains persist in the hospital environment for at least 6 months and found suggestive evidence of healthcare-associated spread of *A. fumigatus* in two patients *(136)*. Thus, the healthcare-associated origin of infection can be demonstrated if environmental strains identical to the strains from patients are isolated in a prospective survey a few days before the patient's aspergillosis is diagnosed *(136)*. More recent studies done by other molecular methods *(137,138)* have confirmed this link.

The major advantage of REA is that it allows for differentiation of one strain from another without relying on the expression of a given phenotype *(139)*. The major limitation of REA has been that the number of chromosomal bands produced (~103) is so large and overlapping that the specific bands are difficult to identify; thus, it does not lend itself to a comparison of various isolates *(139,140)*. This limitation of REA has largely been overcome by using PFGE instead of agarose gel electrophoresis(see later discussion).

PULSED-FIELD GEL ELECTROPHORESIS

PFGE of chromosomal DNA is a variation of agarose gel electrophoresis that allows analysis of bacterial DNA fragments over and above conventional REA *(88)*. Although it is more expensive and demanding than conventional REA, a highly reproducible restriction profile is provided with PFGE that shows distinct, well-resolved fragments representing the entire bacterial chromosome in a single gel. PFGE banding patterns can readily discriminate among endemic and epidemic strains, especially for *E. coli* and *Mycobacterium avium-intracellulare* but not for MRSA and *H. influenzae* serotype b. RFLP patterns of *Mycobacterium* species can be easily interpreted with PFGE, unlike the pattern obtained with routine electrophoresis *(127)*.

Back et al. *(139)* investigated a recurrent epidemic of erythromycin-resistant *S. aureus* infection in a well-baby nursery. Initial traditional epidemiologic techniques suggested that these were two separate outbreaks. However, REA of plasmid DNA along with genomic DNA typing by PFGE of the isolates demonstrated that the two epidemics resulted from the same strain. A nursing assistant was assumed to be responsible for the first epidemic, because she carried a *S. aureus* strain with the same antibiogram. However, she was infected with an unrelated strain, as assessed by REA with PFGE. Instead, a physician who attended on the unit during both epidemics had the same epidemic strain and was the most likely source of the outbreaks. The authors concluded that traditional epidemic investigations might engender misleading conclusions that can be avoided with molecular epidemiologic techniques. The cost for epidemiologic typing of this outbreak was $1,000 for REA and $1,500 for REA with PFGE.

REA of genomic DNA with PFGE provides DNA fingerprinting of various microorganisms, especially *S. aureus*, which is highly discriminatory and stable enough to reliably characterize many strains *(140,141)*. Such molecular typing has been used recently to identify and characterize the clonal expansion of community-acquired MRSA in a Native American community *(142)*. This technique identified 31 or 32 isolates of MRSA from the community that were highly related, yet distinguishable from 32 hospital-acquired MRSA strains.

In another study, endemic MRSA in a Veterans Administration Medical Center was evaluated using PFGE analysis *(143)*. A large amount of strain variation was detected, and 40% of patients observed over time were colonized or infected with more than one strain of MRSA. This form of molecular typing was very useful in evaluating the epidemiology of MRSA in this setting.

PFGE has also been useful in studying the spread of GAS in an outbreak setting. Healthcare-associated transmission of GAS occurred from a single-source patient to 24 HCWs in a hospital *(144)*. PFGE analysis revealed that all of the isolates were identified to that of the source patient. The 24 HCWs developed symptoms of pharyngitis <4 days after exposure to the source patient. Rapid identification, early treatment, and adherence to infection control practices were able to control the outbreak.

Outbreaks from gram-negative bacilli have been successfully evaluated with PFGE. Multidrug-resistant *K. pneumoniae* caused an outbreak in a university hospital in Lisbon, Portugal *(145)*. PFGE identified an endemic strain that presented in different wards in the hospital. In another study, a healthcare-associated outbreak of *K. pneumoniae* producing extended-spectrum β-lactamase was shown by PFGE to be of the same clone *(146)*.

PFGE of chromosomal DNA was found to be a reliable method for epidemiologic typing of *S. odorifera (147)*. In this investigation, neither biotype nor antibiogram was useful in differentiating strains. Although no source for the microorganisms or mode of transmission was identified, the isolates from the two patients in a cardiothoracic surgery unit were identical by PFGE of chromosomal DNA, suggesting possible healthcare-associated transmission.

PFGE of genomic DNA combined with clinical epidemiologic analysis was successfully used to investigate an outbreak of *M. abscessus* pseudoinfection *(148)*. Fifteen patients had positive cultures for *M. abscessus* without evidence of infection following endoscopy. Environmental and case-patient isolates had identical large restriction fragment patterns of genomic DNA separated by PFGE. An automated endoscope washer was implicated as the source of the pseudoepidemic. A similar outbreak of pseudoinfection by *M. abscessus* was detected by molecular typing (random amplified [RA]-PCR in this instance) in which the use of in-house prepared distilled water was the source of a pseudo-outbreak *(149)*.

Phenotypic differences among strains of the same *Candida* species may not reflect true strain differences because *Candida* is able to switch phenotypes. Because different phenotypes can coexist at the same site of infection, genotyping techniques were developed *(150)*. REA with PFGE has shown that isolates of the same *Candida* strain share the same DNA profile, whereas epidemiologically unrelated isolates have patterns that are distinctly different *(150)*. RFLP has also been used to delineate specific strains of *Candida* species for epidemiologic studies *(150)*. By the use of DNA content as an epidemiologic marker of strain identity, studies have shown that transmission of *Candida albicans* probably occurs through indirect contact between patients by way of the hands of HCWs *(150)*. Vazquez et al. *(151)* found that REA patterns of chromosomal DNA from *C. albicans* isolates cultured from patients who were geographically and temporally associated were identical.

This study also suggested that healthcare-associated acquisition of *C. albicans* occurs by way of indirect contact between patients. More recently, Vazquez et al. *(152)* have found similar molecular epidemiologic evidence that indirect contact between patients is an important factor in healthcare-associated colonization by *C. glabrata*. Finally, *C. inconspicua* has been identified by similar molecular typing techniques as a healthcare-associated pathogen in patients with hematologic malignancies and appears to emanate from a common source within the hospital environment *(153)*.

Combining several isolate-typing methods may allow for surveying a large population consisting of many different microorganisms. Chetchotisakd et al. *(154)* used PPA (for *E. coli*, *K. pneumoniae*, and *E. cloacae*), REA of plasmid DNA (for *S. aureus*), and/or PFGE of chromosomal DNA (for *S. aureus*, enterococci, *P. aeruginosa*, and other bacteria) to demonstrate that endemic bacterial cross-transmission in ICUs is relatively infrequent. DNA typing of these isolates found cross-transmitted bacteria not to be common causes of endemic ICU-related healthcare-associated infections.

Using a combination of PFGE, ribosomal RNA (rRNA), and PCR analysis, Bonilla et al. *(155)* demonstrated an outbreak of linezolid-resistant *S. epidermidis* infection in two hospitals in two different cities and states, which was caused by the clonal spread of a *cfr* gene–containing strain. In another study, an extended-spectrum β-lactamase producing *E. coli* was responsible for causing a significant number of serious infections throughout the United States *(156)*. A combination of susceptibility testing, PCR, and PFGE was used to demonstrate clonal spread of the *E. coli*, with the latter methodology suggesting ongoing dissemination among locales.

Multidrug-resistant gram-negative bacteria (GNB) are causing a greater risk to public health than gram-positive bacteria (GPB) for a variety of reasons. Resistance develops much faster in GNB than GPB, and newer antibiotics with activity against GNB are scarcer than for GPB. Emergence of a new antibiotic resistance mechanism with readily transferable plasmids was demonstrated using a combination of technology. PPA, PFGE, and PCR demonstrated international spread of highly resistant *E. coli* and *Klebsiella* producing a carbapenemase between Pakistan, India, and the United Kingdom *(157)*.

Another multidrug-resistant GNB, *A. baumannii* is an emerging pathogen that causes life-threatening infections in ICU patients and has high levels of resistance to antibiotics. Healthcare-associated outbreaks of *Acinetobacter* have been reported with increasing frequency, and prompt initiation of isolation precautions is warranted. Morgan et al. *(158)* demonstrated gowns, gloves, and unwashed hands of HCWs were frequently contaminated with multidrug-resistant *Acinetobacter*. They also demonstrated that *Acinetobacter* was more easily transmitted than multidrug-resistant *P. aeruginosa* using PFGE.

DNA HYBRIDIZATION

Genetic probing or DNA hybridization involves denaturing double-stranded DNA into single-stranded DNA. The single strands from the isolate can be joined to the complementary single-stranded DNA probe that is labeled with a marker such as P_{32}. The hybrids formed are then measured. The primary requirement for a successful probe is that the sequence be both unique and conserved in the group of microbes to be identified *(93)*. For diagnostic tests, useful probes are prepared by cloning-specific DNA sequences from the microorganism to be probed (106). The stringent requirement for complementarity as a precondition for strand reassociation is the basis for the great specificity of the DNA hybridization probe test (106).

DNA probes can be used with the method of Southern hybridization for epidemiologic studies and have been used successfully to investigate the epidemiology of infections caused by *Vibrio cholera*, *Yersinia enterocolitica*, enteroadherent *E. coli*, enteroinvasive *E. coli*, *Salmonella* species, *P. aeruginosa*, and *Legionella pneumophila (93,105)*. The genes that encode *E. coli* enterotoxins have been cloned from toxigenic strains and used as probes to detect the presence of the target gene in a clinical isolate (106). These probes are important in differentiating pathogenic *E. coli* from nonpathogenic *E. coli* found in the stool of ill and healthy patients *(105)*.

Because small amounts of homologous DNA can be detected, DNA hybridization is useful when isolation of a pathogen is impossible, insensitive, or too time-consuming (106). See Table 95-4 for additional advantages of using the DNA hybridization technique.

Besides toxin production genes, antibiotic resistance genes have been analyzed with DNA probes. DNA hybridization determined the extent of homology between two plasmids that suggested transfer of antibiotic resistance among different species *(110)*. Through the use of DNA probes, *E. coli* plasmid DNA was shown to have a high degree of relatedness with plasmid DNA from tobramycin-resistant strains of *E. cloacae* and *K. pneumoniae* that had been isolated from burn patients *(159)*. This pattern sug-

TABLE 95-4

Advantages of DNA Hybridization

Does not require the pathogen to be propagated or be viable
Able to safely handle difficult-to-grow and highly pathogenic (hazardous) microorganisms
Reduces the number of bands for analysis with restriction endonuclease and highlights specific DNA restriction sites
Can distinguish individual strains of bacteria
Can detect pathogens (cytomegalovirus, rotavirus, papillomavirus, chlamydia, and mycoplasma) in clinical specimens that are abundant but difficult to cultivate
Can track transposon movement

gested that interbacterial transfer of the plasmid between different species had probably occurred on the burn ward. Interbacterial transfer of a plasmid-mediating gentamicin resistance was first described in 1981. In this report, separate outbreaks involving *P. aeruginosa* and *S. marcescens* followed by *K. pneumoniae* and *S. marcescens* were related by the presence of plasmids that contained a common transposable sequence. This suggested transfer of a transposon (translocatable DNA sequence) between plasmids as the mechanism for transmission of gentamicin resistance *(160)*. Recent work suggests that dissemination of resistant genes carried on transposable elements may be important in vancomycin-resistant enterococci *(161)*.

DNA probes have also been used to characterize other microorganisms than bacteria such as mycobacteria, viruses, and fungi. DNA hybridization has identified fingerprint patterns to help define the epidemiology of infections caused by *C. albicans (162)*. The DNA probe can be used for mycobacterial cultures but is not sufficiently sensitive to detect microorganisms directly from clinical specimens *(163)*. Identification of individual *Mycobacterium tuberculosis* (MTB) strains is now possible through DNA fingerprinting *(163)*. Because most MTB strains share common drug susceptibility patterns and bacteriophage types, it has been difficult to document transmission of specific strains from person to person *(163)*. However, DNA fingerprints of individual MTB strains remain relatively stable over time and permit delineation of patterns of tuberculosis transmission *(163)*. DNA probes are available not only for MTB but also for *M. avium-intracellulare*, *M. kansasii*, and *M. gordonae*; these probes used with the Bactec system can provide identification within 2 to 4 weeks *(164)*. Despite the many uses of DNA hybridization, a few drawbacks exist. DNA hybridization is costly, slow to perform, and cumbersome. It is often less sensitive than culture when done on an individual basis, and radioisotopes may be required for its use (Table 95-5) (89,*105*,*110*).

RIBOTYPING

rRNA represents highly conserved nucleotide sequences that are found in most microorganisms. Probes have been produced based on rRNA that are unique to species, genus, and groups like all gram-negative bacilli and the intracellular pathogen *Legionella (105)*. Fingerprinting of rRNA has been valuable for typing strains of *S. typhi*, *Campylobacter* species, *Pasteurella multocida*, and various *Staphylococcus* species *(84,105)*. REA of rRNA can be used to distinguish isolates of *Staphylococcus* species and strains of *H. influenzae*, *Providencia stuartii*, and *Candida* species *(165)*. rRNA gene restriction patterns were used to show that *H. influenzae* isolates cultured from the trachea and blood of an infant and from the mother's cervix were identical, indicating that the mode of transmission was from mother to child *(165)*.

Ribotyping was found to be a more reliable technique than biochemical typing when evaluating *S. marcescens* strains. Identical ribotypes of *S. marcescens* were found colonizing 12 children in five different hospital wards over a 20-day period *(166)*. Combining epidemiologic findings with the ribotype patterns suggested cross-contamination between the patients on four of the wards.

Epidemiologic studies of *E. cloacae* have relied primarily on the study of phenotypic traits such as biochemical profiles; antibiotic resistance; and serologic, bacteriocin, and phage typing *(167)*. Because of insufficient discrimination, poor reproducibility, or low typeability, these methods are unsatisfactory for analyzing *E. cloacae*. Using RFLP of total DNA and ribotyping, Lambert-Zechovsky et al. *(167)* were able to document endogenous bacteremia and meningitis resulting from *E. cloacae* that originated from colonization of the gastrointestinal tract in an infant. Each of the five isolates from the infant had identical ribotypes, whereas the comparison strains exhibited different unique ribotype patterns. This case study supports the use of RFLP analysis of total DNA and ribotyping to study the epidemiology of healthcare-associated infections resulting from *E. cloacae* strains.

Ribotyping and PFGE can be used to characterize multidrug-resistant gram-negative bacilli. The prevalence of carbapenem-resistant *A. baumannii* and *P. aeruginosa* in Brooklyn, New York, was determined by ribotyping and PFGE on 419 and 823 isolates, respectively *(168)*.

Ribotyping revealed a single clone accounted for 62% of the samples and was isolated from patients at all 15 hospitals in the area. Ribotyping revealed that three clones accounted for nearly half of the isolates and were shared by most hospitals.

In another study, ribotyping and PFGE were used to characterize a foodborne outbreak. Acute gastroenteritis developed in 21 nursing home patients with 2 deaths after consumption of minced beef heart contaminated with *C. perfringens (169)*. PFGE was not able to characterize a majority of the *C. perfringens* isolates. However, ribotyping successfully distinguished four different groups of *C. perfringens*. The same ribopattern was detected in a food sample, autopsy samples from the two deceased patients, and stool samples from six further patients who had fallen ill with diarrhea.

C. difficile has surpassed MRSA as the most common healthcare-associated pathogen in many hospitals. In addition to an increase in the incidence of *C. difficile*–associated colitis is an increase in the severity of illness. Risk factors that promote the spread of *C. difficile*–associated colitis include, overcrowding, understaffing, high levels of anti-

biotic use (particularly of fluoroquinolones), and an aging population. PCR ribotyping and PFGE have successfully characterized the emergence of a hypervirulent strain of *C. difficile* that causes more severe colitis and a higher mortality than other strains *(170)*. These hypervirulent isolates have a genetic mutation that causes hyperproduction of toxins A and B. In addition, they are resistant to fluoroquinolones. The spread of this strain from North America to Europe and other parts of the world are of growing concern *(170)*.

The spread of *C. difficile* within and between hospitals can also be better tracked using molecular-based epidemiologic techniques. PCR ribotyping was used to identify epidemic strains of *C. difficile* causing an outbreak at multiple hospitals *(171)*. Unlike other studies, Jump et al. *(171)* found that the use of fluoroquinolones with enhanced antianaerobic activity was not associated with increased infection rates (see also Chapter 37).

Besides outbreak investigations, rRNA has been very useful in phylogenetic analysis. The gene sequence in ribosomal DNA was pivotal in the discovery of the causative agents of bacillary angiomatosis, human ehrlichiosis, Whipple's disease, and Tyzzer's disease *(172)*.

POLYMERASE CHAIN REACTION

PCR is the repetitive cycling of three simple reactions in a semiautomated, self-contained system capable of amplifying a single strand of DNA or RNA with 50 to more than 2,000 base pairs more than a million-fold in only a few hours (173). More than 22 different microorganisms that grow slowly or not at all on routine culture media can now be detected using PCR *(172)*. With this tool, the healthcare epidemiologist can rapidly diagnose an otherwise difficult-to-detect pathogen and, thus, initiate specific infection control measures promptly *(174)*.

By virtue of its speed and high degree of sensitivity and specificity, rapid and reliable detection of microbes present in small numbers is now possible. For diagnosis, PCR goes beyond the detection of microorganism-specific immunoglobulin M or antibodies in serum, demonstration of seroconversion to a microorganism on testing acute and convalescent sera, or detection of microorganisms in clinical specimens using cultures or antigen assays *(175)*. Pathogens that are difficult to culture, are in the latent stage, or require an antibody response to be detected can potentially be detected with PCR *(176)*. PCR is useful when other tests provide ambiguous results or are subject to technical failures. See Table 95-6 for the benefits of PCR use in epidemiologic investigations. Like other detection systems, PCR has some limitations and pitfalls. The nucleic acid sequence of the pathogens to be detected must be known to develop the appropriate primer. If the sequence is known and the microorganism is detected, the significance of a positive test result still depends on the clinical situation. For example, cytomegalovirus viremia detected by PCR or by culture could indicate asymptomatic shedding versus active infection, making clinical correlation an essential part of the investigation.

Noroviruses cause major outbreaks of gastroenteritis worldwide and cause healthcare-associated outbreaks, especially in nursing homes, pediatric wards, and cancer centers. Because of their environmental stability, ability to use different transmission routes, and low infection doses, their source may be difficult to determine during an outbreak *(177)*. Verhoaf et al. *(177)* were able to distinguish between viral genotype profiles from human feces and sewer-contaminated food using genotype analysis and PCR technology. They found that one-quarter of the outbreaks reported as food handler associated were probably caused by source contamination of the food *(177)*.

PCR has been used in several outbreak investigations and sheds new light on the pathogenesis and spread of difficult-to-detect microorganisms. Enterotoxigenic *E. coli*, a very difficult microorganism to separate from nontoxigenic strains, was successfully detected and identified with the PCR technique *(178)*.

PCR along with other techniques can evaluate infection control surveillance systems. PPA combined with PFGE and PCR was used to study the utility of surveillance for multidrug-resistant *Enterobacteriaceae* in the absence of an outbreak in new organ transplant patients *(179)*. The authors conclude that this form of surveillance is costly and provides little or no benefit for infection control or predicting clinical infections in this population. However, surveillance of colonization may play a greater role in the event that a clonal outbreak is identified.

PCR can also verify the accuracy of other techniques such as PFGE used in outbreak investigations. An outbreak of vancomycin-resistant *E. faecium* was identified in a teaching hospital in Medellin, Columbia, by using PFGE.

TABLE 95-6

Benefits of PCR in an Epidemiologic Investigation

Direct typing for specific microorganisms
Detection of genes that code for toxins, virulence factors, and antimicrobial resistance
Rapid diagnosis
Detection of microorganisms in low numbers
Detection of microorganisms that are slow growing or do not grow at all *in vitro*
Does not require an antibody response to the infecting agent
Does not require active replication; latent stage is able to be detected
Able to study the reservoirs and modes of transmission of difficult-to-track pathogens
Detection of microorganisms in body fluids (cerebrospinal fluid, ocular fluid, fetal blood)

(Data from Soll DR, Pujol C, Lockhart S. Laboratory procedures for the epidemiological analysis of microorganisms. In: Murray PR, Baron EJ, Jorgensen JH, et al., eds. *Manual of clinical microbiology*. 9th ed. Washington, DC: American Society for Microbiology, 2007:129–151; Eisenstein BI. The polymerase chain reaction: amplifying our options. *Rev Infect Dis* 1991;13:166–171.)

PCR identified all 23 isolates as identical, thus complimenting the use of PFGE *(180)*.

The reservoirs and modes of transmission of healthcare-associated *Legionella* infection have been further elucidated using newer molecular techniques such as PCR methodology *(181–183)*. An indoor hot tub at a resort condominium complex was implicated as the source of an outbreak of Pontiac fever by using PCR *(184)*. Although cultures of water for *Legionella* were negative, direct fluorescent antibody and PCR were positive, thus incriminating nonviable and nonculturable *L. pneumophila*.

PCR was used to study two outbreaks of infection with a hypervirulent strain of hepatitis B virus (HBV) that was associated with a high mortality *(185,186)*. Mutations in the HBV genome were detected from the index patients and their contacts but absent from unrelated infectious patients, thus implicating the virulent strain as the cause of the outbreaks. The most notable outbreak investigation using PCR involved HIV transmission from a dentist to five of his patients in a healthcare setting *(187)*.

With the recent surge in the incidence of tuberculosis, rapid and accurate diagnosis is becoming increasingly important. As few as one or two microorganisms in a given *Mycobacterium* species can be detected with the PCR method *(127)*. This method can diagnose pulmonary tuberculosis when acid-fast bacilli (AFB) smears and cultures are negative *(127)*. Eisenach et al. *(188)* reported a sensitivity of 100% and a specificity of 99% when using PCR techniques to analyze sputum from patients with and without tuberculosis. Kirschner et al. *(189)* over a longer 18-month period noted a sensitivity of only 84.5% and a specificity of 99.5%.

In addition to REA with PFGE and RFLP, PCR has also been used to type *Candida* species. van Belkum et al. *(190)* successfully typed *C. albicans* strains with PCR amplification of variable DNA domains. They suggest that all colonies of *C. albicans* isolated from clinical specimens can be typed by PCR both prospectively and longitudinally. With this technique, suspected outbreaks resulting from *Candida* species can be investigated more thoroughly to clarify the role of exogenous transmission versus endogenous colonization leading to infection.

A novel variant of conventional PCR, AP-PCR, or random amplified polymorphic DNA, has been used successfully in several outbreak investigations. With this new technique, arbitrarily selected primer DNA is annealed to the template DNA under low-stringency conditions for the initial cycles of DNA replication *(191)*. This step requires no prior knowledge of the sequences to be amplified. The products of the initial cycles of low-stringency polymerization are amplified under high-stringency conditions, as in conventional PCR, and separated by gel electrophoresis *(191)*. The pattern generated is highly reproducible and specific for a given strain; furthermore, it can be used to distinguish different strains within a single species *(192)*.

Current typing schemes for meningococci include serogrouping of capsular polysaccharides or outer membrane proteins, multilocus enzyme electrophoresis of metabolic enzymes, and genomic restriction endonuclease digestion with or without PFGE *(193)*. An outbreak of meningococcal meningitis at a college campus was successfully investigated using AP-PCR *(193)*. All 3 disease isolates and 7 of 11 carrier isolates were identical, as found by using four different primers, and were easily distinguishable from unrelated isolates. AP-PCR further demonstrated the clonal nature of meningococcal disease outbreaks in which most disease isolates are of the same clone *(193)*.

Healthcare-associated transmission of multidrug-resistant gram-negative bacilli in intensive care settings has been elucidated with RA-PCR. A burn unit experienced an outbreak of multidrug-resistant *P. aeruginosa*. RA-PCR identified two predominant genotypes that were responsible for recurrent outbreaks *(194)*. One of the strains was endemic to the burn ward and developed multidrug resistance at the end of the study period. In another study, two outbreaks of multidrug-resistant *K. pneumoniae* in an ICU were analyzed by RA-PCR *(195)*. The first outbreak was caused by two different types of *K. pneumoniae*. RA-PCR identified yet a different strain that caused the second outbreak. The authors conclude that RA-PCR is easy to perform, highly reproducible, and had a high discriminatory power.

Typing of *C. difficile* to differentiate highly pathogenic from nonpathogenic strains has been accomplished with a number of techniques including bacteriophage, bacteriocin, toxinotyping, and REA of DNA *(119–121)*. Complex and difficult-to-interpret DNA patterns are sometimes produced with REA of DNA. Silva et al. *(196)* successfully used AP-PCR to genotype *C. difficile* isolates from various sources. Two strains isolated from patients on the same floor but different wards had the same DNA banding patterns, suggesting a common source of cross-infection through hospital contact. Others have found AP-PCR to be useful for genotyping *C. difficile (120)*.

The epidemiology of *Staphylococcus* species can be characterized using RA-PCR. Neonates are susceptible to infections caused by methicillin-resistant coagulase-negative *Staphylococcus*. Dissemination of one particular clone was identified using the RA-PCR technique among a group of neonates in a hospital ward *(197)*. In addition, persistence of the isolate and reinfection was effectively identified with this methodology. In another study, PFGE and PCR were used to characterize colonization of children and their guardians with *S. aureus (198)*. When both members of the child–guardian pair were colonized with *S. aureus*, transmission within the family was implicated because 67% of the colonizing isolates were the same strain.

An outbreak of MRSA in a burn unit was investigated with AP-PCR and restriction endonuclease analysis of plasmid (REAP) DNA *(192)*. Complementary evidence of a clonal relationship among isolates from patients and staff in the burn unit was established with these techniques. MRSA isolates from other hospital wards were clearly distinguishable from the epidemic isolates. The authors concluded that the combination of AP-PCR and REAP may be a useful means of tracking the healthcare-associated spread of microbial strains and their mobile genetic elements *(192)*. Conventional epidemiologic methods may be inadequate in some outbreak investigations, as this study suggests.

The ability of the healthcare epidemiologist or IP to identify patterns of MRSA spread is dependent on distinguishing the epidemic strain from unrelated MRSA strains *(199)*.

During the investigation of the MRSA outbreak in the burn unit mentioned previously, antimicrobial susceptibility patterns suggested a general grouping of MRSA strains, but definitive typing was not possible with this method. However, REAP analysis (plasmid fingerprinting) yielded useful information for strain typing but resulted in some ambiguities that were resolved by AP-PCR *(192)*.

Because of decreasing susceptibility of MRSA to vancomycin, newer antibiotics with MRSA activity, such as linezolid, are being used with increasing frequency, especially in severely ill patients in ICUs. With increasing use of an antibiotic, resistance quickly follows. Garcia et al. *(200)* reported the first clinical outbreak of linezolid-resistant *S. aureus* with demonstration of healthcare-associated spread. Genotype analysis with PCR and PFGE identified one predominant clone. Reduction of linezolid use and infection control measures terminated the outbreak.

Mycobacterium and *Candida* transmission has been documented with AP-PCR. An outbreak of *M. abscessus* from benzalkonium chloride antiseptic solution was investigated with RA-PCR and PFGE *(201)*. Joint and periarticular soft tissue infections developed after steroid injection from the same physician. Clinical and antiseptic solution strains of *M. abscessus* were indistinguishable by RA-PCR.

After the occurrence of two chronologically related cases of *C. tropicalis* fungemia in a neonatal ICU, a prospective study of fungal colonization and infection was initiated *(202)*. RFLP and RA-PCR identified fungemia more commonly in colonized than in noncolonized neonates, and no environmental source was found. The authors conclude that these molecular diagnostic tests can improve our understanding of the epidemiology of *Candida* infections, including the mode of transmission. It is likely that techniques for epidemiologic typing for application during outbreak investigations will continue to advance in the age of the evolving PCR technique.

SELECTIVE CULTURE MEDIA AND SPECIAL MICROBIOLOGIC TECHNIQUES

Selective Culture Media

Selective culture media, which inhibit microorganisms in the clinical sample that might obscure or inhibit the growth of the desired strain, may be used during outbreak investigations. For example, the ideal medium for stool specimens would inhibit the competing microorganisms from the normal flora and select out the pathogenic strain desired for analysis. *E. coli* O157:H7, the cause of severe bloody diarrhea and hemolytic uremic syndrome, was first linked to human illness in 1982. Modified MacConkey medium containing sorbitol allows for culture of stool specimens to diagnose *E. coli* O157:H7 infection *(203)*.

The laboratory diagnosis of antibiotic-associated colitis caused by *C. difficile* usually requires the detection of cytotoxin or enterotoxin in stool. However, investigations of *C. difficile*–induced outbreaks of colitis require the isolation of strains for comparison. Selective medium was developed for isolating *C. difficile* in the late 1970s, with cefoxitin-cycloserine fructose agar (CCFA) deemed most satisfactory *(204)*. Various modifications of the original formulation of CCFA now exist for selective culturing of *C. difficile* for use in epidemiologic studies *(205)*.

When investigating MRSA outbreaks, the ideal medium allows the growth of MRSA or clearly differentiates between MRSA and multiresistant coagulase-negative staphylococci *(206)*. Currently, the best discriminating medium to select for MRSA is mannitol salt agar (7.5% sodium chloride) or Mueller-Hinton medium supplemented with 4% sodium chloride, each containing methicillin, oxacillin, or both *(207)*.

A selective medium consisting of Mueller-Hinton agar with vancomycin (20 μg/mL), polymyxin (100 μg/mL), and streptomycin (100 μg/mL) was successfully used to culture for vancomycin-resistant *E. faecium* from rectal and environmental swabs during an outbreak investigation *(115)*.

Special Microbiologic Techniques

Susceptibility testing for penicillin-resistant pneumococci has rapidly evolved. Previously, this was done in most microbiology laboratories using the National Committee for Clinical Laboratory Standards (NCCLS) method with Mueller-Hinton agar containing added sheep blood and a 1-μg oxacillin disk to screen for penicillin resistance *(208)*. Today, disk diffusion and/or E-test methods are preferred *(209)*. In the future, PCR may become the standard *(210)*.

Traditionally, specimens for isolation of mycobacteria have been inoculated on Lowenstein-Jensen American Thoracic Society medium or Middlebrook 7H10 or 7H11 medium. Incubation for 4 to 6 weeks is required to detect growth with these methods. A more recent approach is to inoculate a thinly poured plate of Middlebrook 7H11 medium and examine with a conventional microscope *(127)*. This allows for slow-growing mycobacteria to be detected in as few as 3 days and identified in 7 to 10 days *(99)*. A biphasic broth culture system, the Roche Septi-Chek AFB system (Roche, Rockwell, MD), is comparable to the Bactec system *(127)*. Another newer method now available is the mycobacteria growth indicator tube (MGIT) (Baltimore Biological Laboratory). The MGIT system consists of a modified Middlebrook 7H9 broth and a sensor embedded in silicone on the bottom of a tube. The appearance of orange-colored fluorescence in the sensor when excited indicates the growth of mycobacteria *(211)*.

Antimicrobial susceptibilities for mycobacteria are generally determined by comparing the amount of growth in the media containing known drug concentrations with growth in the control media *(127)*. Traditionally, antimicrobial susceptibility results obtained by using Middlebrook 7H10 or 7H11 agar with the antituberculosis agents added at specific concentrations takes about 4 weeks of incubation. Currently, the Bactec radiometric system for mycobacterial susceptibility testing can provide results in a week or less *(127)*. The MGIT offers equal speed for mycobacterial susceptibility testing *(212)*.

CONCLUSIONS

The microbiology laboratory has become an integral part of a healthcare epidemiology and infection control program. The constantly changing spectrum of healthcare-associated

pathogens and their susceptibilities and the availability of newer technologies require constant communication, cooperation, and collaboration between microbiology personnel and IPs. In the 21st century, this relationship is more critical than at any time in the past.

The key to effective healthcare epidemiology and infection control efforts in the 21st century will be the proper application of diverse phenotypic and genotypic methods for detection, identification, susceptibility testing, and typing of healthcare-associated pathogens. Phenotypic methods, although readily available, are frequently misleading and, therefore, have limited value in epidemiologic studies today. Genotyping has overcome almost all of the limitations of phenotyping and now provides very effective tools for the healthcare epidemiologist and IP to use in epidemiologic investigations. Important genotypic methods are briefly summarized.

One of the first genotypic methods, PPA, is well suited for the analysis of outbreaks that occur over a relatively short period. This technique is convenient for use in diagnostic laboratories and requires a minimum of equipment and expense. Because many bacterial species harbor plasmids infrequently and because plasmids can be gained or lost, PPA may not be satisfactory for long-term follow-up studies.

REA of plasmid or chromosomal DNA has been very useful for typing many microorganisms in epidemiologic studies. RFLP profiles produced by REA can detect different strains of the same species because of variation in their DNA sequences. The advantages of total DNA RFLP include universal applicability, high sensitivity, and ease of performance. Because some REA patterns were too large and indistinct when obtained with agarose gel electrophoresis, PFGE was developed to provide clearer patterns with better discriminatory power. PFGE appears to give the best results for investigating staphylococci, enterococci, and *P. aeruginosa*.

DNA hybridization with Southern blotting is another molecular method that uses a labeled DNA probe to reduce the number of visible fragments to a manageable number and, thus, produces a clearer fingerprint of the microorganism.

Ribotyping has taken advantage of highly conserved sequences that are found in most microorganisms to delineate the epidemiology of a number of outbreaks. Ribotyping with rDNA is the method of choice when evaluating *Enterobacteriaceae*, *Burkholderia cepacia*, and *Stenotrophomonas maltophilia*; this method takes about 5 days.

Finally, the most sensitive of all molecular typing methods, PCR, has allowed the identification of new entities and discrimination of nearly identical appearing strains. AP-PCR is the most rapid method (1–2 days) and is also the least expensive method that soon may be applicable to all bacteria.

The rapid development and use of genotypic typing techniques has significantly expanded the understanding of the epidemiology of many healthcare-associated pathogens. The challenge for the microbiology laboratory in the 21st century is to make these techniques readily available (in-house or from a reference laboratory) and affordable. With such tools, the healthcare epidemiologist and the IP should be able to achieve more effective investigations of outbreaks and, thus, will be able to develop better prevention strategies.

CHAPTER 96

Economic Analysis in Healthcare Epidemiology

Linda M. Mundy and Anucha Apisarnthanarak

Economic analysis requires technical skill and clinical expertise with results that contribute to fiscal accountability, programmatic support, policies, legislation, and ongoing resource allocation. Medical and technical advances in healthcare have occurred in parallel with rising healthcare expenditures and improved methods for economic analysis worldwide. In the United States (US), mandates for public reporting of healthcare-associated infections (HAIs) exist along with federally authorized expenditure of US$1.1 billion to conduct comparative effectiveness research of healthcare under Title VIII of the American Recovery and Reinvestment Act of 2009 *(1)*. In the United Kingdom, the National Institute of Clinical Excellence has created several hundred guidance reports on clinical-effectiveness and cost-effectiveness in medical conditions and debate exists over how national targets contribute to improved infection control practice *(23)*. From a global perspective, the World Health Organization is engaged in the promotion of healthcare epidemiology and relevant issues of economic analysis (4).

Attention to providing healthcare that satisfies both clinical and economic criteria exist, with stakeholder input from consumers, academicians, collaborative groups, and representatives from government and from industry. Healthcare insurers readily assess the type and the extent of service coverage, with contractual arrangements based on a variety of clinical and economic indicators with pay for performance strategies, incentives, and fund-transfer agreements over time. Policymakers influence public expenditures via mechanisms of healthcare coverage, patient safety, and allowable payments *(5)*. Forecasts from the Office of the Actuary at the Centers for Medicare and Medicaid Services estimate healthcare expenditures of US$3,600 billion, almost 20% of the US gross domestic product, by year 2014. As federal oversight of affordable medical care continues to evolve in the United States, healthcare epidemiologists will have a key role in comparative effectiveness research and practice.

Healthcare epidemiology programs in infection control and occupational health have had unique sustainability challenges given that these programs do not generate direct revenue streams and have historically been challenged to prove their worth (6,7). Resources for the treatment and prevention of HAIs among patients and the provision of health and safety among healthcare personnel require careful revenue assessments that include averting untoward events and optimizing clinical and economic returns on investment (*8–11*,12). In recent years, the methods used to determine the costs of HAIs have been analyzed in detail, with particular emphasis focused on measures to estimate incremental costs (12). Most economic analyses in infection control have focused on hospital-based point of care and a paucity of data exists for infection control interventions across the continuum of care. Gaps in economic analysis of infection control and occupational health programs are especially evident in resource-limited settings *(13–15)*.

From a historical perspective, two broad recommendations from the 1993 Panel on Cost-Effectiveness in Health and Medicine were that the economic analysis of healthcare studies should focus on cost-effective analysis (CEA), rather than cost-benefit analysis (CBA), and that decision making for resource allocations should be society based using reference case analysis *(16)*. In traditional CBA, the effect is monetary rather than units of health outcome and the recommendation for the societal perspective aims for study investigators to incorporate all costs and health effects regardless of who incurs the costs and who obtains the effects. Integration of these broad recommendations into healthcare epidemiology research and practice is plausible as infection control and occupational health programs aim to provide a safe healthcare environment for patients, families, and employees. In the early 1970s, the Study on the Efficacy of Nosocomial Infection Control (SENIC) project confirmed that a 32% reduction in HAI among patients was associated with the presence of hospital-based infection control programs *(17)*. In subsequent decades, the SENIC goals expanded to improve outcomes across the continuum of healthcare. Over the past decade, the number of economic analyses in healthcare epidemiology has increased, with attention now directed toward standardized methods for conducting economic analysis, improving mathematical models, and training infection control providers in economic methodologies (12). Of relevance, the inclusion of applied economic theory into practice, reports, and policies remains a core component and mission of healthcare epidemiologists' education worldwide. This chapter provides an overview of economic analysis in healthcare epidemiology and is intended for healthcare epidemiologists,

professionals in infection control and occupational health, prevention specialists, and administrative staff. The goal is to describe how to incorporate economic methods into the design, execution, and evaluation of infection control and occupational health programs.

APPROACH TO ECONOMIC ANALYSIS IN INFECTION CONTROL AND OCCUPATONAL HEALTH PROGRAMS

The approach to considering an economic analysis in healthcare epidemiology can be structured into three broad categories: output and cost factors, principles of economic theory, and practical considerations.

1. *Outputs and costs:* In determining if and when to conduct an economic analysis, the comparative outputs (effects) and anticipated cost estimates need to be identified (6,7). The output, potential mediating factors, and costs of the existing (A) program can be compared to the output, mediating factors, and costs of one or more alternative (B) programs (Fig. 96-1). While the most effective program may also have the lowest cost (dominant scenario), it is not necessarily true that the lowest-cost option is the most cost-effective. Consideration must be given to the scenario whereby production of the most units of a given outcome may be impractical to implement, because it is so costly from a supply and demand perspective and it either diverts limited resources from other uses or requires more resources than are available. The cost estimate should include identification of cost factors, data entry methods, calculation of program costs, and determinants of cost saving. If the feasibility assessment of effects and costs are dominant for one program versus the other, it would be plausible to proceed with a simplified cost-minimization or cost-consequence analysis. If instead the feasibility assessment suggests differential effects and costs, the inclusion of an incremental CEA should be explored as an aid to the decision-making process. While the purpose of economic analysis in occupational health typically facilitates an investment in health and safety, the efficiency of this process means that the costs of doing a little more (the marginal cost) to enhance safety equal the benefits (18). Hence, the marginal returns in terms of health and welfare enhancements of the healthcare personnel result from risk reduction (18).
2. *Principles of economic theory:* Economic analysis within healthcare epidemiology is complex given the dynamic algorithms for resource allocation, revenue generation, expenditures, opportunity costs, and assessment of health outcomes in hospitals, alternative care sites, and home-based care. Economic analytical methods are based on a fundamental concept of efficient use of available resources which includes the economics of resource allocation and the efficiency in the use of these resources *(19)*. Analytical difficulties include the estimation of a market price for the resources and the decisions related to allocation of limited resources among seemingly unlimited demands *(19)*. Opportunity cost is relevant to economic evaluations in healthcare epidemiology and represents the value of the resource when it is dedicated in its next best use. Opportunity costs are expressed as the value of lost output if the resource is employed in an alternative productive process *(19)*. Opportunity cost analysis is an important component of business decisions but is not equivalent to a line-item cost in a financial statement. The benefits from the next-best use in resource allocation may be smaller than those of the current use, indicating that the current use is best, or the benefits may be greater, in which case the alternative would be considered preferable *(20)*. Opportunity costs are incorporated into the methodology of CEA.
3. *Practical considerations:* Three core questions have been identified as relevant for assessment of HAI (21): Why measure the cost? What outcome should be used to measure the cost? And what is the best method for making the selected cost measure? (21). First, the costs permit objective assessment of the allocated resources. Second, in hospital-based analysis, one cost measure is the number of bed-days saved valued in dollars (21). A health economist may further value bed-days saved as the next best alternative use or the economic opportunity value of the marginal healthcare resources released as a result of fewer HAI (21). Lastly, the selected cost measure is at risk for measurement bias that pertains

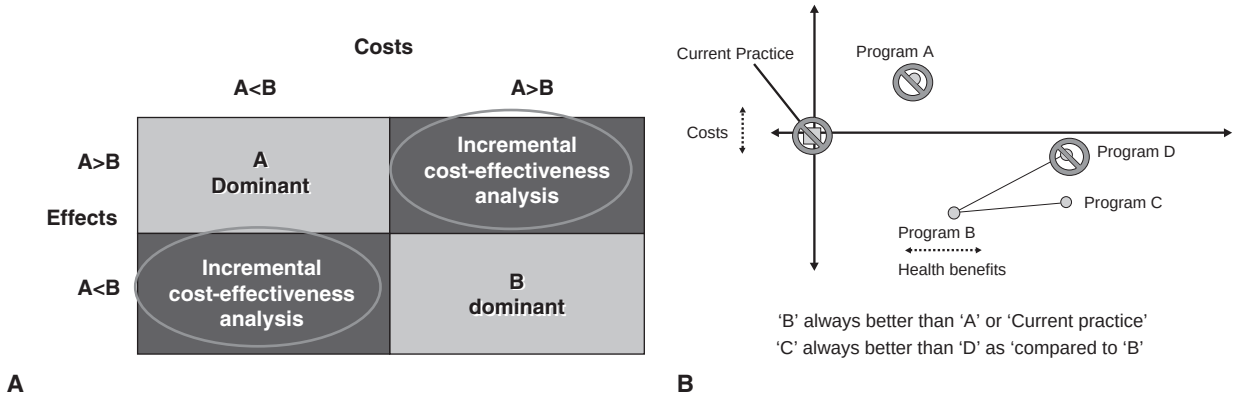

FIGURE 96-1 **A:** Determining when to conduct a cost-effectiveness analysis for program A versus program B. **B:** Is more infection control a smart investment?

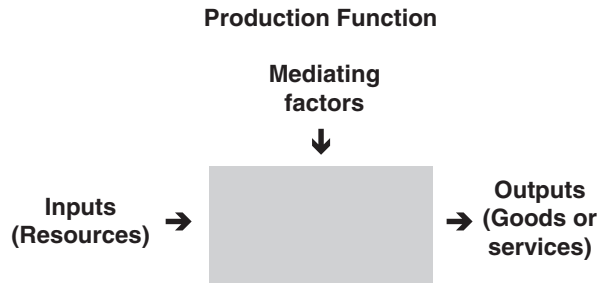

FIGURE 96-2 Production function. (Redrawn from Morris S, Devlin N, Parkin D. *Economic analysis in health care*. London, UK: John Wiley & Sons, 2007.)

to identification of the comparator group as well as time-dependent bias (21,22). After the decision to embark on a robust economic analysis has been made, the relationship between the resources involved in the output (outcome of interest) and the estimate of costs must be considered in more detail. The resources, or inputs, require a unit of measure such as health personnel hours or number of encounters, medical supplies, and diagnostic tests. Measuring this productive process in healthcare epidemiology is especially complicated because the patient is both an input and an output in the process *(19)*. The relationship between inputs and outputs can be extrapolated from an applied understanding of production function (22). A production function focuses on analysis of the relationship between quantities of the input and quantities of output in which the details are often a "black box" (Fig. 96-2). Three major components of the evaluative method are input or resources, mediating factors, and outputs that are goods, services, or outcomes. The mediating factors may influence the relationship between the inputs and outputs involved in the production of health. The cost estimates are typically categorized as direct costs, in dollar expenditures, and indirect or intangible costs, which influence the outcome of interest. Based on supply and demand economics, differentiators within the model are due to efficiency, product choice, and product distribution. Efficiency involves the obtainment of maximum output from productive inputs. Product choice includes determining what goods and services should be produced to meet the demands, and product distribution involves who gets the products produced *(19,23)*. For infection control and occupational health programs, different combinations of inputs can produce the same level of output. Hence, substitution analysis of inputs may identify cost saving and opportunity costs, and several analytical techniques exist for the economic analysis of healthcare programs and evidence-based medical care *(24,25)*.

Several specific issues should be clarified prior to the initiation of an economic analysis within an infection control and occupational health program, as detailed in the following:

1. *Type of institution:* As the site of an episode of healthcare becomes a continuum from the acute to alternative care settings, measurement of risks and resource allocations become more complicated for infection control or occupational health programs.
   a. *Acute care institution:* Resource allocations for healthcare epidemiology programs are often determined by hospital size (licensed bed number). In general, infection control budgets include supplies, overhead, and the salaries of staff such as a part-time physician, nurse, secretary, and data programmer. Based on a program budget, outcomes and economic analysis contribute to justification of the return on investment, if not break-even point, for a healthcare epidemiology program *(26,27)*.
   b. *Long-term care facilities:* Over 1.5 million persons annually reside in US long-term care facilities and the estimated number of infection preventionists per nursing home is fourfold lower than the estimate for infection preventionists in hospital-based care *(28)*. Guidelines exist for prevention and control of infections in long-term care, with endorsement to specifically reduce HAIs (29).
   c. *Home care and other alternative settings*: The role of infection control in home care is often collapsed into the general responsibilities and resources available to nurses within the individual home care organization. Identified unmet needs for infection control in home care settings are the development of valid definitions for home care–acquired infection and practical methods of surveillance *(30)*. Once established, estimates of incidence and risks can be determined in order to characterize effective interventions *(30)*.
2. *Endemic versus epidemic infection control strategies:* As the majority of healthcare epidemiology efforts are dedicated to the control of endemic infections, rather than epidemic infections, resource allocations should parallel this distribution of activity. In infection control programs, CEA needs to distinguish between endemic and epidemic infection control strategies and aim to identify estimates of economic burden incurred from the societal perspective. The Centers for Disease Control and Prevention (CDC) recommend four key components for infection control programs targeted to control the spread of multidrug-resistant pathogens: surveillance, applied research, prevention and control strategies, and development or expansion of infrastructure *(31)*. Infection control programs that target prevention and control of spread of multidrug-resistant pathogens should ideally take these components into consideration for CEA.
   a. *Surveillance:* The degree of pathogen surveillance within a healthcare setting can range from none to that of intense specimen procurement, reporting, and evaluation during an epidemic. The surveillance plan may vary, contingent on the identified pathogen, intervention, and goals of the program. For healthcare systems dedicated to the prevention and control of the spread of multidrug-resistant microorganisms, the options for surveillance span from a threshold alert on clinical isolates to the use of a suppressed or routine passive surveillance system to the incorporation of more elaborate programs with formalized active surveillance.
   b. *Applied research:* To adequately assess the impact of infection control programs by CEA, resource

allocation is needed for integration of molecular epidemiology methods such as molecular diagnostics of clinical specimens, data programming, and analysis from one or more information systems.

c. *Prevention and control strategies:* The strategies employed in healthcare epidemiology and infection control programs are myriad. Such strategies may be categorized as environmental, educational, behavioral, and pharmacologic.

d. *Development or expansion of existing infrastructure:* Secure, dynamic infrastructure is crucial for an effective healthcare epidemiology or infection control program. The infection control specialists in large and small programs need access to administrative leadership, database management support, performance monitoring systems, and ongoing educational programs. As a program or hospital department, infection control programs are accountable for patients, healthcare workers, and the public health components of assigned environments. During times of accreditation, healthcare personnel are expected to report on performance and update policies and procedures for the Joint Commission, Health Care Financing Administration, and other federal and state regulatory agencies.

3. *Interventions:* Infection control interventions that are best as candidates for widespread implementation are those that are readily modifiable and feasible. Primary prevention interventions involve strategies to reduce risk factors or prevent exposure. Interventions in secondary prevention reduce the effects of the risk or exposure. Treatment interventions treat the insult resulting from the risk or exposure. In occupational health programs for healthcare personnel, the worksite provides an opportunity to promote and sustain healthy behaviors related to diet and exercise *(32)*. Uptake of immunizations by intensive care unit personnel was associated with education and a committed occupational health team in at least one resource-limited setting *(33)*.

COMMON ECONOMIC ANALYTICAL METHODS

Economic analysis may be simple or complex. A simple analysis includes measure of the costs of an output (such as an infection) without a comparison group, similar to accounting (12). Five types of economic evaluations are commonly used in healthcare: analysis of cost minimization, cost consequence, cost-benefit, cost-effectiveness, and cost utility (18). In each of these analyses, there is the valuation of inputs (costs) and the distinctions are in how the effects (outcomes) are measured (Table 96-1). The first method is a partial economic analysis as it focuses solely on costs, while the latter four methods focus on costs, outcomes, and the incremental or additional costs or benefits of the intervention or program.

1. *Cost-minimization analysis:* A cost-minimization analysis includes the incremental costs of alternatives that achieve the same outcome. Competing interventions are the same, the only input is cost, and the aim is to decide the least costly way of achieving the same outcome. This simple cost analysis method entails a balance of risk and costs to optimize clinical operations *(34)*.
2. *Cost-consequence analysis:* A cost-consequence analysis considers the incremental costs and effects that achieve the same outcome, without an attempt to aggregate the costs and effects *(35)*.
3. *Cost-benefit analysis:* As an analytical tool, CBA estimates the net societal benefit of a program or intervention and is measured as the incremental benefit of the program minus the incremental cost, with all benefits and costs measured in dollars *(16)*. The goals in using a CBA are to eliminate procedures when the cost outweighs the benefit and to facilitate or encourage implementation of the procedure when the benefit outweighs the cost *(36)*. The methods include the estimates of costs and benefits and there is a clear decision rule to undertake an intervention if the monetary value of its benefits exceed

TABLE 96-1

Five Types of Economic Analyses for Healthcare Interventions and Programs

	Measure(s)		
Analysis (Type)	***Cost***	***Outcome***	***Distinctions***
Cost-minimization analysis (partial)	Monetary	Monetary	Focus on conditional, objective cost reduction within acceptable risk
Cost-consequence analysis (comparative)	Monetary	Monetary	Alternative outcome for which the components of incremental costs and consequences are calculated without aggregation into a CER
Cost-benefit analysis (comparative)	Monetary	Monetary	Monetary value to benefits (outcome)
Cost-effectiveness analysis-(comparative)	Monetary	Health unit	Net costs per outcome; cost saving incorporated into net cost with CER
Cost-utility analysis (comparative)	Monetary	Outcome equilavent across interventions such as QALY or DALY	Special type of cost-effectiveness analysis; interventions with differential outcomes can be compared

CER, cost-effectiveness ratio; QALY, quality-adjusted life year; DALY, disability-adjusted life year.

its costs. The two major limitations of this method are determining the level at which the benefit is significant enough to implement the intervention and its lack of a societal perspective *(36,37)*.

a. *Estimations of cost:* Estimations of cost for HAI require that the incremental costs associated with diagnosing and treating the infection be distinguished from the costs attributable to diagnosis and management of the primary medical problem. Incremental costs of HAI include costs allocated for laboratory, pharmacy, procedures, and additional hospital days. Haley et al. *(38)* reported in 1981 that approximately half of the additional costs of treating such infections were accounted for by extra days of hospital stay. Several methods for estimating costs by estimating incremental excess length of stay resulting from HAI have been identified: unmatched group comparison, matched group comparison, implicit physician assessment, and an appropriateness evaluation protocol method *(39,40)*.
   i. *Unmatched group comparison:* In this comparative approach to HAI, the total number of hospital days attributable to HAI is determined by comparing patients with and without HAI. There are no adjustments for severity of illness, and hence this method consistently overestimates additional incremental costs of HAI *(41)*.
   ii. *Matched control comparison:* For assessment of HAI using this method, patients with HAI are matched to uninfected patients who have comparable age, severity of illness, and underlying disease *(42–46)*. Alternatively, sites of care can be matched as part of the study design and evaluation *(47)*. These studies are likely to give the most accurate assessment of the additional incremental costs of the HAI *(44,45)*.
   iii. *Implicit physician assessment:* In this method, a chart review by a designated person is conducted via an outlined protocol. This method is limited by subjectivity and, in comparison with other methods, consistently underestimates the true incremental costs of HAI *(48)*.
   iv. *Appropriateness evaluation protocol method:* This method distinguishes original causes of hospitalization from those related to the identified HAI *(40,49)*. Each day of hospital care is linked to one or both of these categories. Objective categorization protocols are designed for this labor-intensive approach.

b. *Estimations of benefits:* Benefits of infection control strategies include subjective and objective determinations of the decrease in the occurrence or effects of infections resulting from infection control interventions. Such benefits may include a decrease in the number of hospital days or a decrease in estimated HAI rates *(50)*.

4. *Cost-effectiveness analysis:* The core purpose of a CEA is to provide a relative value to different healthcare interventions and to relate the value of the impact of these interventions to the value of specific health outcomes. Costs and benefits are not reduced to a common denominator. Instead, the costs and effects of an intervention or program and at least one alternative approach are calculated and presented in a ratio of incremental cost to incremental effect, with the effect being a measurable health outcome. Opportunity costs are incorporated into the cost-effectiveness ratio—most commonly as dollars per year of life saved *(19,20)*. Notably, wide variation in cost-effectiveness ratios has been reported in medical and public heath disciplines. To put CEA for infection control into perspective with studies of cancer screening and athletic cardiac evaluations, some traditionally accepted healthcare interventions save money, whereas others cost more than US$1 million per year of life gained. An intervention to promote colorectal cancer screening among veterans at average risk of developing colorectal cancer had a cost-effectiveness ratio of US$978 per person screened (95% confidence intervals, US$767–US$3,213) *(51)*. The estimated cost of continued mammography screening to age 75 to 80 years was US$34,000 to US$88,000 per life-year gained, compared with discontinuation of screening at age 65 years *(52)*. The calculations in CEA include the following:

a. The cost-effectiveness ratio is a mathematical ratio in which the numerator includes all changes in resource utilization relative to at least one stated alternative and the denominator includes all the health effects of an intervention relative to the stated alternative(s). Ultimately, the CEA provides ratios that show the cost (in monetary terms) of achieving one unit of health outcome *(53)*.
   i. *Numerator:* Variables for the numerator should include the costs of healthcare services, patient time expended for the intervention, paid and unpaid caregiving services, costs associated with lost productivity or illness (e.g., travel, child care, missed employment), costs linked to the nonhealth impact of the intervention (e.g., the environment), and time spent seeking an intervention.
   ii. *Denominator:* Variables for the denominator include those that are effects of the health intervention such as subsequent morbidity and length of life.

b. *Costs:*
   i. Direct costs are the value of all resources, goods, and services consumed in the provision of an intervention or in dealing with the consequences of the intervention. These estimates include both medical and nonmedical costs.
   ii. Indirect costs pertain to productivity gains or losses related to illness or death.
   iii. Marginal costs are the extra amount of resource consumption incurred for providing a service as compared with the costs of not providing the same service.
   iv. Incremental costs are the costs of one alternative (comparator) minus the cost of another alternative. The incremental cost-effectiveness ratio is the difference in costs between two alternatives compared with the difference in effectiveness between the same two alternatives.

c. *Discounting:* Discounting is the process of converting future dollars and future health outcomes to a present value.

d. *Reference case analysis:* When a CEA will contribute to decisions that pertain to broad or societal allocation of resources, a reference case analysis is recommended *(16)*. A reference case analysis includes a baseline computation of the cost-effectiveness ratio along with a meaningful set of sensitivity analyses that allows for comparison of the results with other published studies. This reference case analysis should include validated measurement of health-related quality of life that can incorporate the effects of morbidity on productivity and leisure. In addition, the health intervention of interest should be compared with existing practice rather than an unattainable alternative.

5. *Cost-utility analysis:* The cost-utility analysis is a special type of CEA, in which quality of life is also considered as part of the outcome. The outcome or benefit is measured in quality-adjusted life years (QALYs) and expressed as utilities which comprise both length of life and subjective levels of well-being. The outcomes of the intervention are translated into a measure that includes dimensions of both morbidity and mortality. The effect of competing interventions is expressed in a calculation of costs per QALY. An intervention is deemed efficient, relative to an alternative, if it results in higher or equal benefits at lower cost. Advocates for a payer threshold for a cost per QALY, such as US$50,000 per QALY, cite that an arbitrary value is validated (54). Of relevance, the source of the often-cited $50,000 per QALY cost-utility threshold in US healthcare is uncertain, and debate continues for a set cost per QALY threshold in healthcare (55,*56*,*57*,58). A proposed alternative is for the cost per QALY to vary across payers, populations, interventions, and time, and hence the weight of evidence for and against the US$50,000 per QALY benchmark, or any unique cost per QALY threshold, will likely remain a topic of US healthcare debate for several years (55). From an international perspective, few countries other than the US have economic thresholds to ration or limit healthcare based on cost-effectiveness estimates. Exploratory efforts are under way to determine if willingness-to-pay and value-of-life estimates offer additional determinants for decisions related to increases in health benefits in exchange for incremental expenditures and for transferability of estimates and values across populations (59–62).

COMPONENTS OF AN ECONOMIC ANALYSIS

The outcomes evaluation process begins with the identification of one or more desired outcomes. The measures of health outcomes most commonly employed are the number of lives, life years, QALYs, and disability-adjusted life years. If an intervention varies in intensity or periodicity, incremental cost-effectiveness ratios are calculated that express the additional cost per each additional unit of outcome obtained. Most importantly, the perspective taken for the evaluation of costs provides the foundation of the economic analysis. Additional components include costs, output, structured and process measures, and utility.

1. *Cost perspective:* The perspective taken for the evaluation of cost provides the foundation of the economic analysis. The cost-effectiveness construct and the ultimate results obtained from it depend on the perspective taken from the population affected by the intervention. Efficiency in resource use, or "getting the most out of limited resources," is a goal of every healthcare organization regardless of one's cost perspective *(19)*. Four such cost perspectives include the patient, provider, payer, and society.
   a. *Patient perspective:* Costs to the patient include copayments, lost time from work, and lost value or even years of life if there is a health status change.
   b. Provider perspective: For providers, profit must be considered. Short-term decisions are measured as the difference between receipts and the variable cost of providing the service, whereas long-term decisions are measures that include fixed and variable costs.
   c. *Payer (insurer) perspective:* Payers are accountable for contracted rates for services that often depend more on the contract than on the actual services delivered.
   d. *Hospital perspective:* An economic evaluation from this perspective is restricted to the clinical and economic outcomes that occur within the hospital system. In these analyses, the costs (or savings) associated with outpatient healthcare services and time lost by patient or family are not considered (12).
   e. *Societal perspective:* If the nature of the problem is broad, the perspective of the CEA should be equally broad and reflect the societal perspective *(16)*. In such an analysis, everyone affected by the intervention and all significant health outcomes and costs that flow from the intervention must be included in the analysis. Society is interested in a balance that ensures that resources are allocated in such a way that each unit is put to its most productive use. This type of analysis is rarely reported, so on a more practical basis, society prefers options that produce more output for a given amount of resources. Although health outcomes are often represented by years of life gained in CEA using the societal perspective, the measure of outcomes should be defined more broadly. In application of the reference case analysis, economic evaluation may vary between countries and the societal perspective must be that of the country in which the intervention is performed.
2. *Outputs versus outcomes:* Outputs are the number of service units that a program delivers. Outcomes are the results of the specific intervention. In setting up a health outcome analysis, it is imperative that long-term outcomes be distinguished from intermediate and short-term outcomes to better characterize the study design.
3. *Structured and process measures:* Structured measures assess organizational or programmatic features that are perceived to influence performance. Process measures assess the ways in which the intervention occurs.
4. *QALYs:* Quality of life is a rather broad construct that attempts to comprise all valued aspects of an individual's existence (e.g., aspects of health, economics, environment, politics, culture, and spiritual values). In health outcome measurement, QALYs are assigned to each time

period of evaluation with a weight, ranging between 0 and 1, which corresponds to the health-related measure during that period *(16)*. In analysis, a weight of 1 corresponds to optimal health, whereas a weight of 0 corresponds to a health state judged equivalent to death *(16)*. The major assumption that must be addressed with this measure is that a QALY may not be of equal value to all who gain from it, and the gain may not be equal during all components of the life span *(38,63)*.

5. *Utility and patient preference:* In quality of life measurement, utility refers to the preference for a particular health outcome. Patient preference for a particular health outcome can be quantified with standardized metrics and expressed as utility functions or preferences for a particular outcome and incorporated into CEA. Common patient preference measures include standard gamble and time trade-off.
   a. *Standard gamble:* Standard gamble is a determination of patient preference, or utility, for a particular outcome. A comparison is made between the probability of a particular health state (e.g., assured perfect health) versus an alternative health state (e.g., chronic infection, bed-bound, or death). In measurement of the gamble, the probability p is varied until the preference for the assured health state is equal to the preference for the alternative $(1 - p)$.
   b. *Time trade-off:* In this patient preference metric, a patient is asked to trade off years of life in a state of less than perfect health for a shorter life span in a state of perfect health *(11)*. Although occasionally patients will not trade any years of life for less than perfect health, this time trade-off measurement is calculated as the ratio of the number of years in perfect health equivalent to the often longer span in less than perfect health.

ECONOMIC ANALYSES IN STUDIES OF INFECTION CONTROL AND OCCUPATIONAL HEALTH

Economic analysis and comparative effectiveness research will become more prominent in healthcare epidemiology over the next decade. In a systematic audit of economic evidence in studies that linked HAI and infection control interventions between years 1990 and 2000, most (85%) of the 55 identified studies were conducted in either North America or Europe and were of analyses that were from the hospital perspective (64). Higher associated costs were reported in the occupational health studies than most other infection control prevention interventions, few investigations discounted future costs, and only one study used an end outcome measure with QALY that met the criteria of reference case analysis (64,*65*). In a subsequent systematic review of published studies from 2001 through mid-2004, 70 studies were identified that had economic analyses for HAI and infection control interventions (12). Most studies (80%) were from the US or Europe, with wide variation noted in the cost estimates of HAI (12). An additional key feature of the review was inclusion of a quality measure to systematically audit economic evaluations *(66)*. The overall mean attributable costs and standard deviation (SD) of specific HAI for the subset of publications worldwide that reported the outcome cost per patient were US$25,546 (SD US$39,875) for surgical site infection, US$36,441 (SD US$37,078) for bloodstream infection, US$9,969 (SD US$2,920) for ventilator-associated pneumonia, and US $1,006 (SD US$503) for urinary tract infection *(67–87)*. Most notably in the two systematic reviews, the use of a reference case analysis with economic analyses was uncommon and such reference in healthcare epidemiology remains best exemplified by immunization programs (12,64,*88–97*). A survey of publications in 2003 on cost-effectiveness research targeting preventive interventions identified 232 publications with original economic evaluations, 31% of which focused on infectious diseases (98). In an exemplary approach to methods, the investigators converted all local currencies to euro currency values of the base years of the study, per the advice of the Organization for Economic Cooperation and Development, and recalculated the costs to 2008 values using the price index of Statistics Netherlands (98,*99*,*100*).

Recent economic analyses of infection control and occupational health vary in design, execution, analysis, and year(s) of study. The following summary provides some cost estimates and a framework for comparative economic analysis in infection control, occupational health, and efforts specific to resource-limited settings.

1. *Infection control programs:* The estimated US burden of hospital-acquired infection was US$1.7 million, or approximately 4.5 infections per 100 hospital admissions in data from 2002 (101). Such infections ranked sixth in leading causes of US deaths (101). In a network of 28 hospitals in 2004, the median annual cost for HAI was US$594,683 (interquartile range US$299,057–US$1,287,499) per hospital *(20)*. The weight-adjusted mean cost estimate for specific infections in this study was US$23,242 per healthcare-associated bloodstream infection, US$25,072 per episode of ventilator-associated pneumonia, US$10,443 per surgical site infection, and US$758 per catheter-associated urinary tract infection *(20)*. Central venous catheter dressing changes by ward nurses (case) versus an infusion team (control group) were associated with catheter-related bacteremia in 1.7% of cases and 1.4% of the control group *(102)*. There were no differences in catheter-site infection rates, and the estimated cost savings was in excess of US$90,000 per year by delegation of this dressing change to the ward nurses *(102)*. Estimates of HAI in Europe, as well as estimates of excess costs, approach numbers in the US *(103,104)*. A hospital-based program to avert transmission of influenza A/H1N1 2009 viral infection concluded that protection measures targeting only infected patients had an incremental cost of US$23,000 per death averted, and if expanded to a universally enforced hospital program, the estimate was US$2.5 million per death averted *(105)*.
2. *Occupational health:* The losses to society from work-related accidents and illnesses are very large and often underappreciated from a nonsocietal perspective. The costs associated with a case of ill health include medical treatment, furloughs, and administrative costs inclusive of recruitment and replacement (106,*107*). Exemplary of an analysis of cost savings in occupational health,

occupational sharps' injuries in Sweden were first estimated to cost €1.8 million, or €272 per reported injury, of which €1 million was for hollow-bore sharps injuries *(108)*. The introduction of safety devices was estimated to avert 3,125 injuries, with a corresponding cost offset at €850,000 from the Swedish healthcare perspective *(108)*.

3. *Healthcare epidemiology in resource-limited settings:* Estimates of risk for HAI are 2- to 20-fold higher in developing countries relative to developed nations, and challenges associated with feasible, efficacious infection control interventions in developing countries have been identified *(109–112)*. The execution and report of economic analysis for infection control and occupational health studies from resource-limited settings, with distinctions in perspectives for middle-income versus low-income countries, will contribute to robust understanding of resource allocations for health and wellness in the decades to come. The financing of health and wellness is particularly complex in low-income countries. Global health initiatives may mobilize substantial resources, but the major challenges involve the need for institutional capacity to manage harmonization and ensure durable programmatic support when global health initiates expire *(113)*. While capacitance building will continue to impact infection control and occupational health programs in resource-limited settings, clinical and economic benefits are evident with improved diagnostic tools, surveillance programs for select pathogens and infectious diseases, and population-based research targeting improvements in public health *(114–118)*.

STRENGTHS AND LIMITATIONS OF ECONOMIC ANALYSIS IN HEALTHCARE EPIDEMIOLOGY

Economic analysis is basically about resource use and, hence, is pertinent to healthcare decisions in infection control and occupational health programs. To leverage resources it is often necessary to present a business case to key leaders and stakeholders, using well-aligned clinical data and economic analysis. The information must be readily understandable by all users with flexibility for an oral presentation, written technical report, peer-reviewed publication, or web-based program.

The assumptions, potential bias, generalizability, and limitations of the analysis should be considered and made transparent. At the level of dissemination and uptake, reporting bias for CEA exists, with a predominance of studies that report favorable incremental cost-effectiveness ratios (119). In a review of published studies between 1976 and 2000, studies categorized as those of higher methodological quality and those conducted in the United States and Europe, relative to elsewhere, were less likely to report incremental cost-effectiveness ratios below US$20,000 per QALY (119).

Economic analyses do vary in assigned monetary values, are limited by the validity of the assumptions incorporated into the evaluation, and at risk for overly simplistic results. In the assessment of the quality of the strengths and limitations of an economic analysis, there is a proposed list of 10 questions for reviewers to consider *(120)*. This list includes the following: (a) Is the analysis based on a hypothesis that tests a clearly defined question about a clinically relevant and economically important issue? (b) What viewpoint and cost perspective is considered for the defined costs and benefits? (c) Is the comparison of an intervention(s) effective? (d) Are the interventions practical within the recommended settings? (e) Which method of economic analysis is used, and is this appropriate? (f) How are the costs and benefits measured? (g) Are incremental, rather than absolute, benefits considered? (h) Is the here and now given precedence over the distant future? (i) Is a sensitivity analysis conducted? (j) Are "bottom line" aggregate scores overused?

FUTURE DIRECTIONS IN ECONOMIC ANALYSIS FOR HEALTHCARE EPIDEMIOLOGY

As the basics of economic analysis are incorporated into healthcare epidemiology educational programs, it is anticipated that more robust CEA will be conducted, reported, and published.

Published studies with economic analysis of infection control and occupational health, using a societal perspective, are uncommon, as are economic analyses of infection control in home-based settings and resource-limited settings. Studies comparing efficacy, safety, and cost-effectiveness of alternative ways to prevent and control HAI and promote safety will fill important information gaps facing clinicians, patients, and payers in the years to come and provide evidence to support appropriate allocation of limited resources.

CHAPTER 97

Legal Issues in Healthcare Epidemiology and Infection Control

Mary Anne Bobinski

Infection control in hospitals is a major problem associated with significant personal and economic costs. There are about 2 million cases of hospital-acquired infection (HAI) each year, some by drug-resistant infectious agents, causing serious health consequences and nearly 100,000 deaths annually in the United States (*1–4*,5). Public health authorities, hospitals, physicians, and others use a number of strategies to reduce or eliminate the threat of infection. Efforts to reduce the risk of infection are medically appropriate; however, they also have serious legal implications. Hospitals thus necessarily consider legal rules and the need to limit liability as they design and implement infection control practices intended to preserve life and health.[1]

In many cases, of course, the two goals of preventing injury and limiting liability overlap. Thus, standard epidemiologic and infection control policies both protect health and serve to reduce or eliminate legal liability. The legal landscape is complicated. Legal obligations can be created at different levels of government (federal, state, and local) and promulgated in different ways (statutes, regulations, and court decisions). Some legal rules explicitly address infection control policies, while other rules (e.g., those governing medical confidentiality and discrimination against persons with disabilities) have an indirect but important impact on infection control regimens. Persons who work with healthcare epidemiology or infection control policies, therefore, must have an understanding of both the legal and the medical implications of their work.

The hospital setting creates risks for three different groups of persons: hospital patients, hospital workers, and persons who come into contact with either patients or workers. Hospital patients are most clearly at risk: surgical incisions can become infected, for example, or patients may suffer from infections transmitted by other patients or healthcare workers (*3,4*,5). Hospital workers, too, face risks in the healthcare environment. Workers may come into contact with patients suffering from a wide range of communicable diseases, of which tuberculosis (TB), viral hepatitis, and infection with human immunodeficiency virus (HIV) are currently among the most common examples *(6)*. The risk of infection is also present for others, such as family members or other hospital visitors *(7)*.

The legal system responds to the risk of infection in two major ways. First, state licensure standards, federal provider eligibility standards and reimbursement standards, and federal worker safety regulations each impose explicit or implicit duties on hospitals and hospital employees to reduce the risk of infection. Licensure standards can impose direct requirements to employ infection control practices. Payment schemes that deny hospital reimbursement for certain HAI indirectly establish a standard that these infections should be prevented. Regulations designed to protect hospital workers from the risk of workplace infections may impose specific duties on employers.

Second, the legal system allows persons injured by hospital-related infections to sue for damages. Courts throughout the country have been willing to hold hospitals liable for lapses in infection control procedures. These liability decisions, often called common law rules, indirectly define standards or duties for hospitals. A court's decision that holds a hospital liable for its failure to provide a piece of equipment, for example, implicitly suggests that other hospitals wishing to avoid liability should acquire the same equipment.

Statutory, regulatory, and common law duties are often interrelated: A jury might find, for example, that a hospital was negligent in its administration of an infection control plan, because the hospital failed to meet standards established in a state licensure statute. The legal rules can also appear to be in conflict, such as when a hospital has to implement its duty to prevent transmission of illness while meeting its legal obligations to protect the confidentiality of patients and the employment rights of its workers. Understanding the sources, scope, and limits of these legal rules is an important task.

THE HOSPITAL'S DUTY TO PROTECT PATIENTS AND VISITORS

Hospitals must comply with several types of legal rules designed to protect patients. These rules can be found in federal or state statutes and regulations, in the standards

[1]This chapter provides general information about some of the legal issues raised by epidemiology and infection control policies. A licensed attorney should always be consulted for specific legal advice.

of private accrediting organizations, and in the judgments of juries holding hospitals liable in tort cases. This complex regulatory structure can create an intricate and sometimes contradictory web of duties.

Hospital Regulation

There are several different types of hospital regulation. All hospitals in the United States are subject to state licensure requirements *(8)*. Hospitals seeking reimbursement from the Medicare and Medicaid programs must also meet standards established under federal and state laws *(8,9)*. Important standards also are established by public health authorities, such as the Centers for Disease Control and Prevention (CDC) and the CDC's Healthcare Infection Control Practices Advisory Committee (HICPAC) *(6,10)*, and by private accrediting groups, such as the Joint Commission (formerly the Joint Commission on the Accreditation of Healthcare Organizations) *(11,12)*.

Hospital licensure statutes are designed to protect patients. These statutes generally require that hospitals reduce the risks of infection to patients, staff, or others by maintaining appropriate equipment, employing persons with specialized training, and implementing mechanisms to reduce the risk of infection. The Florida statute provides, for example, that hospital regulators must adopt "reasonable and fair minimum standards for ensuring that hospitals implement "[i]nfection control, housekeeping, sanitary conditions, and medical record procedures that will adequately protect patient care and safety" (13).

The guidelines of public health entities such as the CDC and HICPAC are important even though they may not be incorporated into a specific statute or regulation, because they might be used, explicitly or implicitly, by licensing authorities or others *(10)*. The Joint Commission's hospital accreditation requirements are incorporated into many state licensure statutes *(14)* and the federal Medicare and Medicaid regulations *(15)*. The end result is that hospitals are subject to specific performance-based standards designed to ensure that they monitor and reduce the risk of infection. The CDC's National Healthcare Safety Network also creates the opportunity for studying the results of hospital infection control policies *(16)*.

These general infection control standards are supplemented by more specific requirements for some diseases. The special rules governing HIV and hepatitis B virus (HBV) are particularly important. Several states have enacted statutes designed to protect hospital patients from HIV or HBV infection *(17)*. Under federal law, states generally must implement the CDC's recommendations to reduce the risk of HIV or HBV transmission from healthcare workers to patients (18). The CDC's 1991 recommendations require healthcare workers who perform "exposure-prone procedures" to know their HIV and HBV status and to refrain from engaging in those procedures without the consent of an expert review panel (19). Depending on state law, hospitals may have a role in implementing these recommendations by defining which procedures are exposure-prone or through establishing expert review panels that can advise HIV- or HBV-infected practitioners (19,*20*). It has been difficult for hospitals to implement these regulations in the absence of consensus about either the degree of actual risk posed by HIV-infected healthcare workers or the identification of exposure-prone procedures (18,*21*).

A hospital's compliance with government regulations, public health guidelines, and private accreditation requirements can be very important in three respects. First, hospitals that fail to meet these requirements risk suspension of licensure, the imposition of civil fines, and the attendant bad publicity. Second, hospitals without effective infection control policies might lose eligibility for Medicare reimbursement, an important source of revenue. Third, a hospital's failure to comply with these public or private regulatory schemes increases the risk of tort liability. Injured patients will be able to claim that a hospital's violation of a particular statutory or regulatory requirement is evidence that the hospital was negligent in providing for the welfare of its patients.

The Deficit Reduction Act of 2005 resulted in significant changes to Medicare reimbursement policies with respect to HAI. The Act required the U.S. Secretary of Health and Human Services to identify certain HAIs that create higher Medicare costs and "could reasonably have been prevented by evidence-based guidelines" (22). Hospitals are denied Medicare reimbursement for care associated with these infections in many circumstances as of October 2008. The effort to use the financial incentive of nonpayment to encourage hospitals to act to reduce infections has its critics *(23–25)*. For example, critics argue that the rule places an undue burden on hospitals by refusing to pay for conditions that are not preventable *(24,25)*.

Hospital Tort Liability

Hospitals and healthcare professionals are increasingly concerned about tort liability. The charitable or governmental immunity doctrines that long protected hospitals from lawsuits have crumbled over the past 50 years *(26,27)*. The tort system requires a defendant to compensate a plaintiff when the plaintiff can show that the defendant's negligence caused the plaintiff's injury (28). *Negligence* is a legal term meaning that a defendant failed to exercise the degree of care owed to the plaintiff (28). Generally, individuals or institutions have the duty to exercise reasonable care (28). In the healthcare context, hospitals are often required to observe the standard of care that would reasonably be exercised by other hospitals under similar circumstances (28). Statutes, regulations, or accreditation requirements can be used to define a hospital's required standard of care (29).
There are several different types of hospital liability (28,30). Hospitals are generally held liable for the negligent acts of hospital employees under the doctrine of *respondeat superior* (28). Hospitals also are directly liable for institutional negligence, such as for failing to have equipment necessary to prevent HAI or for failing to establish policies or procedures designed to reduce the risk of infection. Matters are complicated somewhat by the fact that hospital patients are often treated by private physicians who are not hospital employees. A hospital generally will not be held liable for the negligence of a private physician so long as it is clear to patients that the physician is not a hospital employee (28). However, the hospital can be held liable if its employees knew or should have known of the risk of infection and failed to take appropriate action, even if the patient is also under the care of a private physician.[2]

There are four elements to a patient's tort claim against a healthcare professional or hospital. The plaintiff must show that the defendant owed her or him a duty to provide a particular standard of care, that the defendant failed to meet the required standard of care (negligence), that the breach of the standard of care caused the plaintiff's injury, and that the plaintiff's injury is of a type that deserves compensation (28). The plaintiff must prove these four elements by a preponderance of the evidence.

The first element has two parts: The hospital must have a duty to the plaintiff to provide a particular standard of care. In general, a hospital has a duty to protect persons who are foreseeably at risk for harm from the hospital's conduct. This is a relatively easy element for plaintiffs to prove. Patients are under the care and control of the hospital, and it is foreseeable that the hospital's failure to take care in the provision of its services could cause its patients harm. A hospital's duty to protect its patients from infection also arises from the statutes, regulations, and standards discussed previously. Hospitals clearly have a duty to protect patients from the risk of infection (29–31). Hospitals have an additional duty to protect nonpatients who are the foreseeable victims of hospital negligence. A hospital may in some circumstances be held liable, for example, for injuries sustained by the family members or visitors of infected patients who are foreseeably exposed to infection (30–32,*33*).

However, the issue of a hospital's duty is not always clear, particularly when family members and friends of a patient are involved. Courts sometimes hold, for example, that hospitals do not owe a duty of care to nonpatient family and friends who visit the patient or who provide care for the patient *(34–37)*.

The second part of the first element requires plaintiffs to establish the hospital's required standard of care. For hospitals, the standard of care is measured by what other hospitals would do under like or similar circumstances. Sometimes the standard of care can be determined by examining the relevant statutes or regulations. In *Ford v Saint Francis Hospital, Inc. (38)*, for example, a patient who contracted staphylococcal infection of his aortic valve while hospitalized for heart surgery alleged that the defendant hospital was negligent *per se*, because it was violating federal regulations governing infection control. The hospital was able to defend the action by showing that it had passed a state agency's surprise inspection shortly before the surgery took place.

Plaintiffs and defendants might also rely on the guidelines issued by public health authorities, such as the CDC and the HICPAC, to establish the standard of care. Both sides may also present testimony about the customary practices of other hospitals as a method of establishing the required standard of care (29). The testimony of medical experts generally is used to establish the standard of care against which the hospital's conduct will be measured (28,29). Newly emerging threats, such as the threat of bioterrorism, may complicate the situation because healthcare institutions and physicians must rapidly identify and implement a newly emerging standard of care (39).

The second element of the plaintiff's cause of action requires proof that the defendant breached the standard of care. This is often a difficult task for the plaintiff who may not be able to present evidence showing, for example, that a particular hospital employee failed to use the sterile technique required by the standard of care. Courts sometimes use the legal doctrine of *res ipsa loquitur* (the thing speaks for itself) to assist plaintiffs who cannot identify the specific act of negligence committed by the defendant (28). Under *res ipsa loquitur*, the jury might be permitted to presume the existence of a breach of the standard of care under some circumstances, such as where the patient's infection is rare and difficult to acquire in the absence of negligence (28). Courts have rejected the application of *res ipsa loquitur* and have required plaintiffs to prove a breach of the standard of care in cases alleging injury from some common types of infections because the inference that hospital negligence caused the infection is no longer justified *(40–43)*.

The first two elements of a negligence claim, therefore, require the plaintiff to prove that the defendant hospital breached a duty it owed to the plaintiff to provide a particular standard of care. There have been a number of cases analyzing a hospital's duty to protect its patients or visitors from infection; several examples can be used to illustrate how the first two legal elements apply in the typical hospital setting.

The first example involves the scope of a hospital's duty to exercise care in selecting and assigning staff. In *Taaje v St. Olaf Hospital* (44), the court held a hospital liable for an infant's death from TB based on a nursing supervisor's failure to "exercise due care to see that her nurses were free from communicable disease." Despite this decision, hospitals do not have an absolute continuing duty to screen all employees for all communicable diseases. The hospital's duty to screen—the standard of care governing screening—is established by medical knowledge and community practice at the time the patient received care. In one 1962 case, for example, the court refused to find a hospital liable for the transmission of *Staphylococcus aureus*, in part, because the standard of care did not require employee screening during the relevant time period *(41)*.

The debate about hospital duties to screen and select employees currently is focused on the risks presented by HIV- or HBV-infected healthcare workers. As noted previously, hospitals are required to follow the CDC's 1991 HIV- and HBV-infected healthcare worker guidelines (18,19). These guidelines impose the duty on healthcare workers to know their own HIV and HBV status rather than requiring hospitals to screen healthcare workers (19). Could a hospital avoid liability altogether by implementing even stricter restrictions on the continued practice of HIV- or HBV-infected healthcare workers? The answer is no. Healthcare workers infected with contagious diseases are considered persons with disabilities who are protected by federal and state laws prohibiting discrimination based on disability. Hospitals may only discriminate against an infected healthcare worker when the worker presents a significant risk to the health or safety of others, such as that identified in the CDC guidelines *(45)*. Workers who

[2]Individual healthcare professionals can be held personally liable for their negligent acts; however, the focus of this chapter is on institutional liability for errors in healthcare epidemiology and infection control.

present minute or insignificant risks are protected from discrimination (46).

The second example of litigation about the standard of care involves hospital decisions regarding the acquisition and maintenance of equipment and facilities. In *Bush v Board of Managers of Binghamton City Hospital* (47), the plaintiff claimed that his wife had died from diphtheria acquired in the course of her hospital stay. The court held that the hospital defendant could not be held liable for the woman's death, in part because the evidence indicated that its facilities were "suitable, adequate, and safe for the purposes in the manner used; that the means of sterilization and disinfecting employed were safe and adequate; and that the rooms were surgically clean" (47).

The third type of standard of care litigation involves disputes over the adequacy of hospital policies designed to identify and respond to the presence of infection. In *Helman v Sacred Heart Hospital* (48), the plaintiff claimed that he had acquired a staphylococcal infection from his hospital roommate. The plaintiff presented evidence on the required standard of care, including the existence of "hospital … rules … requiring isolation of all patients known to be infected with staphylococci and requiring all medical personnel to report open sores, boils and pimples, which emitted purulent drainage, among both patients and hospital personnel" (48). The plaintiff also presented evidence that hospital employees had breached this standard of care by failing to "observe the sterile techniques prescribed by the hospital in cases where infection is suspected; they [also] did not wash their hands or leave the room between administering to the patients, even after the plaintiff's roommate experienced a boil with purulent drainage" (48). The plaintiff, thus, presented evidence defining the required standard of care and demonstrated that the defendant had violated this standard of conduct.

In other cases, however, defendants have avoided liability by showing that hospital personnel followed standard practice in caring for a patient *(49)*. In *Roark v St. Paul Fire & Marine Ins. Co*. (31), the plaintiff claimed that he had acquired a staphylococcal infection because of the negligence of the Glenwood Hospital. The defendant was able to avoid liability because:

> *[e]vidence introduced at trial show[ed] [that the] plaintiff was given a shower with antiseptic soap, and that the surgical site was scrubbed with antiseptics prior to surgery. The standard procedures employed by the hospital to establish the sterility of the supplies, instruments, and environment were also detailed. The evidence show[ed] that the procedures employed me[t] or exceed[ed] national standards. (31)*

Similar results have been achieved in transfusion-related HIV transmission cases; most jurisdictions have shielded hospitals from liability so long as the hospital blood banking organization followed the standard of care in effect at the time the transfusion took place (*50*,51,52).

The degree of care required may vary with the type of patient. A hospital has a heightened duty to protect patients who it knows are particularly vulnerable to infection. In *Kapuschinsky v United States (53)*, for example, the hospital was held to a greater duty to exercise care because premature infants were particularly susceptible to infection. Hospitals generally have a heightened duty to protect immunocompromised patients.

The discussion of tort liability thus far has focused on the first two elements of the plaintiff's claim: establishing that the hospital has breached a required standard of care. The third element of a plaintiff's case is causation. The plaintiff must show that the defendant's negligence was the actual and legal cause of the plaintiff's injury (28). The causation requirement is another source of protection for hospital defendants and another source of problems for plaintiffs. Common infections, such as those resulting from staphylococci, present particular difficulties of proof for plaintiffs because there are multiple possible sources of infection *(54)*. Medical tests designed to determine the source of infection are extremely important. In the early 1990s, researchers relied on a genetic analysis of HIV in determining that dentist David Acer was the source of HIV infection for five of his patients *(55)*. Other techniques, such as contact tracing, historically have been used to identify possible sources of other HAIs *(56)*.

Causation can also be difficult to prove because of the lack of evidence linking the hospital's conduct to the plaintiff's injury *(57)*. In *Contreras v St. Luke's Hospital* (58), for example, Solomon Contreras brought suit against St. Luke's Hospital and his surgeon after he sustained a surgical site infection caused by enterococci. The court held that the evidence was insufficient to impose liability, because "there is no evidence that th[e] delay [in removing a bedpan] or understaffing had any connection with the infection. Similarly, there is nothing to indicate that the failure of the nurses to trim the plaintiff's ingrown toenail had anything to do with the infection" (58). Mere negligence and injury are not sufficient; the plaintiff must be able to show that the defendant's wrongful acts actually caused the injury *(59)*.

The fourth and final element of the plaintiff's tort claim is the requirement of a legally recognized injury. Often the plaintiff will seek compensation for the extra expenses associated with a lengthened hospital stay or for the additional pain and suffering accompanying the negligently inflicted infection. Occasionally, the patient dies from the infection, and the patient's estate and beneficiaries will bring survival and wrongful death claims. In *Jistarri v Nappi (60)*, for example, the decedent's estate sued the defendant doctors and hospital, claiming that a series of negligent acts during the decedent's treatment for a broken wrist had allowed staphylococci to enter the decedent's bloodstream, after which it weakened her heart and eventually caused her death.

Courts currently are struggling with whether to permit plaintiffs to recover damages for their fear of acquiring a disease when transmission does not actually occur. The cases largely arise in the context of HIV: Patients who might have been exposed to HIV in the healthcare environment argue that they should be compensated for experiencing fear about the risk of HIV transmission. Courts are divided on whether the fear of disease transmission is a legally compensable injury (61).

A small number of courts have adopted a liberal standard under which plaintiffs are permitted to recover for their fear of transmission so long as it is "reasonable." In *Faya v Almaraz* (62), for example, the plaintiffs learned from news

reports that their oncologic surgeon had HIV infection. They became afraid that the surgeon might have infected them with HIV during surgery. Both plaintiffs underwent HIV-antibody testing; both tested negative. They then sought compensation for their emotional distress from the physician's estate and from the hospital in which the physician had practiced. The Maryland Court of Appeals upheld the plaintiffs' complaint, noting that "we cannot say that [the plaintiffs'] alleged fear of acquired AIDS was initially unreasonable as a matter of law, even though the averments of the complaints did not identify any actual channel of transmission of the AIDS virus" (62). The court did restrict the plaintiffs to receiving compensation "for the period constituting their reasonable window of anxiety—the period between which they learned of Almaraz's illness and received their HIV-negative results" (62).

The New Jersey Supreme Court added a refinement to this approach. In *Williamson v Waldman (63)*, the court held that plaintiffs could recover for fear of HIV transmission even without proof of actual exposure to HIV so long as current medically accurate information about HIV would lead a reasonable person to experience substantial emotional distress about the risk of HIV transmission in a similar situation.

These cases represent the minority view. Most courts have placed serious restrictions on acquired immunodeficiency syndrome (AIDS) phobia claims. There are three major types of requirements: plaintiffs must show "actual exposure" to HIV-infected body fluids *(64,*65,*66–67)*, they must show that the alleged exposure followed a medically recognized channel of transmission *(68)*, and/or they must show a high probability that HIV transmission could have occurred (69).

The Minnesota Supreme Court's decision in *KAC v Benson* (65) illustrates the "actual exposure" principle. In this case, a plaintiff argued that she had suffered severe emotional injuries after learning that Dr. Benson had performed gynecologic procedures on her while he was infected with HIV. The plaintiff repeatedly tested negative for HIV antibodies. The court rejected the plaintiff's claims for damages associated with her fear of acquiring HIV, in part because she could not prove that the actual exposure to HIV had occurred during the medical procedures (65). Similarly, the Tennessee Supreme Court rejected a claim brought by a patient in an alcohol and drug treatment center who was not informed that his roommate had HIV infection. The plaintiff argued that he had used the room's toilet while suffering from an open sore and that he had shared his roommate's disposable razor. The court held that this did not constitute evidence of an actual exposure *(67)*.

Courts may also require the plaintiff to show a medically accepted "channel" for transmission of the virus. The Supreme Court of New Mexico applied this restriction in a suit brought by a woman whose hands with unhealed cuts were exposed to medical samples containing blood *(68)*. In this case, the court permitted the plaintiff's claims to go forward because she alleged a medically appropriate channel of potential transmission.

Finally, some courts require plaintiffs seeking compensation for the fear of a disease to prove that transmission of the disease is highly probable. In *Kerins v Hartley* (69), a patient of an HIV-infected surgeon sued for damages based on her fear that she had acquired HIV during surgery. The court rejected the claim, holding that the plaintiff was required to show that it was "more likely than not" that she would become HIV positive as a result of the surgery. This standard is clearly very difficult for plaintiffs to meet in HIV-exposure cases because the risk of transmission is usually very small. Some courts have held that "actual exposure" need not be proved where the plaintiff was exposed to a scientifically accepted means of transmission of HIV and the defendant unreasonably or intentionally interfered with information regarding the injured party's ability to prove the actual presence of HIV (70,*71,74*).

Some courts have explored whether and how to limit the time period for which the fear of HIV transmission will be compensable (*64*,70). Courts in several cases have held that the plaintiff's fear of developing AIDS was reasonable for 6 months after actual exposure, but became unreasonable after 6 months with repeated negative test results *(64)*. These decisions were rejected by a 2008 New York Court of Appeals decision, which held that a plaintiff should have been permitted to present evidence regarding emotional distress even after the 6-month HIV-testing period (70). The court held that judges and juries were capable of resolving these claims:

> *It also bears noting that defendants remain free to challenge AIDS phobia and other emotional distress evidence by presenting medical and scientific proof concerning the probability of a plaintiff contracting HIV after having tested negative at various points in time to ensure that the jury understands the risk a plaintiff actually faced and the future risk of a plaintiff testing positive. Likewise, defendants may question a plaintiff and any treating physicians to ascertain what information was available to the plaintiff concerning testing time frames and probabilities. A rational jury might conclude, based on evidence of this nature, that a particular plaintiff[']s fear of contracting HIV ceased to be reasonable at a certain point in time and, after that point, any residual anxiety was not sufficiently causally related to the underlying exposure incident to warrant recovery. Similarly, since a plaintiff "is not permitted to recover for damages that could have been avoided by using means which a reasonably prudent person would have used to … alleviate the pain" … a defendant who believes that a plaintiff has unreasonably failed to take steps to relieve emotional distress arising from an exposure incident can raise a failure to mitigate damages defense. (70)*

These cases involve plaintiffs who were tested using older HIV-antibody tests; courts will continue to grapple with whether and how to limit liability given the availability of quicker and more accurate, direct tests for HIV.

Most jurisdictions thus have severely restricted HIV/AIDS phobia claims. Hospitals and healthcare professionals should recognize, however, that the law remains in flux and that plaintiffs claiming HIV/AIDS phobia may be able to recover significant damage awards in some jurisdictions.

As noted previously, a hospital's tort liability for patient or visitor injuries rests on the plaintiff's ability to prove that a hospital had a duty to observe a particular standard of care, that the hospital breached that standard, and

that the breach caused the plaintiff's injuries. Injured plaintiffs have sought very significant damage claims in these cases. For example, the plaintiff in *Riggs v West Virginia University Hospitals* sought damages after allegedly becoming infected with serratia bacteria during anterior cruciate ligament (ACL) surgery *(72)*. The plaintiff endured complications and was required to undergo several subsequent operations before her infection was diagnosed. The jury awarded the plaintiff $10 million in noneconomic damages. The award was reduced to $1 million when the Supreme Court of West Virginia confirmed that the state's medical malpractice cap applied to the damages *(72)*.

Hospitals may offer some defenses to tort liability claims. For example, the hospital's liability might be reduced if the patient's own negligent conduct contributed to the injury (28). A patient may have failed to follow postoperative instructions, for example. However, it often will be difficult for hospitals to prove that a patient's own negligence contributed to her or his injury.

Healthcare workers and hospital administrators concerned with liability issues should understand these general tort rules. The best method for reducing the risk of liability is to reduce the risk of injury to patients and visitors. Hospitals should review their policies to ensure that they meet national standards of healthcare epidemiology and infection control as reflected in statutes, regulations, public health standards, national accreditation standards, and the practices of other hospitals. The special risks of infection for immunosuppressed persons should be considered. The development of appropriate policies is not sufficient, however. Hospitals must ensure that the policies are followed in practice and that appropriate records are maintained. A hospital's ability to prove that it met the standard of care and to present an appropriate defense ultimately will depend on whether appropriate documentation can be produced at trial.

THE DUTY TO PROTECT HEALTHCARE WORKERS

Hospitals also have a duty to protect their workers from harm. This duty is created under federal and state laws. Breach of the duty can lead to licensure suspension, civil penalties, and civil liability. The regulations designed to protect healthcare workers can be divided into roughly two types: those imposed to prevent injury and those designed to provide compensation to healthcare workers who are injured in the course of their employment.

Regulations Designed to Protect Healthcare Workers

The federal government regulates the safety of workplaces under the Occupational Safety and Health Act, which is enforced by the Occupational Safety and Health Administration (OSHA) (see also Chapters 74 and 79). All private hospitals are subject to OSHA regulation, and all federal hospitals are subject to equivalent standards *(73)*. State and local government hospitals are exempt from OSHA regulations, although many states have laws or regulations imposing safety and health standards similar to those imposed by OSHA *(74,75)*.

Under OSHA, an employer must provide a workplace that is "free from recognized hazards that are causing or are likely to cause death or serious physical harm to his employees" (76). In addition, employers must comply with all OSHA standards and regulations *(77)*. Therefore, hospitals must comply with specific standards issued to protect healthcare workers. Employees are also required to comply with OSHA regulations, but the statute does not impose penalties or other sanctions on noncompliant employees, only on noncompliant employers *(78)*.

OSHA has issued an extremely important regulation designed to reduce the risk of transmission of blood-borne pathogens in healthcare settings (79). Hospitals must comply with the blood-borne pathogen standard along with other standards governing the use of personal protective equipment *(80)*, the use of biohazard warning signs *(81)*, the proper implementation of sanitation and waste disposal *(82)*, and housekeeping *(83)*. OSHA was forced to withdraw a proposed rule designed to limit occupational exposure to TB *(84)*. The blood-borne pathogen standard explicitly requires that hospitals implement a variety of programs designed to reduce the risk of infection for employees. This standard can be divided into three major parts.

First, the regulation requires hospitals to analyze all employment positions to determine which employees have "reasonably anticipated" exposures to blood or other potentially infectious materials and to design an exposure control plan that specifies how employee exposures are to be eliminated or minimized *(85)*. Employees must be provided with adequate training to implement and update the exposure control plan *(86)*.

Second, the blood-borne pathogen standard directly requires the implementation of specified mechanisms to reduce the risk of infection for workers. Hospitals must implement Standard Precautions (formerly Universal Precautions) *(87)*. They must provide free and ready access to hand washing facilities and personal protective equipment such as gowns, masks, and gloves *(87)*. The standard specifies certain work practices that are forbidden, such as the recapping of used needles or the improper disposal of potentially infectious materials *(87)*. Employers must provide free and voluntary HBV vaccination to certain employees (see also Chapters 73, 74, and 79). All employees are to be offered voluntary and confidential postexposure incident evaluation and follow-up care *(88)*. After an exposure incident, the blood of the potential source of infection may be tested only if the source consents or if the consent is not required under state law *(88)*.

Third, hospitals are required to observe certain monitoring and record-keeping requirements *(89)*. Employers must keep records for each employee with an exposure incident for the duration of employment plus 30 years. The records are to be confidential and released to others only with the employee's consent *(89)*. The OSHA rules are consistent with the CDC's recommendations governing the management of occupational exposures to HBV, hepatitis C virus, and HIV (90).

OSHA can impose hefty penalties for violations *(91)*. Nonserious and serious violations can draw up to $7,000 in civil fines per incident; willful violations have a minimum penalty of $5,000 and can reach $70,000. A willful disregard of an OSHA standard that results in a death can be prosecuted criminally with convictions resulting in

imprisonment or fines. Hospitals seeking to limit OSHA liability should establish programs to comply with all OSHA requirements and, as importantly, should monitor employee compliance.

Injured Healthcare Workers and the Tort and Workers' Compensation Systems

Injured healthcare workers can bring claims under either workers' compensation or tort law. Most persons injured in the course of their employment are forced to seek compensation under the workers' compensation scheme established in each state or, for some types of employment, under the compensation system established under federal law *(92)*. The workers' compensation laws generally provide relatively quick access to preset levels of reimbursement for medical expenses and lost wages. Persons who are not covered by the workers' compensation scheme can pursue ordinary tort claims. The tort system generally provides higher levels of compensation to injured persons, but it is more difficult for injured workers to successfully pursue their claims because of the larger number of defenses available to defendants (93).

Generally, workers' compensation laws create a "no-fault" system in which injured workers do not have to prove that their employers were negligent to receive compensation and in which an employee's own negligence is not likely to bar recovery *(94)*. The workers' compensation rules also cover occupational diseases *(94)*. Employees usually have the most difficulty proving that the disease is "occupational." Coverage under the workers' compensation system is contingent on proving that the disease was acquired during the course of employment because of the particular risks created by that employment.

In many jurisdictions, it is not enough for an employee to show that she or he was exposed to an illness on the job; she or he must show that the employment creates some special risk of acquiring this illness. In *Paider v Park East Movers (95)*, for example, a truck driver sought workers' compensation benefits after acquiring TB from a coworker. The driver argued that he was exposed to TB, because his employment required that he be confined in the cab of the truck with his coworker. The New York Court of Appeals rejected this contention, holding that the claimant's disease resulted not from the ordinary and generally recognized hazards incident to a particular employment but rather from the general risks common to every individual regardless of the employment in which he is engaged. The claimant's illness, therefore, was not an occupational disease *(95)*. Fortunately for injured healthcare workers, certain types of illness, such as TB or hepatitis, are often covered under the workers' compensation laws as ordinary and generally recognized hazards of employment in hospitals *(95,96)*.

However, even where a particular illness is recognized as an occupational hazard, healthcare workers often must present proof that they actually acquired their illness on the job *(97)*. There is some disagreement about the nature of proof required. Sometimes courts have upheld workers' compensation awards based on evidence that the disease was an occupational hazard and that it was unlikely to be acquired in the employee's nonwork environment *(94,98)*. Other courts seem to require additional evidence of workplace exposure, such as evidence that the healthcare worker came into contact with a particular patient suffering from the disease or condition *(97,99)*.

The tort system provides compensation to injured healthcare workers who are not covered by state or federal workers' compensation schemes. Nonemployee physicians, for example, might be able to bring their claims under tort law rules (100). These healthcare workers must prove the four basic elements of a tort claim discussed previously (28). The worker must prove that the hospital had a duty to observe a particular standard of care, that the hospital breached its duty, that the breach caused harm, and that the harm was of a type recognized as deserving compensation (28). Hospitals can defend these claims by arguing that one or more of these four elements are absent; they can also reduce their liability by arguing that the injury was caused by the healthcare worker's own negligence.

It is clear that hospitals have a duty to protect their employees from foreseeable injuries such as occupationally acquired infectious diseases (28). The scope of this duty can be defined in the same way as the scope of the hospital's duty to its patients. The applicable standard of care can be derived from licensure codes, occupational safety and health regulations, accreditation standards, and the general practices of other hospitals (28,29).

The employee must prove that the defendant hospital breached the standard of care. In *John Doe v Kaiser* (100,*101*), for example, a surgeon sued the hospital in which he practiced, claiming that it "did not enforce Universal Precautions or provide its medical staff with materials or training on those precautions." In *Prego v City of New York* (102), an unpaid extern working at Kings County Hospital brought suit against the hospital, contending that it had breached its duty by providing "inadequate disposal facilities for contaminated needles."

The employee must prove that the defendant's breach of the standard of care actually caused the employee's injury. This may present problems for healthcare workers who cannot identify specific sources of infection. Thus, the surgeon in the *John Doe v Kaiser* case contended that the hospital's conduct caused his HIV infection. The hospital argued in response that there was no proof connecting the surgeon's HIV infection to his work at the hospital; it noted that "[d]uring the seven months that the surgeon worked at Kaiser before testing HIV positive, he did not report being exposed to body fluids or encountering lapses in Kaiser's Universal Precautions policies" *(101)*. In contrast, Veronica Prego had documented evidence of two different exposures to blood from HIV-infected patients (102). Healthcare workers should be attentive to the need to document potential exposures.

Healthcare workers must also meet the legal injury requirement. A healthcare worker who acquires TB, hepatitis, or HIV infection easily meets this requirement. This leaves claims by workers based on the fear of transmission alone. Court rulings here follow the general trends noted above. Some jurisdictions have adopted a liberal approach that permits disease phobia claims based on reasonable fears. Most jurisdictions have imposed some additional requirements, such as proof of actual exposure (62,*63–64,* 65,*66–68,*69,70,*71,72,103*).

Hospital defendants in tort suits brought by healthcare workers who are not covered by the workers' compensation system may reduce their liability by arguing that the

employee was contributorily negligent (28). The hospital must show that the employee's negligent conduct contributed to her or his injury. This claim is likely to be asserted whenever the healthcare worker has failed to observe a workplace policy. Healthcare workers who acquire hepatitis or HIV infection after failing to use universal precautions or attempting to recap a needle would be particularly vulnerable to this type of hospital defense. However, courts might excuse an employee's deviation from required practices, particularly where the employee is injured while responding to an emergency situation *(104)*.

Hospitals seeking to reduce liability to healthcare workers, either under the workers' compensation or tort systems, should implement healthcare epidemiology and infection control programs that meet all federal, state, and community standards. This should reduce the number of claims made under the workers' compensation system because it will reduce the total number of injuries. Appropriate implementation will additionally limit tort liability because the hospital will be able to demonstrate compliance with the required standard of care. Hospitals should devote resources to updating policies, as necessary, and to documenting the implementation of all policies.

CONFLICTS BETWEEN THE DUTY TO MAINTAIN CONFIDENTIALITY AND THE DUTY TO PREVENT INJURY

This discussion of the legal rules governing healthcare epidemiology and infection control has revealed a complex regulatory framework that places many demands on healthcare institutions. These legal obligations can come into apparent conflict. The most difficult problems are raised by the hospital's ability, or even its legal duty, to prevent injury by warning third parties of the risk of infection. Conflicts between confidentiality and risk reduction can arise in the relationship between the hospital and its patients or in the relationship between the hospital and its employees.

Historically, the duty to preserve the confidentiality of medical information was derived from constitutional law (for public entities) *(105)*, common law *(106)*, or statute *(107)*. These traditional confidentiality rules were applied to hospitals and to individual healthcare providers such as physicians. Many states also enacted specific statutes protecting the confidentiality of certain types of information, such as HIV status *(17*,108,*109,110*). Although still important, these traditional approaches have been eclipsed by the federal government's Health Insurance Portability and Accountability Act (HIPAA) privacy rule (111). The HIPAA privacy rule restricts "covered entities" (including hospitals) from using or disclosing "protected health information" except as permitted by the regulation *(112,113)*. By way of example, the statute provides that a physician may only disclose confidential information without written consent under limited conditions such that even filing a lawsuit does not necessarily waive the confidentiality of health information *(114)*. The federal rules create a "floor" for protection—weaker state confidentiality protections will be preempted, but stronger state confidentiality rules can still be enforced. This "floor" for protection, however, has been suggested to be inadequate, causing some to advocate for additional reforms *(115)*.

Despite its wide and deep legal underpinnings, the duty to maintain confidentiality is not absolute. What happens when this right to confidentiality is pitted against the hospital's duty to protect others from the risk of infection? There are two different paradigmatic examples of this conflict: In the first, the hospital is concerned with a patient's infectious condition; in the second, the hospital must respond to the medical condition of an employee.

In the first case, the hospital may wish to disclose the patient's contagious condition to employees or other third parties whom it knows might be put at risk of infection. Both federal and state rules permit the disclosure of otherwise confidential medical information to third parties where the goal is to prevent the transmission of disease. Under the HIPAA privacy rule, for example, a covered entity may disclose individual healthcare information "to carry out treatment, payment, or … operations" without securing patient consent *(116)*. Texas law provides an example of a common state law approach to the protection of healthcare providers. The statute permits physicians to disclose otherwise confidential medical information to "another physician or other personnel acting under the direction of the physician who participate in the diagnosis, evaluation, or treatment of the patient" (117). A hospital is also authorized to provide information to third parties. Under HIPAA, "[a] covered entity may disclose protected health information for the public health … to … a person who may have been exposed to a communicable disease or may otherwise be at risk of contracting or spreading a disease or condition, if the covered entity … is authorized by law to notify such person …" (118). Many states have similar rules derived from statutes or court decisions *(105–107)*.

There is a distinction between permitting and requiring disclosures. The fact that a hospital or healthcare provider is permitted to disclose healthcare information to protect third parties does not mean that it will be held liable for failing to make the disclosure. Courts have expressed concern about whether healthcare providers should owe a duty of care for nonpatients *(34–37,119)*. Even if there is a duty, it is not clear that the standard of care would require providers to breach confidentiality by disclosing information to a third party. The healthcare provider's duty may be discharged by counseling the patient about how to avoid transmission of the condition to others *(120)*.

Despite these caveats, healthcare workers infected by patients occasionally bring suit against hospitals for failing to disclose a patient's contagious condition *(121)*. Healthcare facilities tempted to permit disclosures of patient status to healthcare workers should monitor the process to restrict unwarranted disclosures of information *(122)* and to ensure that healthcare workers do not unlawfully discriminate against a patient based on that patient's disabling illnesses *(123,124)*.

Similar arguments apply to claims brought by nonpatients and nonemployees against healthcare providers for an allegedly negligent failure to disclose confidential information about a patient's contagious condition. In *Lemon v Stewart (125)*, for example, an HIV-infected patient's extended family sued a hospital for failing to disclose the patient's HIV status. The court rejected the claim, noting that there was no duty to disclose, despite the fact that the plaintiffs alleged that they had been exposed to the patient's

urine, feces, saliva, blood, and serum. Although there is no general rule resolving the conflict between the patient's right to confidentiality and the hospital's duty to protect others, the most straightforward solution is to secure the patient's consent to any proposed disclosure.

The second paradigmatic situation involves conflicts between the hospital's duty to protect patients and its obligations to protect the confidentiality of its employees and to refrain from discriminating against employees who have disabling illnesses. HIPAA excludes records held by the hospital in its role as an employer from the scope of "protected health information" *(112)*. Employees nonetheless have a right to confidentiality and a right to nondiscriminatory treatment that is protected by a variety of laws, including the OSHA blood-borne pathogen rule (79) and the Americans with Disabilities Act *(126)*.

Despite these protections, two courts have held that the need to protect patients can outweigh the healthcare worker's rights. In one case, the court upheld a trial court order authorizing the release of certain information about an HIV-positive surgeon to his colleagues and patients *(127)*. The court found that the hospital had demonstrated a compelling need for the disclosure because of the need to warn patients of the risk of HIV exposure *(127)*. Similarly, in *Estate of Behringer v The Medical Center at Princeton (122)*, the court upheld a hospital policy that required an HIV-infected surgeon to disclose his status to his patients before performing surgery. These cases may represent judicial and medical overreaction to the risks of HIV transmission by healthcare workers *(21)*, but they nonetheless indicate a trend toward diminished confidentiality protections for healthcare workers.

LEGAL ASPECTS OF EMERGING INFECTIOUS DISEASES AND THE RISK OF BIOTERRORISM

The recent emergence of health threats, such as SARS, West Nile virus, and H1N1, has created additional stresses for epidemiology and infection control. These diseases have spread across national borders and created diagnostic and treatment challenges. At the same time, the public and private healthcare systems are focusing on the need to prepare for possible bioterrorism events, such as the release of highly contagious and destructive agents, as well as novel infectious diseases and weather or climatic events that will strain the provision of healthcare *(128)*. These events have created three different sorts of legal issues.

First, it may be difficult for healthcare providers and patients to determine *ex ante* the standard of care for identifying and treating these newly dispersed diseases. The standard of care develops quite rapidly and may or may not be captured well by periodic updates in online journals, traditional medical journals, and the reports and guidelines issued by advisory groups and public health authorities. As one example that could give rise to legal claims, providers did not initially realize that the West Nile virus could be transmitted by blood transfusion *(128,129)*.

The second set of issues involves a reexamination of the relationship between public health law and public health policy. Recent pandemics and fears about bioterrorism have combined to make private and public health entities more conscious of the need to understand when and how individual liberties can be constrained to protect the public health. Would a renewed SARS epidemic or the threat of smallpox justify the imposition of mandatory medical examinations, vaccinations, treatment, or isolation and quarantine? Would private healthcare entities be required to seek a court order in these cases or would public health authorities intervene? Can public health authorities require healthcare providers to collect and to report on a wide range of health data to facilitate efforts to identify a public health threat? How will public and private entities interact in a public health emergency? Many public and private organizations are working on responses to these important questions *(130,131)*. A detailed review of the state of the law is beyond the scope of this chapter. In general terms, public health authorities are likely to be given whatever power is needed to address a serious health crisis, including the power to impose serious restrictions on individual liberty.

The third area of legal concern relates to the need to build an infrastructure of public and private healthcare facilities, which will be prepared to provide services in public health emergencies. The difficulties can be demonstrated with the small but significant example of the failure of a plan to use smallpox vaccinations to create a nationwide team of healthcare workers who would be able to provide immediate support in the event of an outbreak *(132)*. Legal concerns about compensation for vaccine-related injuries appeared to be at least one factor in the slow implementation of the project, although criticism of the risk-to-benefit calculations underlying the program undoubtedly played a larger role *(133)*.

CONCLUSIONS

No one can be sure what threats to public health will emerge in the coming years. The legal rules governing healthcare epidemiology and infection control policies are complicated and sometimes conflicting. Hospitals have a duty to protect patients and third parties from the risk of infection. A hospital's failure to meet this obligation can result in sanctions under licensing statutes and in civil liability. Hospitals also have a duty to protect their employees from the risks of infection. Breaches of this duty can also result in administrative sanctions and in civil liability. Hospitals seeking to meet their obligation to prevent transmission of disease also must be conscious of the need to safeguard confidentiality and to prevent discrimination against persons with disabling illnesses. Hospitals must also focus attention on documenting compliance with all relevant legal standards. Finally, the emergence of new public health threats has created new areas of legal concern for professionals engaged in epidemiology and infection control.

SECTION XVI

Healthcare Epidemiology and Infection Control in Special Settings for Healthcare Delivery

CHAPTER 98

Epidemiology and Prevention of Infections in Residents of Long-Term Care Facilities

Jennie Johnstone and Mark Loeb

Infectious diseases pose an important threat to the health of residents of long-term care facilities (LTCFs) (1) who are at increased risk of infection due to advanced age and multiple comorbidities. Environmental factors such as close living conditions facilitate outbreaks of infection by increasing the likelihood of exposure among the often frail residents of LTCFs. Given demographic trends in aging, it is anticipated that this burden of infection will continue to increase. Infection prevention and control programs therefore play a paramount role in preserving the health and quality of life of residents of LTCFs. In this chapter, we outline the most common infections that place residents of LTCFs at risk and discuss both the reasons why the burden of disease is so high in this population and strategies that can be implemented for prevention. The role and structure of an LTCF infection control program are outlined, and the current scientific evidence for prevention of infectious disease in LTCFs is reviewed.

DEFINITION

Although LTCFs are often thought to be synonymous with nursing homes, the term in fact encompasses a heterogeneous group of institutions including nursing homes, psychiatric facilities, stroke rehabilitation facilities, facilities for the developmentally challenged, and group homes. The risk of infection in these facilities varies greatly but is highest in skilled nursing homes. Nursing homes, which may be freestanding or affiliated with acute care hospitals, are inpatient facilities for persons who require nursing care and related medical or psychosocial services. This chapter focuses primarily on infections that occur in the nursing home setting, because they account for the majority of LTCFs. The vast majority of LTCF studies about infection and its prevention are set in nursing homes. Wherever possible, this chapter includes observations and data from other types of LTCFs, but the description of infections in these other settings is unfortunately sparse.

As a prime example, an important recent infection control challenge comes from long-term acute care hospitals (LTACHs) *(2)*. These facilities combine the acuity of acute care with long-term placement. Patients often have severe respiratory and other medical problems that include need for chronic ventilation and reside in these facilities for a prolonged period of time *(2)*. Residents of LTACHs typically have had long lengths of stays at their acute care hospitals including stays in intensive care; hence, the burden of infection with antimicrobial-resistant microorganisms is high. Surveillance data from these facilities are relatively limited; however, one surveillance study performed in the Unites States found that 64% of patients were colonized or infected with methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), or both *(3)*. Clearly, further defining the burden of infectious disease in LTACHs and its prevention requires further study and is an important area of future research *(2)*.

DEMOGRAPHICS

Demographic trends in the United States and Canada suggest that older adults are the fastest growing sector. In fact, it is estimated that in 2030, 30% of the population will be 65 years and older *(4)*. As a consequence, rates of admission to LTCFs are increasing. It has been estimated that the lifetime risk of a 65-year-old entering a nursing home is approximately 50% *(5)*. In terms of infection control, these figures raise challenges with respect to the burden of illness in this population.

INCIDENCE AND PREVALENCE OF INFECTION IN LONG-TERM CARE

The overall incidence of infection in various types of Canadian and US LTCFs is estimated to range from 1.8 to 9.4 infections per 1,000 resident care days. One well-designed inception cohort study estimated the incidence of infection to be 7.2 per 1,000 resident care days (6). This rate did not include cases of asymptomatic bacteriuria and used standardized definitions and involved intensive surveillance by a nurse practitioner who visited all residents 2 to 4 times per month. One limitation of the study is the fact that it was conducted prior to the development of LTCF surveillance definitions. Other study designs were limited by not including patients with upper respiratory tract infections or bronchitis, thereby underestimating the true frequency of infection *(7)*. Studies using the Centers for Disease Control and Prevention (CDC) definitions for healthcare-associated infection may have underestimated their rates, because some LTCFs lack routine access to laboratory and radiologic investigations.

A number of 1-day prevalence studies have been conducted in LTCFs in an attempt to capture the burden of illness due to infection in this population. Most have focused on nursing homes or other specific units for the elderly. The prevalence of infection on the day of study in all surveys ranged from 2.4% to 18.4%. This broad range likely reflects differing definition of infection *(8–13)*. For example, some studies counted asymptomatic bacteriuria, whereas others used CDC definitions of healthcare-associated infection that may have underestimated the prevalence of infection *(9,12,13)*.

WHY THE BURDEN OF INFECTION IN LTCFs IS HIGH

The reason for the high burden of infectious disease in LTCFs is multifactorial. Residents of LTCFs have multiple comorbidities and functional impairments and can be malnourished, all of which contribute to risk of infection. Furthermore, most residents of LTCFs are elderly and are at increased risk of infection due to immunosenescence, the waning of protective immunity with age. Outbreaks of infection in LTCFs are facilitated by environmental factors. Last, recognition of an outbreak may be missed due to unique challenges in diagnosis of infection in this population.

Comorbidities

Many residents of LTCFs have comorbidities. The most commonly reported diagnoses are circulatory system disease (26%), mental disorders including Alzheimer's disease (26%), and diseases of the respiratory system (11%) *(14)*. Diabetes mellitus is also common, affecting 20% to 30% of nursing home residents, and is known to affect immune dysfunction *(15)*. Underlying comorbidities predispose nursing home residents to infection including lower respiratory tract illness, skin and soft-tissue infection, and urinary tract infections through a variety of mechanisms.

At any point in time, nursing home residents are on an average of six to eight different medications *(16)*. Frequently prescribed drugs include sedatives, neuroleptics, and narcotic analgesics, which may depress the level of consciousness and increase the risk for lower respiratory tract infections *(17)*. Medication such as tricyclic antidepressants can precipitate urinary retention predisposing residents to subsequent urinary tract infections. Other commonly used medications in the long-term care setting include H_2 blockers and proton pump inhibitor therapy, which may increase the risk of lower respiratory tract infection *(18,19)*; corticosteroids, which reduce immune function; and antibiotics, which encourage colonization with resistant microorganisms.

Invasive medical devices such as urinary catheters, feeding tubes, tracheostomies, and intravenous catheters further increase risk of infection by breeching the already compromised host defenses of nursing home residents. Urinary catheters are particularly common and are used in 5% to 10% of nursing home residents (20).

Functional Impairment

Functional impairments such as immobility, incontinence, and dysphagia have been reported to increase the risk of infections (*21*,22). In one study, 95% of nursing home residents needed assistance with at least one self-care activity, and three quarters were dependent in three to five such activities *(14)*. Approximately 60% of all nursing home residents use a walker and almost half are incontinent of urine *(14)*. Decreased mobility and incontinence predispose residents to respiratory tract infections, skin and soft-tissue infections, and urinary tract infections.

Malnutrition

Protein calorie malnutrition is common in nursing home residents affecting between 52% and 85% of residents in one study *(23)*. Malnutrition is associated with impaired immune function manifested by a decrease in cell-mediated immunity. The consequences of malnutrition such as delayed wound healing, decreased level of consciousness, and decline in functional status all increase the risk of infection.

Effect of Aging on Immunity

There are a number of changes that occur to the immune system with age and are collectively called immunosenescence *(24)*. Although all components of the immune system appear affected by aging, changes in T-cell parameters are by far the most pronounced *(25)*. Changes include a reduction in the number of naive T cells and a corresponding

increase in memory T-cell subsets. Notably, aging is associated with accumulation of terminally differentiated memory T cells *(26)*. The lack of naive T cells is thought to impair the ability of the host to respond against novel pathogens *(24,27)*. The terminally differentiated memory T cells are considered to have poor functionality, resulting in impaired responses to recall antigens and is the mechanism thought to be responsible for increased risk of infection and poor response to vaccines seen in the elderly *(24)*.

Environmental Reasons

In addition to the risk factors for infection described above, residents of LTCFs are at increased risk of infection simply by living in an LTCF (28). Outbreaks of infectious diseases are extremely common due to environmental factors including sharing sources of air, water, the close proximity of residents to other residents, and shared medical care and caregivers (28).

Diagnosis of Infectious Disease in LTCFs

The diagnosis of infectious diseases in LTCFs can be a challenge as the classic presenting signs and symptoms of infection are often blunted, altered, or absent in elderly nursing home residents. Reasons for this include cognitive impairment or reluctance to complain *(29,30)*. In addition, comorbid conditions can mask the symptoms of infection or make them difficult to interpret. Declines in functional status in the frail elderly may be the chief herald of serious infection *(31)*. Thus, urinary tract infections may present with confusion rather than dysuria and pneumonia with a fall not a cough *(32)*. Compared with younger patients, older persons with bacteremia are less likely to develop chills, diaphoresis, altered mental state, physical complaints, or lymphopenia *(33)*. The signs of infection are often subtle and appreciated only by staff members who know the resident well.

In general, the principals and criteria used for the diagnosis of infection in LTCF residents are comparable to those used for healthcare-associated infections. It should be noted, however, that LTCFs often lack ready access to laboratory and radiologic services, and physicians may not be present to diagnose infections as they occur. McGeer et al. (34) offered a comprehensive set of definitions for surveillance in LTCFs that account for the unique circumstances of these institutions (Table 98-1).

LONG-TERM CARE AND INFECTION CONTROL: CURRENT CHALLENGES

The main infection control challenges in LTCFs include managing antimicrobial resistance (e.g., MRSA, VRE, and *Enterobacteriaceae*-producing extended spectrum beta-lactamases [ESBLs] among others); reducing the burden of endemic infections such as respiratory, urinary, skin, and soft-tissue infections; providing surveillance and early recognition of outbreaks; and recognizing emerging infectious diseases.

Antimicrobial Resistance

Nursing homes play an important role in the problem of antimicrobial resistance. The most common and worrisome resistant pathogens in LTCFs are MRSA, VRE, and ESBLs (*35–37*,38,*39–54*). Also concerning but less common antibiotic-resistant pathogens include aminoglycoside-resistant gram-negative bacilli (38,*47*), high-level aminoglycoside-resistant enterococci (38,*53*), multidrug-resistant pneumococci *(46,55,56)*, and fluoroquinolone-resistant gram-negative bacilli *(46,51,57)*.

The frequency of antimicrobial-resistant pathogens in LTCFs varies by location, stressing the importance of knowledge of local resistance patterns (*10,35,*38,*44,52–54*). For example, Scheckler and Peterson *(10)* found antimicrobial resistance to be rare in their survey of eight small rural nursing homes in Wisconsin. Likewise, Mylotte et al. *(54)* found antimicrobial-resistant pathogens uncommonly (in <20% of admissions) in residents of community nursing homes admitted to an inpatient geriatric service in Buffalo. In contrast, a number of large urban facilities have reported high frequencies of resistant pathogens. Trick et al. *(44)* found at least one antimicrobial-resistant bacterial isolate in 43% of 117 LTCF residents screened in one urban facility in Illinois. Of the 50 culture-positive residents, 24% harbored MRSA, 18% ESBL-producing *Klebsiella pneumoniae*, 15% ESBL-producing *Escherichia coli*, and 3.5% VRE.

Eradication of antibiotic resistance in LTCFs is particularly challenging due to high frequencies of antibiotic use and difficulties in eradication due to serious underlying disease, poor functional status, open wounds such as decubiti, presence of invasive devices, and prior antimicrobial therapy (*35,36,*38,*43,44,52,53*). As a result, residents of LTCFs can remain colonized for months to years. Resistant microorganisms can also be reintroduced from hospitals following a transfer for management of acute illnesses (*35,*38,*49,50*).

Endemic Infections

Common endemic infections in LTCFs include lower respiratory tract infections, symptomatic urinary tract infections, and skin and soft-tissue infections *(58)*.

Lower Respiratory Tract Infections Pneumonia in nursing home residents (nursing home–associated pneumonia [NHAP]) is associated with significant morbidity and mortality in this population *(59–61)*. NHAP occurs approximately once per 1,000 resident days of care, which is 10 times more frequent than in community dwelling elderly *(62,63)*. Residents are at increased risk of pneumonia due to decreased ability to clear the airways, altered oropharyngeal flora, poor functional status, and swallowing difficulties leading to aspiration (1). Although there are over 100 etiologies that can cause NHAP, *Streptococcus pneumoniae* is the most common *(64)*. Influenza is also an important cause of lower respiratory tract infection in residents of LTCFs and is discussed in the "Outbreak" section.

NHAP is the most frequent cause of death among nursing home residents *(65)* and has an estimated 30-day case–fatality rate of 10% to 50% *(59,62)*. The costs associated with NHAP are substantial (66) as one third of the patients who develop NHAP require transfer to hospital for management *(67)*. Hospitalization may be associated with a reduced quality of life and a decline in functional status *(68)*. A cluster randomized controlled trial evaluated a clinical pathway for the management of nursing home

TABLE 98-1

Definitions of Infection for Surveillance in Long-Term Care Facilities

I. Skin and soft-tissue infections
- A. Cellulitis/soft-tissue/wound infection—pus at a wound, skin, or soft-tissue site or four of the following: (a) fever (>38.0°C) or worsening mental/functional status and/or at the affected site, the presence of new or increasing (b) heat, (c) redness, (d) swelling, (e) tenderness or pain, (f) serous drainage
- B. Fungal skin infection—both a maculopapular rash and either physician diagnosis or laboratory confirmation
- C. Herpes simplex and herpes zoster infection—both vesicular rash and either physician diagnosis or laboratory confirmation
- D. Scabies—both a maculopapular and/or itching rash and either physician diagnosis or laboratory confirmation
- E. Conjunctivitis—pus appearing from one or both eyes for at least 24 h or new or increased conjunctival redness, with or without itching or pain, for at least 24 h

II. Respiratory tract infections
- A. Common cold syndromes/pharyngitis—two of the following new signs or symptoms: runny nose or sneezing; stuffy nose (congestion); sore throat, hoarseness, or difficulty swallowing; dry cough, swollen or tender glands in the neck
- B. Influenza-like illness—fever (>38.0°C) and three of the following during influenza season: chills, new headache or eye pain, myalgias, malaise or loss of appetite, sore throat, or new or increased dry cough
- C. Bronchitis or tracheobronchitis—a negative chest radiograph (or no chest radiograph was taken) and three of the following: new or increased cough; new or increased sputum production; fever (>38.0°C); pleuritic chest pain; new or increased findings on exam (rales, rhonchi, wheezes, bronchial breathing); and new or increased shortness of breath, respiratory rate >25 per min, worsening mental status, or worsening functional status
- D. Pneumonia—two of the signs listed under bronchitis or tracheobronchitis and a chest radiograph demonstrating pneumonia, probable pneumonia, or an infiltrate
- E. Ear infection—either a physician's diagnosis or drainage from one or both ears (ear pain or redness also required if drainage is not purulent)
- F. Sinusitis—physician diagnosis
- G. Mouth and perioral infection—physician or dentist diagnosis

III. Urinary tract infection
- A. The resident who does not have an indwelling urinary catheter must have three of the following: fever (>38.0°C) or chills; new or increased burning pain on urination, frequency, or urgency; new flank or suprapubic pain or tenderness; change in character of urine; worsening of mental or functional status (may be new or increased incontinence)
- B. The resident who has an indwelling catheter must have two of the following: fever (>38.0°C) or chills, new flank or suprapubic pain or tenderness, change in character of urine, worsening of mental or functional status

IV. Primary bloodstream infection—either two or more blood cultures positive for the same microorganism or a single positive culture with a microorganism not thought to be a contaminant and one of the following: fever (>38.0°C), new hypothermia (<34.5°C), a drop in systolic blood pressure >30 mm Hg from baseline, worsening mental or functional status

V. Gastroenteritis—one of the following: two or more loose or watery stools above what is normal within a 24-h period, two or more episodes of vomiting in a 24-h period, or a stool culture positive for *Salmonella*, *Shigella*, *E. coli* O157:H7, or *Campylobacter* or a toxin assay positive for *C. difficile* toxin and one symptom or sign of gastrointestinal infection (nausea, vomiting, abdominal pain or tenderness, or diarrhea)

VI. Unexplained febrile episode—fever (>38.0°C) on two or more occasions at least 12 h apart in any 3-d period with no known infectious or noninfectious cause.

(Adapted from McGeer A, Campbell B, Emori T, et al. Definitions of infection for surveillance in long-term care facilities. *Am J Infect Control* 1991;19:1–7, with permission.)

residents with pneumonia. In this trial, 680 residents aged 65 years and older in 22 nursing homes in Hamilton, ON, were randomized to either management according to a clinical pathway that included use of oral antimicrobials, portable chest x-rays, oxygen saturation monitors, rehydration, and close monitoring by a research nurse or usual care. Thirty-four (10%) of 327 residents in the clinical pathway group were hospitalized compared with 76 (22%) of 353 residents in the usual care group. After adjusting for clustering of residents in nursing homes, the weighted mean reduction in hospitalizations was 12% (95% CI 5–18%; $p = .001$). There was no significant difference in mortality, health-related quality of life, or functional status.

Tuberculosis is an important consideration in any resident of an LTCF presenting with a lower respiratory tract infection. The diagnosis of tuberculosis can be difficult in LTCFs as the clinical signs and symptoms are nonspecific (1). Sputum for acid fast bacilli should be obtained in any resident with an unresolving pneumonia or pneumonia with a characteristic radiograph (e.g., either cavitating disease or infiltrates in the upper lung fields). Healthcare workers should have a low threshold for suspecting tuberculosis in residents, and every institution should have standards for

control of tuberculosis that are summarized by the Society for Healthcare Epidemiology of America (SHEA)/Association for Professionals in Infection Control and Epidemiology (APIC) guidelines for infection prevention and control in the LTCF (1).

Urinary Tract Infections Although urinary tract infections are often cited as the most common infection affecting residents of LTCFs, most urinary "infections" actually represent asymptomatic bacteriuria (1). The prevalence of bacteriuria is high; thus, a positive urine culture in the absence of symptoms, even when pyuria is present, does not meet criteria for infection *(69)*. When careful clinical definitions of urinary tract infections are used, they are less frequent in residents of LTCFs than lower respiratory tract infection *(70)*. Antibiotics are generally indicated only when symptoms of infection are present, and bacteriuria in the absence of symptoms should not be treated. Symptoms of urinary tract infections can include frequency, urgency, dysuria, fever, or flank pain (in cases of pyelonephritis). Alternatively, urinary tract infections can also present as nonspecific functional decline or delirium. Because of the challenges in accurately diagnosing and treating urinary tract infections in nursing homes, a multifaceted intervention was tested in a cluster randomized controlled trial (71). The diagnosis of urinary tract infection was outlined in an algorithm (Fig. 98-1).

Skin and Soft-Tissue Infections Residents of LTCFs suffer from a number of skin and soft-tissue infections including decubitus ulcers, cellulitis, and scabies. Decubitus ulcers are exceedingly common, occurring in 20% of all residents, and are associated with increased risk of mortality (1,*72–74*). Decubiti are at high risk of becoming secondarily infected leading to deep soft-tissue infection and osteomyelitis. Once infected, they are difficult to treat and require complex medical and surgical intervention and are best treated by an interdisciplinary team. Prevention of pressure sores is the best approach. LTCFs should focus on turning, positioning, removing focal pressure, limiting shear forces, and keeping skin dry in residents at risk (1).

Cellulitis is typically due to group A streptococci and *S. aureus*. Areas of skin breakdown increase the risk of cellulitis; however, cellulitis can occur in the absence of open wounds (1). Cellulitis should be promptly treated to limit its spread and prevent complications such as bacteremia.

Scabies is a mite capable of causing skin infection and can be problematic in LTCFs. Scabies is characterized by extremely pruritic, small, burrow-like lesions associated with erythema, classically in interdigital spaces of the hands, but can also occur in the axilla, waist, buttocks, and perineal area. Scabies is very contagious, and the presence of a case should prompt an investigation by infection control for secondary cases (1). The mite can be transmitted by linen, clothing, and

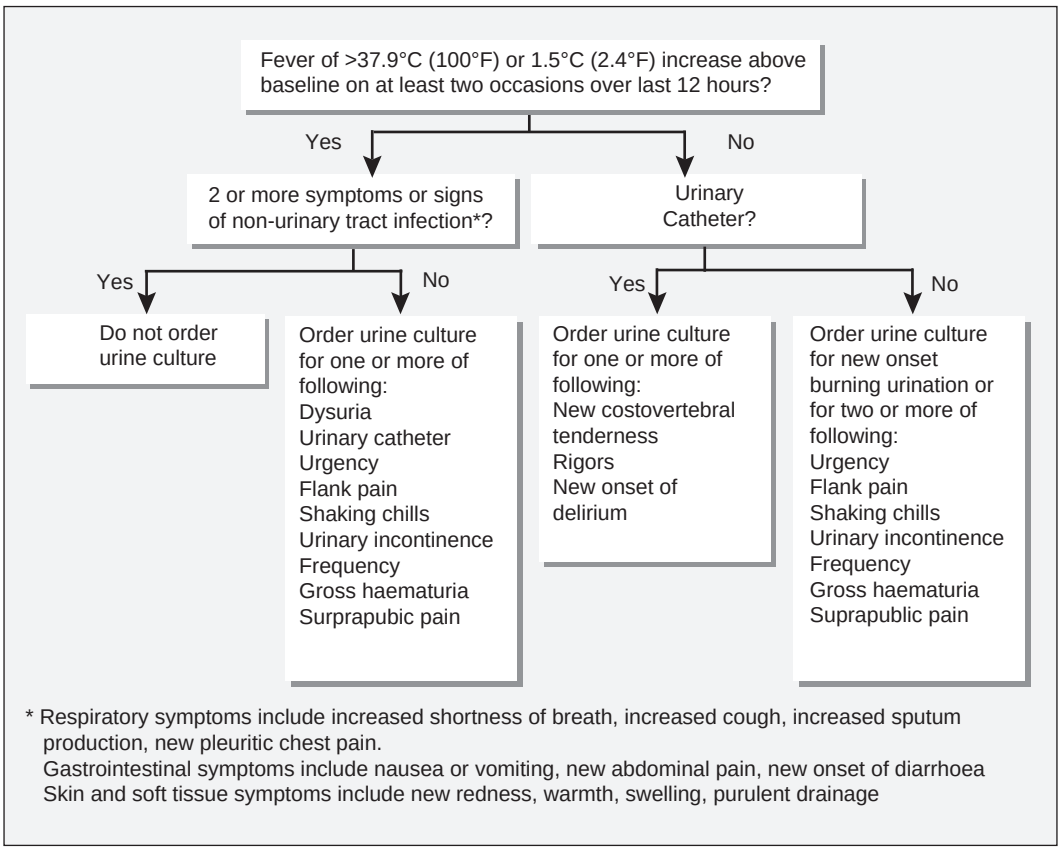

FIGURE 98-1 Algorithm for diagnosing urinary tract infections in long-term facilities. (From Loeb M, Brazil K, Lohfeld L, et al. Effect of a multifaceted intervention on number of antimicrobial prescriptions for suspected urinary tract infections in residents of nursing homes: cluster randomized controlled trial. *BMJ* 2005;331:669–673.)

carpets; thus, all washable items should be washed using a hot cycle, and carpets should be thoroughly cleaned.

Other Infections There are a myriad of additional infections found in LTCFs, and the infections described above are by no means exhaustive. Other examples of common infections include gastrointestinal illness due to viruses (e.g., rotavirus, enterovirus, and norovirus) as well as bacterial infections including *Clostridium difficile*. Other endemic infections include bacteremia (either primary or secondary), herpes simplex, and herpes zoster. The wide spectrum of infections seen in residents of LTCFs illustrates the predisposition of residents of LTCFs to acquire infection.

Outbreaks

It is estimated that several thousand outbreaks occur at LTCFs in the United States each year (1). In a systematic review examining outbreaks in LTCFs, the largest number of reported outbreaks by a single pathogen was influenza virus followed by norovirus, group A *Streptococcus*, and *Salmonella* species *(75)*. The respiratory tract accounted for 45% of all outbreaks, and the gastrointestinal tract accounted for 36% *(75)*, consistent with previous studies *(58)*. Outbreaks in LTCFs affect both residents of the facility and healthcare workers, although the attack rates are generally higher in the residents *(75)*.

Influenza is an important threat to the health of residents of LTCFs. Influenza is highly contagious, with attack rates ranging from 25% to 75% and case–fatality rates >10% (1). Epidemics of influenza typically occur annually between November and April in the Northern hemisphere *(76)*. Fever and cough have been shown in a systematic review to be the best predictors of influenza in the general population; however, these findings may be more subtle in residents of LTCFs *(76)*. Diagnostic testing therefore plays a critical role in identifying residents with influenza, and a nasopharyngeal swab should be performed in any resident suspected of having a respiratory illness when influenza is circulating in the community as rapid diagnosis is key to preventing the spread. Polymerase chain reaction testing has emerged as the preferred gold standard approach for the detection of influenza infection because of the high sensitivity and specificity and because sample quality is less dependent on sample collection when compared to DFA and virus culture *(77)*. Once infected, transmission can occur 1 day prior to the onset of symptoms and can continue for at least 5 to 6 days. Infected residents are generally treated with antivirals and are isolated. Contacts can also receive prophylaxis. During an influenza outbreak, visitors and admissions are usually restricted, and infected staff should not work (1).

Norovirus accounts for the majority of acute gastroenteritis in LTCFs. A study evaluating the epidemiological and genetic characteristics of norovirus outbreaks in LTCFs in Oregon, between 2003 and 2006, showed that 8% of all facilities were affected each year *(78)*. Certain LTCFs experienced repeated outbreaks, sometimes with identical strains and sometimes with different strains. Between 2005 and 2006, the number of norovirus outbreaks more than doubled. It is hypothesized that this was secondary to the emergence of a GII, 4 strain of norovirus, a strain that appears to have emerged as the dominant strain in Europe as well *(78)*. The rising rate of norovirus infections in LTCFs emphasizes the need for more effective infection control strategies in LTCFs.

Outbreaks of hepatitis B and C virus infection (HBV and HCV) in LTCFs have been increasingly recognized *(79)*. Out of 33 nonhospital healthcare-associated HBV and HCV outbreaks identified in the United States between 1998 and 2008, 15 outbreaks occurred in LTCFs *(79)*. In total, 97 residents were identified as acquiring incident HBV infection. All 15 outbreaks were a result of lapses in infection control procedure. The patient-to-patient transmission of HBV infection was primarily through reuse of finger-stick devices meant for individual use on multiple persons or through other shared equipment such as blood glucose monitors *(79)*.

Emerging Infections

Emerging infectious diseases such as pandemic influenza and those due to multidrug-resistant bacteria have posed variable challenges in LTCFs.

Pandemic H1N1 influenza emerged as a novel pathogen in April 2009. Although pandemic H1N1 predominantly affected children and younger adults, outbreaks of pandemic H1N1 were still reported in LTCFs, stressing the importance of respiratory illness surveillance in all LTCFs *(80)*.

Recently, the multidrug-resistant bacterium *Acinetobacter baumannii* has become a challenge for LTCFs *(81)*. *A. baumannii* has the capacity to cause multisystem infection, including respiratory tract infection, bloodstream infection, soft-tissue infection, urinary tract infection, and central nervous system infection, and is associated with substantial morbidity and mortality *(81)*. A study performed in Michigan between 2003 and 2008 described the changing epidemiology of *A. baumannii* in community hospitals and LTCFs *(81)*. Over the study period, the prevalence increased by 25% and pan-resistant isolates increased from 0% in 2003 to 13.6% in 2008 ($p < .001$). Furthermore, resistance to antibiotics in the isolates obtained from residents of LTCFs increased from a mean of 4.5 antibiotic classes in 2003 to 5.7 in 2008 ($p < .01$).

INFECTION CONTROL PROGRAM ELEMENTS IN LTCFs

Prevention of infection is critically important as infections in LTCF residents are associated with mortality and frequently result in transfer to hospital (82,*83,84*). Infections are also associated with decline in functional status, which is also a risk factor for further infection as individuals with lower function are at greater risk for subsequent infection (22). Over the last two decades, the need for prevention of infections in LTCFs has gained increased recognition, and there has been increased adoption of LTCF infection control programs. The SHEA and APIC developed a guideline for infection prevention and control in the LTCF, which is summarized below (1).

The overall structure of an infection control program can be found in Table 98-2. Most infection control programs should include surveillance for infections, an epidemic control program, education of employees in infection control methods, policy and procedure formation and review, an employee health program, a resident health program, and monitoring of resident care practices (Table 98-3).

TABLE 98-2

Long-Term Care Facility Infection Control Program Structure

Leadership	*Expertise/Training*	*Role(s)*
Infection Control Committee/Oversight Committee		
Core members	Administration, nursing representative, medical director, IP	Identify areas of risk Establishes priorities
Ad hoc members	Food service, maintenance, housekeeping, laundry services, clinical services, resident activities, employee health	Plans strategies to achieve goals Implements plans Develops policies/procedures Allocates resources Assesses program efficacy at least annually
IP		
IP	Qualification via education, experience, certification	Surveillance Data collection and analysis Implementation of policies/procedures Education Reporting to oversight group/ICC Communication to public health Communication to other agencies Communication to other facilities

IP, infection preventionist; ICC, infection control committee.
(Adapted from Smith P, Bennet G, Bradley S, et al. SHEA/APIC Guidelines: infection prevention and control in the long-term care facility. *Am J Infect Control* 2008;36:504–535.)

The infection control program may also be involved in quality improvement, patient safety, environmental review, antibiotic monitoring, product review and evaluation, litigation prevention, resident safety, preparedness planning, and reporting of diseases to public health authorities.

The Infection Preventionist

The infection preventionist is the core component of any successful infection control program as he or she is the staff member dedicated to coordinating infection control activities (1). In a survey of LTCFs in New England, the mean time spent on infection control activities by the infection preventionist was 11.8 hours (median 8 hours, range 1–40 hours). The majority of time was spent on surveillance, 24% on teaching, and 22% on other activities including meetings *(85)*. The number of LTCF beds justifying a full-time infection preventionist is unknown; however, typically an LTCF with more than 250 to 300 beds requires a full-time person.

The Infection Control Oversight Committee

Each LTCF should have a small infection control working group consisting of the infection preventionist, an administrator, medical director, and nursing home supervisor. This committee should meet regularly to review infection control data, review policies and monitor program goals.

Surveillance

Data about LTCF-associated infections are essential to plan control activities and educational programs and to prevent epidemics. Good surveillance requires well-defined criteria for infection and sensitive case finding methods (Table 98-1). It is recommended that surveillance be performed one or more times per week for case finding in conjunction with review of reports from nurses, charts, laboratory reports, and medication records. Data should be compiled and analyzed on a regular, usually monthly, basis. Data regarding infectious morbidity are optimally presented in terms of incidence rates (e.g., the number of infections per 1,000 resident care days). Distribution of this information to appropriate committees and personnel and storage of the records are also important.

Outbreak Control

Routine surveillance facilitates the recognition of outbreaks. Once an outbreak is suspected, the infection preventionist may need to gather additional data to confirm the existence of an outbreak, develop a case definition, analyze the pattern of disease occurrence, formulate hypotheses regarding transmission, design control measures, evaluate control measures, consult with an experienced epidemiologist, or prepare reports for local authorities and supervisors.

Isolation and Precautions

LTCFs need defined policies for identifying and containing the risks of disease transmission posed by infected residents, staff members, and visitors. Some facilities use one of the major systems developed for use in the hospital, whereas other facilities develop their own. The availability of private rooms for patients requiring Contact Precautions or respiratory isolation rooms to prevent transmission of airborne pathogens is an important consideration in developing local policies. Specific guidelines for dealing with antimicrobial-resistant pathogens in LTCFs have been published in two SHEA position papers (38,*86*).

TABLE 98-3

Long-Term Care Facility Infection Control Program Elements

Elements	*Examples*
Infection control activities	
Establish and implement routine infection control policies and procedures	Hand hygiene Standard Precautions Microorganism-specific isolation Employee education
Infection identification	Develop case definitions Establish endemic rates Establish outbreak thresholds
Identification, investigation, and control of outbreaks	
Microorganism-specific infection control policies and procedures	Influenza Tuberculosis Scabies Multidrug-resistant organisms
Disease reporting	Public health authorities Receiving institutions Long-term care facility staff
Antibiotic stewardship	Review of antimicrobial use
Monitoring of patient care practices	Aspiration precautions Decubitus ulcer prevention Invasive device care and use
Facility management issues	General maintenance (i.e., plumbing/ventilation) Food preparation/storage Laundry collection/cleaning Infectious waste collection/disposal Environment (i.e., housekeeping/cleaning, disinfecting/sanitation, and equipment cleaning)
Product evaluation	Single-use devices
Resident health evaluation	Tuberculosis screening Immunization
Employee health evaluation	Tuberculosis screening Immunization Occupational exposures
Other program elements	
Performance improvement	Serve on performance improvement committee
Resident safety	Study preventable adverse events
Preparedness planning	Develop pandemic influenza preparedness plan

(Adapted from Smith P, Bennet G, Bradley S, et al. SHEA/APIC Guidelines: infection prevention and control in the long-term care facility. *Am J Infect Control* 2008;36:504–535.)

Hand Hygiene

Hand hygiene is one of the most important infection control measure in LTCFs, but adherence remains low *(87)*. LTCFs should adhere to available hand hygiene guidelines, and hand hygiene compliance should be monitored by the facility (1).

Resident Health Program

Comprehensive resident health programs ensure administration of appropriate vaccines; secure admission, annual, and postexposure tuberculin skin tests; and address risk reduction in residents prone to aspiration, obstructive uropathy, decubiti, and other medical conditions that may be complicated by infection.

Employee Health Program

Employee health programs ensure that all employees are free of communicable diseases at the time of employment. They also ensure that tuberculin skin tests are administered annually and as indicated after exposure, that appropriate vaccines are offered, and that exposures to certain infections (e.g., tuberculosis or HIV infection) are managed properly.

Antibiotic Stewardship

Resistant pathogens, high levels of use, and inappropriate use are well-recognized problems associated with antimicrobial agents in nursing homes (38,*86*). For this reason, regular review of antimicrobial use and patterns of resistance is recommended. Presentation of this information to the medical staff can guide practice patterns and decrease the prevalence of resistant pathogens.

Policies and Procedures

As in the hospital, the development and regular updating of infection control procedures to cover such topics as hand hygiene, laundry, dietetic services, physical therapy, disinfectant and antiseptic use, medical devices, pets, visitors, and disposal of infectious wastes form an integral part of the infection control program. Pet-assisted therapy warrants specific policies in LTCFs that use this approach *(88)* (see also Chapter 94).

Disease Reporting

LTCFs, like other healthcare organizations, are obligated to notify public health authorities in a timely manner about the occurrence of reportable infections within the facility.

Performance Improvement/Resident Safety

Infection control is an important aspect of any quality management program within LTCFs. As in the hospital, the infection preventionist in LTCFs, by virtue of training, experience, and focus, can uniquely contribute to the facility's quality management program.

EVIDENCE-BASED PREVENTION AND CONTROL OF INFECTION IN LTCFs

Although infections in LTCFs are common, there are few evidence-based strategies to reduce infections in LTCFs. However, those for which there is evidence can make important impact and should be implemented by infection control programs. The following section will review existing evidence-based prevention strategies.

Strategies to Decrease Antimicrobial Resistance

LTCFs are an important reservoir for antimicrobial resistance, and MRSA in particular *(89,90)*. There have been few methodologically rigorous studies investigating ways to prevent spread of MRSA in LTCFs. Recently, a cluster randomized trial took place that evaluated the role of an infection control education and training intervention program on the prevalence of MRSA in residents and staff in the United Kingdom *(91)*. Prior to randomization, all participants ≥65 years and the nursing staff in 43 eligible LTCFs underwent testing for MRSA colonization. An infection control audit was carried out using an audit tool that measured compliance with infection control standards. LTCFs randomized to the intervention arm received detailed information on their baseline infection control scores including methods to improve practice and in-depth infection control training that consisted of a 2-hour training session delivered via PowerPoint and DVD presentations. These training sessions were repeated at 3 and 6 months after each infection control audit and feedback. The control arm consisted of usual practice, and no additional training or feedback was delivered to the staff. Sixteen matched pairs of LTCFs involving 793 residents and 338 staff were evaluated. The intervention had no effect on MRSA prevalence among residents or staff over the 12-month study period despite the intervention group having significantly higher infection control audit scores (47/244 [19%] vs. 44/234 [19%] in the intervention group; RR 0.99 [95% CI 0.69– 1.42]; $p = .95$). Further trials evaluating alternative interventions are needed to identify other measures to reduce MRSA prevalence in LTCFs.

Proper hand hygiene may be the most important strategy to reduce the spread of antimicrobial resistance in LTCFs; however, there have been few studies of hand hygiene practice in LTCFs. One cross-sectional study used direct observation methods to measure adherence to hand hygiene among healthcare workers in two LTCFs in Hamilton, ON *(87)*. A total of 459 hand hygiene opportunities were observed, and overall compliance with hand hygiene was 14.7%. The study concludes that there is significant room for improvement in hand hygiene in LTCFs, and techniques to improved hand hygiene adherence should be investigated further using randomized controlled trials.

Antimicrobial use is an important driver of antimicrobial resistance in nursing homes *(92,93)*. In addition, overuse of antibiotics is associated with adverse events, drug interactions, and increased costs. Thus, a consensus conference was held to establish minimum criteria that should be present before initiating antibiotics in LTCFs *(94)*. Minimum criteria were outlined for common infections in LTCFs such as skin and soft-tissue infections, respiratory infections, urinary tract infections, and fever where the focus of infection is unknown. Studies are needed to validate these criteria and to document their impact on antimicrobial resistance.

Strategies to Prevent Infection

A list of available vaccination and prophylaxis recommendations for LTCF can be found in Table 98-4. Most evidence-based prevention strategies in LTCFs have focused on prevention of lower respiratory tract illness including prevention of pneumococcal pneumonia, influenza infection, and aspiration pneumonia and are summarized below.

TABLE 98-4

Vaccination and Prophylaxis Recommendations for Long-Term Care Facilities

Vaccine/Prophylaxis	*Recommendations*
Influenza vaccine	Optimal time for nursing home vaccination is October to November. Immunization of unvaccinated residents should continue as long as vaccine is available Contraindication—anaphylactic hypersensitivity to eggs Consider immunization for any LTCF resident
Influenza antiviral medications	When influenza vaccination is contraindicated: administer throughout influenza season or during peak community influenza activity Adjunct to immunization: administer to LTCF residents who are vaccinated after a community outbreak of influenza has begun until immunity has developed (~2 wk) Institutional outbreaks: administer to all residents regardless of immunization status for at least 2 wk, continuing for 1 wk after the end of the outbreak and as an adjunct to immunization if influenza is noted in the community before vaccination
Pneumococcal polysaccharide vaccine	All residents 65 and older and anyone with a chronic condition that increases the risk of pneumococcal disease (i.e., chronic lung disease, heart disease, diabetes, renal failure, alcoholism) Revaccination—persons 65 or older first vaccinated before age 65 should be given a one-time revaccination 5 y after initial vaccination
Tetanus-diphtheria toxoid (Adult Td)	Unimmunized/history unknown administer full series All other residents, booster every 10 y Clean wounds—Td if >10 y since last vaccination Dirty wounds, puncture, frostbite—Td if fully immunized and >5 y since last booster dose; if unimmunized, inadequate primary series (<3 doses) or history unknown, tetanus immune globulin plus primary immunization series Contraindications—neurologic reaction or hypersensitivity to previous dose

LTCF, long-term care facility.

Guidelines recommend immunizing residents of LTCFs against *S. pneumoniae* with the 23-valent pneumococcal polysaccharide vaccine *(95)*. Although NHAP has over 100 etiological agents, the most common cause of pneumonia remains *S. pneumoniae (64)*. At least 12 outbreaks of serious pneumococcal disease have also been reported in LTCFs *(96)*. A Cochrane review of randomized controlled trials found that the 23-valent polysaccharide vaccine prevented invasive pneumococcal disease in the elderly *(97)*. Since this meta-analysis was published, the efficacy of the 23-valent pneumococcal vaccine in preventing pneumonia was studied in nursing home residents *(98)*. In this prospective, multicenter, double-blind randomized controlled trial of 1,006 nursing home residents in Japan, residents were allocated to either the 23-valent pneumococcal vaccine or placebo groups and the participants were followed for 3 years. Vaccination with the 23-valent pneumococcal vaccine was associated with a reduction in pneumococcal pneumonia (12/502 vs. 32/504 in the placebo group, $p = .0015$) and all-cause pneumonia (55/502 vs. 91/504 in the placebo group, $p = .0006$) but not nonpneumococcal pneumonia (43/502 vs. 59/504 in the placebo group, $p = .0805$). The trial was not powered to detect a difference in invasive pneumococcal disease. The generalizability of this study to other nursing homes could be questioned as <10% of the participants died during the 3-year follow-up period and not a single participant dropped out of the study, which is unusual *(99)*. Regardless, there is evidence that the 23-valent pneumococcal vaccine can prevent invasive pneumococcal disease, and the vaccine is well tolerated; thus, it makes sense to administer the vaccine to nursing home residents *(99)*. The question of whether to administer the new pneumococcal vaccine formulations including the pneumococcal conjugate vaccine versus the 23-valent polysaccharide vaccine will need to be addressed in this population in the future.

It appears as though the benefits of influenza vaccine effectiveness in the elderly have been substantially overestimated *(100)*. Studies that are able to better adjust for functional status or other measures of frailty demonstrate a nonsignificant benefit of vaccination in terms of hospitalization and mortality, strongly suggesting substantial residual confounding factors arising from observational studies of vaccine effectiveness *(100)*. However, vaccination of healthcare workers with the influenza vaccine has been shown to decrease the incidence of mortality among nursing home residents in randomized controlled trials and should be encouraged. Potter et al. *(101)* randomized 12 LTCFs either to offer healthcare workers vaccination or no vaccination. The authors noted that vaccination of healthcare workers was associated with a reduction in total patient mortality from 17% to 10% (OR 0.56; 95% CI 0.40–0.80) *(101)*. Carman et al. *(102)* conducted a randomized trial using cluster randomization in 20 geriatric care hospitals that compared mortality in hospitals where healthcare workers were vaccinated with mortality in hospitals where no vaccination was offered. Vaccination of healthcare workers significantly reduced mortality of elderly people over a period of 6 months in hospitals where influenza vaccine was offered, compared with hospitals where influenza vaccine was not offered (OR 0.58, 95% CI 0.40–0.84, $p = .014$) *(102)*.

Increased aspiration is an established risk factor for NHAP *(103)*. A systematic study reviewed randomized controlled trial interventions to prevent aspiration pneumonia in the elderly *(104)*. Eight studies met eligibility criteria: two dietary interventions (pureed food vs. nonaltered food and compensatory positioning during feeding), two pharmacological therapies (amantadine vs. no treatment and cilostazol vs. no active treatment), one trial that compared enhanced oral care with usual care, and three trials that looked at the use of feeding tubes in patients at risk of aspiration. When amantadine was compared to no treatment, amantadine was protective from pneumonia (5/83 in the amantadine group vs. 22/80 in the no treatment group, OR 0.17, 95% CI 0.05–0.50, $p < .001$). However, amantadine is associated with gastrointestinal, neurological side effects and drug–drug interactions precluding wide adoption of this strategy. Furthermore, amantadine has activity against influenza, which may explain its benefit *(104)*. Similarly, the antithrombotic agent cilostazol prevented aspiration pneumonia (12/152 in the cilostazol group vs. 35/145 in the no treatment group, OR = 0.33 [95% CI 0.15–0.71, $p < .001$]), but the 7% risk of bleeding in the cilostazol arm limits its use as a preventative strategy. None of the other interventions reduced the incidence of pneumonia. However, the effect of using enhanced oral hygiene was of borderline significance (OR 1.74 [95% CI 0.93–3.26]).

A subsequent systematic review built upon this finding of potential benefit from enhanced oral hygiene and reviewed all randomized and nonrandomized controlled trials investigating its preventative effect from pneumonia in the hospitalized elderly and nursing home elderly *(105)*. In total, 15 publications met inclusion criteria; 4 of these were unique randomized controlled trials. All four trials showed a reduction of pneumonia in the elderly (absolute risk reduction [ARR] ranging from 6.6% to 11.7%); however, all of the trials were small (sample size ranging from 40 to 184), which likely explained why the 95% CIs crossed 0 in two of the trials. A larger, adequately powered trial is now underway.

CONCLUSION

The burden of infections in LTCFs is high. Having a formal infection prevention and control program in LTCFs is essential for limiting spread of infection. Infection control programs should ensure that existing evidence-based infection prevention strategies are implemented. However, given the burden of infection in LTCFs, research into novel prevention strategies in LTCF is an urgent priority.

ACKNOWLEDGMENTS

We would like to acknowledge Dr. Larry Strausbaugh and Dr. Carol Joseph who contributed to an earlier version of this chapter. Dr. Johnstone receives salary support from the McMaster University Bayer Healthcare Infectious Disease Research Fellowship (2009–2010) and Canadian Thoracic Society (2010–2011).

CHAPTER 99

Epidemiology and Prevention of Infections in Home Healthcare

Philip W. Smith and Angela L. Hewlett

BACKGROUND

The Home Healthcare Field

Home healthcare is the most rapidly growing segment of the healthcare delivery system; about as many persons in the United States receive healthcare in the home as in acute care settings *(1)*. More than 20,000 agencies deliver home care to 7.6 million individuals, generating about $40 billion in expenditures *(2)*. Medicare is the largest payer of home health services *(3)*. The most commonly used services are skilled nursing care, personal care, and physical therapy.

Home healthcare specialists provide many services traditionally given in the hospital or in a long-term care facility (LTCF). The number and types of patients who receive professional care in the home setting are increasing; major categories of home care services include infusion therapy, respiratory therapy, dialysis, diabetic monitoring, wound care, other skilled nursing care, physical therapy, nutritional therapy, occupational therapy, social services, and hospice care. Also included in these general categories are patients requiring special nursing support by virtue of medical needs (e.g., enteral nutrition) or disease complexity (e.g., acquired immunodeficiency syndrome). In total, about 950,000 persons are employed in the home healthcare industry, mostly home care aides and registered nurses *(2,3)*. Other professionals including respiratory therapists, physical therapists, social service workers, speech therapists, pharmacists, and durable medical equipment suppliers are also involved in providing home healthcare.

Infections and Risk Factors in Home Healthcare Patients

Patients cared for at home have conditions that predispose to infectious diseases such as advanced age, multiple underlying comorbidities, and immunosuppressive conditions (*2–4*,5,*6–9*). Many infections acquired in the home are related to devices or breaks in local defenses (Table 99-1). Invasive devices were noted in up to one third of patients in the home (*4*,5,*9*), most notably urethral or suprapubic catheters (12–21%), nasogastric tubes (11%), intravenous (IV) catheters (6–17%), gastrostomy tubes (7%), and tracheostomies (2%). Some infections in the home setting are hospital-acquired (attributable to a prior hospital stay), most commonly urinary tract infection (UTI) and skin/wound infection (*10*). Although comparative data are not available, home healthcare patients are presumably less immunosuppressed than typical hospital or LTCF patients but more at risk for infection than other community-dwelling individuals.

Home healthcare patients may have a variety of infectious diseases that require infection control in the home. Limited data suggest that the prevalence of infection in home healthcare patients is 16% to 20% *(4,9)*. One prevalence survey found an overall infection rate in the home of 16%, with 8% of these infections being home care acquired, 16% hospital acquired, 41% community acquired, and 35% unknown *(9)*. The most common infections involved the urinary tract (27%), respiratory tract (24%), skin and soft tissue (24%), surgical wounds (12%), and bloodstream (2%). Others (11) have noted a relatively low rate of device-associated infection in the home (0.22 central line–associated bloodstream infections [BSIs] per 1,000 device days, and 1.24 UTIs per 1,000 device days). The definitions of infection in the home care setting are discussed below in "Surveillance."

The occurrence of an infection in a patient in an acute care hospital or LTCF does not imply that the infection was caused by the facility, or necessarily preventable. Infections that occur in home healthcare patients are much more difficult to ascribe to the home health agency, which has contact with the patient usually only a few minutes per day compared with 24 hours for the hospital or LTCF. Exposure to microorganisms from family members, visitors, or the environment are usually beyond the control of the home health agency, as are factors such as home sanitation, compliance with basic hygiene, and exposure to contagious persons (12). In the case of intravascular catheters, multiple providers may have access to the device *(13)*. The incidence, origin, risk factors, and preventability of infections in the home healthcare setting still remain largely to be defined.

HOME INFUSION THERAPY

The home infusion industry has grown rapidly, greatly advanced by the development and widespread availability of devices to secure long-term venous access.

TABLE 99-1

Infections of Importance in Home Health

Infection	*Associated Condition or Device*
Bacteremia	Intravenous access device
Urinary tract infection	Bladder catheter
Pneumonia	Nasogastric tube, tracheostomy
Peritonitis	Peritoneal dialysis catheter
Wound infection	Recent surgery

Antibiotic therapy, parenteral nutrition, hydration therapy, chemotherapy, and pain medications account for most IV home medications.

Infections in Home Infusion Therapy

Most infections in home infusion therapy are related to vascular access devices. The measured incidence rate of central line–associated bacteremia varies widely in the literature, from 7 to 58 bacteremias per 10,000 catheter days (*14*,15,*16–18*). Noninfectious complications of venous access in the home environment include thrombosis, bleeding, and air embolism *(19)*.

Infections related to indwelling vascular access devices can present as sepsis or fever without localizing signs or symptoms. Alternately, one may see signs of exit-site infection (erythema, tenderness, or purulent discharge at the catheter exit site) or a tunnel infection (erythema, tenderness, and induration along the subcutaneous tract). Catheter-related sepsis and tunnel infections often require catheter removal *(14)*. The most common microorganisms associated with these infections are coagulase-negative staphylococci, *Staphylococcus aureus*, aerobic gram-negative bacilli (such as *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*), and *Candida* species. In one report, gram-negative microorganisms were responsible for a greater proportion of central line–related bacteremias in pediatric oncology patients receiving home care than in those in the hospital; the mean time between catheter insertion and bacteremia was 133 days *(17)*.

Risk factors for BSIs in patients receiving home infusion therapy include bone marrow transplantation, parenteral nutrition, and use of multilumen catheters (20). The importance of aseptic technique is suggested by the association of lower education and younger age with patient BSI (21). Proper infection control technique is likely an important component of preventing home infusion-related infectious complications *(22)*, although little research has been done in the home setting. One investigator found that routine replacement of peripheral catheters every 3 to 4 days was not associated with a lower rate of complications *(23)*.

Home Parenteral Nutrition

One special area of home infusion therapy is home parenteral nutrition (HPN). Most infections in HPN are related to the indwelling vascular catheter *(24)*. Catheter-related bacteremia in HPN patients occurs at a rate of approximately 20 infections per 10,000 HPN days *(16,18)*. The leading causative microorganisms are coagulase-negative staphylococci, *K. pneumoniae*, *Escherichia coli*, *S. aureus*, and *Candida* species.

Infusate-related bacteremia from contaminated parenteral nutrition fluids is relatively uncommon but remains a concern. A variety of microorganisms have been shown to proliferate in parenteral nutrition solutions, particularly gram-negative bacteria and *Candida* species *(25)*.

Preventive Measures

Infection control recommendations for home infusion therapy pertain mainly to the prevention of vascular access–associated infections. Guidelines for preventing catheter-related infections in the hospital have been published *(22)*. The guidelines address frequency of catheter and administration set change, aseptic technique during catheter insertion, and length of hang time for lipid-containing solutions. The home care agency is responsible for ensuring sterility of solutions prepared for IV infusion. Both the patient and the home healthcare provider need to be familiar with the signs and symptoms of infection, the side effects of infusion therapy, and the maintenance and care of vascular access devices. See Chapters 18 for more information on the infection control aspects of long-term vascular access.

HOME RESPIRATORY CARE

Technologic advances have had a great impact on home healthcare patients with chronic respiratory conditions. Home care of patients with tracheostomies has become an accepted practice. This raises questions regarding the most effective aseptic techniques when performing tracheostomy care and tracheal suctioning. Sophisticated respiratory care equipment is used in the home and requires meticulous maintenance to prevent bacterial contamination and respiratory tract infection by inhalation. Finally, chronic ventilatory support may be provided with in-home ventilators, requiring adaptation of standard acute care hospital respiratory care techniques to the home care setting.

Home respiratory care patients are at particular risk for respiratory tract infections because of underlying pulmonary diseases and devices such as tracheostomies that bypass upper airway defenses. Marrie and Huang (26) found that the overall rate of community-acquired pneumonia (CAP) requiring an emergency room visit for home care patients was 25 per 1,000 person years. Home care patients hospitalized for pneumonia had double the hospital mortality, likely due to their increased age and greater functional impairment. The CAP incidence in patients receiving home ventilation was 1.5 per 1,000 ventilator days *(27)*. The causative microorganisms were similar to those in hospitalized patients with ventilator-associated pneumonia, namely *S. aureus*, *Pseudomonas* species, and other aerobic gram-negative bacilli.

Infection Control Aspects of Home Respiratory Care

There are no controlled studies of the risk of infection or of infection control methods for respiratory patients in the home environment. Recommendations *(28,29)* are based on extrapolations from current hospital practices (see Chapter 22). Areas of concern are listed in Table 99-2.

TABLE 99-2

Infection Control Concerns in Home Respiratory Care

Tracheostomy care
Changing of inner cannula
Tracheostomy site care
Suctioning technique
Reuse of suction catheters
Disinfection of respiratory care equipment
Ventilator circuits
Ventilator apparatus
Humidifiers
Nebulization equipment
Oxygen delivery systems

For patients receiving mechanical ventilation in the home, cleaning of the ventilatory circuits is important. Several circuits should be provided, and the circuits (including tubing, manifold, and humidifier) not in use should be cleaned and dried before being stored. Adequate precleaning of equipment is an important part of the disinfection process.

Room humidifiers that produce a fine spray of water droplets are frequently used in the home and are often contaminated with bacteria. These humidifiers are difficult to clean and pose significant risk to immunocompromised patients. Drying between uses decreases bacterial contamination. Humidifiers that work by simple evaporation are safer than those that produce a fine mist spray.

Guidelines for prevention of healthcare-associated pneumonia *(29)* have relevance for home care, including immunization recommendations (pneumococcal vaccine, influenza vaccine), suctioning, ventilator care, aspiration prevention after enteral feeding, and humidifier care. The American Association of Respiratory Care provides clinical practice guidelines for home suctioning, home ventilation, postural drainage, and ventilator circuit changes *(28)*, as well as a discussion of frequency of ventilator tubing change and infection control aspects of humidification. The home suctioning guideline discusses cleaning and reuse of suction catheters *(30)*.

HOME DIALYSIS CARE

Technologic advances have resulted in the ability of many patients with chronic renal failure to receive dialysis at home. Both peritoneal dialysis and hemodialysis may be administered in the home setting. Most infections in dialysis patients are related to access devices.

Infections in Home Dialysis

One of the most serious problems associated with peritoneal dialysis is infection involving either the catheter exit site through the skin or the peritoneal cavity itself. The former infection, analogous to indwelling central IV access device infections, may involve either the exit site or the tunnel. The latter generally presents as peritonitis *(31)*. The incidence of infectious complications related to continuous ambulatory peritoneal dialysis (CAPD) is about 1.1 to1.3 episodes per patient year *(32)*. Recurrent peritonitis is a leading cause of CAPD failure.

Most bacteria causing CAPD-related peritonitis are gram-positive bacteria (specifically, coagulase-negative staphylococci and *S. aureus*), reflecting the important role of skin flora in catheter-related peritonitis *(31,32)*. Polymicrobial infections and the presence of gram-negative bacteria suggest a bowel perforation by the catheter. Nasal carriage of *S. aureus* may be a risk factor for catheter exit-site infections by this microorganism *(33)*.

Preventive Aspects

A key to minimizing the risk of peritonitis due to CAPD is appropriate care of the exit site and surrounding skin. Initial care after catheter placement has been described and consists of cleaning the exit site and surrounding skin with an antiseptic agent, drying the skin, covering the exit site with a sterile gauze dressing, and securing with surgical tape. The catheter should be protected from mechanical stress. After the exit site has healed, routine care includes frequent examination of the exit site and tunnel for signs of inflammation as well as cleaning of the exit site *(34–36)*. The potential for contamination of the peritoneal dialysis system exists when the system is opened to connect or disconnect bags of fluid. Hand washing and aseptic technique are important. Infections in peritoneal dialysis are discussed in greater depth in Chapter 64.

A guideline for preventing infection transmission in chronic hemodialysis patients discusses cleaning and disinfection of equipment *(37)*. Hemodialysis and related complications are discussed in Chapter 63. Patients should be educated in basic hygienic techniques and the signs of access-site infection and sepsis.

INFECTION CONTROL ASPECTS OF OTHER TYPES OF HOME HEALTHCARE

Urinary Catheterization in the Home

The home healthcare patient may require continuous or intermittent urinary catheterization *(38)*. One study found an infection rate of 4.5 symptomatic UTIs per 1,000 catheter days (15). A survey of home care patients with urinary catheters during a 6-month period found the mean duration of catheterization to be about 300 days *(39)*. One quarter had a UTI at the start of catheterization, and 43% of the remainder acquired infection during the study period. Frequent catheter change was an infection risk.

Intermittent catheterization is usually limited to individuals with neurogenic bladders who are able to actively participate in their own care. Clean rather than sterile technique is often used in the home setting *(40)*, but virtually no data are available to guide infection control in the home in this area.

Guidelines for prevention of UTI associated with indwelling catheters can be found in the literature *(41)* and in Chapter 20. They emphasize aseptic catheter insertion, maintenance of unobstructed flow, use of a closed drainage system, and minimization of drainage tube disconnections.

The ideal approach to leg bags and equipment reuse in the home setting is not yet defined.

Home Skin/Wound Care

A Michigan prevalence survey found that 36.3% of a large sample of home care patients had wounds present—most commonly surgical wounds, pressure ulcers, and vascular leg ulcers. Of patients with wounds, 41% had multiple wounds *(42)*. In another survey, 9% of home care patients had a stage II or deeper pressure ulcer, and one third had more than one ulcer (43).

Fresh surgical wounds are not frequently encountered in the home setting; thus, clean technique is adequate for most wound care. Proper wound care involves minimizing touching and glove use for clean wounds, the use of gloves for infected or draining wounds, and proper disposal of soiled dressings. The patient, the family, and the home healthcare provider need to be educated on the signs and symptoms of wound infection, such as fever, pain, swelling, induration, erythema, and warmth. Guidelines for pressure ulcer prevention are available *(44)* and discuss pressure ulcer staging, diagnosis, prevention, and treatment, as well as skin assessment and nutrition.

Enteral Feedings in the Home

Enteral feeding via nasogastric or another enteral feeding tube is often undertaken in the home setting. The risk of infection is primarily related to the potential for aspiration resulting from the presence of the nasogastric tube. The possibility of bacterial contamination of enteral feeding solutions must also be considered *(45)*. In general, clean technique is appropriate for preparing and administering enteral feedings. To minimize the risk of aspiration pneumonia, tube placement should be confirmed and the patient should be kept in the erect or semierect position *(29)*.

Multidrug-Resistant Microorganisms in the Home

Multidrug-resistant microorganisms (MDROs) have become prominent in healthcare in recent years. Although most of the concern has been focused on hospital and LTCF settings, methicillin-resistant *S. aureus* (MRSA) has become a major concern in the community and the home *(46)*. A Brazilian home health service found a prevalence of 15% of MRSA carriage in a home service; although most were positive on admission, there were eight instances of cross-transmission to home health employees *(47)*. Another study noted a prevalence of 12% of MRSA colonization in posthospital patients admitted to home care, and almost 20% of household contacts acquired MRSA from the index patient (48).

The environment of patients colonized with MRSA may be contaminated with the microorganism, especially sites touched by the hands such as faucet handles (49,*50*). In one study of patients with MRSA admitted to a hospital, home nursing care was an independent risk factor for MRSA acquisition in the community (51). One of the few cases of vancomycin-intermediate *S. aureus* occurred in a home health patient who had received vancomycin *(52)*. Isolation is discussed below, but standard precautions are important in view of the fact that many MDRO carriers are unknown to healthcare providers.

THE HOME HEALTH INFECTION CONTROL PROGRAM

There is a trend toward formalizing infection control efforts in home health (53). The functions of an infection control program in this setting are listed in Table 99-3. The basic elements of infection control for out-of-hospital settings are (a) managing data, (b) developing control efforts, (c) preventing infections, and (d) training *(54)*.

An administrative structure should identify a designated infection preventionist (IP) who is responsible for the program, and the program may have a formal infection control committee (*55*,*56*,57). Ideally, the IP should be available to conduct infection control activities from within the agency. An infectious disease physician with experience in infection control should be available on a consultative basis.

Communication with other healthcare organizations is important, especially because many home care patients have recently been in acute care hospitals or LTCFs. Exchange of microbiologic and clinical information is helpful for medical decision making by healthcare providers and for infection control planning. Communication includes disease reporting to health departments and healthcare-associated infection reporting to the patients' institutions of recent residence. This is one aspect of regulatory compliance. Surveillance data facilitate detection of epidemics and adverse events and are key to quality improvement efforts.

Employee protection begins with a basic employee health program, addressing such issues as tuberculosis skin testing, postexposure protocols, and immunizations. Policies and procedures for infection control measures are designed to minimize infection transmission; they deal with asepsis, disinfection, and hygiene, including hand washing and waste disposal. Barrier protection methods are also part of employee protection and may vary depending on the patient's infectious condition (e.g., colonization with antibiotic-resistant bacteria) and level of compliance. The IP plays an important role in prevention of cross-infection in the home by education of patients and families.

TABLE 99-3

Components of a Home Healthcare Infection Control Program

Isolation precautions
Education of patients and families
Preparedness

Most agencies have policies and procedures for standard precautions, hand hygiene, handling sharps and needles, and cleaning or disinfecting equipment. A Missouri survey found that 90% of 95 home care agencies had written infection control policies, and 95% had a system for reporting exposures, injuries, or infections in their personnel *(58)*. Seventy percent of the agencies conducted infection surveillance (most used standard definitions, used standard data collection forms, and calculated infection rates). Two-thirds had a routine process for checking the antimicrobial sensitivities of pathogens, but only about half had a designated IP.

Another key element of infection control is education. In view of the limited time the healthcare providers spend in the home, it is important that they teach the patient and family about hand hygiene and good infection control techniques. Inadequate education has been associated with infectious disease outbreaks *(59)*.

Surveillance

The first step in developing an infection control program is to create a surveillance system for infections acquired in home healthcare and for employee exposures. Surveillance for home care–associated infections is a difficult task. Unlike the hospital or LTCF patient, the home care patient has contact with healthcare providers for a very small amount of time (a few minutes per visit, with contact perhaps not occurring daily). Multiple home agencies may serve the same patient. It is, therefore, not always clear which infections occur as a result of normal daily life (community acquired) and which are related to care received in the home (home care associated).

Collecting infection incidence or prevalence data in the home setting may be problematic *(60)*, requiring sharing of data by hospitals and laboratories and collection of information by home care nurses in the field. Laboratory data are often difficult to obtain in the home setting. Device-related denominator data are not readily obtained if devices are inserted or removed at various facilities without notification of the home care nurses. Denominator data permitting calculation of rates per 1,000 device days (e.g., urinary catheter, central venous catheter) are preferable (15) but not always readily obtained.

Surveillance has been advanced by publication of definitions of infections for the home care setting *(61)*, although the definitions have not been validated. Of necessity, these definitions rely more heavily on clinical signs and symptoms and tests that can be performed at the bedside like urine dipstick testing. For instance, according to the Centers for Disease Control and Prevention definitions of infection for hospitalized patients *(62)*, the diagnosis of pneumonia requires an abnormal or changed chest radiograph. Healthcare-associated pneumonia in a home care patient may be diagnosed without chest radiograph if the patient has any three of the following signs or symptoms:

1. New *or* increased cough
2. New *or* increased sputum production
3. New *or* increased purulence of sputum
4. Fever
5. Pleuritic chest pain
6. New *or* increased physical finding on chest examination
   a. Rales
   b. Rhonchi
   c. Bronchial breathing
7. Change in status or breathing difficulty
   a. New *or* increased shortness of breath
   b. Respiratory rate >25 per minute
   c. Worsening mental or functional status

Surveillance data should be collected and reviewed by the IP. Both outcome (e.g., BSIs per 1,000 central line days) and process (e.g., compliance with hand hygiene) measures may be monitored. Data can be used to provide valuable information to healthcare providers about the patient's condition, such as detection of febrile episodes in home care patients with hematologic malignancies. Surveillance in the home is also useful for detection of home care–associated outbreaks such as BSIs *(63)*. This is the ideal setting for focused surveillance, including collecting data on a few select infections such as IV-related infections, wound infections, or UTIs. Tracking device-related infections such as BSIs in patients with central lines and UTIs in catheterized patients has the advantage of focusing on high-risk patients and enabling collection of meaningful denominator data (e.g., BSI per 1,000 central line days). Finally, surveillance data facilitate patient safety and quality of care assessment in the home.

Asepsis, Disinfection, and Hygiene

Perhaps the most important infection control measure in the home setting is hand hygiene. A recent guideline recommends a 15-second soap and water scrub or using an alcohol-based rub until dry *(64)*. Waterless agents are convenient since running water is not always available. Adherence to hand hygiene by healthcare providers should be monitored, likely with observation in the home setting.

Reusable objects that touch mucous membranes, such as suction catheters and glass thermometers, should be limited to use on one patient and may be disinfected between uses on the same patient. A discussion of disinfectants is available *(65)*; bleach, 70% alcohol, and 3% hydrogen peroxide are good disinfectants for the home setting. Some household disinfectants (e.g., bleach) have activity against virtually all agents tested, including polioviruses (66).

The home care provider should educate patients and families on the basics of hygiene and asepsis to minimize the risk of infection transmission. This risk was demonstrated by acquisition of hepatitis C by a hemophiliac child from his mother during infusion of clotting factor concentrate in the home *(67)*. One survey of hemophiliac patients found inadequate infection control practices in the home *(68)*; frequent needlestick injuries were noted (often during recapping) and gloves were often not used for cleaning up blood spills or during blood product infusions.

While there are infectious risks in the household, there is little information on rational approaches to control of those risks. Hand hygiene is felt to be the most important measure *(69)*, and a risk-based approach has been suggested (70). Thus, more stringent environmental cleaning

FIGURE 99-1 Home nursing bag. Contents relevant to infection control: nursing bag, biohazard transport bag, biohazard bag, sharps container, isolation gown, masks, N-95 mask, gloves, goggles, cardiopulmonary resuscitation mask, antimicrobial hand soap and paper towels, hand sanitizer, gauze sponges, germicidal wipes, thermometer, methicillin-resistant *S. aureus* kit. The latter contains a disposable stethoscope, red biohazard disposal bag, disposable adult blood pressure cuff and a clear bag. (Courtesy of Bridget Young, Visiting Nurse Association of the Midlands, Omaha, Nebraska.)

may be appropriate for highly immunosuppressed patients such as transplant recipients. One randomized study of households assigned to cleaning with or without cleaning products with antibacterial properties found no significant difference in viral infections in the households *(71)*.

The home nursing bag is an important piece of equipment for the home healthcare professional (Fig. 99-1). The inside of the bag should ideally be clean, although the outside of the bag is often contaminated *(72)*. Contaminated items that cannot be cleaned or discarded in the home should be placed in an impervious container in the nursing bag, and hands should be washed before handling equipment inside the bag. The bag should contain a spill kit to deal with large volume of blood or body fluid spills.

Isolation Issues

Isolation techniques used in the home should follow the general principles of standard precautions *(73)*. Basic protective measures are indicated for use with all patients. This includes wearing gloves for contact with blood and body fluids, wearing masks for contact with a patient who is coughing frequently or unable to control secretions, and using a cover gown or apron if soiling with blood or body fluids is likely. Goggles should be available to protect the eyes from splattering of blood or body fluids. Blood spills should be cleaned up, after donning gloves, with a 1:10 to 1:100 solution of fresh bleach, and good hand hygiene technique should be followed.

Transmission-based precautions are additional barriers needed for patients with certain contagious diseases. For example, masks are also necessary for contact with a patient who has a contagious disease such as tuberculosis, influenza, mumps, measles, chickenpox, or pertussis. The high prevalence of patients carrying unknown infectious diseases such as MDROs, HIV, and hepatitis C underscores the importance of barrier precautions. Items such as gloves, goggles, gowns, and masks should be in the home nursing bag (Fig. 99-1). See Chapter 90 for more information on isolation precautions for patients with communicable diseases.

Waste Disposal

State regulations for medical waste vary considerably and may require the healthcare provider to remove medical waste generated in the home *(74)*. Liquid wastes, such as urine, can be flushed down the toilet, with care being taken to avoid splashing during disposal. Used needles and other sharp objects should be placed in a puncture-resistant container such as a portable sharps container. Other contaminated materials can be placed in a plastic bag that is sealed and discarded in the routine trash disposal system. The Environmental Protection Agency provides information on waste disposal in the home care environment including recycling and disposal options *(75)*.

Employee Health Program

Employee health information for hospital employees is available in the medical literature and in many cases is applicable to the home healthcare professional *(76,77)*. The employee should have updated immunizations, including tetanus, diphtheria, pertussis, measles, mumps, rubella, influenza, and hepatitis B. The varicella immune status should be known. Baseline and periodic tuberculosis skin testing should be performed. Other issues to be addressed include a protocol for postexposure prophylaxis for exposures to blood or body fluids containing HIV and hepatitis B or C *(78)* and recommendations for work restrictions for ill employees (see Chapters 73–76).

Employee education in infection control is an important part of employee protection. A study of home healthcare workers found that most blood exposures could have been prevented by simple glove use *(79)*. Employees need to be educated in Standard Precautions, barrier precautions for specific contagious diseases, and reporting of exposures.

There are significant data on the frequency of percutaneous injuries in home health nurses. In one survey, 14% of registered nurses reported one or more percutaneous injuries in the prior 3 years (80), while several surveys found that only about half of the needlestick exposures were formally reported to their employers (80,*81*). Injuries correlated with lack of compliance with Standard Precautions and use of available personal protective equipment (PPE) such as gloves, masks and gowns *(82)*. The infection control program should monitor employee compliance with preventive measures (e.g., influenza vaccination) as well as employee exposures.

Quality Improvement/Patient Safety

Quality or performance improvement (PI) principles can be applied to home healthcare as well as to healthcare facilities. The Joint Commission has proposed standards for patient safety in home care *(83)* as part of its ORYX initiative. This is an error-reduction program in which data collected are incorporated into PI initiatives. Elements to be studied include infection control, surveillance, and disease reporting. Measurable outcome indicators should

be selected, such as immunization levels, compliance with infection control practices, employee exposures, medication errors *(84)*, or home care–associated infection incidence.

The Centers for Medicare and Medicaid Services (CMS) in collaboration with the Centers for Health Policy Research has developed the Outcome and Assessment Information Set (OASIS) to measure patient outcomes and improve quality in home care. In 2008, a new risk-adjustment model for publicly reporting quality measures was created for home health OASIS, which can be found on the CMS Web site (www.medicare.gov) under Home Health Agencies. The updated OASIS data sets were implemented in 2010, and the user manual is available online (*85*, and see Chapters 10–12). Although case mix adjustments have been included, there have been problems with both ORYX and OASIS data sets regarding standardization of definitions and completeness of data *(86)*.

CMS has used OASIS to collect performance-based quality information. The CMS quality domains are effectiveness, efficiency, equity, patient centeredness, safety, and timeliness *(85)*. Risk adjustment is critical in the process of quality assessment in the home setting *(87)*. PI studies in the home setting have been shown to be feasible (88). Examples of publically reported quality measures include outcome measures (such as improvement in status of surgical wounds and acute care hospitalization) as well as process measures (such as whether pressure ulcer risk assessment was conducted, whether influenza vaccine was administered annually, and whether pneumococcal vaccine was ever administered).

Disease Reporting and Regulatory Compliance

Proper reporting is an important issue to be considered by the home healthcare professional. Home care–associated infections may be initially detected by the visiting home health practitioners and should be reported to patients' physicians for consideration of therapy and to the appropriate hospital or LTCF (if they are institutionally acquired). Contagious diseases (e.g., hepatitis, tuberculosis, impetigo, pertussis, and scabies) are especially important to report, and certain diseases are reportable to the health department. A proper home healthcare medical record should be kept.

The IP needs to be aware of regulatory compliance issues including Medicare, the Joint Commission *(89)*, the Occupational Safety and Health Administration, and state and local regulations that affect home care.

Home Healthcare and Preparedness

The home healthcare industry would be significantly affected by a national or regional disaster. Disaster preparedness involves a number of areas (see Table 99-4), including an internal readiness assessment, development of a disaster plan, and exercising the plan (e.g., in a tabletop simulated disaster drill). Before a disaster occurs, the issues of command and control must be clearly delineated and roles well defined. Reimbursement will depend on concurrent documentation, and communication is vital (e.g., with other healthcare facilities, public health, suppliers).

In any major disaster, hospitals and LTCFs will rapidly exceed capacity; hence, ill patients who normally reside therein may be discharged earlier to home care *(90)*. At the same time, the agency workforce may be depleted due to personnel who are ill, injured, or unwilling to report to work (e.g., in a SARS or influenza pandemic). This may necessitate healthcare personnel performing tasks beyond their normal scope of practice. If the event is an infectious disease, personal protective equipment will need to be provided even if normal supplies are disrupted. Mental health support is also important for healthcare providers during a crisis. Individual home healthcare workers should do some advanced planning in the area of personal preparedness *(91)*.

Preparedness reflects the growth and diversity of the home healthcare role. Home healthcare represents a dynamic equilibrium between the community and healthcare facilities like hospitals and LTCFs.

CHAPTER 100

Infection Control in Countries with Limited Resources

Paul A. Tambyah, Nordiah A. Jalil, and Jennifer Ho

Infection control in developing countries that are relatively resource limited is a challenging topic. Rarely do we hear about "road construction in developing countries" or "airplane navigation in developing countries" as there are often basic universal standards that are adopted in all countries regardless of their wealth or affluence in the fields of building construction, road maintenance, and airport safety. Of course, the reality is that the implementation of these standards varies considerably as has been seen with tragic effect in the tremendous death and destruction that have followed natural disasters such as earthquakes in Haiti or Sichuan. These are in contrast with the relatively limited human impact of the higher magnitude earthquake in developed countries with strict building codes and enforcement of regulations. Similarly in the infection prevention and control field, there are those who argue that the standards for infection control for developing countries must be the same as they are for developed countries *(1)*.

While this would appear to be an ideal, the reality is obvious—the gulf in resources is often so great that it would be impossible to expect poor countries to have the same standards in healthcare or building or airports as rich countries. This has been the rationale in the past for avoiding "unattainable targets" and somewhat mirrors the huge debate that is going on in the United States on whether "zero" is an attainable goal for the prevention of healthcare-associated infections (HAIs) (2). Even the opponents of "unrealistic targets" would agree that such goals are ideal. Indeed, a review of process measures and outcomes in central line–associated bloodstream infections (CLABSIs) in US and non-US (including Middle Eastern and Latin American) hospitals showed no significant differences between US hospitals in terms of infection control infrastructure, practices, and CLABSI rates *(3)*. This suggests that given a commitment to improving standards and processes together with adequate resources, there is no reason why healthcare facilities in the "developing" world cannot achieve standards of infection control comparable to the United States. The key issue is thus to ensure that the capacity is built up locally so that these universal standards of infection control can be realistically implemented in stages, if necessary, beginning with the most fundamental.

Often the resources available for healthcare are simply not available at the onset. In many developing countries, healthcare is seen as a lower priority on the national agenda, and even within healthcare, preventing HAIs has a lower priority than preventing infant or maternal mortality, for example, and probably rightly so. In addition, "structural adjustment programs" instituted by international financial authorities have mandated "user fees" and other restrictions on spending on government subsidies for healthcare *(4)*. However, there is light at the end of the tunnel! The recent developments in international relations including the commitment of leading industrialized countries to the Millennium Development Goals, together with the involvements of foundations such as the Gates and Clinton Foundations and programs such as PEPFAR, have put global public health firmly near the top of the international agenda, especially in development circles. Again, while the majority of these goals relate to maternal and child health, it has been recognized that the gains in maternal and child health will be rapidly lost if insufficient attention is paid to the prevention of infections associated with delivery and provision of basic child health services.

Furthermore, the World Health Organization (WHO) has taken the lead in global patient safety with its successive and successful global patient safety challenges (5). The WHO was founded in 1945 together with a number of international bodies including the United Nations out of the embers of the Second World War. It was the successor to the Office International d'Hygiene Publique of the League of Nations that was established primarily to prevent the cross-border transmission of infectious diseases, most notably cholera and plague. The WHO has a distinguished track record, most notably for leading the efforts to eliminate the scourge of smallpox. That was a concerted global effort driven across international and ideological divides—as a result, a disease that once claimed the lives of millions was finally eliminated in 1978. To date, this is the only disease that has ever been eliminated from the face of the earth. It is striking that the last cases of smallpox in history were acquired through laboratory transmission at a university medical facility in Birmingham, United Kingdom *(6)*. This led to marked improvements in biosafety worldwide. In recent years, the WHO has been at the forefront of the battle against emerging infectious

diseases, most notably during the SARS crisis. This was an unprecedented international collaboration that resulted in the rapid identification of a novel emerging pathogen from East Asia and international efforts to prevent its spread *(7)*. Although several agencies were involved in controlling SARS, the WHO was limited by the fact that it was unable to work in Taiwan, one of the affected areas, because Taiwan had been denied representation at the WHO *(8)*. The WHO published guidelines, notably case definitions for epidemiological purposes and issued travel advisories as well as sent experts to the affected areas through its Global Alert and Outbreak Response Network. These all contributed significantly to what was essentially an infection control response to an emerging pathogen and also raised the credibility and status of the WHO.

One of the other legacies of the SARS response was the strengthening of the International Health Regulations (IHRs) in 2005. The amendments were made to the regulations because of the recognition that failure to recognize, document, and at least attempt to control an emerging infectious disease outbreak in one part of the globe would have international consequences. The revised IHRs were adopted at the World Health Assembly in 2005 to "prevent, protect against, control and provide a public health response to the international spread of disease." Details of the revised IHR are available online at http://www.who.int/ihr/en/.

The WHO published its core components for infection prevention, and control programs earlier this year (9). These are the critical elements that have to be incorporated into *all* countries' national and local healthcare authorities. This forms a practical framework by which infection prevention and control programs can be structured in developing and developed countries. A summary of the core components is given in Table 100-1. We believe that a stepwise approach to infection control in low-income countries beginning with the basic elements covered by the core components should be part of every country's national health program.

The rest of this chapter is organized according to the WHO core components.

FORMAL ORGANIZED STRUCTURE

At the national level, this should include a national authority with qualified staff, a budget, and defined functions. This authority should also be tasked with ensuring preparedness and coordination of infection control and prevention activities for communicable diseases. At the local hospital level, each hospital should have dedicated leadership and authority for infection and control programs.

The ministries of health of most countries are concerned with many issues including maternal and child health; regulation and provision of primary, secondary, and tertiary healthcare; and often the training of physicians, nurses, and allied healthcare professionals. Few countries in the developing world have national infection control bodies similar to the different agencies operating within the U.S. Centers for Diseases Control and Prevention (CDC), for example. However, with the advent of the IHR, all countries are required to have some system in place for monitoring, detection, and reporting of outbreaks of international health significance. Some countries such as Egypt have established an infection control program within the Ministry of Health and Population *(10)*.

The Egyptian experience is very instructive. The national infection control program was developed in response to widespread outbreaks of blood-borne pathogens that were widely reported in both scientific and lay media. These included some of the world's highest rates of hepatitis C as an indirect result of widespread campaigns for population-based eradication of schistosomiasis *(11)* and outbreaks of HIV infection associated with dialysis centers *(12,13)*. There was the recognition by national health authorities that something had to be done to control the spread of infections in both private and public healthcare institutions. In addition to these highly publicized outbreaks of blood-borne pathogens, there were scientific studies documenting a high prevalence of HAIs in Egypt *(14)*, as well as antibiotic-resistant infections, in particular, those caused by extended-spectrum beta-lactamase–producing gram-negative bacilli (15).

This led to the formation of a working group that included the U.S. Naval Medical Research Unit, the WHO, several Egyptian universities, medical schools, professional bodies, and nongovernmental organizations. This eventually led to the creation of a department within the Ministry of Health and Population and the publication of national guidelines, establishment of training programs, promotion of infection control advocacy, and institution of regulatory measures to ensure attention to critical supplies and occupational health (15).

With a number of variations, the same thing has happened in many other countries in Asia, Africa, and Central and South America. A crisis occurs—most memorably, the SARS and avian influenza outbreaks resulting in huge amounts of media attention, much of it critical. This has led to major changes in most of the affected countries both at the central and the local hospital level to prepare for emerging infectious diseases including healthcare-associated respiratory viral infections *(16)*. In many of these countries, the national health authorities have become much more sensitized to infection control, especially to novel emerging pathogens. This was played out during the recent influenza A H1N1 2009 pandemic when many of the SARS-affected countries reacted very strongly to the new influenza *(17)*.

While these highly publicized outbreaks followed by strong public health–driven responses can provide a boost for infection control efforts in a country, it is the follow-up after the initial burst of attention that is the most challenging. The situation in Egypt was aided by international collaborations as well as strong participation by local experts. This is likely to be a sustainable approach in many middle-income countries as well as those with strong international collaborations or with well-developed domestic medical expertise such as India or the Philippines. The challenge is greatest in the least developed countries where medical resources are extremely limited, especially in those countries that are currently beset by civil war where even the provision of basic healthcare is severely constrained. Paradoxically, those are the settings with the greatest needs for infection control.

TABLE 100-1

Essential Requirements for Infection Control for ALL Countries Based on the World Health Organization's Core Components

(a) Infection control infrastructure
- Ministry of Health section dedicated to infection control
- Each healthcare facility should have a designated infection control officer
- A multidisciplinary infection control team should be constituted in each healthcare facility and should be recognized for its work
- There should be integration between the local infection control team, infection control officer, and national and international agencies

(b) Technical guidelines
- National Infection Control Guidelines, which can be adapted from WHO regional office guidelines
- Written Hospital Infection Control Policy, which can be an adaptation of national guidelines

(c) Trained healthcare workers
- There should be access to training either locally or through international or regional agencies for infection prevention and control staff
- Healthcare worker protection needs to be a priority specifically addressing blood-borne pathogens and healthcare-associated respiratory infections including tuberculosis and respiratory viruses
- A concerted effort should be undertaken to reduce injections and ensure that sharps are safely disposed

(d) Surveillance
- There should be some kind of surveillance system in place for healthcare-associated infections. At its most rudimentary, this can be surveillance for in-hospital mortality or readmissions or returns to the operating room for infection
- Surveillance should make use of what technology is available including mobile phone technology
- Checklists should be implemented to reduce the incidence of surgical site infections
- Closed urinary catheter drainage should be used with improvisation, if necessary, to ensure closed drainage
- A system of reminders possibly nurse based should be used to reduce the utilization of devices including urinary catheters
- Sedation protocols and education on aseptic technique are important for all facilities that mechanically ventilate patients
- Oral rehydration should be encouraged as much as possible to reduce the use of vascular access devices including peripheral intravenous catheters
- Bundles should be considered in attempts to reduce the incidence of central line–associated bloodstream infection

(e) Microbiology laboratory
- All healthcare facilities should have access to a microbiology laboratory
- The laboratory should make use of software such as WHONET to generate local antibiograms
- These surveillance data should preferably be aggregated at a national level to monitor the emergence of novel and resistant pathogens
- External quality assurance whether national or international should be considered for all microbiology laboratories

(f) Environment
- Healthcare facilities should ensure clean and safe water for clinical use
- Adequate ventilation should be provided for healthcare facilities using natural cross-ventilation if appropriate
- Locally produced, alcohol-based handrubs can be used effectively even in settings without running water

(g) Monitoring and evaluation of programs
- Infection prevention and control programs should be monitored on a regular basis, both internally and externally

(h) Links with public health and other services
- Procedures have to be in place to ensure adequate linkages with ministries of health and agriculture and other appropriate agencies in preparation for pandemic or epidemic infections
- Adequate waste management procedures need to be in place including incineration of medical waste
- Sterilization and disinfection need to be adequately monitored

This need in the least developed countries is best illustrated by the cholera outbreak in Goma a decade ago. During the Rwandan genocide, thousands of refugees fled their homes and were assembled in refugee camps, most notably in Goma, eastern Zaire (now the Democratic Republic of the Congo). The camps in Goma were affected by a devastating outbreak of cholera that claimed more than 10,000 lives *(18)*. Case fatality rates were as high as 48% on a single day, while the pandemic cholera in the neighboring country of Burundi had a case fatality rate of 6% to 1% *(19)*. While the majority of the deaths in Goma were ascribed to problems with the clinical management of individual cases of cholera, it is quite likely that failures in infection control led to an exacerbation of an already difficult situation in the camps.

In "peacetime" as well as in disasters, in many of these countries with very limited resources, basic healthcare is often provided either by traditional healers or

by international aid organizations. In the absence of a well-functioning national health authority, it is critical therefore that the international organizations that provide disaster or emergency relief have well-established infection control guidelines and policies that can be transferred to the local situation and even perhaps transmitted to traditional healers. This has been well recognized for outbreaks of viral hemorrhagic fevers—Ebola and Marburg—but should perhaps be part of the standard operating practice for all international aid organizations providing emergency and disaster assistance. The renowned international aid organization Medicins Sans Frontiers (MSF) was involved in the response to the Marburg virus outbreak in Angola in 2005 *(20)*. When the first few cases were recognized by the doctors in Uige, Angola, in March 2005, an international response was coordinated by the Angolan Ministry of Health and the WHO. MSF helped to establish an isolation facility—a Marburg ward—to ensure the isolation of patients with viral hemorrhagic fever and to ensure that those patients received some care. The ward was eventually handed over to the local authorities in June 2005, and the outbreak officially ended in July 2005. In the process, 18 healthcare workers (HCWs) died from Marburg hemorrhagic fever. There were many challenges in the MSF response to that outbreak including attempting to alter existing protocols, providing psychological support and providing supportive care for patients infected with viral hemorrhagic fevers.

While traditional healers have been recruited for the control of sexually transmitted infections and HIV/AIDS *(21)* to our knowledge, there are limited efforts to engage traditional healers in the practice of infection control. There is evidence that many people in developing countries would seek traditional healers before "Western" medicine for symptoms that might be related to contagious respiratory illnesses such as tuberculosis (TB) *(22)*. It does make sense that national health authorities are trusted and consulted far more often than modern medical facilities in the overall infection control program. The specifics of how to go about doing this are a challenge and remain to be worked out.

In between these extremes of deadly viral hemorrhagic fevers in remote hospitals, and middle-income countries with the potential to develop mini-CDCs, the majority of limited healthcare resource facilities have the potential to develop a national infection control authority that can establish at least some kind of reporting system for hospital mortality, ensure that there is a national plan for preparedness for diseases of international health significance as defined by the WHO's IHR, and have trained individuals who can enforce these plans. International agencies that provide assistance to these countries have the opportunity to assist in the development of these national authorities by providing training and short attachments with their own national infection control agencies that can be invaluable to developing country leaders in infection control.

At the local hospital or healthcare facility level, each hospital needs at least an infection control officer or a senior clinician, a laboratorian, or an administrator who reports to the chief of the facility who has at least 50% of his or her time devoted to infection control and prevention. Although the WHO document does not specify the specific fraction of time that needs to be dedicated to infection control and prevention, there are data from the SENIC study that show that hospitals with a dedicated healthcare epidemiologist have a reduced risk of HAI *(23)*.

In reality, most hospitals in developing countries, and many hospitals in developed countries, especially in rural or inner city settings, do not have a full-time healthcare epidemiologist. In countries where regulatory requirements mandate the designation of a healthcare epidemiologist or "infection control doctor," often, the person so designated does not have the required training or expertise. In the best of cases, the hospital microbiologist is designated as the infection control officer. In hospitals without a full-time microbiologist, often some other clinician—an internist, an intensive care unit (ICU) doctor, or a senior nurse clinician—is assigned the responsibility.

This is an opportunity for international agencies and professional scientific societies to provide training to HCWs from developing countries who have an interest in infection control so that they can take on the role of the infection control officer and lead an infection control team (ICT) at their own local healthcare facility.

In Brazil *(24)*, the Brazilian Ministry of Health mandated the establishment of hospital infection control committees in 1983, but the impact was limited. Subsequently, two other decrees were issued that led to the introduction of hospital infection control services with mandated staffing levels and independence. Physicians assigned to infection control are to be paid for 4 hours daily, while nurses are paid for 6 hours daily. Over the years, the structure and organization of infection control have evolved in Brazil, so that in many centers, interventions have been practiced that have a marked impact on patient care *(25)*.

The minimum that every developing country should have in terms of infection control infrastructure are as follows:

a. In the absence of a national infection control authority, a designated section of the Ministry of Health responsible for infection prevention and control.
b. At the local hospital, each hospital should have a significantly senior physician or administrator designated as the infection control officer for the hospital, who is empowered to take action for infection prevention and control activities.
c. Each healthcare facility should have an ICT made up of nurses, physicians, laboratory staff, and those with the expertise required for effective infection control and prevention activities.
d. It would be good to integrate the activities of the ICTs and authorities with international bodies including aid agencies and local medical facilities including traditional healers.

TECHNICAL GUIDELINES

Technical guidelines should be developed and disseminated at the national level for prevention and control of infections.

As mentioned above, national infection control guidelines have been developed and published in many developing

countries such as Egypt (15) and Brazil *(24)*. While countries might not have their own local infection control guidelines, regional bodies, such as the regional offices of the WHO, have issued guidelines primarily aimed at novel influenza. For example, the Western Pacific and Southeast Asian regional offices (WIPRO and SEARO) have published guidelines that are freely available online at http://www.wpro.who.int/NR/rdonlyres/006EF250-6B11-42B4-BA17-C98D413BE8B8/0/practical_guidelines_infection_control.pdf.

These guidelines were written mainly in response to the SARS epidemic when it became apparent that many countries in the Southeast Asian and Western Pacific region did not have much of the essential infrastructure that has been taken for granted in many developed countries (26). These guidelines are appropriately entitled "Practical Guidelines for Infection Control in Healthcare Facilities" and cover the whole range of infection control activities ranging from establishing an infection control program, the recommended structure and accountability for the infection control program to practical issues such as Standard Precautions, transmission-based precautions, environmental management including air and water, waste management, reuse of devices, disinfection and sterilization, care of HCWs, and special situations such as SARS, multiresistant microorganisms, and viral hemorrhagic fevers. These guidelines bearing the imprimatur of the WHO are accessible to countries in the region and can form the basis for national infection control guidelines.

These guidelines were published in 2004 and did not cover avian or pandemic influenza. The avian influenza zoonotic pandemic began to cause a great deal of concern in 2005 to 2006, and as a result, new guidelines were published to cover infection control for avian influenza and pandemic influenza. These guidelines were updated and, interestingly enough, had differences with the US CDC guidelines that were published around the same time. The differences between the US CDC guideline and the WHO guideline probably reflect the limited resources available to most WHO member countries. In particular, the US CDC recommended N95 respirators for all patients with pandemic influenza, while the WHO guidelines, from the beginning, recommended surgical masks.

At the local hospital level, the WHO core components include a recommendation that each hospital or healthcare facility draw up its own infection control policy (9). Most of these can be devised by adapting the WHO practical infection control guidelines, but other guidelines are available from international organizations such as the International Federation for Infection Control (IFIC; available at http://www.theific.org/) and the Asia Pacific Society for Infection Control (APSIC), among others. Many developing countries in Asia have developed their own local guidelines, some of which are shown in Figure 100-1.

These infection control policies should be published locally in the form of infection control manuals. These manuals can be taken off templates using the WHO, IFIC, or APSIC guidelines and then adapted to local conditions with details such as the contact person for sharps injuries, specifics about waste disposal, and other details added in to make the manuals useful for staff in the local healthcare facility. An example of this is the Infection Control Manual

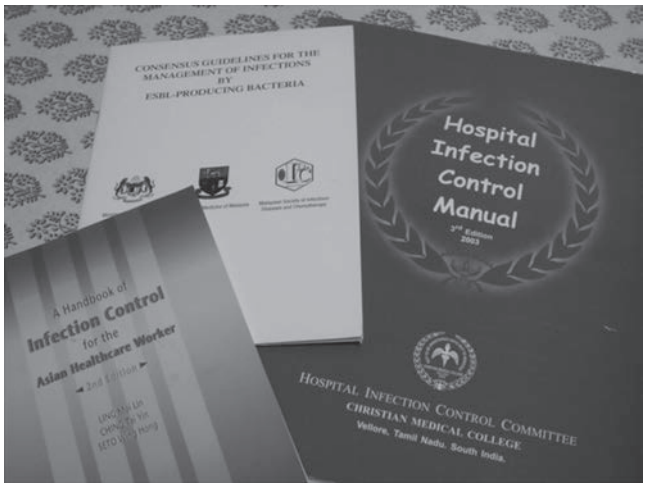

FIGURE 100-1 Infection control guidelines published at the local, national and regional level in Asia.

produced by the Christian Medical College in Vellore, India. This has been produced locally at a tertiary hospital in a rural setting in India and is widely disseminated in India through training programs conducted by faculty of the Christian Medical College, Vellore, in collaboration with international organizations such as the Society for Healthcare Epidemiology of America.

Many hospitals, especially in the middle-income countries in Asia, have sought accreditation from international bodies such as the Joint Commission International (JCI). The JCI has highlighted infection prevention and control as one of the key areas in its accreditation process. JCI-accredited hospitals can be found in Bangladesh, Brazil, Egypt, Indonesia, Jordan, the Kingdom of Saudi Arabia, Malaysia, Mexico, Thailand, Turkey, Vietnam, and Yemen, to name a few of the countries where healthcare facilities have met the criteria for JCI accreditation. This perhaps illustrates some of the issues with intracountry differences in the quality of healthcare delivery as some of these countries also have predominantly rural areas with very limited resources for healthcare and little in the way of infection control practices. At the same time, the presence of internationally accredited institutions in many developing countries provides a living demonstration of what can be achieved outside of Europe, Australasia, and North America. Many HCWs or their families will go to these facilities for their own healthcare. They experience the impact of international best practices without having to travel to some remote high-tech international location, but rather in their own country. The impact of JCI accreditation with improvements in medical technology in these hospitals will surely be felt over time. The diffusion of infection control standards thus could potentially be aided by good practices within centers of excellence, private or public in these developing countries.

Accreditation does not need to be done by an international agency. In the middle-income countries with established cores of well-trained individuals, accreditation by a credible government or non-governmental body can help to raise standards in infection control and

patient safety. This has been noted in the Lebanon *(27)*. In countries with even more limited resources, assistance from international aid agencies can be tapped to provide hospital accreditation standards to cover infection control practices in both urban and rural healthcare facilities. An example of this is in Uganda *(28)*, where assistance from USAID helped establish the Yellow Star hospital accreditation project in 2000. Although the project was not funded from 2005 onward, there remained a strong desire among leaders of local Ugandan healthcare facilities for an accreditation program for hospitals that encompassed infection control protocols, patient safety, and various infrastructure standards.

There is clearly a demand from the citizens of low-resourced countries for quality healthcare delivered locally at affordable prices. Governments and healthcare providers will need to respond to this demand, and accreditation of infection control programs will be a critical element in this drive.

At a minimum, each developing country should have the following:

a. National guidelines on infection control—these can be simple adaptations of the WHO practical guidelines for infection control.
b. Each healthcare facility should have its own infection control policy—these policies can be based on international guidelines from organizations such as the WHO, IFIC, and APSIC and need to be locally adapted. These policies need to be available to staff and disseminated as widely as possible.

HUMAN RESOURCES

At the national level, there should be standards for adequate staffing of infection preventionists and protocols or opportunities for training of HCWs in infection control.

International medical and nursing education has developed a great deal in recent years. There has been a proliferation of medical and nursing schools, and many of these in Asia, Africa, and Latin America have been established in collaboration with major teaching institutions from Europe, North America, and Australia. While the tertiary education sector is a major site for training of medical and nursing professionals in infection control, continuing education and outreach efforts into primary care settings are critical, because this is where the bulk of healthcare is delivered.

Countries need to establish national standards for training for infection preventionists. This has not been universally done in developed countries, but opportunities abound for developing countries, in particular middle-income developing countries that have partnerships and educational collaborations with developed countries.

Many countries do not have specialized training for infection control nurses or physicians. There are courses available, although these are primarily provided by professional societies such as the Society for Healthcare Epidemiology in America, the Hospital Infection Society, and the Association for Professionals in Infection Control and Epidemiology. Some universities provide postgraduate diplomas or degrees with a focus on infection control, but these are very limited. The experience of South Korea is instructive. Although Korea is not a limited-resource country, there are lessons to be learned from the experience there. In 1992, the Ministry of Health and Welfare in Korea mandated that every hospital with more than 80 beds needed to have an infection control committee. In 2003, a graduate specialist training program for nurses with a specialization in infection control was introduced *(29)*. This has raised the professionalism of infection preventionists and has raised the salaries and status of infection control nurse professionals.

In addition to training and providing the human resources to staff infection control programs, HCW safety is a critical issue in developing countries. HCWs in developing countries are exposed to infectious risks at least an order of magnitude higher than HCWs in developed countries.

Blood-Borne Pathogens

The rates of HIV, hepatitis B, and hepatitis C are much higher in many developing countries compared with developed countries. For example, the rates of hepatitis B in China can be as high as 7% to 9% *(30)*, and in West Africa, hospitalized patients have a hepatitis B seropositivity rate of 15% to 20% *(31)*. Many countries do not have national vaccination programs for hepatitis B vaccination *(32–34)*. This is critical. Hepatitis B vaccination has been shown to be highly effective in prevention of hepatitis and its complications. HCWs worldwide have a higher rate of death from hepatitis and its complications—this was noted in developed countries before the onset of Universal Precautions and hepatitis B vaccination. Efforts are under way to increase the hepatitis B vaccination rates for healthcare providers in developing countries. A recent study conducted in Uganda *(35)* found a hepatitis B vaccination rate of only 6%. Nearly half of all HCWs in that Ugandan tertiary hospital were still susceptible to hepatitis B. Volunteers or those who are going to provide healthcare in mission or relief efforts must be aware of the hepatitis risks and should make sure that they are up to date with hepatitis B vaccination.

HIV rates are very high in many developing countries, especially in sub-Saharan Africa. There is evidence that there are high levels of ongoing healthcare-associated transmission of HIV in healthcare facilities in these settings *(36)*. Postexposure prophylaxis for HCWs who sustain sharps injuries in these settings are not often routinely available. This has to be a high priority for any infection control program. Medical students and HCWs from developed countries who travel to areas with a high endemicity of HIV have been known to take along their own supply of postexposure prophylaxis for HIV *(37)*. This raises a number of ethical questions as the local staff are exposed obviously for far longer to greater risks. Other issues that have arisen are the high rates of resistance to antiretrovirals that have been documented in some developed country settings and, more alarmingly, the absence of resistance testing in the vast majority of resource poor settings. If an HCW sustains a sharps injury from a patient with a high viral load of HIV with a resistant virus, the postexposure prophylaxis regime is likely to be far more complicated than most protocols currently extant in developing countries.

It is also more likely to require salvage therapies that might not be available in that country.

Hepatitis C is also endemic in many developing countries. Paradoxically, a large part of this endemicity is due to unsafe injection practices in the first place. Often, this is the unintended consequence of well-intentioned public health programs such as the schistosomiasis eradication program in Egypt *(38)*. Testing for hepatitis C is not widely available although ELISA testing for blood safety has increased the prevalence of hepatitis C testing markedly in many resource poor settings. There may be limited facilities for follow-up of HCWs who sustain sharps injuries from patients who are hepatitis C positive. While hepatitis C treatment is now routine in most developed countries, many developing countries lack access to the expensive agents used to treat hepatitis C and the notion of preemptive therapy as recommended in some centers is thus even more remote.

Other blood-borne pathogens are even more lethal—most notably the viral hemorrhagic fevers—Ebola and Marburg, which have claimed the lives of large numbers of HCWs *(39)*. Other viruses that have had documented transmissions and are endemic in the tropics include dengue fever *(40)*.

Sharps injuries in the developed world have been markedly reduced by the use of safety devices including needleless access devices, blood-drawing equipment with retractable needles, and other safety devices *(41)*. Many of these devices are not available in resource poor settings and HCWs need to take extra precautions to ensure that they do not sustain these injuries. Some simple interventions that can reduce sharps injuries in developing countries include the provision of adequate lighting during procedures; the use of simple, safe sharps disposal containers (Fig. 100-2); destruction of sharps to prevent their reuse; use of containers to transfer sharps in the operating room rather than passing instruments; and training staff to ensure that at least one-handed recapping is done if the process of two-handed recapping cannot be eliminated altogether.

In addition to the issue of patient-to-provider transmission of infection, the other concern about provider-to-patient transmission becomes particularly acute in settings with a high endemicity of blood-borne pathogens. In some Asian countries, for example, students are barred from medical school if they are found to be hepatitis B surface antigen positive *(42)*. This potentially acts as a powerful disincentive for HCWs to disclose their status and poses potential risks to patients and the HCWs themselves as they might not be adequately treated for their own infections. There have been very few reports of provider-to-patient transmission of blood-borne pathogens from developing countries despite the much higher seroprevalence. This is most likely a result of lack of investigation or detection of these outbreaks. There have been a couple of tragic outbreaks of HIV disease that have led to litigation where HCWs have been blamed for transmission of HIV to patients in Libya *(43)* and Kazakhstan (44). None has been completely explained, but these cases have caused a considerable amount of distress among HCWs in general and may contribute to increased stigmatization among HCWs looking after patients with HIV/AIDS.

The risks of blood-borne pathogens are very real, and even if the estimates that have been reported are on the high side, there are potentially hundreds of HCWs who are infected with HIV in developing countries every year. In these settings with intense stigma and discrimination, the pressure on these HCWs can be tremendous. There is already an exodus of HCWs from developing countries to the North *(45)*, and the fear of blood-borne pathogens can only act as another push factor. Ganczak et al. *(46)* made use of the Haddon matrix to identify the risk factors for sharps injuries in the United Arab Emirates and observed pre-event factors including lack of training, event-related factors such as failure to use safety equipment, and post-event factors such as underreporting.

In developed countries, the incidence of healthcare-associated HIV transmission has declined significantly with the advent of safer devices and widespread training, education, and use of postexposure prophylaxis *(47,48)*. It is hoped that well-designed prevention programs can help to reduce the risk of transmission of blood-borne pathogens to HCWs and patients in developing countries. The basics of these programs include the following:

a. Reducing injections—where possible, oral rehydration and oral medications should be used instead of the ubiquitous injections that are routinely given in many healthcare facilities in developing countries.
b. Ensuring safe disposal of sharps—solid sharps boxes should be available wherever sharps are used. These boxes should be promptly incinerated to reduce the opportunity for recycling of needles.
c. Use disposable gloves wherever possible for procedures involving sharps.
d. Practice no-touch transfers in operating rooms—by using containers rather than passing instruments from staff to staff.
e. Ensure that multidose vials are not used for multiple patients or, if they must be used, that fresh needles are used for each patient.
f. Ensure adequate lighting and infrastructure so that sharps are used in a safe manner.
g. Ensure that all healthcare personnel, who are not immune, are vaccinated against hepatitis B.

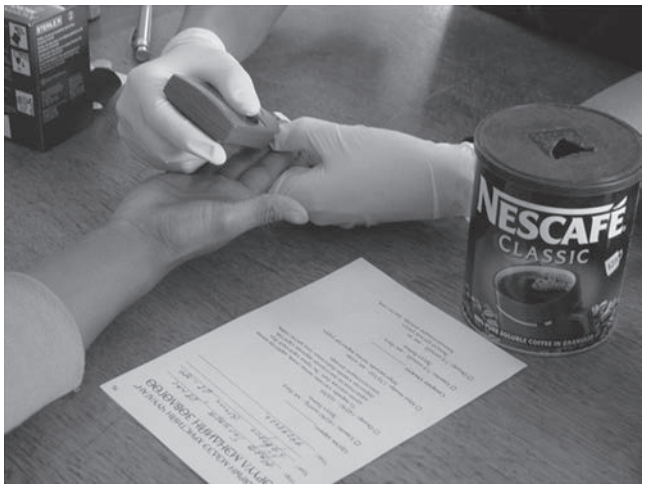

FIGURE 100-2 An improvised sharps box in East Asia.

Many of these recommendations are contained in the WHO document on reduction of blood-borne viral transmission in healthcare settings, which is available online at http://www.who.int/injection_safety/toolbox/docs/en/AM_HCW_Safety.pdf.

In addition to blood-borne pathogens, there are obvious concerns about respiratory pathogens. Here the literature is a little less clear. TB is the main disease that causes concern in Europe and North America, but there are also concerns about emerging respiratory viral pathogens. TB is endemic with very high rates of infection throughout the developing world. There have been documented healthcare-associated transmissions of TB with fatalities associated with drug-resistant TB *(49)*.

Interestingly, the majority of these outbreaks have occurred in the developed world—primarily in the United States. This is most certainly due to increased detection and recognition. There has been a recent review of extremely drug-resistant TB from South Africa, where 10 of 334 patients with extremely drug-resistant TB were found to be HCWs *(50)*. Eight of the ten were HIV-negative, and four of the ten died, despite treatment, probably because of delayed diagnosis. There are limited studies conducted in Malaysia *(51)* and documenting high rates of skin test conversion in HCWs in developing countries. Even in Singapore, which is not a developing country, interns working in public hospitals have an annual 5% conversion rate using interferon γ release assays to detect tuberculous infection *(52)*. On the other hand, there are data from Hong Kong that suggest HCWs have a lower TB rate than the general public (53). The argument made was that HCWs have a higher standard of living than the general public and that in turn might be associated with a lower rate of clinical TB.

In the United States, a hierarchy of controls including administrative controls, engineering controls, and personal protective equipment are used for protection against healthcare-associated transmission of TB to HCWs. Isolation in airborne isolation rooms with negative pressure is recommended *(54)*. These were almost nonexistent in most developing countries prior to the SARS and the avian influenza epidemics. With the emergence of these high-mortality infections with actual (SARS) and potential (avian influenza) healthcare-associated transmission, some facilities have been created in many developing countries (Fig. 100-3) *(55)*. While these facilities are unattainable in most low-resource countries, there are encouraging data that have come out showing that cross-ventilation especially in the older hospitals can be associated with higher air exchanges that can be achieved in many negative pressure rooms *(56)*. These air exchanges are also protective and using an animal model, the rates of TB transmission from patients with active cavitary disease are markedly lower in these rooms with good cross-ventilation, open windows, high ceilings, and ceiling fans. This was probably recognized a century ago in the design of older hospitals, many of which were situated on hills when TB was the major cause of death worldwide. It is reasonable to revive those ideas even as TB continues to plague many parts of the world and the specter of multidrug and extremely drug-resistant TB hangs over the world.

Disposable masks and N-95 respirators are not widely used in developing countries; however, cloth masks have been used for many years. These have been shown to be effective against pneumonic plague during the outbreaks of plague in Manchuria in the early part of the 20th century *(57)*. During the SARS crisis, in China, the 12-ply cloth mask was used primarily in most of the SARS wards and hospitals, and this successfully protected staff from contracting SARS *(58)*.

FIGURE 100-3 Negative pressure ICU in Southeast Asia.

In addition to TB, in recent years, there has been a much greater attention to influenza. Guidelines have been issued by both the WHO through its regional offices (WIPRO and SEARO) and many international governments in the developed and developing world. These are available online at http://www.searo.who.int/en/Section10/Section1027/Section1943.htm and http://www.who.int/csr/resources/publications/swineflu/en/.

While these guidelines focused mainly on pandemic and avian influenza, they have been carefully crafted to be applicable to all the member states of the WHO. These form a very useful base for infection control precautions both for endemic respiratory illnesses and for emerging and novel pathogens. The core elements of these are as follows:

a. Standard Precautions with an emphasis on hand hygiene and appropriate use of personal protective equipment and handling of samples, waste, and environmental surfaces.
b. Respiratory hygiene or cough etiquette.
c. Identification of potentially infectious cases. For novel pathogens, this would depend on broad clinical case criteria for the symptomatic and an even lower threshold for evaluation and observation for those who are contacts of confirmed or probable cases.
d. Patients who have confirmed or probable novel or avian influenza should be in well-ventilated single rooms or cohorted.
e. HCWs in developing countries should be at high priority for influenza vaccination when it becomes available, especially in situations with novel or pandemic viruses.

In summary, all developing countries need to have trained individuals who can conduct infection prevention and control programs. In addition, they need to ensure protection for staff from the following:

a. Blood-borne viruses: using vaccination for hepatitis B, reduced use and safe handling of sharps, and procedures for injury reporting, postexposure prophylaxis, and follow-up

b. Respiratory diseases: using adequate ventilation, administrative controls, appropriate personal protective equipment, and ventilation.

SURVEILLANCE

Surveillance should be standardized at the national level as far as possible with standardized case definitions and surveillance methods. At the local level, surveillance should include assessment of the local situation, selection of appropriate methods, and reporting.

Surveillance is an essential component of infection control programs worldwide. The objectives are to establish endemic baseline rates of HAI and to identify outbreaks and evaluate the effectiveness of IC prevention activities. Surveillance data can be used to identify preventable infections in high-risk areas, to help limited resources be more effectively targeted to high priority areas, for example, surgical site infections (SSIs) or ICU-acquired infections. Alert microorganism surveillance can be done if there is a good microbiology laboratory and support from the clinicians and senior management *(59)*. In developing countries with limited resources, the ICT can carry out basic surveillance to identify key issues and areas of concern. The simplest forms of surveillance that can be done at most hospitals and healthcare facilities in developing countries include mortality or readmission rates per surgical procedure or per ICU admission. Most healthcare facilities would at least track admissions and discharges for billing and state support purposes. These data can be mined to track trends in mortality, which act as a very crude measure of quality in institutions. This simple measure has not been widely practiced although a spike in hospital deaths is clearly something that administrators in developing countries would be very concerned about. If the ICT makes use of its expertise in healthcare epidemiology to conduct mortality surveillance for patients admitted to the ICUs, then this would be additional evidence of the value of an ICT to the healthcare facility in the developing country.

There have been a number of reports in both local and international media about deaths from complications of surgery in developing countries, and these have had a detrimental effect on allopathic healthcare in those countries. Similarly, there have been reports of SSIs in patients who travel to developing countries as medical tourists *(60,61)*. These highly publicized incidents involving medical tourists can only help to prompt the local authorities in developing countries to improve the safety of surgical procedures in their country.

Surgical site surveillance in developing countries can be done by a variety of methods as in developed countries. The sheer volume of workload handled by most surgical teams in these countries would probably preclude self-reporting by the surgical teams. In addition, even in many developing countries, the pressure on hospital beds has led to similar moves toward same-day surgery, which have occurred in the developed world. This has created problems in terms of postdischarge surveillance. These problems are even more acute as many individuals travel for long distances often over days to reach tertiary and secondary health facilities where they get their surgical procedures done. This makes it very difficult to track SSIs in patients from remote areas.

The WHO's second global patient safety challenge has been directed at safe surgery. This is a strategy aimed at all the WHO member states, the majority of which are low-resource countries. The key element in the strategy is the use of checklists. These incorporate elements including confirming the right site, right patient, equipment, and appropriate prophylactic antibiotics. This is freely available online at http://www.who.int/patientsafety/safesurgery/en/index.html. The WHO global patient safety challenge has been adopted by 300 institutions on five continents. Checklists have been shown in a variety of settings, including very resource limited ones to have a significant impact on clinical outcomes (62). This 19-point checklist, which was used in countries as diverse as India, Tanzania, England, Canada, and Jordan, was shown to significantly improve the timing of antimicrobial prophylaxis from 56% correct to 83% correct. The overall complication rate was reduced from 12% to 7% in the low-income sites and the mortality rate from surgical complications from 2.1% to 1% in those settings.

Periodic point prevalence surveillance can be used to monitor the effectiveness of infection control measures. These have been used previously in many countries using standardized methodologies that can be web based for ease of use.

In Iran, a series of point prevalence studies on bloodstream infections, urinary tract infections (UTIs), and SSIs were performed, revealing important data on the distribution of HAIs and providing a baseline for improvement programs *(63)*. Similar efforts have been undertaken in Saudi Arabia *(64)* and Malaysia *(65)*. The Malaysian study, in addition to detecting HAIs, also did an assessment of antimicrobial use.

In order for a point prevalence survey to be useful, it is critical that the staff members involved are trained and that the definitions and protocols are standardized. Many institutions use the US CDC's National Health and Safety Network (NHSN) definitions *(66)* as these are the most widely disseminated and are readily available. The concern is that on occasions, the interpretation and application of these definitions is not easy. For limited-resource countries that are planning on point prevalence surveys, it is critical to ensure that the surveyors are trained and tested. In addition, pilot surveys need to be conducted to validate the procedures and protocols. It would also be good for the results of the pilot surveys to be communicated to the clinical leaders in the relevant wards and facilities. This is very important as feedback can be provided to identify gaps that the surveyors might not be able to appreciate. The Internet can be used if hospitals and healthcare facilities across a country are conducting the point prevalence survey at the same time. This has been used successfully, for example, in the Pan EuroAsian Prevalence study of infections in urology *(67)*. A simple web-based data entry format is used for urology patients across the globe to assess community- and healthcare-associated UTIs. This global web-based effort in UTIs has continued to expand.

In many limited-resource settings, Internet access might be patchy and this might be a limitation for web-based surveillance systems. However, mobile phone networks have

a far greater penetration rate, and in many developing countries, mobile phones are used to communicate public health messages. It is possible that these might be used in the near future for surveillance of HAIs. In Sri Lanka *(68)*, field veterinarians used mobile phones to interact with central animal health surveillance authorities who received a marked increase in surveillance reports and detection of a possible outbreak in animals. In China, following the Sichuan earthquake, more than half of the infectious diseases reported to the local health authorities were reported by mobile phone *(69)*.

Mobile phone technology has probably even greater potential for national surveillance of HAI than for surveillance of HAIs in rural health as most healthcare facilities in developing countries are located in areas with reasonable mobile phone coverage.

In addition to doing surveillance for important outcomes such as SSI, length of stay, and mortality, it is also important that the ICT devote time to regular audits (process surveillance). Audits are usually simple to perform and are less resource intensive than outcome surveillance. They will help the ICT to identify inappropriate and unsafe infection control practices immediately. In addition, they will help the ICT to identify wasteful practices and help divert resources to implement evidence-based and cost-effective practices *(59)*.

There are surveillance protocols in existence in low-resource countries, most notably the International Nosocomial Infection Control Consortium (INICC). The INICC is the first multinational, collaborative HAI control program with a surveillance system based on that of the US NHSN, established to control HAIs in hospitals in limited-resource countries *(70)*. It was founded in Argentina in 1998, expanding to a network of 173 ICUs in 25 countries (*70*,71).

The INICC aims to create a global network of hospitals in the developing world that conducts surveillance of HAIs using standardized definitions and established methodologies; as a result, they hope to promote implementation of evidence-based infection control practices. The INICC also hopes to carry out applied infection control research; provide training and surveillance tools to individual hospitals that can allow them to conduct outcome and process surveillance of HAIs, measure their consequences, and assess the impact of infection control practices; and improve the safety and quality of healthcare worldwide through implementation of systematized programs to reduce rates of HAI, associated mortality, excess lengths of stay, excess costs, and bacterial resistance. The INICC published a surveillance study from 2003 through 2008 in 173 ICUs in Latin America, Asia, Africa, and Europe *(72)*. During the 6-year study, prospective data were collected from 155,358 patients hospitalized in the consortium's hospital ICUs for an aggregate of 923,624 days. Although device utilization in the developing countries' ICUs was remarkably similar to that reported from the United States in the CDC's NHSN; however, when standard definitions and accurate case finding were used, rates of device-associated HAIs were markedly higher in the ICUs of the INICC hospitals: the pooled rate of CLABSIs in the INICC ICUs, 7.6 per 1,000 central line days, is nearly threefold higher than the 2.0 per 1,000 central line days reported from comparable US ICUs, and the overall rate of ventilator-associated pneumonia (VAP) was also far higher: 13.6 versus 3.3 per 1,000 ventilator days, respectively, as was the rate of catheter-associated UTI (CAUTI), 6.3 versus 3.3 per 1,000 catheter days, respectively. The frequencies of resistance of *Staphylococcus aureus* isolates and Enterobacteriaceae were also far higher in the consortium's ICUs, and the crude unadjusted excess mortalities of device-related infections ranged from 23.6% (CLABSI) to 29.3% (VAP).

While the INICC is one model for surveillance of HAIs in developing countries, there are other potential models that can be tailored to the needs of the different regions. One of the strengths of the INICC model, however, is its focus on device utilization in addition to HAI rates.

There have been a number of success stories in developing countries in terms of reducing device utilization rates. This has been seen with CAUTIs.

CAUTIs are the most common HAIs worldwide in both developing and developed countries. The most important advance in the prevention of CAUTIs in developed countries has been the use of closed catheter drainage. In an early editorial by Beeson, significant bacteriuria rates of up to 95% of patients with indwelling urinary catheters were cited *(73)*. This high rate of catheter-associated bacteriuria in the era before modern closed drainage systems is likely to be comparable to rates in developing countries that are still using open drainage systems for urinary catheter drainage. When the urinary catheter system is open, there are multiple opportunities for pathogens to enter the catheterized urinary tract due to contamination of the drainage container or contamination of the drainage tube by individuals collecting urine from the end of the catheter.

Commercially available closed urinary drainage systems might not be within the reach of many healthcare facilities in developing countries. However, closed urinary catheter drainage can be achieved through modification of open drainage systems using improvised urine drainage containers.

More recently, efforts in both developed and developing countries have focused on reducing the incidence of urinary catheterization. In Thailand, a system of nurse-driven reminders as part of a multifaceted intervention can reduce the incidence of healthcare-associated CAUTIs *(74)*. This was a before and after study of an intervention that made use of nurse-generated reminders that began from the third day of catheterization. This resulted in a reduction of inappropriate catheterization from 20% to 11%, reduction in mean duration of catheterization from 11 to 3 days, and a significant reduction in CAUTIs from 21.5 to 5.2 per 1,000 patient days. The benefits of this intervention were most marked in the ICUs, and the nurse-generated reminders were accompanied by education programs to emphasize the importance of prevention of CAUTIs. The costs for patients in terms of antibiotics and overall hospital costs were reduced between 58% and 63%. This is clearly a simple, cost-effective intervention that can be applied in a number of developing countries.

The Thai experience replicated the experience of a group from Taiwan who also showed a significant reduction in CAUTI in ICUs by using nurse-generated reminders, which resulted in a 69% reduction in antibiotic costs due to a reduction in CAUTI from 11.5 to 8.3 per 1,000 catheter days with a reduction in duration of catheterization from 7 to 5.6 days *(75)*.

In Nigeria, a prospective randomized trial was conducted to assess the impact of early removal of the indwelling urinary catheter after caesarean section, and this showed no adverse impact and a nonsignificant reduction in CAUTI *(76)*. More recently, a group in Egypt successfully reduced the incidence of CAUTI post-cesarean section by simply not using indwelling urinary catheters *(77)*. This was not associated with an increase in urinary retention and in fact was better tolerated by the women compared to those who had indwelling urinary catheterization. These are two examples of initiatives from Africa that have shown that it is possible to reduce the use of urinary catheters and thus to decrease the incidence of CAUTI in healthcare facilities in developing countries.

VAP is another major problem in developing countries. In countries with access to ventilators, they can be lifesaving for endemic diseases such as tetanus in addition to other conditions seen more commonly in developed countries, including severe respiratory infections. VAP rates are high in developing countries due to a variety of factors, including sharing of suction catheters, solutions used for suctioning, reuse of ventilator tubing with inadequate sterilization, and possibly overuse of mechanical ventilation related to lack of availability of noninvasive ventilation means. Arabi and colleagues have recently performed a systematic review of VAP in developing countries *(78)*. They found 22 studies from the Middle East, Southeast Asia, and South America that made use of the US CDC's NHSN definitions for VAP. The most common pathogens associated with VAP were gram-negative bacilli, most commonly *Pseudomonas aeruginosa*, and the crude mortality associated with VAP ranged from 16% to 94%. There were eight studies that performed interventions, and outcome data were analyzed from before and after the intervention. The interventions that were effective in reducing VAP rates in developing countries included education campaigns to improve hand hygiene compliance, aseptic technique, and appropriate use of suctioning. Arabi's group also demonstrated that a sedation protocol and an educational program could reduce VAP rates from 28 to 11 per 100 ventilated patients.

Intravascular access device–associated bloodstream infections are a major problem in developing countries. This is particularly acute as in many developing countries, open infusion systems are still in use. These have been associated with higher rates of intravenous access device–associated bloodstream infections *(79)*. In addition, because of cost issues, many devices stay in place for far longer than is necessary, and there is often an incentive from either the patient or the provider to supply parenteral rehydration rather than oral rehydration.

Although use of large volumes of fluids in developing countries has been associated with better survival and improved outcomes *(80)*, there are considerable risks associated with intravenous therapy in low-resource settings. Furthermore, the efficacy of oral rehydration solutions has been established for more than 20 years in the treatment of severe dehydration due to endemic gastroenteritis in children *(81)*. Some of these problems were illustrated many years ago by Rhinehart and colleagues who investigated increases in mortality in children with dengue hemorrhagic fever that turned out to be due to HAIs (primarily bloodstream infections), in an ICU with limited hand hygiene and other resources. Through a skilful adaptation of the US CDC recommendations, these were brought under control *(82)*.

In recent years, the introduction of "bundles" to reduce the incidence of CLABSI has made a significant impact in many developing countries. A quasi-experimental study in Brazil demonstrated a reduction in CLABSI from 6.4 per 1,000 catheter days to 3.2 per 1,000 catheter days in an ICU *(83)*. Similar success stories have been recorded in Thailand *(84)*, where a sustained reduction of between 54% and 78% was sustained a year after the introduction of a CLABSI bundle together with a hand hygiene promotion campaign. It is important to note that in the Thai study, the baseline rate of CLABSI was high—14 cases per 1,000 catheter days—and the intervention was associated with a significant decrease in device utilization.

While the ability to implement these bundles will vary across the wide spectrum of healthcare facilities in developing countries, there is good evidence that educational interventions making use of locally produced guidelines can have a positive impact on CLABSI *(85)*.

SUMMARY

1. All developing countries need to have some form of surveillance for HAIs.
   a. This can take the form of a periodic point prevalence survey conducted across a range of healthcare facilities.
   b. Definitions need to be standardized to ensure that data can be meaningfully compared across institutions and can be used as a basis for quality-improvement programs.
   c. Countries should make use of whatever technology is available, including mobile phone applications to increase the accuracy and reliability of surveillance systems.
2. SSI surveillance is critical to safe surgery.
   a. SSI surveillance can be augmented by monitoring readmissions or returns to the operating room for infectious complications.
   b. Checklists, for example, the 19-item WHO surgical safety checklist, should be considered in all healthcare facilities. These can improve timing of perioperative antimicrobial prophylaxis and reduce SSIs together with other complications of surgery.
3. CAUTIs should be monitored together with urinary catheter use.
   a. Where possible, closed urinary catheter drainage should be used. Where this is not available routinely, it can be improvised.
   b. A simple nurse-based reminder system can be used to reduce the duration of catheterization and thus the rate of CAUTIs, antibiotic use, and costs.
   c. Strict attention to aseptic technique can reduce CAUTI and other device-associated infections.
4. VAP surveillance should also be done according to standardized definitions.
   a. Hand hygiene campaigns and attention to asepsis can reduce VAP rates in all hospitals.

   b. Sedation protocols should be used together with other evidence-based interventions to reduce VAP.
   c. Where possible, the duration of mechanical ventilation should be limited to as short a time as necessary.
5. CLABSIs should be monitored as with VAP and CAUTI using standardized definitions and with concomitant measures of device utilization. In addition:
   a. It is critical to increase the use of oral rehydration where possible to reduce the utilization of venous access devices.
   b. Educational programs should be put in place to ensure that all HCWs taking care of patients with venous access devices are trained in their use and care.
   c. The use of open intravenous fluid systems should be discouraged where possible. If they need to be used, strict attention needs to be paid to asepsis sterilization and disinfection.
   d. Elements of evidence-based CLABSI bundles should be introduced into all healthcare facilities.

MICROBIOLOGY LABORATORY

At the national level, there should be promotion of standardized laboratory techniques and defined biosafety standards. At the local hospital level, there should be access to laboratory services and protection of laboratory staff.

Historically, in many developing countries, the microbiology laboratory director has doubled up as the infection control officer. This has been inevitable because of the specialized expertise of the microbiologists and, in fact, the origins of many infection control programs to control the spread of resistant pathogens.

Developing countries have high rates of multiresistant pathogens. This is exemplified by the Asian guidelines on the management of healthcare-associated pneumonia, which list key pathogens causing healthcare-associated pneumonia as methicillin-resistant *S. aureus* (MRSA), multidrug resistant *Acinetobacter baumannii*, and multidrug resistant *P. aeruginosa*. The recommended second-line therapy for patients with healthcare-associated pneumonia is polymyxin *(86)*.

For some unclear reasons—perhaps climatic—multiresistant gram-negative pathogens appear to be more of a problem than gram-positive pathogens in tropical and subtropical countries, with the possible exception of MRSA *(87)*. Many protocols for identification of gram-negative pathogens are not as well standardized or as easily accessed in developing countries, and this is a further challenge. Resistance testing itself has to be done according to standardized protocols, and there are agencies with international arms that provide access to quality assurance programs that can be tapped to ensure some standards in resistance testing and reporting.

Microbiology laboratories associated with healthcare facilities need to have some form of external quality assurance to ensure that the data provided to clinicians are accurate and reliable. It has been recognized for some time that lack of reliable clinical microbiology laboratories is a barrier to the delivery of effective healthcare in Africa and other low-resource settings *(88)*. One potentially deadly consequence of the lack of reliable clinical microbiological resources has been the overdependence on syndromic management of patients (89). A recent review of community-acquired bloodstream infections in Africa *(90)* pointed out that multiple studies have demonstrated the importance of bacterial pathogens such as *Streptococcus pneumoniae*, *Salmonella typhi*, and non-typhoidal salmonellae in patients who present with undifferentiated fever to healthcare facilities in Africa. Many are inappropriately treated for malaria even in settings where the season or location is not typical. The authors point out that widespread use of simple appropriate blood cultures could ensure that appropriate treatment is provided to children and adults with community-acquired bacterial infections that are probably at least as common as malaria in many parts of the developing world. The alternative, which might appear tempting and is practiced in some parts of the world, is to add an empiric antibiotic to the antimalaria regime in the syndromic treatment of fever. The danger associated with this is the antibiotic pressure, which can only add to the antimicrobial resistance problem. As mentioned, antimicrobial resistance in healthcare-associated pathogens is a major problem, but this has also been noted in the community *(91)*. Blood cultures can be accurately performed in sub-Saharan African countries with proper training. Indeed, a study performed by Archibald and colleagues showed a lower rate of blood culture contamination in Tanzania and Malawi compared with a major US teaching hospital using the same protocol *(92)*. Blood cultures are fundamental as they can be performed by trained technicians, and they provide objective data to guide treatment and can provide useful parameters for surveillance. For example, the United Kingdom (again, most certainly not a low-resource country) has made MRSA bacteremia a notifiable infectious disease under public health law. This has arguably contributed to the lowering of MRSA infections throughout the United Kingdom. Many countries in Asia and Latin America have considered using bloodstream infection rates as national surveillance tools both to define healthcare epidemiology and to monitor infection control parameters. Thus, accurate and reliable blood cultures are critical in all settings.

The problem of drug resistance in the community is thought to be exacerbated by the easy access to antimicrobials bought over the counter. While many of us in developed countries would decry this practice, the reality is that with the shortage of healthcare manpower in developing countries—in particular doctors who can write prescriptions, rather than have a child die from an *Escherichia coli* urosepsis or pneumococcal pneumonia because the nearest physician is 200 miles away, it makes much more sense to go to the local market to pick up some potentially life-saving antibiotics. Perhaps the solution is to stop exacerbating the medical and nursing manpower shortage in developing countries by addressing the root causes of this issue (93). This has been recognized, but there are no obvious solutions readily available.

Antimicrobial drug resistance in hospitals in low-resource countries is an even bigger problem. This is due to a combination of factors including deficiencies in infection control practices and infrastructure as well as the pernicious practice by which physicians and hospitals

are compensated more for prescribing more expensive and broader-spectrum agents than for targeted antimicrobial therapy. This has led to severe distortions in antimicrobial prescribing and the situation that has led to the emergence of "untreatable" infections, for example. This is an issue that has to be addressed.

It is important to have longitudinal surveillance of resistance rates in hospitals. Okeke has pointed out that few sub-Saharan countries can reliably produce annual antibiograms that report resistance rates consistently *(91)*. The WHO has the freely available WHONET software that is widely used by a number of countries to collate and report antibiotic resistance rates. This can be used for benchmarking longitudinally in a healthcare facility, across the healthcare facilities in a region and internationally. In addition, over the years, there have been a number of antimicrobial resistance surveillance programs that have been sponsored primarily by industry. Although commercially driven, they have provided much useful information for practitioners in these countries and regions, so they have some idea of the epidemiology of resistant pathogens in their area.

One area of success in recent years has been the WHO's campaign to increase the laboratory detection and confirmation of TB and increase resistance testing. The WHO has set goals for the proportion of cases of TB, which are identified by smears as opposed to the traditional approach of syndromic treatment based on symptoms or on chest radiographs, which can be of variable quality. Other agencies such as the US CDC have also worked with developing countries to standardize microbiological diagnosis of TB and ensure quality control (94).

In addition, there have been a number of technological advances in the diagnosis of drug resistance in TB. Recently, a tabletop molecular diagnostic device that can rapidly, with minimal sample preparation time, generate accurate and reliable molecular evidence of the presence of *Mycobacterium tuberculosis* together with rifampicin resistance, which was found to be a sensitive marker for multidrug resistance in TB. This might be out of reach of most low-income countries, but there are alternatives including the innovative MODS approach to diagnosis of drug resistance in TB, which involves a series of wells and visual inspection *(95)*. This has been validated in Peru and potentially can be applied in a number of low-resource settings, but it will require training for the laboratory staff.

The recent 2009 H1N1 pandemic together with the H5N1 avian influenza outbreaks has greatly advanced the cause of molecular diagnosis of respiratory viral pathogens across the globe. Influenza polymerase chain reactions were performed in laboratories across Asia, Africa, and Latin America during the peak of the influenza pandemic, and the WHO and its partner agencies were able to provide timely epidemiological data that demonstrated the rapid spread of the 2009 H1N1 epidemic across international boundaries *(96)*. The capacity that has been built up for the molecular diagnosis of respiratory viral infections has the potential to be used for the molecular diagnosis of other pathogens such as TB or dengue virus, which are major problems in many low-income countries. In addition, there are efforts under way to use molecular methods to diagnose drug-resistant microorganisms or to rapidly identify bacterial pathogens in critically ill patients.

Another important element in microbiology laboratories is the ability to turn to a regional or international reference laboratory. There are a number of international laboratories run by the Wellcome Trust, Pasteur Institute, and the U.S. Military, which have served as reference laboratories for many low-income countries in the past. While there have been issues with ownership of specimens from developing countries and the enforcement of the biological diversity protocols (97), there is clearly a need for in-country expertise in the establishment of reference laboratories. For infection control, the ability to do molecular typing of isolates, which is often taken for granted in developed countries, can be a tremendous help when available in low-income countries. There is the possibility that diagnostic molecular laboratories that are now available in many countries in the developing world can perform molecular epidemiology studies with the appropriate protocols.

Summary

All countries need to have the following:

a. Adequately resourced clinical microbiology laboratories that can perform blood and other cultures and have access to external quality assurance programs that ensure that the results are reliable and accurate.
b. Antibiograms produced from each healthcare facility, which allow for the tracking of resistance patterns and epidemiology.
c. The ability to make use of software such as WHONET to report antibiotic resistance patterns longitudinally and across the country.
d. Laboratories that are integrated with ICTs so that alert microorganism surveillance can be put in place and appropriate isolation precautions can be enforced.

THE ROLE OF THE ENVIRONMENT MUST BE ASSESSED

Although a clean environment plays an important role in the prevention of HAIs, historically, many countries have placed an overemphasis on the role of the environment to the detriment of programs focusing on hand hygiene and isolation precautions. At the national level, there should be definition of the minimum standards for infection prevention and control purposes. At the local healthcare facility level, design and planning should ensure adequate safe water supply, ventilation, hand hygiene facilities, patient placement and isolation facilities, storage of sterile supplies, and rules and protocols for building and renovation as well as appropriate waste management facilities and practices.

All healthcare facilities should provide safe water for clinical use. There are low-cost means of doing this, and they should be put in place. Municipal tap water is a potential reservoir of healthcare-associated pathogens in many countries with limited resources. Tap water contaminated with gram-negative bacilli or nontuberculous mycobacteria has been associated with bacteremia, burn infections, and SSIs. This is particularly acute in developing countries where contaminated infusions or ventilator suction

using nonsterile water can lead to outbreaks *(98–100)*. In the developed world, Anaisie et al. *(101)* have described contaminated hospital water sources causing healthcare-associated outbreaks from many pathogens including mycobacteria, *Pseudomonas*, *Stenotrophomonas*, *Serratia*, *Acinetobacter*, *Aeromonas*, and molds such as *Fusarium* and *Aspergillus*. The ability of gram-negative bacteria to survive wet environments for long periods explains their common occurrence in multiple sites, especially in humid climates *(102)*. These microorganisms can potentially be spread to patients by HCWs whose hands become contaminated during hand washing *(98,99,102)*. In hospitals in countries with limited resources, infection control personnel must periodically do "sink" rounds to ensure proper functioning of sinks and adequate water chlorination. All water leaks and water damage should be repaired and remediated within 24 hours to prevent dissemination of pathogenic bacteria and moulds *(103)*. One of the best ways to ensure this is to have hospital engineering staff represented on infection control committees and/or have protocols in place so that a quick infection control risk assessment can be made when a leak occurs. Where safe water is not available, it is recommended to boil water to render it safe for utilization. Alternatively, water purification units may be used. Viable pathogens can grow in many sources of hospital water including drinking water, hand washing water, ice, dialysis water, shower water, water in storage tanks and distribution systems, ventilation ducts, and building materials that have become wet. Thus, it is important to ensure that the hospital environment is kept clean and dry and that staff exercise aseptic technique as carefully as possible.

Hand hygiene is the cornerstone of effective infection control programs worldwide. Hand hygiene facilities should be made available at the point of patient care. At the national level, governments must be committed to hand hygiene and allocate budgets, produce national guidelines on hand hygiene, produce posters and educational materials, and promote hand hygiene campaigns. The WHO's "Clean Care is Safer Care" campaign has succeeded in getting commitments from Ministers of Health of more than 100 countries worldwide (Fig. 100-4). Many countries have followed through on these commitments with national campaigns to improve hand hygiene. Although hand hygiene is a simple measure, the lack of compliance among HCWs is problematic worldwide, averaging <40% *(104)*. This is due to lack of time, inadequate facilities, or forgetfulness because of heavy workloads *(105,106)*. Moreover, hand washing facilities in some developing countries are primitive or scarce and inconveniently located. Supplies of soap and paper towels are often inadequate, and multiple-use cloth towels are commonly used; these towels become damp and can harbor gram-negative bacteria *(107)*. It is almost impossible to achieve 100% compliance with hand washing even in well-resourced developed countries *(108)*. To increase hand hygiene compliance worldwide, the WHO recommends making the use of alcohol-based handrubs preferable to hand washing in most clinical situations, unless hands are visibly dirty, when they have to be washed first (109). It is often easier to provide alcohol-based handrubs than sinks with running water and a functioning sewage system, where the overall sink-to-patient bed ratio should be of 1:10 *(110)*. Placement of hand hygiene products (soap and handrubs) should be aligned with promoting hand hygiene in accordance with the concept of the "My five moments for hand hygiene" (111). Pocket bottle handrubs are ideal for use at the point of care. However, if the commercial products are too costly for the local healthcare settings, WHO has

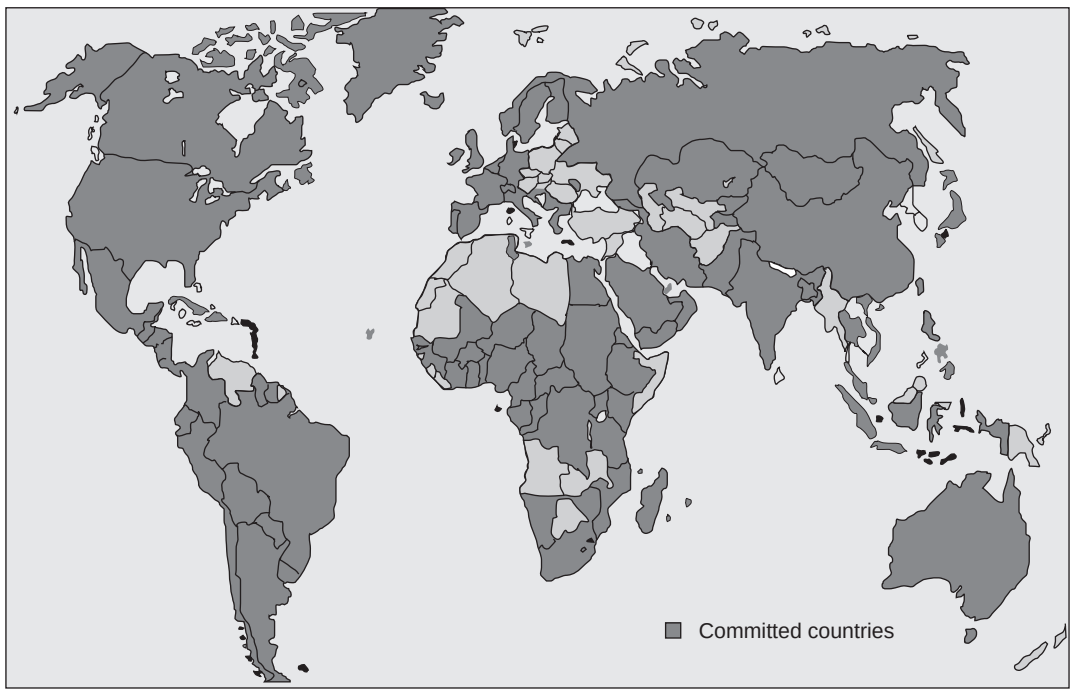

FIGURE 100-4 Countries committed to World Health Organization's hand hygiene campaign.

formulated much cheaper alcohol-based handrubs for local production with proven microbiological efficacy and a good safety profile. A *Guide to Local Production* has been published, which features simple instructions and illustrations detailing the process from procurement of raw ingredients to quality control and storage of the final product *(112)*. Allegranzi and colleagues recently reported their efforts in Bamako, Mali, a very low income country. A concerted effort with strong support from the local administrators involved the local production of a high-quality alcohol-based handrub that had a significant impact on hand hygiene compliance. There was strong support from the HCWs and preliminary evidence that this might have had an impact on HAIs *(113)*.

MONITORING AND EVALUATION

Monitoring and evaluation of infection prevention and control programs should be conducted periodically both at a national and a local or state level. This should be done in a nonpunitive manner that seeks to improve the quality of care rather than find fault with individuals.

Monitoring and evaluation of programs is critical to ensure the success of early efforts. This is self-evident, and there are a number of means by which this can be achieved. For infection control efforts that are funded by international agencies such as the World Bank, there are established protocols for monitoring and evaluation, and these should be put into place as soon as is practical (114).

For programs funded domestically, the international mechanisms for monitoring and evaluation should be adapted to local needs and situations. It is important to ensure a blame-free culture at the local level so that monitoring is not seen as a form of policing. In many countries, there is a lack of trust in systems; so it is important that individuals are not incentivized to "game" the system. International independent systems can be made use of, but there are risks inherent in trying to benchmark performance. The debates over "pay for performance" that have occurred in the developed world *(115)* have recurred in various forms in many developing countries. While flawed, there is a need for monitoring and evaluation of infection control programs to ensure that resources are not wasted and that patient safety is protected.

Summary

There have to be nonpunitive mechanisms for monitoring of infection control and prevention programs at both the local healthcare facility and national level.

LINK WITH PUBLIC HEALTH AUTHORITIES

At the national level, the regional offices of the WHO have links with national health authorities—these have to include infection prevention and control programs in addition to the classical internationally notifiable diseases such as cholera, yellow fever, and influenza.

At the local hospital level, hospitals have to have links with public health authorities for reporting of HAIs and to tap the resources of public healthcare professionals for outbreak investigation.

The SARS outbreak was a clear illustration of the need for infection control programs to have close links with public health agencies both in country and regionally and internationally. The countries that experienced the SARS outbreak were prepared for the 2009 H1N1 pandemic and rapidly implemented comprehensive pandemic plans *(17)*.

On a more mundane level, there needs to be close integration with municipal waste management providers. In low-income countries, there are many situations where medical waste is "recycled" unofficially by individuals who scavenge used syringes, wash them, and sell them to unsuspecting or impoverished patients who are unable to pay for new, sterile equipment. One way of preventing this is to ensure that all waste is segregated and that contaminated medical waste is promptly and securely dispatched to sites where it can be incinerated. A study of more than 100 primary healthcare centers in Iran found that while all used appropriate sharps disposal methods, there were some gaps that needed to be addressed in terms of training of staff and construction of septic tanks and disinfection systems for settings without access to functioning municipal sewerage systems *(116)*.

Sterilization and disinfection in low-resource countries is predominantly and most safely conducted through the use of steam sterilization and heat disinfection. Where disinfectants are used, their use must be carefully monitored to ensure that they are appropriately handled and stored and that there is no contamination. The issue of reuse of single use devices is particularly acute in low-income countries.

Links do not just need to be done locally within a country; ideally, low-resource countries could tap on neighboring middle-income countries to access some of the successful adaptations of international best practices to local situations. An example of this is shown in Figure 100-5, where a local nongovernmental organization funded the training of infection preventionists from a low-income Southeast Asian country in a middle-income neighboring country.

FIGURE 100-5 Training for infection preventionists in Malaysia.

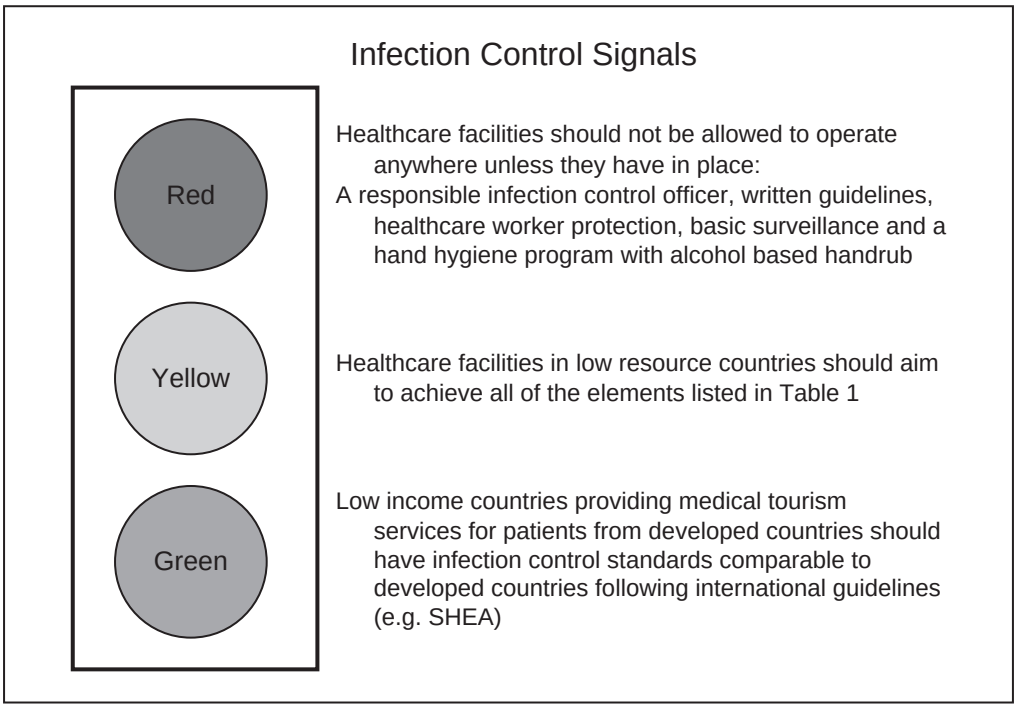

FIGURE 100-6 Proposed traffic signal system of infection control depicting, minimum standards for all healthcare facilities (red light), targets to aim for in low income countries (yellow light) and higher standards for those promoting healthcare to patients from developed nations (green light).

Summary

Links have to be established by infection control and prevention teams with local public health and other municipal authorities to integrate infection control programs with other activities directly related to the potential transmission of infections.

CONCLUSION

Infection control in low-resource countries is indeed a challenge. There is, however, a renewed commitment that has emerged in recent years to infection control. We have proposed a traffic signal system (Fig. 100-6). Even in the least-resourced countries, there are certain minimum standards that should be in place if a facility is to be allowed to conduct medical procedures. Absence of these would constitute a red light, suggesting that unsafe facilities should be shut down and resources channeled to transporting patients to safe facilities nearby. We believe that the recommendations in this chapter can be achieved over time in all developing countries. Importantly too, we recognize that many developing countries are marketing themselves as destinations for "medical tourists" from developed countries. It is vitally important for insurance companies and regulatory bodies in the developed countries to ensure that infection control standards in those facilities are comparable to those in the source country. Overall, low-resource countries themselves and their partners in the developed world need to work together in a stepwise fashion at whatever pace is appropriate to ensure that patients in healthcare facilities all over the world, in the words of Florence Nightingale, "do not suffer harm."

SECTION XVII
Bioterrorism

CHAPTER 101

Biological Terrorism: An Overview

Margaret A. Hamburg* and C. J. Peters

Once considered a remote concern, the possibility that biological agents might be intentionally used to cause widespread panic, disruption, disease, and death is now widely recognized. Neither technical barriers nor moral repugnance can protect us from their use. Future attacks could occur again at any time from many potential sources and using many possible biological agents. Whether an unsophisticated delivery system with a limited number of infections, as we experienced with the anthrax letters, or a more technologically advanced and carefully orchestrated attack with mass casualties, the prospects are frightening. Further, we must recognize that this evolving threat presents the medical, public health, and scientific community with a set of difficult and pressing challenges. Before 9/11 and after 9/11 and the anthrax attacks of the next month, experts and commissions had predicted that biological attacks should be expected, and the drumbeat has continued and intensified in 2010. The type and extent of such an attack will depend on the balance between the technical expertise of the terrorists and the effectiveness of our defenses.

By its very nature, the biological weapons threat—with its close links to naturally occurring infectious agents and disease—requires a different paradigm than that for conventional terrorism, military strikes, or attacks caused by other weapons of mass destruction. A biological event could well unfold as a smallpox epidemic, or foci of less transmissible diseases spread out in time and place before authorities even realize that an attack has occurred. What is more, opportunities for access to dangerous pathogens here or overseas can be relatively routine in nature even with the increased regulations that are in place. Significant damage can be done even without large quantities of material or an elaborate delivery mechanism, and new possibilities for exploitation are embedded in the very science and technology advances that hold great promise for health.

There is an urgent need for systematic study and action concerning what is needed to control the development, proliferation, and use of biological weapons, as well as the crucial elements of response should an attack occur. Clearly, this will require new thinking about how to define and implement meaningful solutions and will require the full engagement of the biomedical community (1).

This chapter attempts to offer an overview of the threat of bioterrorism and some of the critical issues that need to be addressed as our nation prepares to deal with this disturbing and potentially catastrophic threat. Subsequent chapters will expand on the specific elements of preparedness and response at the national, state, and local levels, including discussion of the identification and management of many of the biological agents of particular concern.

WHAT IS BIOTERRORISM?

Terrorism can be most simply defined as "warfare deliberately waged against civilians with the purpose of destroying their will to support either leaders or policies" *(2)*; however, the term, as commonly used, includes the implicit connotations that some weaker group attempts to gain international support or tumble the government targeted in order to achieve their goals and that it often employs an element of fear in the targeted noncombatant population *(3)*.

*The author, Commissioner of the Food and Drug Administration, contributed this chapter in a personal capacity.

The use of these tactics is probably as old as organized governments and has been traced back as far as the 3rd century BCE tactics of Hannibal or the spectacular murders by the 11th century Assassin cult. In any case, this approach has continued to the present day and is evolving according to available technology. Today's terrorists use the Internet and cellular phones and incorporate the most modern destructive weapons. When we talk of bioterrorism, we refer to terrorism carried out using biological weapons. The international definition of biological weapons includes replicating microorganisms such as bacteria and viruses as well as toxins derived from microorganisms.

This definition includes a wide variety of attacks using any of a huge selection of microorganisms. Of course, many of these events would be of lesser impact and might be of little more consequence than a crime or assassination executed with firearms *(4,5)*. However, the element of terror is an important part of the impact. For example, the consequences of cyanide poisoning of analgesics or of imported grapes *(3)* had far-reaching consequences in the public mind and economy. Only 21 anthrax cases with 5 deaths in 2001 resulted in a great deal of fear in the involved areas, paralyzed mail communications, and handicapped government functioning. Even hoaxes can be highly disruptive and expensive.

There is a much more serious side to the threat of bioterrorism, and it is best understood through the history of biological warfare. Attempts at biological attacks date back far in history. For example, in the 1300s, the bodies of plague-infected victims were catapulted over the city walls during the Tatar siege of Kaffa. In the 1700s, during the French and Indian War, native American adversaries were given "gifts" of smallpox contaminated blankets by the British that decimated their numbers *(6)*.

The development of a more modern approach to biological weapons dates to the early decades of the 20th century. During the 1930s and 1940s, the Japanese conducted extensive experiments and large-scale field trials—primarily involving contaminated food and water supplies—on unwitting civilians and prisoner of wars (POWs) in occupied Manchuria. In fact, during World War II, every major combatant had a biological weapons program, although Japan is the only country that is generally agreed to have used biological weapons during the course of the conflict *(6,7)*.

We began our own bioweapons program in 1943, partially in response to the research programs established by the Japanese and the Germans as well. But in 1969, President Nixon renounced the use of biological weapons and ordered that our offensive program be ceased and all stockpiles destroyed *(8,9)*. This decision paved the way for negotiation of the Biological and Toxin Weapons Convention (BWC) treaty, which prohibits possession, or stockpiling, and transfer of bioweapons. The treaty was concluded in 1972 and subsequently ratified by more than 140 nations. The signing of the BWC represented a very important commitment to abandon pursuit of biological agents as weapons, but it did not—and still does not—contain explicit monitoring, inspection, or enforcement requirements *(10)*.

As the 20th century closed, several events gave bioweapons greater prominence on the national security agenda. The first strong indication came from the accident at a Soviet bioweapons factory in Sverdlovsk; a human error led to the accidental release of weaponized anthrax, with resulting cases in humans and cattle in the city. The source of the epidemic was suspected in the military and intelligence community but was denied by the Soviets and some American academics. Later investigations and Soviet admissions confirmed that it was, indeed, an epidemic of inhalation anthrax, practically pathognomonic of a biological weapon in the pattern observed *(9,11)*. As the Soviet Union broke up in the 1980s, there were startling revelations about the magnitude and scope of the bioweapons program in the former Soviet Union—which began in full force the same year as they signed on to the BWC. At the height of their program, they had more than 50 institutes, employed tens of thousands of workers (including an estimated 7,000 scientists deemed "security risks" on the basis of their knowledge and expertise; Ref. *12*), and made literally ton quantities of weaponized anthrax, smallpox, and other microorganisms. In addition they were developing resistant strains and new pathogen variants; and experimenting with innovative strategies to cause disease including recombinant microorganisms such as *Escherichia coli* expressing neuromodulators *(9,13)*.

Concerns were further heightened by the disclosure of an ambitious bioweapons' program mounted by Iraq *(14,15)* and the findings that Aum Shinrikyo, the Japanese group that released nerve gas in the Tokyo subway, had also experimented with botulism and anthrax, as well as sent teams to Zaire in an effort to obtain Ebola virus for use as a weapon *(16,17)*. Episodes here at home involving extremist groups or individuals who were able to obtain dangerous pathogens such as ricin, anthrax, and *Yersinia pestis* for dubious purposes added to the growing perception of risk *(18)*. Of course, the final breach of the barrier to use of biological agents for terrorism or weapons came with the anthrax attacks in October 2001.

WHAT IS THE REAL THREAT OF BIOTERRORISM?

Any consideration of bioterrorism must begin with a consideration of the scenario: who is executing the attack, why are they doing it, and what are their resources? This delineation will allow us to focus on the scope and sophistication we are concerned with and the possible modalities of the attack or defense. A lone person with little microbiological expertise poses a lower risk with microbes than with an automatic weapon. A state-sponsored program is the other end of the threat spectrum and could result in many thousands of deaths. It is possible that the terrorist's desired outcome is merely that the turnout for voting is diminished, as occurred with a sect in Oregon that contaminated salad bars with *Salmonella (19)*, or it may be more lethal such as Aum Shinrikyo's goals *(16,17)*.

Certainly, attacks on a limited scale have occurred and will occur again *(17,20)*. Terrorists or nation states will note the remarkable success of the 2001 anthrax attacks, and they will attempt to repeat them. In fact, anthrax is the most likely agent to be used in the future, because the microorganism is readily available in nature worldwide, the spores are stable on storage and in aerosol without special preparation, and *Bacillus anthracis* is easily grown

TABLE 101-1

Methods of Dissemination of a Bioterrorist Agent and Some of their Drawbacks

Injection—limited numbers
Water—purification plants, residual chlorine, and dilution
Arthropods, rodents—tricky biology
Food—access, synchronization, and wide coverage
Interhuman spread—will the agent really do it?
Aerosol—relatively few agents useful, technical difficulties in preparing for stable, efficient delivery

and purified. It is particularly worrisome that we do not understand who prepared the 2001 anthrax weapon or how it was prepared *(21)*.

However, most attention has been focused on attacks that carry the threat of very large numbers of casualties. It is easiest to analyze these according to how the agent would be disseminated (Table 101-1). Direct injection has been used *(22)* as an assassination tool with ricin, but is impractical in any large scale. Water is often mentioned and of course could be a risk on a small scale, but dilution and residual chlorine make it impractical on a large scale. Arthropods or rodents could be used with some agents such as tularemia or yellow fever and indeed plague-infected fleas were used by the Japanese in World War II *(7)*. However, the biology of such attacks can be difficult to predict or manage, as anyone who followed the arguments about the persistence of West Nile virus after its introduction into North America can attest. Food sources have been increasingly recognized as sources of multistate outbreaks and must be regarded as a vulnerable link, but we are also responding to them more effectively so that surveillance could give early warning and food lots could be recalled unless the dissemination occurred in a setting in which many consume the product synchronously. Clearly protection of the food supply at the source is an increasingly important consideration (23). The most efficient approach to infecting a large number of target humans would be to use an agent that would spread from person to person after the initial infections; only smallpox can actually do this. Influenza strains have been suggested, but they lack "directionality" toward an enemy and the immediacy required in most scenarios. That does not detract from the fact that influenza A is the greatest natural threat we face and that new strains could be responsible for millions of deaths worldwide *(18)*. Other infections such as plague and viral hemorrhagic fevers have a limited possibility for spread and will not cause secondary infections beyond possibly limited numbers of close personal contacts and a few in the medical setting.

This leaves aerosol dissemination on the list (Table 101-1); however, there are only a few agents that can be grown to high titer, are infectious by the aerosol route, and cause severe and fatal disease. The small particle aerosols are subject to ultraviolet inactivation in most cases, can be carried away by wind currents, and require special preparation and skill in dissemination. They have some advantages: they can be disseminated at night under inversion conditions and with attention to meteorological variables and be carried silently downwind to expose large numbers of people and/or animals. In fact, this approach was exactly that chosen by both the United States and the Soviet Union for their biological warfare programs and the testing suggested that it would be highly effective (24). The US program was tested in each step, ranging from indoor and outdoor tests of aerosols, actual determination of the minimal infectious dose in humans for selected agents, and extensive animal testing. They showed that aerosols of simulant microorganisms (microorganisms that resemble the one to be used as a weapon but of minimal virulence) or powders with similar aerosol properties could be disseminated over large areas and would have the potential to produce tens or hundreds of thousands of casualties *(25)*. Thus, each step of the use of such weapons was in place and there is no doubt that they would have been effective *(8,9,22)*.

There is considerable argument over exactly which microorganisms belong in this "rogues gallery" of aerosol infectious agents with lethal outcome. The Centers for Disease Control and Prevention (CDC) has proposed a grouping of categories A, B, and C, with category A being those of most concern (Table 101-2) (26). They were selected because of their catastrophic public health consequences with the expectation that, properly delivered, they would induce mass casualties that would overwhelm medical systems and carry with them a high mortality; no one would quarrel that these agents belong in the highest priority category. Smallpox has the additional threat that it would be contagious and spread among the unvaccinated populace. Botulism may have less potential as a mass casualty agent, but it certainly has a need for public health preparedness to manage the expected respiratory paralysis. This list has been the template for an enhanced defensive public health agenda. There are many arguments about what other microorganisms may be sufficiently dangerous to deserve consideration. Table 101-3 lists some of these, but there are differing opinions among different authorities.

If aerosol delivery of biological agents is so effective, why was it not used in warfare and why did the United

TABLE 101-2

Category A Bioterrorist Agents Defined by the CDC

Variola major (smallpox)
Bacillus anthracis (anthrax)
Y. pestis (plague)
Francisella tularensis (tularemia)
Botulinum toxin (botulism)
Viral hemorrhagic fevers
Filoviruses (Ebola and Marburg)
Arenaviruses (South American hemorrhagic fevers, Lassa fever)

Note: All are capable of efficient aerosol delivery. Only smallpox is highly transmissible from person to person.
(From Rotz LD, Khan AS, Lillibridge SC, et al. Public health assessment of potential biological terrorism agents. *Emerg Infect Dis* 2003;8:225–230.)

TABLE 101-3

Other Microorganisms of Concern in Bioterrorism Defense

Viruses
Other viral hemorrhagic fevers
Rift Valley fever
Tick-borne flaviviruses
Monkeypox virus
Alphaviruses Venezuelan equine encephalitis virus
Nipah virus
SARS coronavirus
Bacteria
Typhus and other critical rickettsiae
Glanders
Other
Crop agents
Veterinary pathogens
Bioengineered
Microorganisms

Note: The agents above are often mentioned in lists of formerly weaponized microorganisms or microorganisms suspected of having that potential.

States renounce its use? There are multiple considerations, but it is worthwhile to note that the Soviet program began in earnest around that time. The United States remained confident of the utility of nuclear weapons, and the Soviets were concerned about US superiority and therefore were seeking other weapons of mass destruction. Another powerful reason comes out of the analysis of why lethal chemical agents were not used by the major powers after World War I: support by the military establishment requires that they understand the capabilities of a weapon and have a systematic doctrine for its use *(27)*. This was not the case within the US military establishment, which has only begun to take biological warfare defense seriously after Desert Storm put them in the arena with an adversary that may have had effective biological weapons and was believed to be capable of using them if the situation demanded. The ability of biological weapons to strengthen the capability of an otherwise poorly armed Third World military with attainable financial and expertise requirements fits into the doctrine of "asymmetric warfare." Biological weapons are much cheaper and more easily produced than the equivalent nuclear capability, so they can provide weapons of mass destruction for nation-states that do not follow the nuclear route.

This discussion begs the question of how much expertise is needed for terrorists to mount such an attack should they not acquire weapons from a nation state. Obtaining many of the most dangerous agents from nature is not difficult for a determined person with the microbiological knowledge needed to produce a significant weapon. Their propagation in simple media or animals is straightforward for an experienced microbiologist and the equipment and supplies needed are readily available. However, a limiting step is to convert this slurry of potentially lethal microorganisms into a form that is stable and readily disseminated in aerosols. This is not an expertise that is readily available in the microbiological community. However, in other skill areas such as pharmaceuticals, cosmetics, and insecticides, there are extensive reservoirs of knowledge and ongoing research in both liquid and powder aerosols. For example, *Bacillus thuringiensis* spores, not pathogenic for humans unlike *B. anthracis* spores, disseminated as a liquid in approximately 120-μm aerosols aimed at settling and eliminating gypsy moths in a Canadian forest also gave measurable concentrations of approximately 7-μm particles near and inside houses (28). Under reasonable assumptions this dose of anthrax spores would result in a 14% to 17% fatality, and calibrating the spray apparatus to focus on smaller droplet size would only increase this *(29)*. Both practical and developmental studies are being carried out to define the conditions for liquid, spray-dried, and freeze-dried powders as success aerosols and published in the open literature (*30*,31).

However, basic expertise is needed to achieve success. One example of a nonstate attempt is provided by the failed efforts of the Japanese group, Aum Shinrikyo, to prepare lethal anthrax and botulinum toxin weapons. Adequate financing, equipment, and a locale were available, but the principal players had such a lack of microbiological expertise that a vaccine strain of *B. anthracis* was selected for their "weapon" *(16,17)*. We cannot depend on the ineptitude of terrorists for our protection.

Before the 9/11 attacks in 2001, several important commissions examined the vulnerability of the United States to terrorism and found the likelihood of a serious attack to be very high. The so-called Bremer (32), Hart-Rudman *(33)*, and Gilmore *(34)* commissions warned of catastrophic terrorist events including bioterrorist attacks, and indeed they were essentially correct in their assessments. Later reports from the Gilmore Commission *(20)* conclude that the post-9/11 status is still precarious. There are indications that Al Qaeda has interests in anthrax as a weapon *(35)*. Thus, the continuing escalation of terrorists dedicated to extreme lethal events and expert assessments suggest that the risks of biological attacks continue to be very real.

PREVENTION OF BIOTERRORISM

The fundamental approach would be to eliminate the seeds of terrorism, but this remedy does not seem to be forthcoming in the foreseeable future (36). The next step would be to design international arms control regimens that would stop the proliferation of biological weapons in state programs. Unlike nuclear and chemical threats, biological weapons do not emit radioactivity or have unique precursors or equipment for manufacture. The prospect of complete control by such a regimen is small; although it is an important and useful counterproliferation modality to have treaties such as the BWC in place and to be seeking improved ways to pursue enforcement and surveillance activities *(10)*.

Another approach has been to deny access of unauthorized persons to the microorganisms that might be used to produce weapons of mass destruction, and this has been pursued through establishing a list of "select agents" and stringently limiting access to these microorganisms. This clearly will have utility in preventing the use of

hard-to-obtain agents such as smallpox, Ebola, or Marburg viruses. It is ineffectual and expensive when applied to agents such as anthrax, plague, and tularemia, which are widely available from nature worldwide. In fact, it is counterproductive through enhancing unrealistic public attitudes, about the danger or research quantities of these agents limiting research, and discouraging scientists from working with these agents.

One might also attempt to protect the public by limiting effective processing of biothreat agents for aerosol dissemination, but much of the knowledge and equipment could be available through the pharmaceutical, cosmetic, agricultural, paint, and other manufacturing communities. Probably the single most dangerous persons are those from the Soviet biowarfare program. They have specific knowledge about processing, stabilization, and other manipulations for preparing infectious agents for aerosolization.

The strongest approach in the short term is to utilize the intelligence community in the United States and abroad to detect the next attack. Although this approach is likely to be successful in many instances, we cannot depend on it to always permit us to intercept a bioterrorist attack before its execution and a medical defense will be needed as well.

In the long run, we must recognize that those same advances in science and technology that hold enormous promise for improving health and combating bioterrorism also present many opportunities for misapplication or inadvertent harm. We need to ensure that the tools of modern genomic biology are not used to create new and more dangerous microorganisms. This is a complex challenge, for no one would want to impede the progress of legitimate and important science. However, we also have a responsibility to face up to the very real concern of the potential misuse of the biotechnological tools increasingly available to those who want to do harm.

With leadership from the scientific community, we must begin to examine the context and conduct of modern science, and what opportunities may exist to constructively reduce this emerging threat. A recent report from the National Research Council of the National Academies emphasizes "that biological scientists have an affirmative moral duty to avoid contributing to the advancement of biowarfare or bioterrorism." The report goes on to state that "scientists can and should take reasonable steps to minimize this possibility," indicating that it is "the responsibility of the research community, including scientific societies and organizations, to define what these reasonable steps entail and to provide scientists with the education, skills, and support they need to honor these steps" (32). On a policy level, such prevention efforts will require a global approach, including the development and implementation of international standards, norms or guidelines for biosecurity, and the practice of biomedical research.

MEDICAL DEFENSE AGAINST BIOLOGICAL THREATS

Because of the diversity of threats, one must settle on defined scenarios for response planning. Uses of biological agents to cause disease in small numbers of people are probably best dealt with by alert medical and public health communities that will recognize the possibility that such outbreaks are due to human intervention and respond accordingly *(4,5)*. At the current stage of national planning, most effort has gone into preparations for mass casualty situations. The scenario usually envisaged is not a "lights and sirens" kind of attack. Most likely there would be no announcement—no envelope saying "this is anthrax, take penicillin." Without a fortuitous discovery early on, there would be no discrete signal that an attack had occurred; no site you can cordon off while you take care of the casualties, search for clues, and eventually clean up and repair the damage. Instead, this type of event would probably unfold as a disease epidemic, spread out in time and place before authorities even recognize that an attack has occurred. We would know we had been attacked only when people began appearing in their doctor's office or emergency rooms with unusual symptoms or inexplicable disease. The "first responders" to a bioterrorism event would not be Hazmat teams but rather public health officials and health care workers. "Ground zero" would be hospitals, labs, and health care facilities. Unfortunately, in many scenarios, diagnosis of the problem may be delayed, because medical providers and laboratories are not equipped to recognize and deal with the diseases of greatest concern. What is more, effective medical interventions may be limited, and where they exist, the window of opportunity for successful intervention would be narrow.

The response to such events must involve above all a strong public health system, an element in the national infrastructure that has been severely neglected and in need of repair for bioterrorism response, protection from emerging infectious diseases, and even dealing with established quotidian disease threats *(18)*. Strengthening surveillance systems will be among the most important elements of the early warning systems. Many innovative ideas such as syndromic surveillance through a variety of electronic means are in urgent need of evaluation for sensitivity and specificity (37) (see also Chapter 103). Some of these approaches may prove more useful for reassurance about nonevents or assessing ongoing attacks than early detection. It is absolutely clear that effective surveillance will require a large investment in basic epidemiological investigation of case clusters, but it is by no means clear that the trained manpower and resources for this effort exist. In addition, improved communication—including computer connectivity—will be essential to quickly collect, analyze, and share information among public health and other officials at local, state, and federal levels as well as other essential partners.

One of the important elements of the response will be an enhanced laboratory response in the public health and the clinical arena. The importance of high volume testing was abundantly clear during the 2001 anthrax episodes, and the CDC's strengthening of the Laboratory Response Network was an important component of bringing existing resources online to respond. In the hospital laboratory there are two important considerations. First, the most dangerous bacterial bioterrorism agents are not necessarily optimally cultivated in the systems used and may even be discarded from considerations by some of the automated processing. Second, the distribution of infectious

diseases is generally log-normal and characterized by the median and the dispersion *(38)*. One consequence of this is that the number of cases is skewed toward the earlier times and so early recognition is important to give an increased therapeutic and prophylactic window. The only way we will be likely to achieve this is if point of care diagnostics are available for many of the threat agents, particularly plague.

It is worth noting that the front line for recognition of a bioterrorist attack will likely be the clinician. This was true in the 2001 anthrax attack, in which a Florida clinician used the classic tools of infectious disease diagnosis to recognize a case of inhalation anthrax with secondary meningitis (39); it is true in most emerging infectious disease outbreaks; and it will likely hold for the next bioterrorist attack. The implications for clinician education and awareness are obvious.

Once an outbreak is recognized, treatment and postexposure prophylaxis will of course be paramount. In the late 1990s, a National Pharmaceutical Stockpile was established to address this concern *(40)*. The response capability of a stockpile of vital medical supplies, including selected drugs, vaccines, antidotes, and medical equipment, was demonstrated in several recent tragedies, including the World Trade Center bombings and the anthrax attacks. Responsibility to maintain and oversee use of this stockpile, now called the National Strategic Stockpile (NSS), has just transferred from the CDC to the new Department of Homeland Security. The NSS is cached in selected locations across the country to be delivered within 12 hours to any place in the nation that requires assistance. Of course, the nature and quantities of materials maintained in the stockpile needs to be reviewed and extended.

OTHER CONSIDERATIONS

There are many rapidly changing fields that we cannot cover in this chapter. Many are discussed in the following chapters in this section. We will touch on some of the others.

1. Absence of surge capacity in acute care hospitals. With the improved efficiency in bed utilization in today's hospitals we have lost the ability to respond to the room and staff demands that would be expected from any significant bioterrorist attack. This is evident in the frequent diversion of ambulances and closure of emergency rooms in response to even a moderate increase in influenza A cases. The experience with SARS in several foreign cities has demonstrated how easily healthcare systems elsewhere can be overwhelmed, and how the breakdown of care and services can contribute to ongoing and international spread of disease.Absence of surge capacity in acute care hospitals. With the improved efficiency in bed utilization in today's hospitals we have lost the ability to respond to the room and staff demands that would be expected from any significant bioterrorist attack. This is evident in the frequent diversion of ambulances and closure of emergency rooms in response to even a moderate increase in influenza A cases. The experience with SARS in several foreign cities has demonstrated how easily healthcare systems elsewhere can be overwhelmed, and how the breakdown of care and services can contribute to ongoing and international spread of disease.
2. Some progress has been made in improving the legal underpinnings of quarantine and other emergency decisions that might be important in dealing with a bioterrorist situation, but this remains geographically spotty and generally untested.
3. Use of drugs and diagnostics that are unlicensed or perhaps licensed for other indications is a major concern. The FDA and others are working positively in this area (41), but we are far from resolving the issues that surround diseases that are not commonly seen in the United States and in some cases anywhere in the world.
4. Communications are always cited as a problem, but the scope of needed improvements in the biodefense field is phenomenal. Obvious basic concerns about sharing information among public health and medical personnel during evolving situations are complicated by the need to extend this to civil authorities, law enforcement, the public, and the media. Some of the issues are not merely solved by computers or phone lists; there are deep cultural divides among these compartments and issues of control. To deal with such an emergency, there will be no substitute for having an informed cadre of reporters who understand the issues and have some rapport with the public health authorities; this will facilitate dealing with the anxious, the incubating, and the sick with minimal public panic.
5. Although public education might be subsumed under the rubric of "communication," this aspect is so important that we mention it separately. An appreciation of the basic facts of infectious diseases and bioterrorism will be essential in obtaining an effective response to an attack and in engendering support for the counterterrorist agenda. We must begin now because there continue to be significant gaps in both media and public understanding of the situation and we remain unprepared.
6. We have not dealt with the issues of infectious agents directed against crops or domestic animals. Even without the loss of one human life, it is resoundingly clear that a terrorist could achieve their goals of producing mass panic, economic damage, and the undermining of public confidence in government by an attack on animals or crops. If the agent is one such as Rift Valley fever, which is an agricultural pathogen and which is also a human pathogen, the complications will be multiplied *(42)*.
7. The research agenda is enormous. It ranges from the psychological effects of bioterrorism through operations research to the most basic molecular biology. Most of the biothreat microorganisms are emerging infectious diseases and/or regional threats outside the United States. However, through global neglect of these agents, we have a poor understanding of their basic biology and treatment. We have not begun to think through some of the trade-offs in our attempts to medically protect the civilian population from bioterrorism. As one example, traditional infectious diseases control as well as protection of the military against biological warfare regards vaccines as the gold standard. However, in today's world with multiple threat agents and no certainty of

the use of any one of them, vaccines present an inherent risk that may not be acceptable. It may be preferable to rely on drugs in many situations; even though they have their own side effects and treatment may not be as effective as vaccine prevention, at least they would be used in the presence of a known risk (43). Certainly, vaccines will be important for a communicable disease such as smallpox, to protect at-risk laboratory workers, and selected populations or circumstances (44).

8. The aerosol mode of delivery presents us with a discipline that is both familiar and yet strangely forgotten. At one time, aerosols were studied as important mechanisms of spread of tuberculosis, measles, and other diseases; in the last two decades much of this knowledge has eroded from the medical curriculum. We need to resurrect this information and add new research findings. The importance in defense against catastrophic bioterrorism is undeniable. Observations on the use of *Bacillus thuringiensis* to kill arthropods have provided a chilling example of large area coverage by this relative of *B. anthracis* (28,*29*). Older observations based on liquid and powder aerosol biological warfare agents have given us a good perspective on the dissemination of airborne infection (*22*,24). However, the properties of the fine, hydrophobic powders that were the most dangerous weapons developed are not well understood by the medical community *(5)*, and the knowledge of their properties to form secondary aerosols is an area of some ignorance to all *(45)*.

CONCLUSIONS

The United States has just begun a long march toward effective biodefense measures. We should not suppose that this threat will disappear or that it is not significant because of the failure to find biological weapons in Iraq. The process will be expensive but will yield dividends through strengthening our national security, our posture toward emerging infectious diseases, and the public health system that protects us every day *(18)*. We still need a national dialogue and deeper thinking to resolve the elements of this complex problem (*20*,46).

FURTHER READING

The best single source for the principles of dissemination, history of biological warfare, and several of the diseases is the *Textbook of Military Medicine* edited by Sidell, Takafuji, and Franz *(22)*. Because many of the diseases are emerging or tropical diseases, that literature often has a more expansive treatment than texts oriented toward North American considerations *(47)*. The series of articles from the Johns Hopkins Center for Civilian Biodefense are excellent treatments of category A agents and are available through their Web site (http://www.upmc-biosecurity.org/). Some excellent Web-based aids are available at www.cidrap.umn.edu. Good popular books about biowarfare and bioterrorism cover the older history *(8)* and more recent events *(9)*. An excellent book for the intelligent layman who needs background is *Living Terrors: What America Needs to Know to Survive the Coming Bioterrorist Catastrophe* (48). It would be of interest to many to read at least one of the pre-9/11 commission reports predicting catastrophic terrorism and bioterrorism (32,*33*,*34*), as well as some of the more recent thinking on where we need to be going in biodefense (46).

CHAPTER 102

The State and Local Response to Bioterrorism

Ann I. Winters, Joel Ackelsberg, Marcelle Layton, Marc Paladini, Debra Berg, and Sara T. Beatrice

BACKGROUND

After the anthrax terrorist events of 2001, there was recognition at local, state, and federal levels of the importance of improving and maintaining the public health infrastructure as a primary defense against bioterrorism. In January 2002, the Department of Health and Human Services announced the availability of $1.1 billion in federal funding that would be made available to all states and four large urban areas (Chicago, District of Columbia, Los Angeles, and New York City) in federal fiscal year 2003 to address critical gaps in bioterrorism public health preparedness and response plans and infrastructure.

Federal funding for biodefense increased over the next several years through FY2006, trended down through FY2008, and has increased modestly in recent years. The FY2010 federal budget for biodefense totaled $6.05 billion *(1)*, with a significant portion applied to programs that serve multiple public health goals in addition to improving bioterrorism preparedness, according to an "all hazards" approach to disaster preparedness.

At the local and state levels, public health preparedness continues to develop on many fronts, creating expanded capacities for rapid and effective responses to incidents caused by intentional (e.g., bioterrorism) or accidental releases of biological threat agents (BTAs). Local and state health authorities must be able to recognize the occurrence of unusual disease manifestations, clustering, or increases in infectious disease illnesses through a variety of surveillance systems. Detection must be followed by prompt epidemiologic, environmental, and laboratory investigation, and an intentional source must be distinguished from a natural cause.

Once a BTA event is suspected, public health authorities need to be able to mobilize rapidly to identify the time, location, and method (e.g., aerosol vs. foodborne) of the release and conduct ongoing surveillance and epidemiologic investigations to characterize the extent of the outbreak. Local and state public health departments must be closely coordinated with the appropriate governmental agencies at the local and state (e.g., emergency management, police, emergency medical services), regional (neighboring state and county authorities, especially public health counterparts), and federal (e.g., Departments of Health and Human Services, Homeland Security, Defense, and Justice) levels. This coordination relies heavily on preexisting relationships and agreements with these agencies.

Local and state health authorities must also be able to communicate with and assist healthcare providers in the community through routine, well-established mechanisms. Linkages with the local healthcare provider, hospital, long-term care, home care, and laboratory communities are essential for successful engagement during a crisis. Public health authorities must determine whether antibiotic or vaccine prophylaxis is indicated and, if so, must be prepared to coordinate with emergency management agencies and the healthcare community to provide medications to potentially exposed persons.

In addition to effective communication with the provider community, local and state public health authorities must be prepared to communicate effectively with and engage the public at every step in the BTA investigation, even when information is limited.

By enhancing their capacities required for rapid and effective responses to outbreaks caused by potential BTAs, public health agencies are better prepared when naturally occurring public health emergencies occur (Table 102-1). This was evident in the local, state, and federal responses to the challenges of the 2009 H1N1 pandemic.

STATE AND LOCAL HEALTH DEPARTMENTS IN THE UNITED STATES

Public health authority in the United States resides mostly at the state and local levels, with the powers of our federal public health agencies being limited and specific to certain key areas (e.g., international and interstate quarantine, and regulation of drugs and vaccines). At the state level, the public health role focuses on ensuring that statutory authority is in place for both routine and emergency health activities, monitoring statewide disease surveillance in coordination with local health units, developing policy and guidelines for disease control activities, providing reference laboratory services, and supporting local public health agencies through financial or technical assistance. In contrast, local public health activities focus more directly on the collection of disease surveillance data; case and

TABLE 102-1

BTA Preparedness Checklist for Local and State Public Health Agencies

1. Coordination and communication
   a. Development and maintenance of an up-to-date contact list, with built-in redundancy, for all key personnel at responding local, state, and federal agencies (e.g., emergency management, police, fire, regional public health partners, FBI, and CDC)
   b. Regular interagency meetings with emergency management, law enforcement, and hazardous material responders to ensure that public health planning efforts are integrated with other agencies' plans
   c. Prepreparation of response protocols for each BTA, as well as various potential scenarios (e.g., threat incidents involving suspicious environmental samples vs. covert large-scale aerosol attack)
   d. Regular tabletop exercises and drills (include representatives from medical and laboratory communities)
2. Surveillance
   a. Illnesses caused by key potential BTAs should be included on the notifiable disease list; in addition, a clause to ensure that any unusual disease clusters or manifestations are reportable should be included in the local and/or state health code
   b. Ongoing provider outreach efforts to enhance knowledge of diseases caused by potential BTAs and to reinforce familiarity with all disease-reporting requirements
   c. Periodic bulletins on disease reporting and bioterrorism, with an emphasis on 24-h telephone contact information for reporting suspect cases of urgent concern
   d. 24-h/7-d response capability with appropriately trained medical staff to triage calls from providers regarding potential cases of public health concern
   e. Consider establishing syndrome-based or unexplained illness/death surveillance with protocols in place outlining response mechanisms if unusual disease activity is identified
3. Epidemiologic capacity
   a. Contingency plans for mobilizing health department staff to assist in a large and/or multiple epidemiologic investigations
   b. Template questionnaires and forms for chart reviews and other surveillance activities can be drafted beforehand; outbreak management database with electronic linkages to the public health laboratory
   c. Pre-established guidelines and procedures for conducting joint investigations with law enforcement
   d. Integrating environmental assessments and laboratory testing with the surveillance and epidemiologic response
4. Laboratory capacity
   a. Education of clinical microbiologists at local hospitals regarding criteria for reporting suspicious laboratory findings
   b. Training in chain of custody requirements and certification in proper packaging and transport of specimens according to government regulations
   c. Public health laboratories should participate in the CDC's LRN—for example, as reference laboratories—and should facilitate integration of clinical hospital and commercial laboratories into the LRN as sentinel laboratories
5. Guidance regarding clinical management of illness due to BTAs
   a. Clinical guidelines for the medical management of diseases caused by potential BTAs drafted before an event
   b. Communication infrastructure to ensure rapid distribution of guidelines and protocols to providers and hospitals, if needed (e.g., broadcast facsimile and e-mail, Web site, and Health Alert Network)
   c. Pre-event planning for establishing a medical hotline to assist clinicians in the management of patients and contacts and to triage reports on suspect cases, including surge capacity and just-in-time training for staff
6. Mass medical and mortuary care
   a. Contingency plans for enhancing capacity for acute medical care and mass mortuary needs (including plans for how federal DMAT and DMORT teams will be used)
   b. Contingency plans for rapidly establishing and maintaining community-based clinics for mass prophylaxis using antibiotics and/or vaccines (including plans for providing prophylaxis to difficult-to-reach populations, such as the homebound and homeless)
   c. Determination of need and feasibility of establishing a local antibiotic stockpile to ensure adequate supplies while awaiting federal reserves (antibiotic stockpiles need to include alternative regimens for pediatric, pregnant, and immunocompromised patients, when indicated)
   d. Prepreparation of multilingual patient information sheets and vaccine consent forms
   e. Contingency plans for establishing and enforcing quarantine of potentially infectious contacts (e.g., contacts of smallpox cases)
   f. Guidelines to assist local medical care institutions' planning for responses to citywide infectious disease emergencies, including treatment of mass casualties and fatalities, staffing, and other resource shortages and the integration of facility-specific plans into regional emergency management. Planning should include providers of acute care, long-term care, home care, and outpatient and emergency medical services
   g. Contingency plans for mass mortuary care including tracking, storage, and disposal of potentially infectious remains

(*Continued*)

TABLE 102-1

BTA Preparedness Checklist for Local and State Public Health Agencies (*Continued*)

7. Communication and mental health issues
   a. In coordination with other responding agencies, predesignation of primary spokesperson(s) and/or agency
   b. Pre-event drafts of fact sheets on potential BTAs for the general public
   c. In partnership with mental health agencies, develop capacities for providing crisis counseling for escalating numbers of potential victims, their families, first responders, the medical and public health community, and the general public
   d. Broadcast facsimile and e-mail capacity (e.g., Health Alert Network) to facilitate urgent communications and notifications of the medical community
8. General infrastructure issues
   a. Establishment of a public health incident management system with training of all staff regarding their expected emergency response roles and responsibilities
   b. Sufficient capacity to support emergency communication (cellular phones, two-way radios, BlackBerries), transportation, information technology, and personal protective equipment requirements

BTA, biological threat agent, CDC, Centers for Disease Control and Prevention; DMAT, Disaster Medical Assistance Team; DMORT, Disaster Mortuary Relief Team; FBI, Federal Bureau of Investigation; LRN, Laboratory Response Network.

contact management activities to control disease spread (e.g., provision of immune globulin for hepatitis A contacts or directly observed therapy for tuberculosis); and, in some localities, direct provision of healthcare *(2)*. However, great heterogeneity exists with respect to personnel capacity, services offered, and organizational structure among state and local health departments in the United States. In some states, public health is decentralized, with most activities and services occurring at the local level, and with state officials providing more of an oversight and advisory role. In other states, there are no local health units, and all public health activities are conducted by the state. An even greater diversity of capacity and services exists among local health departments. In some large urban areas, the local health agencies are larger than many state health departments and function independently, whereas in more rural counties, resources may be quite limited with minimal professionally trained staff, thus requiring a greater reliance on state-level support.

ROUTINE LINKAGES BETWEEN PUBLIC HEALTH AND THE HEALTHCARE SECTOR

Public health authorities routinely interface with the healthcare sector on many levels. One of the core missions of public health agencies is the control of communicable diseases. This legal mandate requires the close coordination between public health officials and their local healthcare provider, hospital, and laboratory communities. Traditionally, disease surveillance activities depend on prompt reporting by healthcare providers and laboratorians concerning suspect or confirmed cases of notifiable diseases to local and state health departments.

One of the most important linkages at the local level is between public health officials, infection preventionists (IPs), and healthcare epidemiologists. IPs and healthcare epidemiologists serve as the primary points of contact in hospitals for surveillance and disease control activities during both community- and healthcare-associated outbreaks and serve a critical role in any hospital's ability to respond to a BTA event. Case investigations by public health officials often require communication with the reporting clinician or hospital IPs, whether for more detailed clinical and/or epidemiologic data or to help facilitate the collection, packaging, and transport of appropriate clinical specimens for testing at public health reference laboratories (e.g., rabies or botulism).

In addition to reliance on IPs and healthcare epidemiologists for surveillance and case investigation, public health officials routinely request assistance from the provider community when postexposure prophylaxis is indicated for contacts at risk of potential secondary transmission (e.g., hepatitis A or invasive meningococcal disease).

Partnerships between health departments and the medical provider community are also essential in implementation of public health prevention campaigns. Examples of this successful partnership include the response to the epidemic of multidrug-resistant tuberculosis in the early 1990s *(3)*; perinatal hepatitis B prevention programs; HIV counseling, testing, and partner notification programs; and vaccination campaigns for seasonal influenza and high-risk groups for hepatitis A *(4)*.

BIOTERRORISM PREPAREDNESS REQUIRES ENHANCED LINKAGES

Bioterrorism preparedness requires building on linkages between the public health, hospital and medical care sectors that are already in place to confront routine public health problems. The terrorist events of 2001 highlighted gaps in the capacity of the healthcare system to respond to large-scale health events. In 2002, the Congress created the Hospital Preparedness Program in the U.S. Department of Health and Human Services. One of the significant outcomes of this program has been the development of healthcare coalitions (5) composed of healthcare facilities and response agencies (including and often led by local and state public health authorities).

Healthcare coalitions work together regionally to create comprehensive response plans tailored to the specific capacities and needs of the local communities. Hospital preparedness programs and healthcare coalitions enable the local medical and public health communities to become familiar with each other before a public health emergency occurs. Recent examples of linkages between public health authorities and the healthcare community include enlisting primary care clinic staff to deliver vaccinations or prophylactic antibiotics, training emergency medicine physicians and nurses to recognize and initiate treatment of BTA-related diseases, and partnering with intensivists to plan for surge capacity in critical care. Additionally, providers from pediatrics, obstetrics, and geriatrics were targeted to increase vaccination among their high-risk patients during the recent 2009 H1N1 pandemic.

Medical providers and key hospital staff (e.g., infection preventionist and microbiology staff) should know the local and state health departments' 24-hour, 7-day-a-week emergency contact numbers and Web site information and should be registered for public health electronic communication systems (e.g., Health Alert Network, broadcast facsimile, and e-mail health alert systems such as the Centers for Disease Control and Prevention's (CDC's) Clinician Outreach and Community Activity Listserv at *http://www.bt.cdc.gov/coc*a) that provide urgent notification of the community during acute events.

Key aspects of plans that need to be in place for the public health response to suspected or confirmed incidents involving BTAs parallel what should be used for naturally occurring infectious disease outbreaks. The 2009 H1N1 pandemic was a naturally occurring outbreak that demonstrated the need for many of these capacities and highlighted some of the ongoing challenges for public health emergency preparedness planners (6).

INTERAGENCY AND INTERSECTOR COORDINATION AND COMMUNICATION

Just as established linkages between public health authorities and the healthcare sector must be enhanced before an emergency occurs, strong relationships must be in place between public health agencies and other relevant local, state (e.g., emergency management, police, emergency medical services, fire/hazmat, and poison control centers), and federal (e.g., CDC and Federal Bureau of Investigation [FBI]) agencies prior to a public health emergency, whether a BTA event or a natural outbreak. A centralized emergency operations center is essential to facilitate intra- and interjurisdictional coordination and communication. In the event of an emergency, predesignated representatives from all involved agencies and any local or state hospital associations should be assigned to this center to ensure effective coordination of the overall response.

The public health sector's communication, transportation, and other equipment or infrastructure needs for disaster response should be assessed prior to an emergency. Essential resources include reliable and redundant communication capacity (e.g., cellular telephones, handheld devices [with e-mail/Internet access], laptop computers with modem, two-way and 800-MHz radios, and satellite telephones); broadcast facsimile and e-mail capability; secure Internet sites (e.g., Health Alert Network) to rapidly notify and inform the healthcare sector regarding events of public health concern; and computer systems that are networked between the local and state health department, the local emergency management command center, and appropriate state and federal agencies. Additionally, hospitals and some primary care clinics have enhanced their own redundant communication systems to improve and ensure internal and external communication with employees, public health authorities, and first responder agencies. Backup generators should be available not only in healthcare settings but also for use by public health authorities, as demonstrated by the 2003 blackout in New York City when a delay in obtaining generators limited the public health response *(7)*. Finally, an alternative location for emergency operations personnel to meet must be identified, in the event that the primary emergency operations center is damaged or otherwise unavailable.

If personnel are expected to use specific equipment and procedures during an emergency, they must be trained and demonstrate proficiency beforehand. To the extent possible, these response measures should be based on routine operations. It is unreasonable to expect unfamiliar plans, protocols, procedures, or equipment to be implemented or used effectively during an emergency.

While training for public health staff should include the clinical, laboratory, and epidemiologic features of disease caused by exposure to potential BTAs, it should also focus on the expected roles and responsibilities of agency staff during response activities. Key challenges facing public health officials once a BTA incident is detected include characterizing the scale and scope of the biological hazard; estimating accurately and rapidly those populations at risk from exposure to the biological hazard; distributing effective countermeasures efficiently and within a time frame that will prevent infection among those exposed; supporting the healthcare system that will be treating potentially thousands of casualties; and disseminating accurate and frequent guidance and updates for the public and providers. Importantly, these activities must be performed within an incident management structure that is consistent with national standards.

Effective training tools include tabletop and field exercises, with involvement of representatives from all key local, state, and federal agencies and representatives from the local medical and laboratory communities. These exercises provide the opportunity to test assumptions in existing plans and work out issues related to decision-making authority and respective roles and responsibilities among the disciplines that would be involved in responding to a BTA event. A successful exercise includes a written after action report that highlights gaps in preparedness that should be addressed through follow-up meetings and revision of written plans, if indicated, and reevaluated with periodic exercises.

DETECTION OF A BTA EVENT: TRADITIONAL AND NONTRADITIONAL SURVEILLANCE SYSTEMS

If there were a delay in detecting an outbreak caused by a BTA release, public health preventive interventions might be less effective than if started sooner, and the impacts on morbidity and mortality could be substantial (8). The

diseases caused by potential BTAs may not be suspected or diagnosed rapidly for a number of reasons: initial presentations may be nonspecific (e.g., influenza-like prodrome of anthrax); most physicians in the United States have little or no clinical experience with the diseases caused by these agents (e.g., anthrax, tularemia, botulism, or smallpox); laboratory diagnosis may require days or longer for presumptive identification (e.g., tularemia); the epidemiology and clinical presentation of diseases caused by intentional dissemination may differ from what is found in naturally occurring disease; and more common microorganisms could be used that might not be associated immediately with criminal intent (e.g., enteric pathogens).

State and local public health officials should consider the different surveillance strategies for detection of BTA-related incidents and need to be alert to potential ways in which they could present. A potential BTA dissemination should be considered by public health authorities or healthcare professionals if any of the following occurred:

1. A single suspected or confirmed case of an illness resulting from exposure to a potential BTA occurring in a patient without a plausible explanation for his or her illness (e.g., a case of plague in the absence of a recent travel history to a recognized endemic area).
2. Multiple patients presenting with a similar clinical syndrome that has unusual characteristics (e.g., unusual age distribution or previously healthy individuals), is clustered by time and/or space (e.g., all became symptomatic within the same approximate time period or attended the same special event), or involves unusually severe illness, without an obvious etiology or explanation.
3. An *unexplained* and marked increase in the incidence or severity of a common syndrome above seasonally expected levels (e.g., a sudden increase in influenza-like illness especially if during the summer and if rapid diagnostic tests were negative for influenza and other common respiratory viruses).

If a potential BTA incident is suspected, an investigation should be initiated immediately to determine the etiologic agent and the likely source of infection, including whether or not a natural route of transmission exists. Because the above circumstances could result from intentional, accidental, or natural exposures, it is important for those evaluating and managing routine cases and/or outbreaks to keep an open mind to all possibilities. Investigations of what appeared to be routine foodborne outbreaks, upon further epidemiologic and laboratory investigation were found to have resulted from intentional contamination of food with enteric pathogens *(9,10)*. In contrast, when diseases associated with exposure to a potential BTA occur in a nonendemic area, intentional dissemination (e.g., bioterrorism) could be a possibility; however, a natural explanation also must be considered. In 2002 in New York City, two bubonic plague cases occurred in residents of New Mexico who were exposed to plague bacilli shortly before traveling to New York *(11)*. Inhalation, cutaneous, and gastrointestinal anthrax also have occurred in recent years following exposure to contaminated animal hides and African *(12–14)*.

There are a number of surveillance methodologies used for detecting BTA incidents that focus on recognizing or detecting (a) a suspected or confirmed case or illness cluster resulting from exposure to a potential BTA; (b) community-wide or localized increases in influenza-like illness activity or other nonspecific syndromes or increases in potential markers of early prodromal illness (e.g., over-the-counter drug sales); (c) an increase in unexplained, severe infectious illnesses or deaths; or (d) nucleic acid from select bacteria or viruses in air samples collected routinely by environmental biomonitoring programs.

Traditional Public Health Surveillance

Traditional public health surveillance for BTA-associated illness relies on enhancing the medical and laboratory communities' familiarity with these agents, with the goal of improved reporting of suspected or confirmed illnesses potentially caused by a BTA, as well as reporting of unusual disease manifestations or illness clusters. Most local and state health codes require that physicians, hospitals, and laboratories report a defined list of notifiable infectious diseases. Many state public health agencies have added all CDC Category A and most Category B agents that were not already included on their reportable disease lists *(15)*. In addition, recognizing the need to detect newly emergent diseases that are not yet listed on the health code, most states also require reporting of any unusual disease clusters or manifestations.

Early recognition of a BTA-associated event depends in large part on astute clinicians and laboratorians recognizing one of the index cases based on a suspicious clinical, radiologic, or laboratory presentation (e.g., a febrile illness associated with chest discomfort and a widened mediastinum on chest radiograph in an otherwise healthy adult suggests inhalation anthrax). Isolated cases presenting at separate hospitals will not be recognized as a potential outbreak unless they are reported promptly to the local health department, where the population-based aberrations in disease trends are more likely to be noticed. Previous examples of astute clinicians recognizing and reporting unusual disease clusters or manifestations that led to the detection of a more widespread outbreak includes an outbreak of hantavirus in the southwestern United States *(16)*, Legionnaires disease associated with the whirlpool on a cruise ship *(17)*, an outbreak of *Cyclospora* associated with contaminated raspberries imported from Guatemala *(18)*, and the initial outbreak of West Nile virus in New York City in 1999 *(19)*. Similarly, the initial detection of anthrax in 2001 was due to a physician who recognized that large gram-positive rods in a patient's cerebrospinal fluid could be *Bacillus anthracis (20)*. By reporting this suspected case of meningeal anthrax, rapid confirmation was facilitated in a state public health reference laboratory. Weeks later, a suspected case of inhalation anthrax was recognized and promptly reported to and confirmed by public health authorities in New York City *(21)*.

To inform clinicians and laboratorians regarding their essential role in recognizing and reporting suspected or confirmed illness caused by exposure to potential BTAs, public health officials need to promote the importance of disease reporting through ongoing educational efforts. Targeted outreach efforts should focus on specialists in key areas, such as infectious diseases, infection control, microbiology, emergency medicine, dermatology, and neurology. Educational

outreach should emphasize the clinical presentations and diagnostic clues for specific BTA-associated illnesses (e.g., anthrax, plague, and smallpox) and unusual illness patterns suggestive of an intentional outbreak. One lesson learned during the 2001 anthrax outbreak was that public health and medical professionals need to keep in mind all potential clinical manifestations caused by BTA exposure. Cutaneous anthrax—not inhalational disease—was the sentinel illness in New York City. Educational materials also should emphasize prompt reporting of any unusual disease clusters or manifestations to the local or state health department as paramount to the early recognition of natural, intentional, and accidental outbreaks caused by BTA releases. Educational outreach is also needed for key members of the local first responder community (e.g., hazmat, police, and emergency medical services).

The following methods can be used to help increase awareness of BTA-associated illnesses in the medical and laboratory communities:

1. Oral presentations targeting specialists in internal medicine, emergency medicine, pediatrics, dermatology, neurology, family practice, infectious diseases, geriatrics, pathology, laboratory medicine, intensive care, pulmonary, radiology, and primary care physicians; physicians-in-training and medical students; medical examiners; veterinarians; and microbiologists.
2. Public health bulletins (22), newsletters, posters, or pocket cards that present overviews of the clinical aspects of infections caused by potential BTAs (e.g., clinical presentation, laboratory diagnosis, treatment, and prophylaxis) and emphasize the importance of promptly reporting any unusual disease clusters or manifestations to the local and state health departments. These educational materials should be updated and redistributed periodically to maintain ongoing awareness of and sensitivity to these issues.
3. Posting educational materials on the health department's public Web site with links to other useful resources (23), including the CDC (*http://www.cdc.gov*), the Infectious Disease Society of American (*http://www.idsociety.org*), the American Society for Microbiology (ASM; *http://www.asm.org*), and the Center for Infectious Disease Research and Policy at the University of Minnesota (*http://www.cidrap.umn.edu*).
4. Development of teaching slides and videos that can be distributed to academic and community-based physicians (train-the-trainer modules). Because many health departments may not have sufficient staff with the expertise or time to meet every request for a talk on the clinical aspects of the BTA and the threat of bioterrorism, efforts should be made to provide teaching materials (e.g., slide presentations with speaker notes) to interested local colleagues in infectious diseases, infection control, or other specialties to do presentations to medical staff at their own institutions or organizations.

Improving the overall relationship between the health department and the medical community is an important element that makes it more likely that providers will report promptly. Efforts to improve provider relations and streamline physician reporting should be prioritized. Web-based and other electronic methods can be offered for routine case reporting. During emergencies, a consistent telephone number could be used for provider hotlines (e.g., 1-800-MD-REPORT). This would facilitate efficient and timely triage of provider and laboratory calls to clinically trained health department personnel. Dissemination of surveillance data routinely and during emergencies also can foster the ongoing, collaborative relationship between public health and the medical and laboratory communities. These efforts have the additional benefit of improving all aspects of local public health surveillance.

Outbreaks of West Nile virus *(24)* and monkeypox *(25)* underscored how public health departments could benefit from establishing and maintaining active collaborations with the animal health community. Many potential BTAs cause zoonotic disease (e.g., anthrax, plague, and tularemia), and animal populations might be affected in unpredictable ways.

Historically, with the exception of rabies-related issues, local and state infectious diseases epidemiologists have not had strong relationships with clinical veterinarians and wildlife specialists in their community. However, with the continued emergence of new zoonotic disease threats, including those related to bioterrorism, local, state, and federal public health agencies have taken steps to improve communication between these communities. Veterinarians have been hired within communicable disease programs to foster collaboration. Requirements have been expanded to include reporting by animal health specialists of suspected or confirmed illness in an animal that might be caused by a potential BTA *(26)*. Similar to the list of notifiable diseases in humans, these regulations also can require reporting of any unusual disease clusters or manifestations in animals.

Nontraditional Surveillance Systems (Syndromic Surveillance)

In the event of an unknown, intentional, or accidental BTA dissemination with the potential to cause thousands of casualties, rapid detection and characterization of the outbreak would be crucial. The swift mobilization of surveillance and epidemiologic resources to determine the place, time, extent, and method of the release would help target preventive measures, speed the epidemiologic and criminal investigation, and reduce public anxiety. For diseases with short incubation periods such as inhalation anthrax, the window of opportunity to respond and to reduce morbidity and mortality is narrow. Therefore, surveillance systems that rapidly provide information on the potential magnitude and geographic scope of a BTA incident, that is, "situational awareness," are paramount.

The traditional public health surveillance system, based on passive reporting of a limited number of defined, notifiable diseases, may not be sufficient for early detection of a large accidental BTA release or for early recognition of the extent of its impact. Some diseases caused by these pathogens (e.g., tularemia) have nonspecific and protean clinical presentations, and laboratory diagnosis may be time-consuming. Thus, alternative systems that allow prompt recognition of unusual disease manifestations, clusters of illness, increases above expected seasonal levels of common syndromes (e.g., influenza-like illnesses), or deaths resulting from unknown infectious causes are potentially useful components of bioterrorism surveillance.

Surveillance for nonspecific clinical syndromes using data available in existing electronic health databases is considered a potentially valuable adjunct system for the timely detection of illness caused by exposure to a BTA. Although many of the most concerning potential infections (e.g., anthrax, plague, smallpox, and viral hemorrhagic fever) have distinct clinical characteristics once the disease is fully manifest, initial symptoms include a nonspecific febrile prodrome similar to influenza-like illness. Large numbers of botulism cases, on the other hand, would present with symptoms pointing to autonomic and voluntary motor nerve dysfunction. Nonspecific gastrointestinal symptoms would predominate if a food item was contaminated with an enteric pathogen.

Because many medical providers and laboratorians in the United States have limited experience with these pathogens, diagnosis may be delayed. Therefore, the first indication that large-scale exposure to a potential BTA has taken place might be an increase in nonspecific symptoms at the community level. Surveillance for these increases in nonspecific syndromes (e.g., respiratory, gastrointestinal, or neurologic) constitutes the cornerstone of syndromic surveillance used for emergency response purposes *(27)*.

The ideal features of a syndromic surveillance system for early detection of a BTA-related outbreak include the ability to detect changes in disease trends that are based on health event information available continuously, in close to real time or at least in 12- to 24-hour increments. Health event information is most timely when it is electronic, gathered routinely for other purposes, and not limited by diagnostic or recording delays. Syndromic surveillance systems based on clinical data have proven most popular, but other sources such as over-the-counter drug sales may also have utility.

Electronic data that may provide a reflection of community-wide illness are increasingly available, including emergency department visit logs *(28)*, ambulance dispatches *(29)*, ambulatory care encounters (30), data from electronic health records (31), and sales of prescription and over-the-counter pharmaceuticals *(32)*. The most reliable electronic data sources are those that already exist (e.g., emergency department and outpatient visits) and that do not rely on additional collection or reporting of data by medical providers. In many systems, these data include geographic information (e.g., home or work zip code or location of store), theoretically enabling the detection of localized disease outbreaks and monitoring of the geographical extent at a given point in time of a potentially widespread event.

Operation of syndromic systems for outbreak detection and situational awareness purposes should be at least daily (including weekends and holidays) and should use statistical algorithms to rapidly detect increases in disease syndromes compared with expected seasonal trends (33). Some systems have the additional sensitivity to detect geographic clusters *(34)*. Hospitals and medical care systems may be able to share data with their local or state health departments, including information on emergency department or primary care clinic visits or hospital admissions. If the data do not contain confidential patient information (e.g., de-identified data limited to age, date of visit, chief complaint, or provider diagnosis), then potential restrictions in the Health Information Privacy and Accountability Act would not apply *(35)*.

When an aberration in a particular syndrome is identified, either a jurisdiction-wide increase or a geographic-specific signal, public health officials need to assess the situation to determine if the finding may represent the first indication of a community outbreak and, if so, conduct an investigation. Similar to traditional outbreak investigations, syndromic signal investigations must determine whether the aberration represents common, background illness versus illness explained by a common exposure. To help separate genuine incidents from statistical anomalies, it is generally assumed that a continued increase in the incidence of the syndrome over two data collection periods is evidence of a genuine event. Interim data from involved facilities (e.g., the most recent 12-hour chief complaint log) can be useful in this evaluation. An aberration generated by one data source may represent unexpected artifacts (e.g., increases in the sale of an antidiarrheal medication resulting from a corporate promotion). However, when multiple signals occur in systems based on independent data sources, the aberrations are likely to reflect a genuine increase in community illness and further investigation would be indicated.

Inspection of the aberrant data may reveal unexpected coding mistakes or the presence of commonalities in demographic variables. Emergency department staff, as directed by geographic clustering, also can be called and asked whether increases in certain illnesses have been seen. As the providers on duty may not be those who worked when the analyzed data were collected, these anecdotes, though reassuring, may have limited value. If aberrations include sudden, marked increases in signal amplitude over baseline, unusual age clustering, or other unexpected features, health department staff can be dispatched to review medical records, conduct interviews, or conduct telephone follow-up on discharged patients. Prospective surveillance also can be augmented with enhanced diagnostic testing for newly presenting patients, as indicated by the syndrome of concern (e.g., rapid antigen tests for influenza, chest radiographs, or blood cultures).

Although initially conceived for early detection of a large, aerosolized covert BTA dissemination, these systems also can be used to monitor natural infectious disease outbreaks and trends in noninfectious events of public health importance. In New York City, syndromic surveillance has been in place since the 1990s, and since that time, numerous other state and local health departments have adapted or developed syndromic surveillance systems for use in their jurisdictions (*36*,37). Information from syndromic systems has proven to be useful for detecting, monitoring, and characterizing seasonal outbreaks of influenza *(38)*, winter gastroenteritis (e.g., norovirus and rotavirus), and asthma, and it has facilitated more timely notification of the medical community and public that preventive measures (e.g., vaccination) were recommended. Furthermore, syndromic systems were utilized extensively during the novel H1N1 influenza pandemic of 2009, along with other methods, to estimate the scale of community-wide influenza transmission (Fig. 102-1).

Health officials in New York City and elsewhere have also found syndromic surveillance useful for providing reassurance that localized to widespread outbreaks were not being missed during times of heightened concern. During the international outbreak of severe acute respiratory

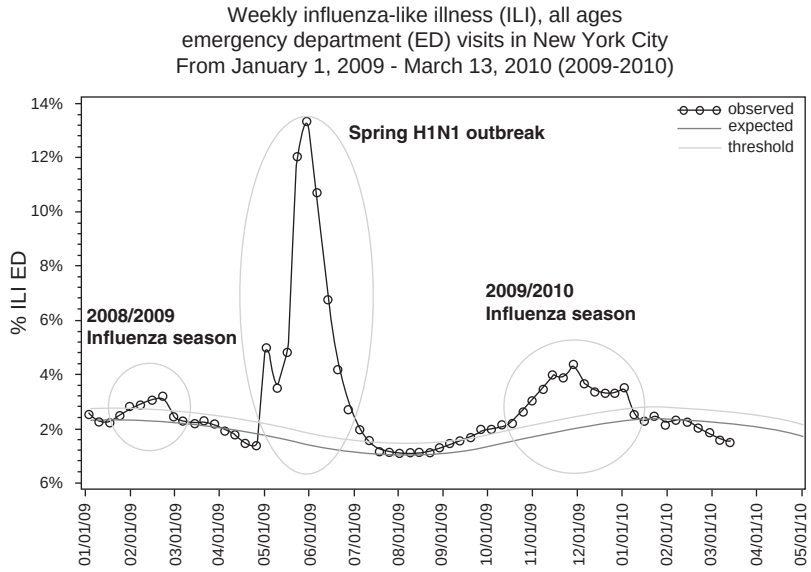

FIGURE 102-1 Weekly ILI syndrome visits to New York City emergency departments (EDs) showing the 2009 H1N1 pandemic and the previous influenza season for comparison. Expected and threshold values are derived from a Serfling model using influenza isolate data and ED syndromic information. ILI visits are defined as visits where the patient's presenting chief complaint include fever and cough *or* fever and sore throat *or* flu.

syndrome (SARS) in 2003, the absence of a persistent city-wide increase or geographic clustering of respiratory or febrile syndromes in any of the current systems in place in New York City provided some assurance that unrecognized SARS transmission was not occurring in the city. Similarly, when cases of inhalation anthrax *(39,40)* and bubonic plague *(11)* were confirmed in New York City, the lack of signals from these systems suggested that these were isolated, not city-wide, events.

Syndromic surveillance data also have been used to monitor trends in noninfectious diseases or conditions of public health concern. Recent applications in New York City have included assessing the cardiovascular morbidity associated with temperature and air pollution; correlating sales of nicotine prevention products—a marker of intent to stop smoking—with increases in the local cigarette sales tax; and identifying areas with increased rates of drug overdose death and domestic violence, through analysis of emergency medical service and emergency department data.

Though the utility of syndromic surveillance systems is well established in many state and local health department settings, particularly for situational awareness for a variety of public health problems, challenges remain. The interpretation of signals and evaluation of syndromic systems for early detection of outbreaks has been complicated by ongoing point-of-care difficulties, including the lack of rapid diagnostic testing of common viral and bacterial respiratory pathogens. As one of the main strategic goals of syndromic surveillance is to detect early signs of BTA-related illness, it would be valuable for emergency department practitioners in locations with syndromic signals to have access to reliable and rapid assays that could rule in the common etiologies of influenza-like illness.

It is not yet clear that syndromic surveillance would detect BTA-related outbreaks of varied scale and scope as there have been no large-scale BTA-related outbreaks to analyze in formal validation studies. Correlations have been seen between large-scale syndromic aberrations and infections from circulating viruses such as influenza and norovirus but small clusters identified by syndromic systems have not been matched to specific microorganisms that may have been causing the disease. However, the benefits beyond early detection of a BTA-related event, including improved situational awareness, may make the investment of resources in syndromic surveillance worthwhile *(41)*. Most importantly, these systems complement but cannot replace traditional disease surveillance for early detection based on disease reporting from astute medical providers. Recent outbreaks of BTA-related disease have been detected after concerned providers rapidly notified the local or state public health authorities regarding a single concerning case or small cluster *(11,20,21)*. Syndromic surveillance has been very helpful in these situations for providing assurance that a larger scale event was not occurring.

Unexplained Deaths and Severe Illnesses Potentially Resulting From Infectious Causes

Surveillance for unexplained deaths or severe illnesses that may be due to unrecognized infectious causes also might prove useful for detecting infectious disease outbreaks caused by BTAs. Sources of data include intensive care unit admissions, vital records (if electronic registrations systems are in place so that death certificates are available for analyses within 24 hours of filing), and medical examiner surveillance *(42)*. These systems also have potential usefulness for detecting new or reemerging infectious diseases with higher rates of morbidity and mortality, such as hantavirus pulmonary syndrome or SARS.

Existing systems focus on potentially infectious deaths or severe illnesses among otherwise healthy adults between the ages of 18 and 65 years, as unexplained infectious deaths are less common in this age group (43). Surveillance for unexplained infectious illness requires establishing collaborations with the critical care community and IPs; providing clear criteria for reporting suspect cases; and ideally including a strong laboratory component that encourages submission of appropriate clinical samples, including

tissue biopsies, for comprehensive testing at reference laboratories. Similar collaborations should be in place with the local medical examiner for unexplained infectious death surveillance, with protocols in place to obtain tissue samples from multiple organs for microbiologic, molecular, and/or antibody-based testing (e.g., immunohistochemical staining).

Simpler systems for monitoring potential infectious deaths involve the use of death certificate data, which are already being collected at the state and some local health department levels. These systems require clear criteria regarding which causes of death should be included (e.g., sepsis without a specific etiology). However, limitations to this method of surveillance include the typical 2- to 3-day delay between the time of death and filing of the death certificate, the lack of electronic death certificate data in most jurisdictions, and the inability to detect clusters at the time of illness onset because the data are restricted to fatal cases only. The usefulness of these systems are also limited by usual concerns regarding the reliability and accuracy of these data and the inability to obtain additional diagnostic testing unless clinical specimens were still available or autopsies were performed.

Although these systems in and of themselves may not be useful for the initial detection of a BTA-related event, they have potential usefulness as adjunct systems. If a suspicious case or cluster were detected, it would be valuable to have these systems in place to assess whether there had been any recent fatalities with similar presentations that could be part of the suspected outbreak. Finally, these systems encourage public health officials to forge relationships with partners in the intensive care and medical examiner/coroner communities—linkages that should be in place prior to the occurrence of a large, infectious disease outbreak of public health concern, whether natural, intentional, or accidental.

Environmental Monitoring for Intentional or Accidental BTA Releases

In 2003, the Department of Homeland Security (DHS) began deployment of BioWatch, an environmental monitoring system for detection of specific potential BTAs in approximately three dozen urban areas. It was meant to function as a biological early warning system, detecting evidence of aerosol dissemination before persons presented with acute illness. The system uses standard environmental air samplers that pump air across a filter membrane. The filters are collected and transported to local or state public health laboratories, where polymerase chain reaction testing is used to identify specific nucleic acid signatures for each of the potential BTAs. Third-generation systems have been planned that would be more automated, allowing for more timely detection using fewer public health laboratory resources.

DHS recently commissioned the National Academy of Sciences to examine the BioWatch program and to characterize the contribution of this system relative to public health and healthcare systems (44). Several areas of concern were identified and recommendations were issued that are intended for implementation prior to the deployment of the third-generation technology. These recommendations include improved integration of the system with the public health systems in jurisdictions where BioWatch is deployed and increased DHS support for local public health agencies so that they can respond more effectively to signals generated by BioWatch. A key report finding was the recognition that deployment of any environmental monitoring system must be accompanied by bolstering of local and state capacity to respond to potential public health emergencies detected by that system. In particular, health authorities must be equipped to rapidly determine whether a signal is real and, if so, define the geographic area affected and identify the potentially exposed individuals.

COORDINATION AND LAW ENFORCEMENT

An outbreak that is suspected or confirmed to be associated with dissemination of a potential BTA may be a criminal event. It requires careful consideration of when and to what extent coordination and collaboration with local, state, and federal law enforcement would be indicated. FBI is the primary agency charged with coordinating with other law enforcement agencies for all criminal investigations of incidents that are suspected to have resulted from the intentional use of a BTA *(45)*. Law enforcement agencies have not historically worked closely with the public health community. One of the lessons learned from the 2001 anthrax incidents was the value of public health and law enforcement officials knowing each other and being familiar with their respective investigational responsibilities *before* a crisis (46). FBI has established a nationwide network of Weapons of Mass Destruction Coordinators in key urban areas. These experienced investigators have been very successful in forming and sustaining valuable and effective collaborations with their public health counterparts.

Public health officials should establish consensus agreements with local law enforcement and FBI that address how all parties will communicate and coordinate activities during the investigation of any incident involving the suspected intentional use of a BTA. Protocols and procedures should acknowledge both shared and separate interests and can involve general counsel from each agency *(47)*. For example, it is crucial for public health to establish standards for joint investigations that minimize potential detrimental impacts on patients and on the routine activities within healthcare facilities. Otherwise, longstanding and critical relationships with providers and the public—necessary for carrying out core public health missions—could be damaged. Procedures can be implemented that acknowledge and protect this public health requirement and that also afford law enforcement sufficient flexibility to respond in ways that would not compromise a criminal investigation. For law enforcement, it is important to be notified by public health investigators whenever the possibility of a BTA release is being considered, to have immediate access to the patient's demographic information, and to be confident that public health investigators can deploy rapidly and at any time and respect the importance of crime scene investigations.

Joint investigation protocols can establish agreements in the following areas: circumstances when one party to the agreement will notify the other(s); response times;

information sharing; and parameters for joint interviews of ill patients and/or friends and household members (e.g., limited to where, when, and how exposures took place). The threshold for providing law enforcement with confidential patient information must be high and consistent with local, state, and federal statutes and regulations.

Clearly designated points of contact should be established between both local and federal law enforcement and local public health agencies, so that information can be shared confidentially, securely, and with confidence. Though it is not required for information sharing between trusted parties in most emergencies, a limited number of federal security clearances also might benefit local public health departments, so that certain officials can maintain work-related access to relevant classified information.

During a joint investigation of a suspected covert BTA release, public health and law enforcement staff will press to determine rapidly and efficiently the time, location, and method of dissemination. With that information, public health authorities may tailor interventions to those persons with specific exposure risk factors, enabling more effective use of finite personnel and material resources. For law enforcement, this collaboration could lead to more efficient determination of the crime scene, evidence collection, and arrest of suspected perpetrators.

Collaborative public health and law enforcement investigations would involve joint interviews of patients and families in hospitals, sharing of potentially sensitive data, and active liaison with and contribution to the respective epidemiologic and criminal investigations. Laboratory specimens obtained as part of the public health investigation, including both clinical and environmental samples, would need to be handled as potential evidence and collected with full attention to chain of custody and Select Agent Program documentation requirements *(48)*.

INITIAL INVESTIGATION AND NOTIFICATION OF ALL KEY PARTNERS IN THE EVENT OF A SUSPECTED OR CONFIRMED BIOTERRORIST EVENT

The initial investigation into a potential BTA-associated event should proceed according to preestablished protocols, as much as possible. Separate protocols may be needed to address the response to at least five potential scenarios: (a) suspected (i.e., by public health authorities) or confirmed cases of illness resulting from exposure to a potential BTA that are reported by a provider or laboratorian; (b) an unusual disease cluster or manifestation reported by a provider or laboratorian (e.g., rapidly progressive respiratory failure in a group of students from the same school); (c) marked statistical aberrations detected by syndromic surveillance (e.g., sudden, extraordinary increase in the number of patients with influenza-like illnesses presenting to emergency departments or unexplained infectious deaths); (d) a suspicious environmental sample identified in the field (e.g., package containing a written threat and a suspected disseminating device); or (e) a positive laboratory result generated by BioWatch or another environmental monitoring system.

When a suspected or confirmed BTA incident is detected by traditional public health surveillance, plans, protocols, and procedures should be used that address the following issues: internal and external notification, including other local agencies (e.g., the mayor's office, police, fire, and emergency management) and state and federal preparedness and response partners (e.g., state health and emergency management departments, CDC, and FBI); rapid diagnostic testing to confirm the presence of a BTA; communication hotlines for medical providers, the media, and the general public; disease-specific information to the healthcare community that addresses medical management of and infection control precautions for case-patients and potentially exposed persons; enhanced passive surveillance through the reporting of suspect cases; active surveillance and epidemiologic investigations that estimate the scale and scope of the incident and the risks associated with it; support for the healthcare sector's treatment of casualties; distribution of mass prophylaxis, when indicated; and addressing mental health needs, environmental recovery, and community resilience. Emergency call-up lists should be maintained to ensure that sufficient public health staff can be mobilized to assist in all aspects of the emergency response.

Depending on circumstances, notification of federal authorities might include a request for support as provided by the National Response Framework. This could include epidemiologic and laboratory assistance from the CDC; medical, pharmaceutical, and/or vaccine supplies from the Strategic National Stockpile; Disaster Medical Assistance Teams (DMATs); or Disaster Mortuary Relief Teams.

The initial responses to syndromic surveillance aberrations and to results from environmental monitors would be different. If the first indication of a BTA release came from a statistical anomaly or a tested air sample, it is possible that patients with suspected BTA-related infections would not yet have been reported to public health authorities. Accordingly, it would be challenging to determine whether or not the aberrant signal or air sample reflected a genuine public health concern. If a syndromic surveillance aberration was sufficiently unusual (e.g., marked increase in amplitude over what had been seen in the past), it is likely that hospitals would be contacted and asked to enhance diagnostic testing of persons meeting a specific surveillance case definition. Public health investigators also might be deployed to hospitals to review charts and to prospectively conduct active surveillance.

The field responses to an environmental monitoring test result or to a suspicious substance would resemble a hazardous material event, involving first responders from the fire, law enforcement and emergency management agencies. Government environmental monitoring programs use specific and federally validated laboratory assays. Positive results could, depending on circumstances, lead to an intensive investigation that assumed that a BTA release had taken place, including interagency notifications and coordination of interagency responses.

Suspicious substance investigations (e.g., powder in mail), though managed as hazardous material incidents, would not result in a full-scale environmental investigation unless a potential BTA were identified in the tested material. Protocols and procedures for evaluating suspicious

substances should address (a) coordination with other responding local agencies (e.g., emergency management, police, and fire hazmat); (b) collecting, packaging, and transporting samples for rapid testing at public health reference laboratories; (c) appropriate protective gear for first responders; and (d) if and when decontamination and prophylaxis of potentially exposed persons would be indicated.

Although there are commercially available kits that can screen suspicious substances for potential BTAs, FBI, DHS, and CDC have advised against using them for field testing because of the potential risks from both false-positive and false-negative results *(49)*. Reference laboratory testing at state or local public health laboratories is available within a matter of hours in most jurisdictions. Therefore, it is currently advised to withhold any preventive measures, such as antibiotics or vaccinations, pending test results. In the event of extenuating circumstances suggesting that an intentional BTA release was likely (e.g., intelligence information or suspicious disseminating device found at the scene), the field response might include additional measures.

The federal government has not published personal decontamination recommendations for suspicious substance incidents, and it is likely that standards vary between jurisdictions. One state has recommended that the decision should be based on both the law enforcement threat assessment and whether there had been direct contact with the suspicious letter or package *(50)*.

Response personnel at the scene should collect accurate, 24-hour emergency contact information for all potentially exposed persons. If polymerase chain reaction results confirmed the presence of DNA from a potential BTA or if cultures grew the microorganism, they would be contacted immediately to arrange administration of postexposure prophylaxis. Antimicrobial prophylaxis should not be started without first consulting the local health department. In most cases, that decision should be based on the results of tests conducted by public health reference laboratories.

Educational sessions and mental health counseling may also be required on-site and should be included in the interagency response plan to suspicious environmental samples. Potentially exposed persons do not require hospital evaluation unless they report symptoms needing immediate evaluation (e.g., chest pain or difficulty breathing).

PUBLIC HEALTH REFERENCE LABORATORY TESTING OF SUSPICIOUS CLINICAL SPECIMENS

A close and active partnership between the public health laboratory and local clinical laboratories is essential to any infectious disease emergency response. Laboratorians in sentinel laboratories must be trained to identify potential BTAs and demonstrate proficiency, including procedures used for reporting suspicious isolates to the local public health authority. Clinical laboratories also must be certified to pack and transport clinical specimens according to government regulations.

In 1999, the Laboratory Response Network (LRN) was established through collaboration of the CDC, the Association of Public Health Laboratories (APHL), and the FBI to ensure an effective and coordinated laboratory response to bioterrorism at the federal, state, and local levels. The LRN is a tiered-response system for testing and confirmation of potential bioterrorist agents and is composed of sentinel, reference, and national laboratories.

Sentinel laboratories include many hospital and commercial laboratories and follow established protocols for the initial testing of suspicious specimens. Protocols have been developed by the ASM in coordination with the CDC and the APHL to assist sentinel laboratories with techniques to rule out potential BTAs. These guidelines are available on the ASM Web site (*http://www.asm.org*) and provide detailed information regarding the staining properties, growth characteristics on routine media, and preliminary biochemical test results for the bacterial agents. If a potential BTA is suspected at the sentinel laboratory level, samples must be referred to a reference laboratory. Reference laboratories include >140 state and local public health, military, federal, and international laboratories (Australia, Canada, and the United Kingdom) as well as veterinary, agriculture, food, and water testing laboratories. These biosafety level 3 laboratories have the ability to confirm agents such as *B. anthracis* and *Clostridium botulinum*. National laboratories, including the CDC and Department of Defense laboratories, have biosafety level 4 capabilities and perform definitive testing of certain exotic microorganisms (such as smallpox) in high-containment environments *(51)*.

At the state and local levels, training should be routinely offered that addresses laboratory diagnosis and biosafety precautions for potential BTAs and chain of custody requirements, with the target audience being clinical microbiologists and laboratorians in local sentinel laboratories. Training materials should emphasize the potential critical role of laboratorians in the early detection of BTA-related incidents, through recognition of suspicious isolates and prompt reporting to local public health authorities.

Despite the establishment of the LRN and the development of protocols for local and state clinical microbiologists, challenges to the laboratory response to a large-scale outbreak remain. The over 2,000 sentinel laboratories in the United States vary in their preparedness (52). In the event of a large-scale BTA dissemination or naturally occurring outbreak, sentinel and reference laboratories may be quickly overwhelmed by demand for testing. They must be ready to coordinate quickly with public health officials in the implementation of incident-specific guidelines that explain which specimens to obtain, referral criteria for confirmatory testing in the local or state public health laboratory, and handling and shipping requirements. The 2009 H1N1 influenza outbreak demonstrated the potential for rapidly overwhelming sentinel and reference laboratories with the increased demand for testing.

ACTIVE SURVEILLANCE AND EPIDEMIOLOGIC INVESTIGATIONS AFTER THE INITIAL DETECTION OF A CONFIRMED BIOTERRORIST EVENT

Once a BTA-related event is recognized and confirmed by laboratory testing, public health officials have two immediate objectives: (a) to determine who was exposed and

potentially at risk by accurately estimating the scale and extent of exposure to the BTA and (b) to track the health impacts of the incident. To accomplish the former, it will be necessary to determine where, when, and how the dissemination occurred. Data will be collected, analyzed, and interpreted from epidemiologic and criminal investigations and from any environmental sampling that is conducted. Data and analyses must be shared between agencies. In some cases, interstate and international coordination of the epidemiologic investigation may be necessary depending upon the scope of the event. Outlier cases occurring among residents of neighboring or other jurisdictions may provide valuable information to help identify the site, time, and manner of release.

Enhanced passive and active surveillance must be initiated immediately to support epidemiologic investigations that rapidly identify risk factors and track ongoing impacts from the incident. Template materials can be prepared before a BTA event—and revised as necessary—to expedite an investigation. Ready-to-go draft documents can include surveillance instruments (e.g., generic questionnaires for case ascertainment and chart review that can be rapidly modified to the specific circumstances under investigation) and public health alerts that could be mass e-mailed and faxed to all hospitals, primary care settings, and key subspecialists throughout the jurisdiction. This would increase the reporting of illness suspected of being associated with the incident to public health authorities. Generic surveillance instruments should include variables that capture patient demographics; clinical illness; exposures to ill contacts; commuter routes (e.g., subway or bus lines); food histories, if warranted; and potential exposures during the likely incubation period of the specific BTA, such as time spent at stores, restaurants, theaters, museums, tourist attractions, parks, places of worship, schools, sports events, other entertainment venues, and other special events. Both paper and electronic copies of these surveillance materials should be readily available.

Efficient and accurate data management is one of the highest priorities and challenges during any high-profile outbreak investigation. Effective outbreak data management requires the linking of clinical and epidemiologic data with laboratory information, to track specimen collection, laboratory testing results, and the patient's case status (i.e., suspect or laboratory-confirmed). Appropriate public health decisions depend on having up-to-date, accurate information about the evolving outbreak, and the healthcare community, political leaders, the news media, and the public need and expect accurate information describing the event's impacts. This requires having flexible, tested databases that can be modified to the specific incident. These systems should be exercised during routine outbreak investigations to facilitate efficient use during emergencies.

GUIDANCE FOR HOSPITAL AND MEDICAL PROVIDERS

Most medical and laboratory professionals in the United States have had minimal clinical experience with the most concerning potential BTAs (e.g., anthrax, smallpox, and plague). In the event of a BTA release, public health authorities must provide timely information that guides the identification, reporting, and medical management of these diseases and how providers, hospitals, clinics, and others in the healthcare sector can coordinate with local, state, and federal public health partners. The launching of the Hospital Preparedness Program in 2002 made available federal monies to all states and four large urban areas (Chicago, District of Columbia, Los Angeles, and New York City). The monies went to hospitals, outpatient centers, long-term care facilities, emergency medical service agencies, and poison control centers to enhance their surge capabilities. Over time, healthcare coalitions were created among hospitals and other nonhospital healthcare facilities to share plans, medical supplies, and personnel through signed memoranda of understanding (5).

During a BTA-related event, it is possible that healthcare workers would be less likely to present for work out of concern for their own health or the health of their families or because of challenges related to transportation or childcare *(53)*. To expand the pool of available healthcare workers, volunteer medical systems have been created in each state. Another source of medical personnel during an emergency is DMATs deployed through the federal government.

Detailed and frequently updated resource libraries for diseases caused by key potential BTAs have been developed and made available online by the University of Minnesota's Center for Infectious Disease Research and Policy (*http://www.cidrap.umn.edu*) and other governmental and academic institutions. These resources address the microbiology, epidemiology, clinical presentations, diagnosis, treatment, prophylaxis, and infection and exposure control considerations for anthrax, plague, tularemia, botulism, smallpox, and viral hemorrhagic fever, and they can serve as an introduction to BTAs and as an ongoing resource for providers and healthcare facilities.

State and local health officials should build upon existing materials when developing guidance specific to the circumstances of an event. Documents can be disseminated to medical providers via varied and redundant mechanisms, including a Health Alert Network; local or state health department public Web sites; Listservs maintained by hospital and provider trade organizations; and other medical groups. Guidance for hospitals and medical providers should include clear criteria for reporting suspect cases (including clinical and epidemiologic features that meet the public health surveillance case definition), instructions for submitting clinical specimens to the public health reference laboratory, treatment and prophylaxis, infection control precautions to prevent healthcare-associated exposures to a contagious disease, and advice on where to find reliable, frequently updated public health information.

In addition to protocols, model tabletop exercises to test an institution's response to BTA incidents have been made available *(54)*.

Health departments also must be able to rapidly mobilize medical hotlines for providers using clinically trained staff to triage calls reporting suspect cases. Questions regarding the medical management of cases, contacts, and asymptomatic exposed persons also must be answered. The staffing, training, and telephone equipment needs for this unit should be predefined. Ideally, preexisting provider hotlines that are used routinely for public health questions

would be supplemented. However, given the potential for a marked increase in calls to this hotline during emergencies, contingency planning should address the likelihood that escalating capacity and training would be needed.

In addition to hotlines, conference calls for healthcare partners provide the opportunity for immediate updates and question-and-answer sessions and may be hosted by local or state health departments or another coordinating group within a regional healthcare coalition. Once again, preexisting relationships among the health department officials, providers, hospital administrators, and emergency management officials facilitate this exchange of information in a time of crisis.

MASS CASUALTY, MASS PROPHYLAXIS, AND MASS MORTUARY PLANNING

Local and state public health authorities should play an active role in planning for how the treatment of mass casualties will be coordinated from a jurisdiction-wide perspective, in collaboration with area hospitals, nonhospital healthcare facilities, emergency medical services, and emergency management agencies. For planning purposes and during responses, accurate and frequently updated information is needed from all acute care facilities within the jurisdiction that capture available staffed beds (i.e., adult, pediatric, medical, surgical, and intensive care), isolation and emergency department capacity, and inventories of key equipment (e.g., ventilators) *(55)*. Local public health officials and area hospitals should work together to evaluate preparedness activities, using tabletop and field exercises to assess the adequacy of planned institutional responses to a BTA release.

Individual hospitals or hospital networks must develop institutional-specific plans for how they would respond to an area-wide infectious disease emergency, including activating the hospital's incident management system; implementing rapid patient discharge plans and bed capacity expansion strategies; managing marked increases in emergency department visits and admissions; outdoor triage—including safe and acceptable personal decontamination, if necessary; canceling all nonemergent admissions and procedures; mobilizing additional personnel and determining emergency staffing strategies; reopening patient units that had been closed; and establishing temporary isolation units, if needed. A number of mass casualty triage tools have been created, initially conceived for rapid assessment of soldiers during wartime, and more recently developed for civilian use. These tools are intended to allow for rapid classification of large numbers of patients according to several physiological parameters associated with clinical presentation. However, these instruments have not been adequately studied, standardized, or universally accepted, limiting their use during a public health emergency or disaster (57).

During incidents of this kind, healthcare facilities are likely to be inundated with "worried well" and strategies to limit the impact of "low-risk patients" have been developed *(57)*. These strategies include dissemination of rapid, clear, and concise information to the public, including who should and should not seek medical attention; rapid updating of health department Web sites with current information on the outbreak; the use of telephone-based consultation with healthcare providers; public hotlines that are staffed by nurses to guide callers on if and where to seek care for their symptoms; and the use of set criteria for rapidly triaging patients at the entry to hospitals or primary care practices to distinguish those requiring immediate evaluation and treatment from those who may be referred back to their homes with planned follow-up by telephone.

Other important, difficult issues that must be addressed ahead of time include the manner in which critical resources (e.g., ventilators) would be fairly distributed if there were insufficient supplies (58), whether alternate treatment sites would be established in certain situations, emergency credentialing procedures for nonaffiliated medical staff and volunteers, and whether specific facilities would be designated to care for contagious patients and their contacts. Mass care planning should be coordinated with local relief agencies, such as the American Red Cross, and public health authorities in neighboring counties and states. Nontraditional use of home care agencies and long-term care facilities may be needed to make hospital beds available. Mutual aid agreements are useful to have in place and to exercise before emergencies, as done routinely by fire and police departments and emergency medical services. Because there also may be a need to request federal support (e.g., DMATs), local authorities need to consider how these resources could be integrated most efficiently with existing acute care facilities.

In addition to medical treatment of mass casualties, health authorities may need to provide mass prophylaxis to potentially exposed persons and/or close contacts (e.g., in the case of anthrax or smallpox). Planning for the rapid provision of antibiotics and/or vaccines to large populations requires the involvement of public health, emergency management, and the local medical community. Efforts should focus on (a) predetermination of which antibiotics and vaccines would be needed in a variety of circumstances, (b) how these medications could be mobilized and distributed rapidly and efficiently, and (c) considerations for certain potentially vulnerable populations, such as children, pregnant women, and those who are isolated and without resources and social supports. Mass prophylaxis plans need to consider the specific challenges in distributing antibiotics and vaccine to difficult-to-reach populations, such as the homeless and homebound. Multilingual medical information sheets and vaccine informed consent forms should be prepared in advance. Although there is currently a federal stockpile of medications and supplies, the Strategic National Stockpile, local and state officials need to consider whether a smaller stockpile should also be maintained locally to ensure supplies are available in the first hours or days after an attack is detected, given cost issues and limited shelf life of many pharmaceutical agents. Specifically, contingency plans for setting up community-based, mass prophylaxis clinics that address staffing resources, equipment and space requirements, and patient flow must be developed ahead of time *(59,60)*.

The capacity of health officials to rapidly vaccinate the community was recently tested in many regions during the 2009 H1N1 pandemic. The effort to provide vaccine

to large numbers of city residents in New York City, including thousands of schoolchildren, demonstrated the need for flexibility and coordination in distribution of vaccine, which included school-based programs, community health centers, pharmacies, and large health department–sponsored vaccination clinics.

Finally, mass mortuary issues (including tracking, storage, and disposition of decedent's remains) must be addressed by the local and state medical examiners, in coordination with local public health officials, emergency management, and hospital associations. Guidance for the safe handling and disposal of potentially infectious remains should be developed *(42)* and may be adapted from established plans already developed for pandemic influenza *(61)*.

In regards to potential BTAs, the standard procedures used to prevent infections during autopsies would be sufficient. Embalming should not be performed in decedents associated with BTA incidents. Cremation without embalming would be recommended following death from anthrax, smallpox or a viral hemorrhagic fever. If cremation were not possible, burial in a sealed container would be an alternative. Smallpox vaccine should be offered to any persons providing direct medical care for—or postmortem examination of—patients with suspected or confirmed smallpox *(42)*.

Any deaths associated with the intentional release of a BTA would be classified as homicides. An efficient mechanism must be established urgently to ensure that all deaths thought to result from bioterrorism are reported to the appropriate local authorities, such as the medical examiner's or coroner's office.

LEGAL ISSUES RELATED TO THE PUBLIC HEALTH RESPONSE TO BIOTERRORISM OR OTHER INFECTIOUS DISEASE EMERGENCIES

In 2002, the CDC asked the Center for Law and Public Health at Georgetown and Johns Hopkins Universities to draft a model state public health law (the Model State Emergency Health Powers Act or Model Act) for jurisdictions to use in addressing a BTA-related event (e.g., bioterrorism) or naturally occurring disease outbreaks (62). The Model Act outlines five major public health functions to be allowed by the law: preparedness, surveillance, management of property, protection of persons, and communication.

In addition to ensuring sufficient authority to collect disease surveillance data, conduct contact tracing, and provide preventive measures to those at risk, public health laws must enable health officials to implement quarantine measures, if needed, to control a contagious disease outbreak with epidemic potential and that could lead to severe morbidity or mortality (e.g., smallpox). This authority should be linked with specific criteria that were scientifically appropriate and that would be met before quarantine could be implemented. In addition, public health laws should provide for due process measures to protect those affected *(63)*. Ideally, quarantine strategies would be determined and operational procedures would be in place prior to an emergency.

Public health agencies should be satisfied that they have operational capacity to implement and enforce quarantine, which could be done in homes, hospitals, and other facilities. Complex operational details that would need to be addressed include thresholds that would trigger decisions regarding implementation of quarantine; situations that would merit home versus facility-based quarantine; and logistics needed to provide food, medical care, and financial compensation (i.e., lost wages) to those who were quarantined.

It may be necessary to request that the federal government temporarily suspend specific laws and grant emergency waivers so that hospitals would not be considered noncompliant with acts such as the Health Insurance Portability and Accountability Act and the Emergency Medical Treatment and Active Labor Act during declared states of emergency. Legal standards of care that are used normally may not be applicable or achievable during emergencies. For example, lay vaccinators might need to be employed for a mass vaccination campaign even though this would not be allowed routinely. Because of shortages of critical supplies, public health agencies also could ask providers and hospitals to make individual treatment decisions that might differ from how they would practice medicine during nonemergencies. Unless temporary "crisis standards of care" are used during emergencies and disasters that protect clinicians from subsequent liability claims, public health agencies may not be able to manage finite emergency resources equitably or effectively *(64)*. It is also essential that these modified standards be developed at a federal level to ensure consistent approaches and criteria are used nationally.

ENVIRONMENTAL ISSUES

Following the dissemination of certain potential BTAs, public health and environmental agencies would be challenged by a number of potentially significant environmental health concerns. The released pathogen might be stable in most or some environmental matrices (e.g., *B. anthracis*, *Francisella tularensis*, and *Yersinia pestis*). Environmental contamination could result in long-term biological hazards, in which case remediation and recovery issues would predominate after the immediate disease control interventions (e.g., prophylaxis for presumed inhalational exposures) had been addressed.

Some potential BTAs are zoonotic pathogens that are normally part of complex life cycles that include insect vectors and nonhuman mammalian reservoirs (e.g., *Y. pestis*, *F. tularensis*, and the virus that causes Rift Valley fever). If one were released in a nonendemic region or where only sporadic human disease was found, entomologists, rodentologists, livestock veterinarians, pest control experts, and others might need to be engaged to assess complicated environmental and ecological issues and address them.

The extensive and prolonged public health responses to the 2001 anthrax clusters underscored some important public health gaps. Enhanced methods are needed to conduct timely environmental risk assessments and BTA remediation *(65)*. More public health expertise in this regard must be developed at the local, state, and federal levels

based on improved and scientifically validated methods for collecting and testing samples from a variety of environmental matrices and for interpreting findings to assess environmental risks. If buildings and other structures were contaminated, new, timely, and effective remediation strategies would be needed. With current tools, public health and other agencies can manage small incidents, such as the ones associated with the use of contaminated animal hides to make African drums *(12,13,66)*. However, these and other available methods would not be adequate if an urban jurisdiction faced large-scale and wide-area anthrax contamination *(67)*.

MENTAL HEALTH PREPAREDNESS AND RESPONSE

Both the 2001 World Trade Center attack and the outbreak of intentional anthrax resulting from contamination of the mail highlighted the dramatic psychological effects that a terrorist event can have on the public, even in sites far removed from the actual events. One of the primary targets of terrorism is the public's mental health, with the potential impact lasting long beyond the immediate event and involving persons far from the area affected. The media often plays an unwitting role in facilitating this with constant replays and graphic images shown frequently on television and in newspapers in the immediate aftermath of an event.

In New York City, soon after the World Trade Center attacks, a telephone survey revealed that between 7.5% and 40% of Manhattan residents had symptoms consistent with posttraumatic stress disorder; the prevalence was higher among those closer to the site or among those who had witnessed the attacks (68). The subsequent large number of "powder incidents" worldwide illustrated that one does not need sophisticated weapon delivery systems to cause public panic. In many of the affected jurisdictions, it was not the outbreak response at the worksite locations where the anthrax letters were delivered that overwhelmed local public health and emergency response authorities but the hundreds to thousands of calls reporting concerns about potential "powder threats." This illustrated the impact that public panic can have on the public health and medical care systems. More recently, the 2009 H1N1 pandemic demonstrated that large-scale naturally occurring infectious disease outbreaks may also result in significant anxiety, leading to overwhelming numbers of "low-risk patients" consuming limited healthcare resources, and especially in emergency department settings *(69)*.

Unfortunately, mental health preparedness is an area in which many local and state public health agencies have minimal experience. Further, hospital preparedness for mental and behavioral health interventions following the release of a BTA or a naturally occurring infectious disease outbreak has not been well studied or evaluated (70). It is essential that jurisdictional bioterrorism response plans address the community's mental health response to terrorism both before and after an event. Preplanning efforts for mental health preparedness should include development of a risk communication strategy with training of all potential public health spokespersons and the establishment of surge capacity for mental health services after an event occurs (71). Ideally, the public and media should be educated ahead of time about the risk of bioterrorism and relevant details of local government BTA response plans, so that they know what steps can be taken to improve personal, family, and community preparedness and what to do in the event of a BTA incident.

Planning for the potential demands on mental health programs and experts should not be limited to the persons directed affected by the incident but should also address the needs of their families and friends, those responding to the event, including traditional first responders and the medical provider community, and the general public. Strategies may include plans for rapidly establishing crisis hotlines and referral sites and for mobilizing additional assistance through creation of a mental health reserve corps. Involvement of community-based organizations, religious leaders, and local government officials in both preplanning and response efforts is essential. Clear and regular communication from public health officials should be prioritized and may address some of the public stress and fear related to the event.

COMMUNICATION WITH THE GENERAL PUBLIC

As with any major disaster, one of the most important components of the governmental response is a proactive, effective, risk communication strategy, essential features of which include preexisting and effective links with the news media (including local and national print, radio, and television outlets). The multidisciplinary nature of government's response to a BTA release may require coordination of media outreach through a joint information center that includes local, state, and federal officials. Public affairs staff at hospitals should coordinate any public messages with their counterparts at the local and state health departments.

Ideally, there should be one primary government spokesperson designated to provide consistent messages throughout the disaster response. This spokesperson should be clearly in charge (e.g., the top elected official); an effective, clear, and concise communicator; and available for frequent press briefings. Although the primary spokesperson does not have to be a medical or public health official, it is essential that persons with such expertise be present to answer or clarify health-related questions or issues. One of the most difficult risk communication challenges following a bioterrorist event and other incidents involving dissemination of a BTA would be the need for frank communication of uncertainty, given that it may take days or weeks before the full circumstances of the event become known. It is important for spokespersons to clearly explain the facts of the situation: what is known, what is not known, and what measures the government is taking to answer all key questions. The public is more likely to be reassured by government's frankness and competence when information is shared promptly and transparently. Frequent updates should be provided to the news media and public when new information becomes available.

Some of the communication strategies used in response to the 2001 anthrax incident underscored how public

confidence can be lost quickly and that spokespersons need to be credible and believable. Trying to reassure the public that the index case of inhalation anthrax might have been caused naturally had a decidedly negative public impact. Once the public and news media's trust has been lost, it is difficult to regain *(72)*.

In the past, the most efficient mechanism for communicating to the general public has been through print, television, and radio news media. More recently, the Internet has served as a major mechanism for public health officials to address the questions and concerns of the general public, by way of official agency Web sites and Internet-based news.

Establishing a hotline for the general public should also be a key component of the public health response planning efforts. Hotlines will likely need to respond to escalating demands during the immediate hours and days after an acute event. Surge capacity strategies and procedures with respect to both staff and telephone infrastructure should be identified before the emergency. Staff must be trained to handle calls from a concerned public, and mechanisms need to be in place to provide ongoing training as the outbreak evolves.

Finally, just as the Hospital Preparedness Program has encouraged public health officials to forge relationships with healthcare providers and emergency responders, public health officials should also develop relationships and agreements with various community-based groups *before* public health emergencies occur. By engaging communities during planning stages, public health policy can be informed through increased understanding of local beliefs and values. These efforts may increase the public's trust in health officials, may expand the capacity of members of the public to play crucial roles in attending to vulnerable members of the community during a crisis, and may enhance community resilience during public health emergencies (73).

SUMMARY

Since the terrorist events of 2001, the importance of improving and maintaining the public health infrastructure at the local, state, and federal levels has been prioritized, reflected by substantial federal funding provided by the Departments of Health and Human Services and Homeland Security. Jurisdictions have used these funds to address the following key areas: all hazards emergency planning and responses to biological, radiologic or chemical terrorism events, as well as for naturally occurring disease outbreaks and other emergencies (e.g., coastal storms); enhancing surveillance and epidemiologic capacity; expanding public health reference laboratory services, especially for confirmation of the CDC Category A and B agents; developing or enhancing environmental health expertise; planning for large-scale antibiotic and vaccine distribution clinics; establishing or enhancing local and state legal authorities for implementing and enforcing isolation and quarantine; ensuring that communication mechanisms and strategies are in place to provide up-to-date information to the medical community and general public; providing risk communication and media training for key public health staff; training medical providers to recognize, treat, and report diseases caused by potential BTAs; and mental health preparedness planning.

Integration of BTA-related surveillance, laboratory, environmental, and communication efforts into routine public health activities should enhance core public health functions and also improve local and state public health responses to large, naturally occurring disease outbreaks, such as the 2009 H1N1 pandemic. Enhancing our public health infrastructure to respond to BTA events is a long-term investment and one that is necessary to protect the public from natural, accidental, and intentional disease threats.

CHAPTER 103

Agents of Bioterrorism

Michael Osterholm, Elizabeth Linner McClure, and C. J. Peters

THE HISTORY OF BIOTERRORISM

The weaponization of biologic agents is as old as recorded history *(1)*. Serpents, tossed onto enemy ships, were used in ancient times as weapons of warfare. The Tartar army, in 1346, used the bodies of plague victims as weapons of war, catapulting them into the city of Caffa. In 1763, the British army intentionally infected Delaware Indians by providing them with blankets used by smallpox victims. Various human and animal pathogens were used on a limited scale as biologic weapons in both World War I and World War II.

Both Twentieth Century World Wars stimulated research and development of biologic weapons. Although many countries, including the United States, Canada, the United Kingdom, and the Soviet Union, continued the development of biologic agents as weapons following World War II, most of these programs were abandoned in the late 1960s and early 1970s. In 1972, the Biologic Weapons Convention Treaty was ratified by >140 nations. This treaty prohibited the possession, stockpile, or use of biologic weapons, although no provisions for monitoring, inspection, or enforcement were made within that treaty.

In the mid-1990s, it became evident that the Soviet Union had secretly continued an aggressive program to weaponize biologic agents *(2)*. Major aspects of that program included the production of large amounts of smallpox virus and research surrounding a means to weaponize it. Other biologic weapons were developed by the Soviets and included *Bacillus anthracis* spores and botulinum toxin *(3)*.

The dissolution of the Soviet Union increased the vulnerability of the world to bioterrorism. Soviet scientists left the Soviet Union and have been actively recruited by rogue nations such as Iraq, Iran, Syria, and North Korea. Stockpiles of biologic agents from the Soviet program are also missing or inadequately contained *(4)*.

After the Gulf War, there was concern that Iraq may be developing an extensive biologic weapons program predominately involving anthrax and botulism. There is also concern that both Iraq and North Korea may have obtained smallpox virus.

Today, there is little doubt that biologic weapons of mass destruction lie within the grasp of many nations and groups. The recent terrorist attack on the United States in 2001 with aerosolized anthrax is just one example of the reality of biologic agents as weapons. Several commissions have recently reviewed the threat of bioterrorism on the United States (United States Commission on National Security/21st Century, 2001; National Commission on Terrorism, 2000; Gilmore Commission, 2000). In November 2001, the Institute of Medicine convened a workshop on *Biologic Threats and Terrorism: Assessing the Science and Response Capabilities*. All these expert panels have uniformly concluded that the United States is highly vulnerable to another bioterrorist attack potentially much more massive in scale than the anthrax attacks of 2001.

BIOLOGIC AGENTS AS WEAPONS

What are the agents that would be employed as biologic weapons or instruments of terrorism? One way to analyze the problem is to narrow the problem according to the scenarios that are most damaging. The modes of dissemination of a biological agent are numerous, but the optimum way to infect large numbers of persons with a lethal agent is to use infectious aerosols. This conclusion allows us to narrow the spread of agents of concern to those that can be grown in large quantities and that are infectious in aerosols, a relatively small subset of the total number of microorganisms that a terrorist might employ. Contamination of the food supply is another possible route of infection that is of great concern, but probably not as potentially severe as an aerosol attack. Other means of infection could be imagined, but none seem to be so effective in producing mass casualties by direct infection. Smallpox is particularly concerning, however, because in addition to its direct aerosol transmission it can be spread from person to person in ever-widening circles and thus could be a highly effective terror weapon even if the initial number of persons infected were relatively small. The Centers for Disease Control and Prevention (CDC) published a list of biologic agents in 2000 selected for their needs for public health preparedness and their likely health and social impact *(5)*. The list is divided into categories A, B, and C. Category A agents are characterized as being easily disseminated or transmitted from person to person. They are capable of causing high mortality, leading to public panic and government destabilization. They also require rapid public health response

TABLE 103-1

Critical Biologic Agents for Use in Bioterrorism

Category A agents: B. anthracis (anthrax), *C. botulinum* toxin (botulism), *Y. pestis* (plague), *F. tularensis* (tularemia), variola major virus (smallpox), Ebola, Marburg, Lassa, and South American hemorrhagic fever viruses (VHFs)

Category B agents: Coxiella burnetii (Q fever), *Brucella* species (brucellosis), *Burkholderia mallei* (glanders), alphaviruses (Venezuelan encephalomyelitis and eastern and western equine encephalomyelitis), ricin toxin from *Ricinus communis* (castor beans), epsilon toxin of *C. perfringens, Staphylococcus* enterotoxin B

Foodborne or waterborne agents also are included under category B. These pathogens include, but are not limited to, *Salmonella* species, *Shigella* species, *Escherichia coli* O157:H7, *Vibrio cholerae*, *Cryptosporidium parvum*

Category C agents: Nipah virus, Hanta viruses, tick-borne hemorrhagic fever viruses, tick-borne encephalitis viruses, yellow fever virus, multidrug-resistant *Mycobacterium tuberculosis*

(CDC. Biological and chemical terrorism: strategic plan for preparedness and response: recommendations of the CDC Strategic Planning Workgroup. *MMWR Recomm Rep* 2000;49(RR-04):1–14.)

and preparedness. Category B agents are moderately easy to disseminate. They cause lower morbidity and mortality and require important public health diagnostic capability and disease surveillance. Category C agents include emerging biologic agents that could be weaponized in the future due to their availability, ease of production and dissemination, and high morbidity and mortality (Table 103-1).

This chapter will focus on CDC category A agents including *B. anthracis*, *Clostridium botulinum* toxin, *Yersinia pestis*, *Francisella tularensis*, variola major virus (smallpox), and the viral hemorrhagic fever (VHF) viruses. Major clinical, microbiologic, and epidemiologic factors will be addressed, particularly within the context of the suitability of each agent as a potential biologic weapon. This list is by no means comprehensive. There are many other known biologic agents suitable for weaponization, which could become the source of a bioterrorist attack in the future. The Soviet Union alone is known to have weaponized at least 30 biologic agents, some of which focus on vaccine or drug resistance *(4)*.

ROUTES OF DISSEMINATION

Many different bioterrorist attack scenarios are possible. As noted above, two important modes of transmission include aerosol and foodborne attacks. Aerosols are an efficient mode of transport to a wide geographic area. The inhalation of small particles (1–5 μm) causes deposition deep in lung tissue, and some agents are capable of very efficiently setting up a systemic infection from that site. There are basically two mechanisms for developing these aerosols. One involves the generation of particles from liquids energized by passage of air over a nozzle, and the other is the production of fine powders that are treated to be electrically neutral and readily propelled into the air by small energy input and to continue to be carried by the air currents. Potentially available means for wide-scale dissemination of aerosolized particles could include the use of crop-dusting planes, small aerosolizing generators in closed spaces such as shopping mall or subways, the dissemination of particles through the ventilation systems of large buildings, and the contamination of items in the environment by fine powders as was the case with the recent anthrax attacks on the United States in 2001.

Foodborne bioterrorism, which could encompass a variety of biologic agents, is also a real threat. These agents are relatively easy to obtain and some agents can cause mortality at very low doses. They are also readily available in the environment and may in fact be the easiest bioterrorism agents to disseminate. Contamination of water sources is much less likely to be effective as the dilutional effect would be too great and most agents are vulnerable to chlorine, a standard additive to potable water.

AGENTS

Anthrax

B. anthracis is a large gram-positive bacillus. It forms long chains *in vitro* but exists in single cells or short chains *in vivo*. It is a nonmotile, catalase-positive aerobe or facultative anaerobe. Colonies are fast growing and exhibit a ground glass appearance. *B. anthracis* also exists as a spore. These spores germinate, forming vegetative cells in nutrient-rich environments. Anthrax bacilli are vulnerable and readily inactivated outside mammalian hosts and will sporulate when nutrients in their environment are exhausted. These spores are highly stable, existing in the environment for years at a time. Spores have been shown to survive in the environment >40 years *(6)*. These spores germinate, forming vegetative cells in nutrient-rich environments.

Laboratory diagnostic procedures beyond culture are not well-standardized. Blood cultures are usually positive in serious cases, but automated systems may reject the early-growing *Bacillus* as a contaminant. Late in infection, direct smears of peripheral blood or cerebrospinal fluid usually show the microorganism directly. Autopsy findings are pathognomonic and tissue Gram stains positive. Polymerase chain reaction (PCR) of tissues and direct tests for toxin in the blood are promising experimental approaches to microbiological diagnosis. Convalescent patients usually develop antibodies to anthrax toxins such as protective antigen.

Modes of Transmission Anthrax is primarily a disease of livestock or other herbivores. Infection is acquired through consumption of soil or feed containing *B. anthracis* spores. Illness in humans most often occurs following exposure to infected animals. Exposure to infected animals occurs from contact with contaminated tissue; the consumption of undercooked, contaminated meat; or the vigorous handling of tainted wool, hides, or other animal by-products during processing. Person-to-person transmission has occurred rarely with cutaneous anthrax, but not gastrointestinal (GI) or

inhalational disease *(7,8)*. Cutaneous disease from laboratory inoculation with *B. anthracis* has also been recognized *(9)*.

Clinical Syndromes Naturally occurring anthrax infection in humans can present as cutaneous anthrax, inhalational anthrax, or GI anthrax. The cutaneous manifestation is the most common presentation. Inhalational anthrax is the disease associated with aerosol dissemination in a bioterrorist attack, although cutaneous disease might result from environmental contamination.

Inhalational Anthrax Inhaled *B. anthracis* spores are deposited deep in the lung. Endospores are then phagocytosed by macrophages and transported to regional lymph nodes. Within the lymph nodes, spores germinate into vegetative cells, multiply, and enter the bloodstream. Bacteremia leads to septic shock and toxemia. Hemorrhagic mediastinitis and massive pleural effusions frequently occur. Secondary meningitis or involvement of other lymph nodes can be seen. The chest X-ray is a critical part of the diagnostic workup because of the typical widened mediastinum from regional lymph involvement *(10)*. It has become apparent that the use of thoracic computed tomography scans is a more sensitive way to detect and quantify the pathognomic node involvement as well as the effusions.

Illness may be biphasic, with an initial prodrome of fever and malaise. If left untreated, a second phase follows characterized by a sudden increase in fever and rapid-onset respiratory distress and cardiovascular collapse. Case-fatality rates decrease with prompt and aggressive antibiotic therapy.

The ID50 for inhalational anthrax has been estimated at 8,000 to 50,000 spores *(11)*, although the minimum infective dose may be considerably less. Extrapolation of dose–response curves from cynomolgus monkeys predict that the LD10 in humans may be as low as 50 to 98 spores, and the LD1 may be only a single spore *(12)*. Host factors may affect susceptibility, as well.

Cutaneous Anthrax Cutaneous anthrax is largely a localized infection caused by the introduction of endospores into a break in the skin. Germination at the site of entry causes localized infection, which appears as a papule with localized edema. Ulceration occurs after 1 to 2 days followed by the formation of a black eschar over the ulcerated lesion. These lesions heal without scarring in 80% to 90% of patients. Rarely, a more generalized lymphadenitis can occur; patients with multiple bullae deteriorate secondary to severe edema and shock. The overall case-fatality rate is extremely low with proper antibiotic therapy. Before the era of antibiotics, the case-fatality rate approached 20%. The infective dose for cutaneous anthrax is not known *(13)*.

Gastrointestinal Anthrax GI anthrax is rare and its etiology is poorly understood. Unlike the other forms of anthrax in which the endospore is the infecting agent, GI anthrax is thought to be secondary to the ingestion of vegetative cells from undercooked meat taken from ruminants dying of anthrax *(13)*. Patients infected with anthrax via the GI tract may exhibit symptoms ranging from oropharyngeal involvement to widespread edema, ascites, hemorrhage, and shock. The overall case fatality is between 25% and 60%. The impact of early antibiotic therapy is not known.

Epidemiology *B. anthracis* can be found in the soil of many areas around the world, particularly those that experience episodic periods of heavy rainfall followed by drought. It is a disease of animals primarily and is endemic in most areas of the Middle East, equatorial Africa, Mexico, Central and South America, and some Asian countries *(14)*. Globally, several thousand cases of anthrax are reported each year *(15)*. These are mostly cutaneous; inhalational and GI anthrax occur at much lower rates.

In the United States, naturally occurring anthrax is relatively rare in humans. Approximately 10 cases of human disease were reported in the United States each year since the late 1960s; a number that has declined from over 100 cases per year in the early 1900s. Since 1990, only two cases of naturally occurring anthrax were reported: one in 1990 and one in 2000. Both were cases of cutaneous anthrax *(16)*. Livestock and wild ruminant disease is common, particularly in the western states.

Anthrax as a Biologic Weapon *B. anthracis* is an ideal biologic agent for weaponization. It is stable in spore form, making it easy to store, transport, and aerosolize *(13)*. It is readily available in nature and has a long history of development as a weapon of mass destruction since the early 1940s. The impact of a massive aerosolized anthrax release attack is not known, but several agencies have conducted hypothetical scenarios that predict extremely large casualties. The Office of Technology Assessment in 1993, for example, concluded that deaths of over 3 million could occur following a 100-kg aerosol release dissemination of *B. anthracis*.

Although aerosolization release of anthrax spores is the most likely mechanism for its use as a biologic weapon, deliberate contamination of food is also a possibility. During World War II, the Japanese reportedly impregnated chocolate with anthrax to kill Chinese children. The apartheid government of South Africa also experimented with anthrax in chocolate *(17)*.

Weaponized anthrax has been the cause of disease outbreaks twice in history. In 1979, an accidental release of weaponized anthrax from a laboratory weapons factory in the Soviet Union caused 75 cases of inhalational anthrax and 2 cases of cutaneous anthrax. The overall case-fatality rate was 86% *(18)*. The release dose amount of anthrax was estimated by investigators to be as low as a few milligrams.

The United States, in 2001, experienced an outbreak of anthrax involving the intentional contamination of mail with anthrax spores. Four letters containing up to 2 g of powder, with over 500 billion spores per gram were mailed from Trenton, NJ, over a 3-week period. Twenty-two cases of anthrax (11 inhalational and 11 cutaneous) were reported. All cases involved the Ames strain of *B. anthracis* and shared identical molecular subtyping. The case-fatality rate for inhalational anthrax was 45% *(19,20)*.

Following recognition of anthrax in postal workers, the U.S. Postal Service initiated a pilot program called the Biohazard Detection System in July 2003, which involves placing anthrax detection systems at selected mail-processing centers around the country.

Therapeutic Countermeasures for Weaponized Anthrax Release

Vaccine Currently, BioPort Corporation manufactures a cell-free anthrax vaccine called AVA (Biothrax) *(21)*. Seroconversion following three doses of the vaccine is reported (in one study) to be 95% *(22)*; however, the correlation between antibody titer and protection against infection has not been defined. The duration of vaccine efficacy is also unknown, but thought to be approximately 1 to 2 years.

Randomized controlled trials on the clinical effectiveness, immunogenicity, and safety of anthrax vaccines were recently reviewed. The authors concluded that vaccines based on anthrax antigens are immunogenic in most vaccines with few adverse events, but data were limited *(22A)*. A recent review of anthrax vaccine-related VAERS (Vaccine Adverse Event Reporting System) reports from 1990 to 2007 showed no unusual pattern or high frequency of adverse events reported *(22B)*.

Preexposure: Biothrax is not available to the general public. Persons who should receive a preexposure vaccination series include the following: members of the military (or other select populations with a risk of exposure to weaponized anthrax), laboratory workers engaged in production of *B. anthracis* cultures, veterinarians or other high-risk persons handling potentially contaminated meat or animal products, and workers who may be making repeated entries into a *B. anthracis* contaminated site after a bioterrorist attack *(23,24,24A)*. Anthrax vaccine is not currently recommended for postexposure use, so it must be given under an investigational new drug application with the Food and Drug Administration (FDA).

Postexposure: Recent Advisory Committee on Immunization Practices guidelines recommend the use of anthrax vaccine in combination with antibiotics following an inhalational exposure to *B. anthracis (24A)*. Exposed persons should receive a three-dose regimen of Biothrax and a 30-day course of antibiotic therapy *(25)*. Anthrax vaccine is not currently licensed for postexposure use, so it must be given under an investigational new drug application with the FDA.

Research into new anthrax vaccines is ongoing. Most vaccines under investigation utilize either recombinant technology or employ novel adjuvant to increase the immune response. Combination vaccines, such as the one against both anthrax and plague, may represent an evolution in vaccine development against agents of bioterrorism *(25A)*.

Antibiotics The FDA has approved doxycycline, ciprofloxacin, and penicillin G procaine for use in postexposure prophylaxis against aerosolized anthrax. Prophylactic antibiotic therapy is recommended for persons exposed to an airspace contaminated with a suspicious material that may contain anthrax spores or those exposed to an airspace with known anthrax release. This includes unvaccinated laboratory workers exposed to suspected aerosolized *B. anthracis* in culture. Antibiotic prophylaxis is not recommended for autopsy personnel, for medical personnel caring for anthrax victims, or for the prevention of cutaneous anthrax *(25)*.

In the event of a massive aerosolized release of anthrax spores, rapid delivery of prophylactic antibiotics would be crucial in preventing large casualties *(26)*. States can request antibiotic and medical supplies from the Strategic National Stockpile through the CDC. State and local health departments should activate their bioterrorism preparedness plans to distribute antibiotics rapidly.

New Therapeutic Approaches In addition to antibiotic treatment protocols, several new therapeutic approaches are being researched; most involve the use of monoclonal antibodies *(26A–26C)*. The Department of Health and Human Services is working with Human Genome Sciences, Inc. to develop a human monoclonal antibody called ABthrax or raxibacumab *(26D)*. Another therapeutic approach under investigation is the use of human hyperimmune plasma and immune globulin from previously vaccinated persons undergoing serial plasmapheresis. Hyperimmune plasma and immune globulin isolated in this way could potentially serve as a basis for a new anthrax treatment *(26E)*.

Implications for Healthcare Workers Standard Precautions are considered adequate for patients with inhalational, GI, and oropharyngeal anthrax since person-to-person transmission for these forms of the disease has not been reported *(13)*. Although people with inhalational anthrax may have residual contamination of hair and clothing from their exposure event on presentation to a medical facility, this does not appear to be a transmission concern to healthcare workers. Standard Precautions are also recommended by most sources for cutaneous anthrax; however, because person-to-person transmission has occurred rarely for this type of anthrax, Contact Precautions have also been recommended *(7,27)*.

Complete information regarding the use of personal protective equipment for first responders and other healthcare workers can be found in the following documents (see Refs. *25* and *28*):

- *CDC:* Protecting investigators performing environmental sampling for *B. anthracis:* personal protective equipment
- *OSHA:* Anthrax in the workplace
- *OSHA:* Fact sheet and references on worker health and safety for anthrax exposure

Botulinum Toxin

Botulinum toxins are the most lethal human toxins known. They are colorless, odorless, and tasteless at concentrations that are lethal. The toxins are produced by vegetative cells following the germination of *C. botulinum* spores and released by cell lysis. In the case of wound botulism or infant botulism the microorganisms may be present in the wound or the bowel, but in foodborne disease or bioterrorist events the toxin is released from the microorganism prior to the intoxication. Several distinct antigenic toxin types are produced by *C. botulinum* and other *Clostridium* species. Types A, B, E, and F cause natural disease in humans; toxin type F accounts for <1% of naturally occurring disease. Other antigenic subtypes, including toxin types C, D, and G, can cause disease in other mammals and birds. Botulinum toxin is inactivated by heating it to 85°C for 5 minutes *(29)*. It is important to note that in the event of an intentional dissemination of botulinum toxin, the causative (vegetative) microorganisms may not be present.

Diagnostic procedures usually rely on the toxicity for mice confirmed by neutralization of the toxin by antiserum.

Toxin can be detected in food, gastric contents, or serum. Antibodies do not usually develop in convalescence because of the very small lethal dose.

Clostridium botulinum *C. botulinum* is a gram-positive spore-forming bacillus. It is "sluggishly" motile and anaerobic and can be found in soil and aquatic sediments. There are several strains of *C. botulinum*; subtyping is based on metabolic characteristics of the microorganism. Groups I and II are responsible for the toxin production, which is lethal to humans.

C. botulinum spores are resilient, resisting destruction with prolonged boiling at high temperatures and desiccation. They have been shown to survive in a dry state for over 30 years. The spores are susceptible to chlorine in dilute concentrations (as in chlorinated water). They undergo germination most readily by exposure to heat ("heat shocking") of 80°C for 10 to 20 minutes *(30)*.

Botulism Pathophysiology and Clinical Presentation Botulinum toxin can enter the body via ingestion or inhalation. Exposure can also occur through local production in the GI tract or necrotic tissue at the site of a wound. Botulinum toxin is activated by proteolytic cleavage; the activated structure contains a heavy and light polypeptide chain. The toxin is carried through the bloodstream to the neuromuscular junction where the heavy chain binds to presynaptic receptors causing permanent inhibition of acetylcholine release. After several months, muscle function is regained based largely on the production of new synapses at the neuromuscular junction.

Clinically, patients present with neuromuscular weakness, ranging from mild cranial nerve dysfunction to complete flaccid paralysis. The severity of disease corresponds to the toxin dose and the toxin subtype; type A creates a more severe clinical presentation than type B or E. The major differential diagnoses include Guillain-Barré syndrome, Eaton-Lambert syndrome, and polyneuropathies such as the recently recognized West Nile syndrome. Botulism is characteristically distinguished by initiation of involvement with the cranial nerves and descending in the neuraxis as it progresses.

Loss of respiratory and pharyngeal muscle function can require a prolonged period of mechanical ventilation. Death often results from complications of prolonged ventilatory support. Prior to mechanical ventilation, death rates approached 50% *(31)*. Case-fatality rates are now lower due to the advent of adequate supportive care including advanced respiratory support capabilities. The current overall case-fatality rate is 5% to 10% for foodborne disease and somewhat higher for wound botulism *(31,32)*.

Modes of Transmission/Epidemiology

Foodborne Botulism Botulinum toxin can be produced in food items that are contaminated with *C. botulinum* spores. Conditions including an anaerobic environment, acidic pH, minimum temperature of 10°C, and availability of a water source must exist to facilitate germination of spores and production of botulinum toxin *(33)*. Food containing the neurotoxin that is not sufficiently reheated to at least 85°C for 5 minutes becomes a potent toxin delivery source for humans *(29)*.

A single case of foodborne botulism is considered an outbreak and declared a public health emergency. All cases of botulism must be reported to the CDC immediately. In the United States, an average of nine outbreaks per year was seen in the late 1990s, with approximately two to three cases per outbreak *(33)*. Improperly home-canned vegetables are the most common source of foodborne botulism; however, over the past 20 years, a variety of commercially produced, preservative-free foods have caused outbreaks. Garlic in oil, baked potatoes in foil, jarred peanuts, and commercially processed cheese sauce have been associated with outbreaks *(34–38)*.

Botulinum toxin is rapidly inactivated by the chlorine, which is a standard additive to potable water. For this reason, cases of botulism have not been associated with contaminated water *(39,40)*.

Wound Botulism *C. botulinum* infection is usually associated with traumatic injuries of the extremities, especially those that involve contact with soil or another natural *C. botulinum* source. Although seen more rarely, cases of botulism following a postoperative infection, the use of intravenous or intranasal illicit drugs, or dental abscess have also been reported. Wound botulism is a rare event; only 78 cases were reported to the CDC for the period of 1986 to 1996 *(33)*.

Inhalational Botulism Inhalational botulism is caused by inhalation of aerosolized preformed botulinum toxin into the lungs and, subsequently, the circulation. It is a very rare exposure event, occurring only once in a veterinary laboratory setting in Germany in 1962 *(39)*. Inhalational disease has also been produced experimentally in primates. Results of this study showed disease onset occurring 12 to 80 hours after exposure *(41)*.

Botulinum Toxin as a Biologic Weapon Botulinum toxin has been manufactured as a potential biologic weapon since World War II. The United States produced the toxin during that time period, but abandoned production after signing the BWTC in 1972 renouncing use, stockpiling, or production of biological weapons in 1968. The Soviet Union, however, continued production into the early 1990s. At the time of the Gulf War, Iraq had produced over19,000 L of botulinum toxin, some of which was weaponized *(42)*. On three occasions between 1990 and 1995, the Japanese cult Aum Shinrikyo attempted to use aerosolized botulinum toxin in Japanese cities, but was not successful.

Botulinum toxin could be disseminated via the deliberate contamination of food or beverages, or as an aerosol. Experts believe that the foodborne route represents the most likely bioterrorist scenario. Deliberate contamination of a large source of commercially available and distributed food or beverage product, particularly one in which adequate heating would be unlikely, could cause massive extensive casualties across the country. The widespread nature of the attack would also create significant panic, economic loss, and social disruption.

The dispersal of aerosolized toxin is also possible and could result in extremely large numbers of casualties, in this instance, concentrated in a single urban setting. One gram of aerosolized botulinum toxin could theoretically

kill 1.5 million people *(43)*; however, it is likely that for practical considerations, the effects of a botulinum toxin attack would be relatively limited compared to one of the infectious agents.

Contamination of a water source is unlikely because of dilution as well as the vulnerability of the toxin to chlorine, a standard additive to potable water.

Therapeutic Countermeasures for Weaponized Botulinum Toxin

Botulinum Antitoxin Supportive care is the mainstay for treatment of botulism; prolonged intensive care, mechanical ventilation, and parenteral nutrition may be required. Botulinum antitoxin can be administered to treat forms of botulism (other than infant botulism) and is most effective when given early in the course of illness. It cannot reverse existing paralysis, but can prevent additional nerve damage if given before all the circulating toxin binds to the neuromuscular junction.

Botulinum antitoxin is of equine origin and has traditionally been developed for use against subtypes A, B, and E. The CDC formulary currently includes a botulinum antitoxin bivalent for types A and B (licensed by the FDA) and botulinum antitoxin equine type E (an investigational product). In the past, the CDC released a trivalent ABE antitoxin, but this product is not currently available. The CDC maintains an active surveillance program for cases of botulism and is responsible through state health departments for the distribution of antitoxin in suspected cases *(39,41)*.

Antitoxin (supplied by the CDC) is maintained at quarantine stations in various metropolitan airports and, once requested, can generally be delivered within 12 hours *(43A)*.

In the event of a bioterrorist attack with botulinum toxin, it is possible that other subtypes will be weaponized. The U.S. Army has developed an equine heptavalent botulinum antitoxin effective against all botulinum toxin types, but its efficacy in humans is not clear. Additionally, as for the licensed product, it carries with it the potential for serious allergic reaction. Additional research into heptavalent botulinum antitoxin has occurred through a U.S. Department of Health and Human Services development contract (Cangene Corp).

The dose of antitoxin required to reduce the effects of the neurotoxin varies with the inoculating dose. In the event of a mass release of weaponized botulinum toxin, the scarcity of antitoxin would be highly likely *(39)*.

Botulinum Toxoid Vaccine Vaccination with botulinum toxoid is currently recommended for laboratory personnel who work with *C. botulinum* and military personnel at risk for exposure to weaponized botulinum toxin *(44)*. The vaccine is not considered a viable countermeasure against a bioterrorist attack. It is not effective against all subtypes; it is painful to receive and requires a yearly booster; it also disallows the recipient from receiving botulinum antitoxin therapy for life.

Emergency Response to a Mass Exposure A single case of botulism is considered a public health emergency *(45)*. In the event of a suspected botulism outbreak, public health officials will assist with appropriate laboratory testing to confirm diagnosis, authorize use of antitoxin, and conduct aggressive surveillance investigations to identify the source of an outbreak to determine if there is evidence to suggest a bioterrorism-related event.

In the event of a mass exposure, such as a widespread aerosol release of botulinum toxin, the rapid administration of antitoxin to ill persons would be indicated. Although antitoxin does not reverse existing paralysis, it binds remaining circulating toxin, mitigating progression of the disease. Rapid mobilization of mechanical ventilators and other ancillary supportive care tools would be critical to successful management of any mass-exposure botulism outbreak.

Implications for Healthcare Workers In the hospital setting, Standard Precautions are adequate for patients with botulism since person-to-person transmission does not occur. In the laboratory setting, *C. botulinum* toxin detection should only be performed by trained individuals at level C or higher Laboratory Response Network laboratories *(46)*. The FDA also released biosafety recommendations for laboratories that test for *C. botulinum*. A partial list includes the following: placement of biohazard signage; the use of appropriate laboratory safety apparel including coats and safety glasses; restriction of solo work shifts; immediate autoclaving of all toxic material; and ready access to information on the location of an antitoxin source *(47)*.

Plague

Y. pestis is the causative agent of plague. It is a pleomorphic gram-negative bacillus, existing as single cells or short chains in direct smears. It is a nonmotile, nonsporulating facultative anaerobe, slow growing in culture. At 48 to 72 hours of incubation on solid media, colonies have a raised, "fried egg" appearance. Data banks for many commercial laboratory identification systems do not include *Y. pestis (*48*)*.

Y. pestis is thought to have evolved from *Y. pseudotuberculosis* 1,500 to 20,000 years ago *(49)*. Recent data suggest the continued evolution of the bacillus through the emergence of several new genotypes *(50)*.

Modes of Transmission Humans are an incidental hosts for *Y. pestis* and are not part of its natural life cycle. Many different animal species (mostly wild rodents) are natural reservoirs for the bacillus *(51)*. Like humans, other nonrodent mammalian species serve as incidental hosts for *Y. pestis*. These animals, however, can serve as sources of human exposure. Disease occurrence in humans is dependent on the frequency of infection in local rodent populations. Human outbreaks are usually preceded by epizootics with increased deaths in susceptible animal hosts *(52,53)*.

The vector for *Y. pestis* is the flea. Over 1,500 species of flea exist; approximately 30 are known to be vectors for *Y. pestis (53)*.

Humans can become infected with *Y. pestis* via the bite of an infected flea, a bite or scratch from an infected incidental host mammal such as a cat, or direct contact with infected animal carcasses or products. Inhalation of respiratory droplets from infected animals or humans can also cause infection *(54)*.

Pathogenesis/Clinical Syndromes The classic forms of plague are bubonic plague, pneumonic plague, and septicemic plague. Rarely, plague can be manifested as meningitis,

pharyngitis, or pestis minor, a milder form of bubonic plague.

Bubonic Plague Bubonic plague is transmitted to humans via the bite of an infected flea, a bite or scratch from an infected animal or direct contact with infected animal carcasses. Between 25,000 and 100,000 *Y. pestis* microorganisms are inoculated into the skin after a bite from an infected flea *(55)*. The microorganisms migrate through the cutaneous lymphatics to regional lymph nodes. Once in the lymph nodes they are phagocytized by polymorphonuclear leukocytes (PMNs) and mononuclear phagocytes. Microorganisms phagocytized by PMNs are largely destroyed, whereas those phagocytized by mononuclear cells proliferate intracellularly and are released when cell lysis occurs *(53)*. Initially, affected nodes contain a thick exudate composed of plague bacilli, PMNs, and lymphocytes. This pattern gives way to hemorrhagic necrosis, which creates the clinical picture of swollen, painful buboes that are characteristic of bubonic plague. Microorganisms also enter the bloodstream causing hemorrhagic lesions in other lymph nodes and organs throughout the body. Eventually septicemia disseminated intravascular coagulation (DIC) and shock ensues. Without prompt antibiotic therapy, death usually results from overwhelming septicemia.

Pneumonic Plague *Y. pestis* can enter the lungs directly through direct inhalation (primary pneumonic plague) or via hematogenous spread of bubonic plague (secondary pneumonic plague). Primary pneumonic plague is acquired by inhalation of approximately 100 to 500 microorganisms *(13)*. Clinically, patients present with fulminant lobar or multilobular pneumonia. Marked edema and congestion of the lungs are also common. Death from overwhelming sepsis, DIC, and multiorgan failure occurs rapidly without prompt antibiotic therapy; untreated mortality approaches 100% *(53)*.

Septicemic Plague Primary septicemic plague is defined as systemic toxicity caused by *Y. pestis* infection without apparent lymph node involvement. Secondary septicemic plague occurs commonly as part of bubonic or pneumonic plague. Septicemia is the syndrome that leads to multiorgan failure, DIC, and death. In the late stages of the disease, high-density bacteremia often occurs, with ready identification of microorganisms on peripheral blood smears or buffy coat preparations *(52)*.

Epidemiology

Historical Perspective Three plague pandemics have occurred during recorded history, causing an estimated 200 million deaths *(56)*. The first recorded pandemic began in Egypt in 542 AD, spread throughout Europe, Central and Southern Asia, and Africa, killing over 100 million people. The second pandemic, widely known as the Black Death, began in Italy in 1347 and spread rapidly across Europe killing one third of the population. The most recent pandemic began in China in 1894 and spread throughout the world over a 10-year period, presumably facilitated by ship travel. This pandemic was responsible for an estimated 12 million deaths, most occurring in India.

Naturally Occurring Plague in the United States Plague was first introduced to the United States in 1900 as part of the third pandemic and created an epidemic in the early 1900s in San Francisco *(57)*.

It was sporadically epidemic largely in urban settings secondary to infected rat populations *(58)*. After 1926, plague became endemic in wild animal populations in the Western United States. Cases have also been associated with infected domestic cats *(54)*.

Today, plague remains endemic in the United States. It is usually seasonal, with a higher case incidence during summer months *(57,58)*. From 1947 through 1996, 390 cases of plague were reported to the CDC with an overall case-fatality rate of 15.4% *(59)*. Bubonic plague accounted for 83.9% of those reported cases. An average of 8.9 cases per year were reported to the CDC from 1990 to 1999 *(60,61)*. Many of these cases developed secondary pneumonia, but no transmission to contacts has been seen. The disjunct between the pneumonic transmission that occurred during the Manchurian epidemics early in the century and the uncommon documentation of pneumonic spread in other settings may reflect the crowding and lack of basic hygiene during earlier epidemics.

Plague as a Biologic Weapon *Y. pestis* is a potentially suitable agent for use as a biologic weapon, because it can be aerosolized and/or transmitted person to person. The pneumonic form of plague is highly fatal, and its communicability could generate widespread fear and panic. Plague was used as a biologic weapon in the Middle Ages when armies catapulted the bodies of plague victims into cities in order to spread the disease *(1)*. In World War II, Japan used plague against the Chinese by dropping plague-infested fleas over populated areas, causing outbreaks of the disease *(1,62)*. *Y. pestis* has also been weaponized by the United States and the former Soviet Union, the latter having also engineered *Y. pestis* for increased virulence and microbial resistance *(63,64)*.

In 1970, the World Health Organization (WHO) modeled a biological warfare attack with *Y. pestis*. This report estimated that the aerosol dissemination of 50 kg of dried powder containing 6×10^{15} *Y. pestis* microorganisms over a city of 5 million people would generate 150,000 cases and 36,000 deaths. They speculated that subsequent person-to-person transmission would create another 500,000 cases and 100,000 deaths, but the actual pneumonic spread is not clearly established in modern times *(65)*.

The primary clinical presentation of persons infected by aerosolized *Y. pestis* would be pneumonic plague, although septicemic disease might occur. Previously healthy patients would present with severe and rapidly progressive multilobular pneumonia. Hemoptysis, GI symptoms, evidence of DIC, and a fulminant clinical course would be highly suspicious for pneumonic plague. Notably, characteristic buboes, associated with bubonic plague would be absent, and patients would not necessarily present with risk factors for plague exposure. This disease requires intensive medical and nursing support with rapid isolation and antibiotic therapy followed by hospitalization for several weeks of convalescence.

Therapeutic Countermeasures for Aerosol Dissemination of Plague A rapid, coordinated public health response is essential to minimize casualties during a bioterrorist attack of weaponized plague. The Working Group on Civilian

Biodefense developed consensus-based recommendations for the treatment of pneumonic plague for two scenarios: In a setting with limited potential casualties, and an adequate medical care delivery system, parenteral antibiotics (streptomycin or gentamicin) should be administered to all patients whenever possible. In a mass casualty setting, in which the medical care resources are outstripped, oral antibiotics (doxycycline or ciprofloxacin) should be administered for a period of 10 days. Antibiotics must be administered early in the course of the infection (perhaps within 24–48 hours of onset), or death occurs in 3 to 6 days. In addition, close contacts of untreated patients should also receive prophylactic oral antibiotics for a period of 7 days *(63)*.

Plague Vaccine A licensed, killed whole-cell vaccine was available in the United States until 1999 *(66)*. It was used by the military and showed some efficacy against bubonic plague, but not pneumonic plague. It is no longer manufactured, and its lack of efficacy against pneumonic plague would limit its usefulness in the event of a bioterrorist attack. A live, attenuated vaccine was developed in the early 1900s and has been used in some parts of the world. The vaccine strain is not avirulent, however, and is associated with significant safety concerns.

Research is ongoing to develop new plague vaccines. Two approaches include the development of a live, attenuated mutant *Y. pestis* vaccine strain and the use of antigenic subunit vaccine *(67,68)*. This recombinant vaccine has shown the best protection against both bubonic and pneumonic plague. It is currently unavailable, but research is ongoing.

Decontamination In general, environmental decontamination following an aerosol event has not been recommended, since experts have estimated that an aerosol of *Y. pestis* microorganisms would be infectious for only about 1 hour *(63)*. A recent study demonstrated that *Y. pestis* can survive on selected environmental surfaces for at least several days, although the potential for reaerosolization of these microorganisms was not addressed *(69)*.

Implications for Healthcare Workers Healthcare workers need to be protected from transmission of *Y. pestis*. Droplet Precautions with eye protection in addition to Standard Precautions are indicated for patients with pneumonic plague *(70)*. Patients should be considered infectious for 48 to 72 hours after appropriate antibiotic therapy has been initiated with evidence of clinical improvement *(9,64)*. The detailed mechanisms of transmission of pneumonic plague are unknown. The Manchurian and Indian epidemics early in the 20th century were associated with crowding and a lack of hygiene and are thought to reflect droplet spread, a conclusion supported by the protection provided to medical staff by surgical masks. There has been no interhuman transmission of plague in the United States since 1924 in spite of numerous bubonic and a smaller number of pneumonic cases. The possibility of aerosol transmission of pneumonic plague, particularly in the unexplored setting of a bioterrorist attack, is unknown but believed to be unlikely *(70)*. Nevertheless, medical staff, like other contacts, who are in close contact with plague patients should receive antibiotic prophylaxis.

Smallpox

Variola viruses are orthopoxviruses from the family Poxviridae. They are DNA viruses, brick shaped and large in size (200-nm diameter). The average genome is 200 kbp, and several strains have been completely sequenced. Efforts are ongoing to determine genetic diversity of existing variola viruses *(71)*. Variola viruses have been classified as variola major or variola minor based on the severity of their clinical manifestations.

Many viruses in the Poxviridae family do not include humans as a natural host. Some, however, in addition to variola virus, can cause natural human infection. These include members of the *Orthopoxvirus* species, including monkeypox, vaccinia, and cowpox viruses. Other poxviruses that cause human infection include *Yatapoxvirus*, *Parapoxvirus*, and *Molluscipoxvirus* (the causative agent of molluscum contagiosum).

Laboratory diagnosis is most readily made from skin lesions by electron microscopy, which can correctly identify viruses as orthopoxviruses, and by PCR and sequencing, which can arrive at a species identification. Cultivation of virus and other approaches are also useful.

Epidemiology/Modes of Transmission Smallpox virus no longer exists in nature. Several important epidemiologic properties of the virus helped facilitate its eradication in the 1970s. Of primary significance is the fact that humans represent the only natural reservoir for the virus. Additionally, the infectivity of naturally occurring smallpox is not generally as high as that for other common exanthems such as measles, usually requiring close contact for transmission. Maximal infectivity also occurs during the height of clinical illness, a time during which infected persons are bedridden and severely ill, limiting contact with uninfected populations. After recovery, infectivity wanes with the resolution of pustules; smallpox cannot exist in a chronic carrier state *(72)*. Currently, declared variola major virus exists in only two WHO-approved facilities: The CDC in Atlanta and the Russian State Centre for Research on Virology and Biotechnology in Novosibirsk *(73)*.

Smallpox is transmitted from person to person via large droplet nuclei or aerosols generated from oropharyngeal secretions of smallpox victims *(72)*. Airborne transmission is unusual but was documented in two hospital outbreaks in Germany in the 1960s *(74)*. Transmission of the virus via fomites has also occurred. This was, in fact, an intentional transmission mode during the French–Indian wars of the mid-1700s *(75)*.

Smallpox is a moderately contagious disease. The infectious dose is presumed to be low (10–100 microorganisms) *(13)*. Unlike some other viruses, persons with the disease are not considered infectious in the prodromal stage of the disease *(76)*. The highest risk for transmission occurs 1 week after the onset of rash when oral lesions ulcerate and release large amounts of virus into the saliva. Patients should be considered infectious at the time of fever onset, however, because some virus may be present in oral secretions shortly before the onset of the rash. Virus is present in skin lesions and scabs so communicability lasts until the pustules have scabbed over and fallen off.

In the pre-eradication era, the average number of cases infected by a primary case was approximately 3.5 to 6 *(77)*.

The secondary attack rate among close contacts varied from 37% to over 70% *(78–80)*. Transmission outside the family and the hospital (patients and medical staff) was uncommon. Random spread to less intimate contacts was not a feature of the European epidemiology in the era in which vaccination was waning and occasional introductions occurred.

Clinical Features Variola major virus can cause several distinct clinical disease manifestations. In the pre-eradication period, distinguishing between these types was based on rash pattern, clinical illness, epidemiology, and laboratory findings. Major types will be reviewed briefly. Monkeypox, a related *Orthopoxvirus*, has some similarities in presentation and will also be reviewed.

Ordinary Smallpox Ordinary smallpox accounted for over90% of variola major infections in the pre-eradication period. After a 10- to 13-day incubation period, a prodrome of fever, chills, and prostration ensues. This lasts 2 to 4 days and is often followed by the appearance of a few skin lesions on the face called "herald spots." Painful, hard lesions progress synchronously on the face and distal extremities including the palms and soles. Fewer lesions are found on the trunk. These are initially maculopapular, then vesicular, and finally pustular, leaving pitting scars after recovery.

Patients may undergo massive fluid shifts, hemodynamic instability, and skin desquamation, resembling a massive burn clinically. The overall case-fatality rate is 15% to 45% in unvaccinated persons *(72)*.

Flat-Type (Malignant) Smallpox Flat-type smallpox is a highly fatal disease, affecting children primarily. It accounted for <10% of variola major presentations in the pre-eradication period. Malignant smallpox has a similar incubation period and clinical prodrome to ordinary smallpox. In this disease, however, lesions develop slowly and have a confluent, flat, velvety pattern. The nonpustular appearance of the rash can obscure the diagnosis. This type of smallpox is almost uniformly fatal.

Hemorrhagic Smallpox Hemorrhagic smallpox was rare in the pre-eradication period, accounting for <5% of overall cases. Pregnant women experienced the greatest mortality among patients with this type of smallpox. The clinical picture of hemorrhagic smallpox is that of DIC, shock, and organ failure. The case-fatality rate for hemorrhagic smallpox exceeds 96%, and death can occur before the development of the rash *(81)*. Because of the atypical presentation and the very high virus levels in blood and throat wash, this clinical form is particularly dangerous epidemiologically.

Monkeypox Monkeypox virus is an *Orthopoxvirus*, which causes an infection similar to smallpox, but generally milder. It occurs sporadically in Western and Central Africa.

Clinically, patients experience a similar prodrome (fever, chills, headache, backache) to smallpox *(82)*. After 1 to 3 days, a smallpox-like rash appears, which lasts 2 to 4 weeks. Lymphadenopathy is a more prominent feature in monkeypox than in smallpox *(82–84)*.

The case-fatality rate for monkeypox is lower, reflecting a milder clinical course. In two reported outbreaks, the case-fatality rate varied from 3% to 11%. All deaths in these two outbreaks involved children under the age of ten with no prior smallpox vaccination *(82)*.

Monkeypox virus can be spread from animal reservoirs (squirrels, rabbits, rodents, prairie dogs) or person to person. The secondary attack rate for household contacts is low; rates ranging from 7% to 15% have been reported among unvaccinated close contacts *(83,85,86)*.

In June 2003, an outbreak of monkeypox occurred in the United States. The outbreak was traced back to infected prairie dogs, which had contracted the virus by close contact during shipping with imported Gambian rats from Africa. Seventy-one cases were reported; 26% were hospitalized, but no deaths occurred. Thirty exposed persons received smallpox vaccine to prevent monkeypox; one of these was later confirmed with the disease *(87)*.

Smallpox as a Bioweapon Smallpox has been considered the most devastating of all global infectious diseases, and its intentional reintroduction would be a "crime of unprecedented proportions" *(4)*. This fact alone makes it an attractive agent of terror.

Smallpox has several features that enhance its potential as a biologic weapon: it is contagious, and at this point in time, most of the population has no immunity to the disease; it is stable and infectious when aerosolized; the virus carries a high rate of morbidity and mortality and would undoubtedly cause widespread panic and social disruption *(88,89)*. Ongoing global vigilance is necessary to detect any recurrence of smallpox through accidental or intentional release *(84)*.

Therapeutic Countermeasures for Weaponized Smallpox

Treatment Supportive care including fluid management, pain alleviation, and surveillance for bacterial superinfection is the only available treatment for patients with smallpox. In the pre-eradication period, there was no available antiviral therapy against smallpox. Today, there have been over 200 antiviral compounds tested for therapeutic benefit against variola virus and other Orthopoxviruses *(72)*. Among those tested, cidofovir, adefovir, dipivoxil, and ribavirin have shown significant *in vitro* activity *(13)*. Animal model testing is the next stage toward the development of a clinically effective antiviral therapy. At least one study has suggested that cidofovir might be useful in postexposure prophylaxis or perhaps treatment.

Vaccination The vaccinia vaccine available from 1970s to 2008 was a lyophilized preparation called Dryvax (Wyeth Laboratories). All lots of Dryvax vaccine expired on February 29, 2008, and all programs that held supplies of Dryvax were instructed to destroy them.

A new cell culture–derived live vaccinia vaccine, produced by Acambis, was licensed by the FDA in 2007. ACAM2000 has been shown to elicit a successful immune response in a similar proportion of subjects when compared with the Dryvax vaccine *(89A)* ACAM2000 has replaced Dryvax smallpox vaccine due to withdrawal of the Dryvax license.

CDC will continue to provide ACAM2000 smallpox vaccine to protect responders as part of state public health

preparedness programs and laboratory personnel at risk for exposure to smallpox and other orthopoxviruses. In terms of new vaccine development, one approach has been to develop vaccines from attenuated vaccinia–derived viruses *(89B,89C)*. The highly attenuated modified vaccinia Ankara (MVA) is a possible vaccine alternative that may be safer than the existing vaccine, but immunogenicity studies are ongoing. Phase 1 and 2 trials IMVAMUNE (an MVA vaccine) showed a high level of immunogenicity with no unexpected side effects or serious adverse events among healthy humans, immunocompromised patients, or those with atopic dermatitis. More attenuated vaccines are under development.

Use of Vaccine for Postexposure Prophylaxis Immunity to variola virus generally develops within 8 to 11 days after vaccination. Since the incubation period for smallpox averages 12 days, vaccination soon after exposure (up to 4 days) may confer some immunity and reduce overall mortality. This may be particularly true for persons who received smallpox vaccination in the pre-eradication period due to the anamnestic immune response that occurs with revaccination *(90)*. The true efficacy and timing of postexposure vaccination prophylaxis remain unclear.

Use of Vaccine During a Smallpox Emergency A "ring vaccination" strategy has been used successfully during the smallpox eradication campaign and is the approach incorporated by the current CDC smallpox plan *(91)*. This strategy involves rapid identification and isolation of smallpox cases, identification and vaccination of contacts with monitoring for symptoms, and vaccination of household members of contacts (where no contraindications exist). In addition to ring vaccinations, rapid voluntary vaccination of a large population may be necessary to aid containment control strategies. Large-scale voluntary vaccination would only be initiated in certain situations under the recommendation from the Secretary of Health and Human Services. Vaccination of the general population before the threat of a smallpox attack is better defined; it would be associated with an unacceptable number of serious and fatal adverse effects.

Vaccination only provides solid immunity if given within the previous 3 to 5 years. However, there is amelioration of severity and protection from mortality for many years, depending on the number of vaccinations. Because infection with rash and spread of virus may occur and because some patients with distant vaccination will be expected to die, history of vaccination should not dissuade revaccination when indicated for protection.

Targeted quarantine of selected high-risk exposures would be expected to have a place in control of smallpox under certain circumstances. Wide-scale quarantine of communities would likely not be effective and are not recommended *(92)*.

Implications for Healthcare Workers Patients with suspected smallpox should be cared for using strict isolation procedures including placement in negative pressure rooms with external air exhaust or high-efficiency particulate air filters where available. In the event of a massive outbreak, smallpox patients should be cohorted and isolated. All healthcare workers caring for patients with suspected smallpox should be vaccinated immediately *(93)*. Contraindications for the vaccination of healthcare workers included history of eczema or atopic dermatitis, persons with other exfoliative skin diseases or burns, immunocompromised patients, and patients with known cardiac risk factors *(94)*.

In October 2002, the Advisory Committee on Immunization Practices and the Healthcare Infection Control Practices Advisory Committee at the CDC recommended smallpox vaccination for persons designated by the appropriate bioterrorism and public health authorities to conduct investigation and follow-up of initial smallpox cases (i.e., smallpox medical response teams). According to CDC, as of October 31, 2005, over 39,608 persons were vaccinated through this program. This represented <17% of smallpox vaccine doses distributed to states for healthcare workers *(94A)*. Reasons for nonparticipation included relatively low risk of a smallpox outbreak, risks associated with the vaccine, hospital costs, and high rates of contraindications to vaccination *(94B)*. (For additional information on smallpox as a bioterrorism agent, see Chapter 104.)

Tularemia

F. tularensis is the causative agent of tularemia. It is a small gram-negative rod, often mistaken visually on Gram stain for *Hemophilus* species. It is a nonsporulating, nonmotile aerobe. There are several subspecies of *F. tularensis*, which are differentiated by biochemical tests and antimicrobial resistance. These microorganisms flourish in moist environments (water, mud, animal carcasses) and can survive for extended periods of time in these settings *(95–97)*. There are several biovars, but the *F. tularensis* biovar tularensis or type A is the most virulent.

Laboratory diagnosis is possible by cultivation from blood or other relevant clinical samples although growth may be slow and conventional media may not be optimum. Investigational techniques include PCR and antigen detection.

Epidemiology/Modes of Transmission The primary vectors for *F. tularensis* are ticks, mosquitoes, and biting flies *(98,99)*. The principal reservoirs include a variety of small animal species including rabbits, rats and mice, lemmings, squirrels, and aquatic rodents *(98–100)*. Humans and other mammals as well as some species of birds, fish, and amphibians serve as incidental hosts. An outbreak of tularemia in commercially distributed prairie dogs was reported in the United States in 2002 but did not result in human cases *(101)*.

F. tularensis can be transmitted to humans by several routes: the bite of an infected arthropod vector *(102)*; ingestion of contaminated food or water *(103,104)*; the handling of infected animal tissue *(105)*; the inhalation of aerosolized bacteria during the mowing of hay or grass *(106,107)*; or during processing of bacteria in the laboratory *(108)*. The average incubation period is 3 to 5 days; *F. tularensis* is highly infectious, but not contagious from person to person.

Most cases in the United States in recent years have been associated with bites from infected arthropods, although animal exposure continues to be a common

source of infection in the southeastern United States *(109)*. States with the highest number of reported cases include Arkansas, Kansas, Missouri, Montana, Oklahoma, and South Dakota *(110)*. Most cases occur in rural or semirural settings and show seasonality, presenting between May and August. Sporadic cases may rarely occur in urban settings with no identifiable source, but would justify additional scrutiny.

Although the number of cases reported each year is declining, tularemia can occur in outbreaks, the most recent of which occurred in Martha's Vineyard in 2000. Fifteen cases of primarily pneumonic tularemia occurred, presumably secondary to aerosolized exposure to *F. tularensis* via lawn mower clippings. There was one fatality in that series *(107)*. Worldwide, tularemia is seen most often in Scandinavian countries and Russia *(98)*. It is endemic in latitudes that include North America, Europe, states of the Russian Federation, China, and Japan *(98)*. Outbreaks have been reported intermittently in Europe as well.

Clinical Syndromes Infection with *F. tularensis* can cause several clinical syndromes ranging from a mild, localized infection to a life-threatening systemic illness. Poor outcomes occur in patients with significant comorbidity or in those in whom diagnosis and antibiotic therapy have been delayed *(98)*.

Glandular, ulceroglandular, and pneumonic tularemia are the most common naturally occurring manifestations of tularemia. Other rare presentations of *F. tularensis* include oculoglandular and oropharyngeal tularemia *(98)*. Typhoidal tularemia is a term used historically to describe pneumonic tularemia. Experts in this field now recommend the term "typhoidal tularemia" to denote systemic infections with *F. tularensis* that lack a clear anatomic focus.

Glandular and Ulceroglandular Tularemia Ulceroglandular tularemia is the most common manifestation of *F. tularensis* infection accounting for over half of all clinical presentations of *F. tularensis* infection. Glandular tularemia represents 25% of cases. In both illness manifestations, microorganisms enter the body through unapparent breaks in the skin or via the bite of an infected arthropod. The infectious dose for humans following percutaneous or inhalational inoculation is 10 to 50 microorganisms *(11)*. Patients with these forms of tularemia usually present with a painful, localized cutaneous infection and tender, regional lymphadenopathy. Fever, chills, axillary adenopathy, and myalgias are also common. Complications of this type of infection include secondary pneumonia, hematogenous spread to other organs, and, rarely, sepsis. Glandular tularemia is distinguished by lymph node involvement, but lack of ulceration at the site of inoculation *(96)*. The case-fatality rate is generally low (<2%), but some subtypes are more virulent than others.

Pneumonic Tularemia Pneumonia caused by *F. tularensis* can result from inhalation of infectious aerosols or via hematogenous spread. Primary pneumonic tularemia often presents as an atypical pneumonia unresponsive to conventional therapy. Symptoms include fever, nonproductive cough, myalgias, and occasionally nausea and vomiting. The disease course is extremely variable. Complications include the adult respiratory distress syndrome, lung abscesses, sepsis, or involvement of other organs through hematogenous spread. Recovery is prolonged, and relapses can occur even with antibiotic therapy. The case-fatality rate with prompt antibiotic treatment has been reported at <3%.

Secondary pneumonia occurs frequently in patients with typhoidal tularemia. Case-fatality rates of this pneumonia presentation have approached 50% in the preantibiotic era but are significantly reduced with appropriate antibiotic treatment.

Tularemia as a Biologic Weapon There is information and evidence to support the use of *F. tularensis* as a biologic weapon *(109)*. During World War II, the Japanese conducted research on *F. tularensis* as a biologic weapon. *F. tularensis* was also investigated for weaponization by the United States in the 1950s and 1960s, although these stockpiles were destroyed in 1973 as part of the BWTC act. The former Soviet Union also weaponized *F. tularensis*, including the development of antibiotic resistant strains. In 1969, a WHO modeling scenario estimated that a 50-kg release with dissemination of *F. tularensis* over a city of 5 million people would cause 250,000 illnesses and 19,000 deaths *(111)*.

A bioterrorist attack with aerosolized *F. tularensis* would be expected to cause primarily pneumonic tularemia; however, some cases of typhoidal (nonspecific) and glandular tularemia may occur as well. Tularemia is highly infectious, and it should be assumed that weaponized *F. tularensis* would be selected for high virulence and engineered for antimicrobial resistance and high virulence.

An outbreak of tularemia from a bioterrorist attack would be differentiated from a naturally occurring outbreak in that persons infected would have no known exposure to the bacteria, and cases would likely present in an urban rather than rural setting *(109)*.

Therapeutic Countermeasures for Weaponized Tularemia Exposure

Postexposure Prophylaxis The prompt initiation of a prophylactic antibiotic treatment regimen is critical for reducing morbidity and mortality as well as providing a community-wide sense of calm and control.

Current recommendations by the Working Group on Civilian Biodefense include the following: If the release of *F. tularensis* becomes known before clinical cases occur (i.e., during the incubation period), persons in the exposed population should be placed on prophylactic oral antibiotics (doxycycline or ciprofloxacin) for a period of 14 days.

In a situation of a known terrorist attack with documented clinical cases, all persons should be watched for signs of fever; any person who develops fever or flu-like symptoms should be placed on parenteral antibiotics, if available, or oral antibiotics in mass casualty settings *(109)*.

Antibiotic Treatment Antibiotic therapy for patients with documented tularemia is similar to prophylactic treatment regimens. The Working Group on Civilian Biodefense has made the following recommendations for treatment during a bioterrorist attack: If parenteral therapy is available, patients should be given streptomycin or gentamicin intramuscularly for 10 days. In a situation of mass casualties where the medical delivery system is unable to meet patient care demands, oral

antibiotics should be administered for a period of 14 days. It is important to watch for posttreatment relapse and consider the possibility that a weaponized form of *F. tularensis* may be engineered for antimicrobial resistance *(109)*.

Tularemia Vaccine There is no licensed vaccine currently available for tularemia. Several vaccine prototypes are under development; however, challenges to develop new, effective vaccines against *F. tularensis* include lack of a complete understanding of the immunodominant antigens and virulence determinants as well as the fact that generation of both humoral as well as cellular immune responses may be necessary for protection against infection.

In addition, postexposure vaccination against tularemia is also not a feasible strategy; the short incubation period of the disease (3–5 days) negates the benefit of vaccine-based immunity, which requires 14 days to develop after injection.

Implications for Healthcare Workers

Healthcare workers exposed to aerosolized *F. tularensis* should undergo postexposure prophylaxis as described above. In caring for patients with diagnosed tularemia, the use of Standard Precautions *(70)* is adequate since the agent, while highly infectious, is not contagious from person to person.

F. tularensis does pose a significant potential threat in the laboratory setting since tularemia can be easily aerosolized and requires an extremely small dose for infectivity. In addition, the agent may be present in virtually any human specimen *(112)*. A recent report described the exposure of 12 laboratory workers after a delay in identification of *F. tularensis (113)*. This led to a recommendation by the authors that any bacterial microorganisms with properties suggestive of *F. tularensis* on initial evaluation be evaluated under a biologic safety cabinet until the microorganism is further identified.

Viral Hemorrhagic Fever

Hemorrhagic fever viruses are a collection of taxonomically distinct viruses that cause the hemorrhagic fever syndrome. Because the clinical presentation of these viruses is similar, they are all considered hemorrhagic fever viruses.

They share commonalities in composition; they are all single-stranded RNA viruses and possess a characteristic lipid envelope. The four taxonomic families represented in this clinical group include Filoviridae, Flaviviridae, Arenaviridae, and Bunyaviridae. Some key characteristics of specific hemorrhagic fever viruses within these families are shown in Table 103-2.

Laboratory diagnosis is specialized and can be achieved by detection of viral RNA through RT-PCR or viral antigen by enzyme-linked immunosorbent assay. Viral isolation is also useful in a longer time frame. After the disappearance of virus-related markers as the patient enters convalescence, immunoglobulin M appears. Hantaviruses are an exception in that patients present with immunoglobulin M antibodies in serum.

Clinical Syndromes/Epidemiology Although each virus family has unique clinical and epidemiologic characteristics, the overall clinical picture for the group of hemorrhagic fever viruses is similar *(122)*. The infectious dose for hemorrhagic fever viruses appears to be extremely low (1–10 microorganisms) *(11)*. Regardless of the route of infection, they induce a systemic illness with fever, capillary dysfunction, prostration, and, in their most severe manifestations, shock and central nervous system dysfunction. Many patients experience hemorrhagic manifestations that occur as a result of thrombocytopenia or severe platelet dysfunction along with endothelial dysfunction *(122)*. A hemorrhagic or purpuric rash, epistaxis, menometrorrhagia, hematemesis, hemoptysis, blood in stools, and nondependent petechiae are common bleeding manifestations.

The Working Group on Civilian Biodefense has compiled a list of hemorrhagic fever viruses that pose the most serious threat as biologic agents of terror. Notable clinical features of these specific viruses will be reviewed briefly *(123)*.

Ebola Hemorrhagic Fever Ebola belongs to the Filoviridae family of viruses. It is an important emerging infectious disease, with increasingly frequent outbreaks documented in Central Africa since its discovery in 1976 (124). Much about the transmission, reservoirs, and pathogenesis of this disease remain unclear; however, its high case-fatality rate (50%–90%) and its potential for weaponization have made it an increasing focus of public health interest in recent years.

Clinically, Ebola hemorrhagic fever presents with fever, maculopapular rash (especially on trunk), myalgias, chest pain, jaundice, and severe prostration. After several days, bleeding ensues, followed by DIC, shock, and end-organ failure. Death occurs usually within 10 days of symptom onset (124,*125*).

Modes of transmission in nature include person to person, via contact with blood or body fluids (including semen), or direct contact with nonhuman primates, and possibly via aerosolization *(126–128)*.

Marburg Hemorrhagic Fever Marburg virus is a member of the Filoviridae family and shares many similarities to Ebola virus. It was discovered in 1967 following an outbreak in laboratory workers in Marburg, Germany (as well as Yugoslavia) *(129)*. It has been responsible for several outbreaks in Central Africa, the largest in the Democratic Republic of the Congo in 1998 *(130)*.

It has a similar but less lethal clinical picture than Ebola virus; case-fatality rates are generally <25%. Like Ebola, its pathogenesis, modes of transmission, and reservoirs have not been completely elucidated.

Lassa Fever Lassa fever virus is a member of the Arenaviridae family of viruses. It is a disease that has become endemic in West Africa over the past 30 years. It was discovered in 1969 in Northern Nigeria and has been responsible for 100,000 to 300,000 yearly infections since that time *(131)*. Occasionally, it is imported into the United States or other Western Countries *(132)*.

Clinically, Lassa fever is characterized by a prodrome of fever and general malaise, followed by severe exudative pharyngitis, occasionally maculopapular rash, prostration, and, in about one-third of cases, bleeding manifestations. The case-fatality rate is about 15%. Ribavirin therapy is helpful in management of severe cases.

TABLE 103-2

Characteristics of Hemorrhagic Fever Viruses

Family	*Agents*	*Characteristics*
Filoviridae	Ebola virus Marburg virus	• Filamentous virions (from the Latin "filo" for "thread") • Genome contains single-stranded nonsegmented RNA • Size: 19 kbp, 80 nm in diameter, variable length • Transmembrane spike glycoprotein produces antigenically distinct viral species
Arenaviridae	Old World arenaviruses: • Lassa virus New World arenaviruses: • Junin virus (Argentine hemorrhagic fever) • Machupo virus (Bolivian hemorrhagic fever) • Guanarito virus (Venezuelan hemorrhagic fever) • Sabia virus (Brazilian hemorrhagic fever) • Whitewater Arroyo virus	• Spherical or pleomorphic virions with "sandy," granular ultrastructural appearance • Genome contains single-stranded RNA with two segments • Size: 11 kbp, generally 110–130 nm in diameter • Distinct club-shaped or spike glycoprotein projections on viral envelope • Lassa fever viruses exhibit four distinct genetic lineages (three in Nigeria, and one in Guinea, Liberia, and Sierra Leone) • New World arenaviruses differ by neutralization tests and rodent reservoirs
Bunyaviridae	• *Phlebovirus* (Rift Valley fever virus) Nairo virus (Crimean Congo hemorrhagic fever) Hanta virus (Hantaan virus; Sin nombre virus)	• Spherical or slightly pleomorphic virions • Genome contains single-stranded RNA with three segments • Size: 11–19 kbp, 80–120 nm in diameter
Flaviviridae	Yellow fever virus Kyanasur Forest disease virus Omsk hemorrhagic fever virus Dengue virus (primary infection only rarely causes hemorrhagic fever)	• Family name from Latin "flavus" for "yellow" • Icosahedral virions • Single-stranded nonsegmented RNA • Size: 10–12 kbp, 40–50 nm in diameter • Virions covered with surface projections composed of M (membrane) and E (envelope) glycoproteins

(Data from References 114–121.)

New World Arenavirus Hemorrhagic Fevers Several different viruses from the Arenaviridae family are responsible for the New World hemorrhagic fevers. Most cases occur in South America, although one strain, Whitewater Arroyo virus, has been identified as a cause of disease in California *(133)*. The virus is transmitted from asymptomatically infected rodents that serve as a reservoir for the virus. The disease is common in the endemic regions of Bolivia and Argentina; however, some viruses have been responsible for only a very small number of cases.

New World hemorrhagic fever viruses that cause disease in humans include Junin virus (Argentine hemorrhagic fever), Machupo virus (Bolivian HF), Guanarito virus (Venezuelan HF), Sabia virus (Brazilian HF), and Whitewater Arroyo virus.

Clinically, they are similar; most cases are notable for fever, sore throat, myalgias, conjunctivitis, petechiae and other bleeding manifestations, neurologic involvement, and occasionally shock. Recovery occurs over 2 to 3 weeks; the overall case-fatality rate is 15% to 30% *(134)*.

Rift Valley Fever Mosquitoes serve as the vector for Rift Valley fever virus, a bunyavirus (family Bunyaviridae, genus *Phlebovirus*), which is endemic in sub-Saharan and North Africa. The virus was first discovered in sheep in 1930 in Kenya *(135)*. Livestock and humans are most often affected. Epizootics in animals characteristically involve high rates of sheep or cattle mortality especially in the young animals and very high rates of abortion in infected animals. Outbreaks are episodic and most often follow heavy rainfall that results in flooding of previously dry areas, allowing for extensive hatching of the primary mosquito vector *(136)*.

Human illness is usually relatively mild, although most infections are subclinically evident. In <1% of cases, VHF with marked hepatitis and bleeding manifestations can occur. Encephalitis is also an infrequent manifestation of the disease. Retinitis occurs in perhaps 10% of cases, is associated with secondary blindness, and may be associated with permanent visual impairment. The overall case-fatality rate is around <1%, but is as high as 50% in cases of hemorrhagic fever.

Yellow Fever Yellow fever virus is a member of the Flaviviridae family of viruses. It has been described as early as the 1600s and continues to be endemic in sub-Saharan Africa and tropical South America *(137)*. A variety of mosquito species serve as vectors for yellow fever virus. The

WHO estimates 200,000 cases per year and 30,000 deaths worldwide, although many of these are unreported.

Many cases of yellow fever are mild or even subclinical. Cases of severe disease are characterized by fulminant hepatitis, bleeding, renal failure, shock, and death. The overall case-fatality rate is from 5% to about 20%, but increases to 50% or more for patients with severe disease.

Kyasanur Forest Disease and Omsk Hemorrhagic Fever Kyasanur Forest disease is a rare, tick-borne infection found only in one region of India. Outbreaks occur periodically and parallel epizootics are found in the local monkey population. Omsk hemorrhagic fever is also a rare form of VHF, limited to regions of Central Asia and Siberia. It is associated with episodic outbreaks that have been documented since the 1940s and 1950s (138). Recently another flavivirus, Alkhurma virus, has shown activity in Saudi Arabia. It is a variant of Kyasanur Forest disease and can cause severe disease, although aerosol infection has not been evaluated *(138A)*.

The clinical picture is similar to other hemorrhagic fever viruses; many cases are mild, but severe disease can be associated with meningoencephalitis and VHF. The overall case-fatality rate for Kyasanur Forest disease is 3% to 10% and Omsk hemorrhagic fever is 0.5% to 10%.

Hemorrhagic Fever Viruses as Biologic Weapons VHF viruses have been the subject of considerable research and development as biologic weapons; the United States, prior to 1972, conducted research on a variety of agents, and the Soviet Union weaponized Marburg virus and conducted research on Ebola, Lassa, and Rift Valley fever viruses as well as others. There is concern that North Korea may have weaponized yellow fever virus *(139)*.

These viruses have characteristics that make them attractive as biologic agents of terror: they are infectious by aerosols at low doses and can be aerosolized; they can cause high fatality rates with a dramatic clinical syndrome that could contribute to subsequent widespread panic and social destabilization; many are readily available and have been extensively researched by several countries. In addition, treatment options are limited or nonexistent.

The CDC, in 2000, listed Ebola, Marburg, and Lassa viruses and New World arenaviruses as category A agents, those most likely to cause mass casualties if deliberately disseminated. In 2002, the Working Group on Civilian Biodefense added Rift Valley fever virus, yellow fever virus, Kyasanur Forest disease virus, and Omsk hemorrhagic fever virus to the list compiled by the CDC *(123)*.

Therapeutic Countermeasures for Weaponized VHF

Treatment The mainstay of treatment for VHF is supportive, intensive care as indicated by the complications of the disease. Management of bleeding diatheses is controversial but generally involves the administration of blood and clotting factor components as indicated by the laboratory findings. Heparin or tissue factor antagonists may be useful therapeutic choices in cases of DIC *(140)*. Steroids have not been shown to be effective, but should be considered with evidence of adrenal involvement *(141,142)*.

Ribavirin has significant *in vitro* activity against members of the Arenaviridae and Bunyaviridae (*123,143,144,145*,146). *In vivo*, the major established therapeutic utility of the drug is in the arenavirus hemorrhagic fevers. Human data are available for Lassa fever, but for the Bolivian, Argentine, and Brazilian viruses there is only animal data with anecdotal clinical reports (*147*,148,149,*150*). There are a number of experimental approaches that are impractical or insufficiently developed, including passive antibody therapy or interferon prophylaxis. Antiviral agents have not been shown to be effective against diseases caused by filoviruses or flaviviruses *(123)*.

Postexposure Prophylaxis There is no effective postexposure prophylaxis for asymptomatic persons exposed to weaponized hemorrhagic fever virus. The Working Group on Civilian Biodefense instead recommends that exposed populations be placed under surveillance for signs of fever or other symptoms suggestive of VHF. In the event of a documented fever >101°F, persons should be given intravenous ribavirin unless the agent is a confirmed filovirus or flavivirus *(151)*. This is an off-label use, and intravenous ribavirin is mainly accessible for compassionate use. Surveillance should continue for 21 days following exposure *(123)*.

Vaccine The only effective licensed vaccine against VHF is yellow fever vaccine. It is a live virus vaccine and has been associated with adverse events including fever, jaundice, and multiple organ system failure on rare occasions. The vaccine is in limited supply and is only recommended for travelers to areas endemic for yellow fever and laboratory personnel with an ongoing exposure risk to yellow fever *(152)*.

In the event of a bioterrorist attack, yellow fever vaccine would not be effective as a prophylactic treatment following exposure, because the disease incubation period is significantly shorter than the time required for developing immunity following vaccination *(123,153)*.

Vaccines against Argentine hemorrhagic fever and Rift Valley fever are known to be efficacious but are available only as investigational drugs *(154)*. Efforts to develop additional vaccines against various hemorrhagic fever viruses are ongoing *(155–157)*.

Implications for Healthcare Workers Transmission within healthcare settings has been documented for several VHF viruses, including Ebola, Marburg, Lassa, Machupo, and Crimean-Congo viruses *(7)*. Healthcare-associated transmission has usually occurred by contact with infected body fluids or blood (158,*159*). Needlesticks or the reuse of needles has also been associated with viral transmission *(155,160)*. Although these viruses form stable infectious aerosols, person-to-person airborne transmission is distinctly uncommon; the potential for airborne transmission in a healthcare setting cannot be ruled out (*123*,161). There is one documented case of airborne transmission of Machupo virus to a nursing student observing a bed linen change. The student had no physical contact with the patient or any associated fomites *(162)*. Contact with cadavers has also been a documented source of infection during outbreaks with Ebola hemorrhagic fever *(163)*.

Healthcare workers must exercise appropriate isolation procedures for patients with suspected or confirmed VHF including a combination of Airborne and Contact

Precautions *(7)*. The Working Group on Civilian Biodefense recommends the following precautions for healthcare settings *(123)*:

- All healthcare workers must have appropriate personal protective equipment, including N95 masks or personal air-purifying respirators.
- Patients must be placed in a negative pressure room, with restriction of nonessential staff and visitors.
- All healthcare workers who have had high-risk close contact with patients suspected of having VHF should be placed under medical surveillance for 21 days following exposure *(123)*.
- If multiple patients suspected of having VHF are admitted to a healthcare facility, they should be cohorted to minimize exposure to healthcare workers and other patients.

All cases of suspected VHF should be reported immediately to state or local public health officials, according to disease reporting requirements.

CHAPTER 104

Preparedness for a Bioterrorist Attack with Smallpox

Whitni B. Davidson, Andrea M. McCollum, and Inger K. Damon

Smallpox is an infectious disease caused by an orthopoxvirus, variola virus, and efforts of a worldwide program led to its eradication. Historical accounts have long placed smallpox as the cause of many epidemics and deaths. Smallpox has a high interhuman transmission rate, multiple transmission routes, and a high case fatality rate. Jenner's inoculation with cowpox in 1798 demonstrated that protection against smallpox could be achieved using dermal infection with a related orthopoxvirus. Shortly thereafter, vaccination with live vaccinia virus was introduced as an individual and population-based method to prevent infection with smallpox. An extensive global campaign including vaccination, surveillance, containment, and infection control practices was led by the World Health Organization (WHO) beginning in 1967. The last case of "natural" smallpox was reported in a Somalian patient in 1977, and two persons were infected as a result of a laboratory exposure in 1978. Worldwide eradication was pronounced in 1980. Childhood vaccination programs ceased before, or shortly after, the declaration of disease eradication.

Smallpox, as known in the historical medical literature, did not have an animal reservoir; thus, there is no risk of "natural" human infections appearing again, and this, in part, contributed to the ability to eradicate the disease. However, the virus itself has not been eradicated. Declared stocks of the virus are securely maintained in two WHO reference laboratories, one at the U.S. Centers for Disease Control and Prevention (CDC) and the other at the State Research Center of Virology and Biotechnology (Vektor Institute) in Russia. There is some belief that undeclared stocks may also exist *(1)*. Thus, the chance of an accidental or intentional release of smallpox is not zero. This, along with an increasing susceptible, unvaccinated, mobile population, causes great concern about the dangers posed by variola virus in the world today.

Large-scale public health efforts have resulted in the development of emergency plans, response guidelines, and acquisition of vaccine stocks. For example, the United States has enough smallpox vaccine in its stockpile to vaccinate each U.S. citizen in the event of a release of the virus. This chapter will review the biology and epidemiology of smallpox, vaccination information including adverse events, and hospital control and prevention of transmission of the disease.

VIROLOGY AND PATHOLOGY

Variola virus belongs to the *Poxviridae* family, subfamily *Chordopoxvirinae*, as a member species of the *Orthopoxvirus* genus. Chordopoxviruses infect a wide variety of animals including birds, rodents, ruminants, and humans, and these viruses can exhibit wide to narrow "host" species specificities and host ranges. The *Orthopoxvirus* genus includes four virus species known to infect humans, variola, monkeypox, vaccinia, cowpox, as well as others not currently known to naturally infect humans. Orthopoxviruses are closely related and immunologically cross-reactive. Edward Jenner demonstrated cross-protection against variola in humans first using cowpox in 1798 and then using vaccinia virus.

Poxviruses have large virions, approximately 140 to 260 nm × 220 to 450 nm. Oval- or brick-shaped virions encapsulate linear, double-stranded DNA genomes of approximately 200 kb in length. There are two epidemiologically characterized variants of variola infection: "variola major" and "variola minor"; each differs in case fatality rates and some viruses associated with the less severe disease manifestations can be distinguished in the laboratory or by genetic markers (2).

Much of the information about smallpox pathogenesis has been gleaned from using animal models with a variety of orthopoxvirus challenges. In human smallpox disease, epidemiologic information indicated that the common route for infection was via the respiratory tract; transmission via the skin or congenitally occurred less frequently. The virus asymptomatically replicates in the endothelium and enters the reticuloendothelial system. Additional replication occurs in the lymph nodes. Macrophages migrate to infected lymph nodes early in infection, and the production of cytotoxic T cells and B cells limits the spread of infection. Neutralizing antibodies can be found during the first week of infection. Secondary viremia followed by initial onset of symptoms occurs on average 12 days after transmission. Hemagglutination inhibition and complement fixation antibodies are present approximately 16 and 18 days postinfection, respectively. These antibodies may dissipate after 1 year; however, neutralizing antibodies are present for many years postinfection (2–4). Currently, humoral immune responses to orthopoxvirus infections are more commonly measured

via immunoglobulin M and/or G enzyme–linked immunosorbent assays and neutralizing responses *(5)*.

A rash develops over the entire body and goes through several stages (described below) as macrophages migrate to the epidermis. Aside from oropharynx and skin lesions, virus can be found in lymph nodes, bone marrow, spleen, liver, kidney, urine, and conjunctival secretions (2,3). In fact, virtually all organs are affected. Endothelial cells lining the sinusoids of the liver swell and can become necrotic, and parenchymal cells swell. The spleen enlarges with increased lymph involvement. Hemorrhaging of renal, gastric, and pharyngeal membranes and endocardium and myocardial tissue occurs. Thrombocytopenia, encephalitis, and necrosis of testis are also occasionally noted. Prominent pitted scarring is likely due to the destruction of sebaceous glands (6).

The exact cause of death due to smallpox is not completely understood. Secondary bacterial infections have been posited to play a role in death, but recent data do not support their role in fatalities. One retrospective study attributed many deaths to cytotoxicity or immune complex disease *(7)*.

FIGURE 104-1 Smallpox: lesions on palms and soles. (From World Health Organization.) (*See color insert.*)

CLINICAL DISEASE AND EPIDEMIOLOGY

Presentation

Clinical presentations of smallpox can vary depending on the patient's vaccination status, level of nutrition, and infectious strain, among a host of unknown factors. Smallpox illness has three phases: incubation, prodrome, and rash. Infection occurs via the respiratory mucosa, and an incubation period of 10 to 14 days on average occurs before a prodromal period of 2 to 4 days. The prodrome is characterized by fever, malaise, vomiting, headache, backache, and myalgia. The prodromal phase can be severe enough to confine many patients to bed and has been described to resemble a severe influenza illness (2,*8*).

Rash initially presents as an enanthem on the mucous membranes of the mouth, tongue, and oropharynx; within 24 hours, a rash, ultimately with centrifugal distribution, develops. Usually, the rash is first evident on the face, then proximal extremities, distal extremities (including palms and soles), and trunk (Fig. 104-1). The rash develops from macules to papules to vesicles to pustules over the course of 1 to 10 days postprodrome (Fig. 104-2). Lesions on any one part of the body generally present in the same stage of development during the course of the rash, and lesions present with a centrifugal density. Lesions are deep, firm, and become umbilicated (Fig. 104-3). Lesion numbers can be denser in areas of trauma or inflammation—the "garter effect"—and are noted in areas where there are scratches or irritation. Scabs eventually form and fall off approximately 2 to 3 weeks postinitial rash onset and leave pronounced deep scars and hypo- and/or hyperpigmentation (2,6,*8*). Nonfatal severe complications associated with variola infections include panophthalmitis, blindness, keratitis, corneal ulcers, osteomyelitis, arthritis, orchitis, and encephalitis.

Forms of Variola

Smallpox has been categorized in a number of different ways including variola major and minor, based on epidemiological criteria such as case fatality rates. Variola major and variola minor, on average, have case fatalities of about 30% and ≤1%, respectively. Variola–alastrim strains (which caused disease in Brazil in the 20th century) have been discretely biologically and genetically discriminated from variola major. However, certain African variola minor isolates by laboratory assays are more like variola major than alastrim *(9)*. Surveillance data (which may be biased by health-seeking behaviors) suggest that nearly 90% of patients develop variola major. Variola major was categorized by the WHO into eight clinical types. Three types of "ordinary" disease are discriminated by the density of rash presentation on the face and body: ordinary discrete, ordinary semiconfluent, and ordinary confluent. In hospitalized patients, these forms are characterized to have mortality rates of 30%, 37%, and 62%, respectively, in unvaccinated individuals and mortality rates of 3%, 8%, and 26%, respectively, in vaccinated individuals. The terms discrete, semiconfluent, and confluent refer to the density of the lesions (6,*10*).

Less severe, somewhat atypical disease, described as modified smallpox, exhibits a faster disease time course with more superficial lesions when compared to ordinary forms of variola major. Another less pathogenic form, variola *sine eruption*, is characterized by a febrile illness without rash and little to no viral transmission. Modified smallpox and variola *sine eruption* occur mainly in vaccinated individuals with little associated mortality (2,6).

The most severe, and rare, manifestations of disease (<3–5% of hospitalized patients) are flat and hemorrhagic forms of smallpox. Flat-type smallpox describes a disease in which the lesions appear flat, likely because of significant tissue edema. In hospitalized patients, the mortality rate is approximately 97% in unvaccinated and 67% in vaccinated individuals. Hemorrhagic smallpox is characterized to have two variants: early and late. In early disease, the characteristic discrete, raised pustules seen in ordinary smallpox do not develop. Instead painful, erythematous,

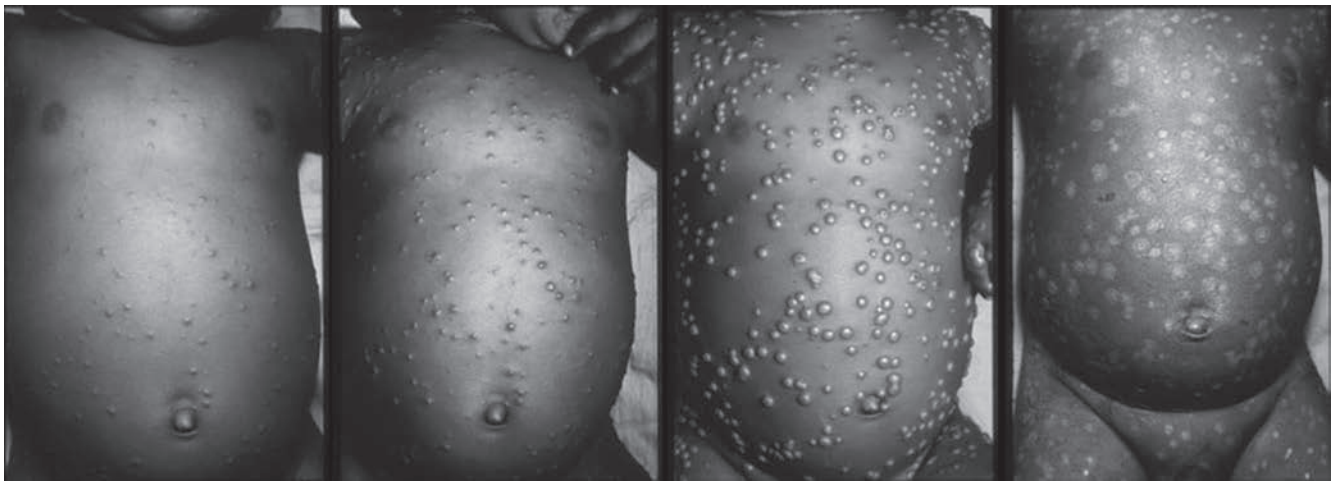

FIGURE 104-2 Smallpox: progression of lesions on the abdomen of child days 4, 5, 8/9, and 20. (From World Health Organization.) (*See color insert.*)

petechial lesions appear. In late hemorrhagic disease, some characteristic lesions develop, and hemorrhage is noted at the base of the lesions. The incubation period for early hemorrhagic smallpox is relatively short and death occurs within 5 or 6 days of rash onset. Death, regardless of vaccination status, occurs in approximately 95% of hospitalized individuals and is most likely due to massive mucosal hemorrhage (2,6,*10*).

Diagnosis

There are a number of illnesses that can be misdiagnosed as smallpox. These have included, and continue to include, varicella (chickenpox), monkeypox, disseminated herpes zoster and herpes simplex, impetigo, drug-induced rashes, erythema multiforme, Stevens–Johnson syndrome, scabies, molluscum contagiosum, and enteroviral infections, especially hand, foot, and mouth disease. The disease most commonly mistaken for smallpox during and after eradication is varicella. Clinical features of varicella that distinguish it from smallpox are a short prodromal phase lasting 1 to 2 days, fever with onset of rash, centripetal rash distribution, lesions in varying stages of development, and shortened lesion progression from vesicles to crusting (3). Human monkeypox, a zoonotic disease endemic to central and western Africa, resembles smallpox in appearance, but patients will typically experience lymphadenopathy as part of their clinical course. Human monkeypox has not been seen in the United States since the 2003 outbreak related to importation of African rodents *(11)*.

Many medical professionals have no experience with smallpox; therefore, an algorithm was developed by CDC that separates patients into three risk categories for smallpox—high, moderate, or low (Fig. 104-4) (3). This algorithm (a) provides information about the symptoms of smallpox and other causes of febrile, vesicular/pustular rash illnesses likely to be confused with smallpox and (b) limits laboratory testing to high-risk patients reducing the likelihood of false-positive test results *(12)*. The algorithm can be found at *http://emergency.cdc.gov/agent/smallpox/diagnosis/evalposter.asp*.

Because of bioterrorism concerns for the potential malevolent use of variola, screening for variola virus from specimens of high-risk individuals can be performed in the U.S. at specific Laboratory Response Network (LRN) reference laboratories. Absent circulating disease, if screening at an LRN facility is positive for variola virus, more extensive testing and confirmation is performed at CDC before results are released. Real-time polymerase chain reaction is the gold standard for detection of variola virus. Previously, unique viral growth on chorioallantoic membrane

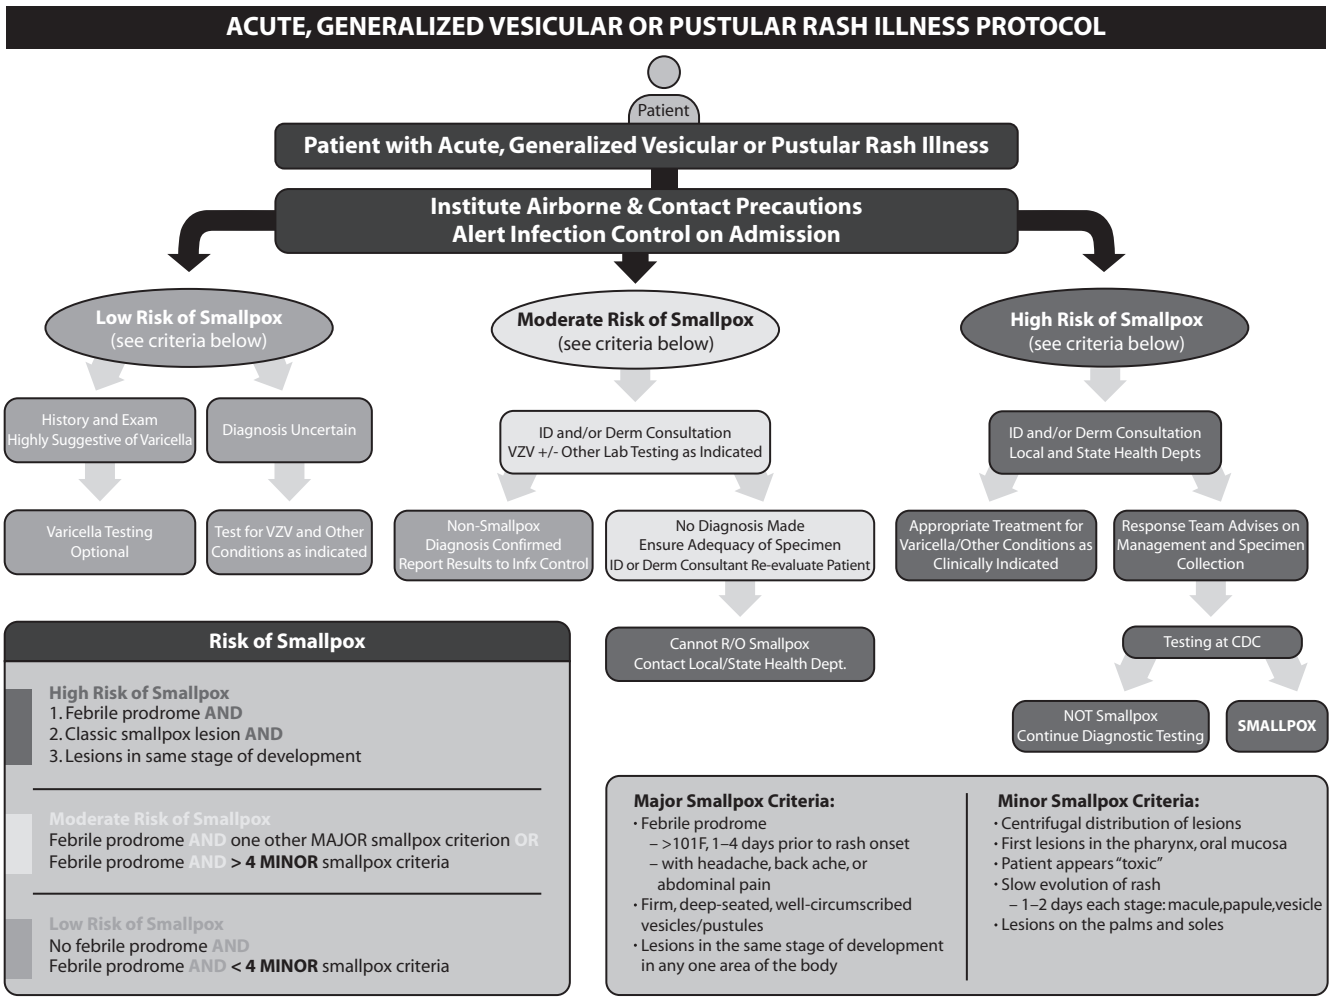

FIGURE 104-4 Evaluating patients for smallpox: acute, generalized vesicular, or pustular rash illness protocol. (From Centers for Disease Control and Prevention. Acute, generalized vesicular or pustular rash illness testing protocol in the United States. Available at *http://emergency.cdc.gov/agent/smallpox/diagnosis/pdf/poxalgorithm11-14-07.pdf.* Accessed June 1, 2011.) (*See color insert.*)

provided definitive confirmation. Other laboratory testing diagnostics such as enzyme-linked immunosorbent assay, electron microscopy, and immunohistochemical staining can diagnose a poxvirus infection; however, these tests are not specific for variola virus. With the exception of parapoxviruses, poxviruses have identical morphology by electron microscopy making it impossible to differentiate one species from another. Assays relying on immune reagents will, at least, identify all members of a poxvirus genus; orthopoxviruses share >90% genetic similarity causing antibodies to cross-react among member species (3).

Therapy

Currently, no antivirals are licensed for the treatment of any orthopoxvirus infection. There are active research programs evaluating various compounds against orthopoxviruses, including variola, in *in vitro* tissue culture, and in various orthopoxvirus-challenge animal disease model systems. Supportive therapy should be offered to smallpox patients. The time period between exposure and case identification or symptom onset is a critical factor in consideration for the use of postexposure prophylaxis (in the form of vaccination) or the use of investigational antiviral medications (2,4,13).

Patterns of Transmission

The infectiousness of a smallpox case depends upon the amount of viral shedding in oropharyngeal secretions and the number and distance of face-to-face contacts with susceptible persons. Smallpox patients have maximum infectivity during the first week of rash when large amounts of virus are being shed from the mouth and pharynx. Severe cases of smallpox typically shed larger amounts of oropharyngeal virus than those with modified-type smallpox. Although a large amount of virus can be detected in smallpox scabs, their infectivity is considerably less due to the enclosure of viral particles within hard dry scabs (4). Transmission rarely occurs before the first day of rash *(14)*. Epidemiologic studies have found that most cases of secondary smallpox caused by importation from an endemic area occurred within 3 weeks of initial exposure *(15)*.

The most frequently infected group is the household or family because of the significance of face-to-face contact in transmission. The secondary attack rate of variola major has

ranged from 1.2% to 88% in close contacts and is significantly affected by the vaccination status of the contact. Because patients with variola major in the prodromal phase usually fall quite ill, they separate themselves from the community, but not from their household contacts. The average attack rate for unvaccinated family contacts was 58.4%, and 3.8% in vaccinated contacts. On the other hand, cases infected with variola minor are more mobile causing more disease within the community despite less viral shedding (4).

Smallpox shows a seasonal variation in incidence with a predilection for winter and spring. However, seasonal fluctuation is limited in areas with uniform temperature and humidity. Aside from the environmental factors that may prolong the viability of virus, cool temperature and low humidity, other considerations have been given to the seasonal incidence of smallpox. These include (a) changes in mucous membrane permeability, (b) alterations in resistance because of changes in diet, and (c) the effect of climate on social activities (4).

VACCINATION

Edward Jenner demonstrated the principles of vaccination in 1796 when he used material from human cowpox lesions to protect individuals against smallpox. Today, live vaccinia virus is used to vaccinate against smallpox. Vaccinia virus is a closely related, yet distinct *Orthopoxvirus* species from variola. Routine vaccination was common in many countries until the early 1970s (4).

Variola virus has no nonhuman animal reservoir, and infection can be prevented with a single-dose, recent vaccination: these two characteristics made eradication a feasible accomplishment. WHO began an intensive surveillance, containment, and eradication campaign in 1967. Surveillance and containment consisted of the following five steps: (a) identification of cases, (b) isolation of patients, (c) identification of ring or close contacts, (d) vaccination of the ring contacts, and (e) vaccination of the associates of the ring contacts. This approach was used to eradicate smallpox and is recommended by WHO for use today if smallpox reappears (2,4). However, if a reintroduction occurs, widescale vaccination may occur in several countries.

In late 2007, the Food and Drug Administration licensed a new smallpox vaccine to replace Dryvax®. This new vaccine, ACAM2000®, is a cell culture grown, fully replicative vaccinia virus derived from a clonal isolate of Dryvax®. ACAM2000® was chosen based on its similar efficacy to Dryvax® *(16)*. Focus of current research on smallpox vaccines is the further development of replication competent cell culture–derived vaccinia; replication deficient, highly attenuated vaccinia; and DNA- or protein-based vaccines. Preclinical and clinical trials are currently underway for some of these newer vaccines to determine their efficacy *(17)*.

The preferred site for vaccination is the upper arm over the deltoid muscle. Vaccine is delivered by scarification using a sterile bifurcated needle that has been dipped into the rehydrated suspension. Fifteen perpendicular strokes to the skin are given through the droplet within a diameter of about 5 mm. The appearance of a drop of blood indicates that the strokes were vigorous enough to puncture the skin. Following successful primary vaccination, a major cutaneous reaction should appear at the site of inoculation by day 6 to 8 (Fig. 104-5). Within 2 to 5 days postvaccination, a papule will appear that will become vesicular, then pustular, and reach maximum size at day 8 to 10. The pustule will dry forming a scab which typically separates within 14 to 21 days, often leaving a pitted scar, and hypo- or hyperpigmentation is not unexpected. Persons who are revaccinated after successful primary vaccination may have a modified cutaneous response but this does not necessarily indicate an unsuccessful vaccination (18).

Because the current smallpox vaccine is a live, fully replicative vaccinia virus and can cause secondary transmission,

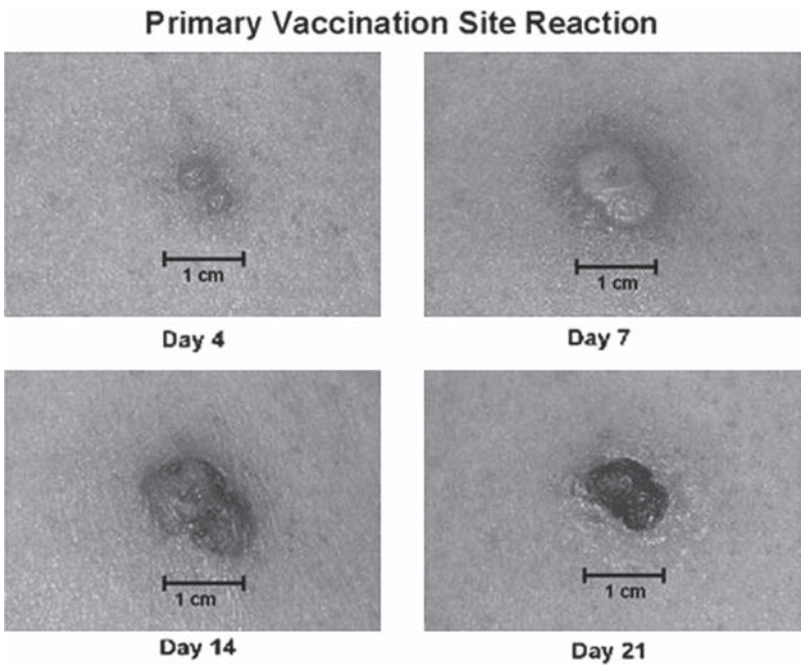

FIGURE 104-5 Vaccination site progression sequence in a normal primary vaccinee days 4, 7, 14, and 21. (From Centers for Disease Control and Prevention.) (*See color insert.*)

the inoculation site must remain covered until the scab has completely detached and a new epidermal layer has formed. A gauze bandage held in place by adhesive tape should loosely cover the site. If the vaccinee has an occupation that puts him or her in direct contact with patients, the gauze should be covered with an additional barrier using a semipermeable dressing and a layer of clothing. The use of only a semipermeable dressing is not recommended as it might lead to maceration of the vaccination site. Maceration can cause prolonged irritation and itching, potentially leading to increased touching or scratching and therefore contamination of hands. If maceration does occur, the lesion should be left uncovered to allow the site to dry. This is only suitable when a healthcare worker has no direct contact with patients or other persons. The vaccination site must remain covered until the scab separates *(19)*. Contaminated bandages should be sealed in a plastic bag and thrown in the trash. After direct contact with the vaccination site, hands should be washed with soap and warm water or with alcohol-based hand rubs. Potentially contaminated clothes, towels, or sheets should be washed separately in warm water (18).

The Advisory Committee on Immunization Practices lists a number of contraindications to smallpox vaccination in a routine nonemergency setting for both vaccinees and their household contacts. For both, these include a past or present history of eczema or atopic dermatitis; acute, chronic, or exfoliative skin conditions such as burns, chickenpox, or Darier's disease; immunodeficiency or those currently on immunosuppressive therapy; inflammatory eye diseases leading to use of steroid eye drops; and pregnancy or plans to become pregnant in the next 4 weeks. Additional contraindications for vaccinees only include: allergy to smallpox vaccine components, including polymyxin B, neomycin, streptomycin, and phenol; symptomatic or asymptomatic heart disease or three or more cardiac risk factors (hypertension, diabetes, hypercholesterolemia, heart disease at 50 years of age in a first degree relative, or current smoker); breastfeeding; persons under 18 years of age, especially infants <12 months, and those older than 65 years; severe allergy to latex; or "moderate" to "severe" illness at vaccination time. There are no absolute contraindications to vaccination for a person with a high-risk exposure to smallpox (18,*20*,21).

In the United States, routine smallpox vaccination of civilians was discontinued in 1971 following reduction of smallpox importations in the 1960s. In 1976, routine vaccination of healthcare workers was also discontinued *(22)*. In 2002, a preparedness plan was initiated to protect the United States against a possible smallpox bioterrorist attack. This plan calls for vaccination of both military and civilian personnel. Under the U.S. Civilian Smallpox Preparedness and Response Program, groups of public health and medical response teams who would care for smallpox patients during the first 7 to 10 days of an outbreak were voluntarily vaccinated (Table 104-1). Approximately 40,000 civilian personnel received licensed vaccine from January to December 2003 *(23)*. Since 2003, CDC continues to provide smallpox vaccine to state public health authorities for vaccination of smallpox response team members. CDC recommends revaccination of volunteer responders on an "out-the-door" basis, meaning only after a smallpox outbreak has been confirmed or is highly suspected, or there is credible evidence of a release or imminent release *(24)*. The US military continues to vaccinate personnel who serve in high-risk parts of the world. Additionally, laboratory researchers who work with or may be exposed to nonhighly attenuated vaccinia virus are often vaccinated (21,*25*,*26*).

TABLE 104-1

Recommended Members of Smallpox Response Healthcare Teams (per ACIP and HICPAC)

1. Physicians, nurses, and unit staff providing inpatient medical care for children and adults, including those in emergency room departments, intensive care units, general medical units, and primary-care facilities
2. Medical subspecialists, including infectious disease specialists, dermatologists, pathologists, ophthalmologists, surgeons, anesthesiologists, or those with previous smallpox experience
3. Infection control professionals
4. Respiratory therapists
5. Radiology technicians
6. Security personnel
7. Housekeeping staff (e.g., those staff involved in maintaining the healthcare environment and decreasing the risk for fomite transmission)

ACIP, Advisory Committee on Immunization Practices; HICPAC, Healthcare Infection Control Practices Advisory Committee. (Adapted from CDC. Recommendations for using smallpox vaccine in a pre-event vaccination program. *MMWR Morb Mortal Wkly Rep* 2003;52(RR-07):1–16.)

Reactions and Adverse Events to Smallpox Vaccination

Successful primary vaccination correlates with the activation of both the humoral and cellular immune responses in >95% of individuals. This includes production of neutralizing antibodies, vaccinia-specific memory B cells, and CD8+ and CD4+ cytotoxic T lymphocytes. Neutralizing antibodies appear approximately 10 days postvaccination. Both peak antibody levels and vaccinia-specific memory B cells decline during the first year postvaccination but then stabilize and can be detected >50 years later. Both CD4+ and CD8+ T cells can be detected by 1 month postvaccination and slowly decline over time but may be detectable for decades (3,*27*). Vaccination against smallpox does not confer complete lifelong immunity. A successful primary vaccination confers full immunity in >95% of individuals for 5 to 10 years (4).

In most cases, vaccination is safe and effective against the prevention of smallpox; however, adverse reactions can occur in individuals with or without preexisting conditions (Table 104-2). Some of these reactions are mild, others serious but treatable, and a rare few can be life threatening (28). Most data regarding adverse reactions to smallpox vaccination were gathered in the 1960s when the public was still routinely vaccinated. Rates of adverse reactions are expected to be higher in today's population given the increase in the number of immunocompromised individuals, such as those with HIV/AIDS, and the widespread use of immunomodulatory medications.

TABLE 104-2

Adverse Events Associated with Smallpox (Vaccinia) Vaccine

Adverse reactions in vaccine recipient or contact of vaccine recipient

1. Local skin reaction and hypersensitivity
   Allergic reaction to bandages/adhesives, robust take, bacterial infection
2. Nonspecific rashes
3. Dermatologic manifestations of hypersensitivity reactions
   Erythema multiforme; Steven–Johnson syndrome
4. Inadvertent inoculation
   Contact inoculation, autoinoculation, ocular vaccinia, eczema vaccinatum
5. Congenital vaccinia (fetal vaccinia)
6. Generalized vaccinia
7. Progressive vaccinia (vaccinia necrosum, vaccinia gangrenosa, and disseminated vaccinia)
8. Cardiac complications
   Myocarditis, pericarditis, atypical chest pain
9. Central nervous system complications
   Postvaccinial encephalitis, myelitis, acute disseminated encephalomyelitis

(Adapted from CDC. Smallpox vaccination and adverse reactions. *MMWR Morb Mortal Wkly Rep* 2003;52(RR-04):1–28.)

Approximately 1 week postvaccination, individuals may experience systemic symptoms such as fever >37.7°C lasting up to 3 weeks, malaise, myalgia, headache, chills, nausea, and fatigue. Soreness at the vaccination site, local lymphadenopathy, and erythema are also common. Expected normal variants include the appearance of satellite lesions close to the vaccination site, viral lymphangitis with a visible track toward the regional nodes in the axilla, local swelling, and intense inflammation surrounding the lesion. These types of local reactions typically only require supportive treatment *(29)*.

Many vaccinees will develop an exanthema 1 to 2 weeks after vaccination that may have multiple etiologies including hypersensitivity to a component of the vaccine. These rashes vary in appearance and often spontaneously resolve on their own. Rarely, individuals develop Stevens–Johnson syndrome with mucosal involvement. These rashes are typically pruritic and, with the exception of Stevens–Johnson syndrome, do not require hospitalization. Bacterial infections can occur at the vaccination site causing lymphangitis and regional lymphadenitis, but most often are superficial in nature (28).

A stringent screening program and exclusion of persons at risk for adverse events before the administration of vaccine coupled with educational information on infection control practices postvaccination can markedly curtail the number of adverse events in both vaccinees and their contacts (21). Inadvertent inoculation (accidental implantation) is the most common adverse event following primary vaccination due to the high titer of virus on the surface of the skin (Fig. 104-6). Inadvertent inoculation

FIGURE 104-6 Inadvertent inoculation of the lip. (From CDC/V. Fulginiti, MD.) (*See color insert.*)

can vary from development of single lesions to massive involvement depending on the degree of skin involvement. Corneal implantation can cause vaccinia keratitis, which results in ulceration, scarring, and vision loss (Fig. 104-7). Eczema vaccinatum (EV) can occur in patients with a previous or current history of atopic dermatitis (Fig. 104-8).

FIGURE 104-7 Inadvertent inoculation of the eye in a 12-year-old boy (*top*) and cloudy corneal lesions in a woman (*bottom*). (*Top*: From CDC/Dr. Weyand. *Bottom*: From CDC/V. Fulginiti, MD.) (*See color insert.*)

(*Top*: From CDC/H. Kempe, MD. *Bottom*: From *MMWR Morb Mortal Wkly Rep* 2007;56(19):478–481.) (*See color insert.*)

FIGURE 104-10 Progressive vaccinia: in a woman with lymphatic malignancy (*top*) and with dissemination in a child with hypogammaglobulinemia (*bottom*). (From CDC/V. Fulginiti, MD.) (*See color insert.*)

The cause of EV is thought to be from a T-cell immunomodulatory defect. Generalized vaccinia results from viremic spread of virus in presumably healthy individuals (Fig. 104-9).

FIGURE 104-9 Generalized vaccinia: in a young boy. (From CDC/H. Kempe, MD.) (*See color insert.*)

However, some patients may have had a minor immunologic defect, most likely an antibody or B-cell deficiency. Congenital vaccinia (fetal vaccinia) is a rare event in which a fetus is directly or secondarily infected after placental or amniotic fluid infection. Congenital infection can lead to fetal or neonatal death. Progressive vaccinia (PV), also known as vaccinia gangrenosa, is the most severe complication following smallpox vaccination (Fig. 104-10). The vaccination site lesion continues to expand leaving necrotic skin behind the advancing edge, and secondary lesions may occur. The severity of PV is determined by the amount of immune deficiency; those with a profound immune defect often die despite copious amounts of intervention. Encephalitis or meningoencephalitis following vaccination has been reported. Approximately 25% of sufferers die and up to one-third of survivors will have a full spectrum of neurologic sequelae (28).

Past rates of adverse reactions gathered from a 10-statewide survey conducted in 1968 and those seen in 2002 to 2003 can be found in Table 104-3. In 1968, complication rates were higher for primary vaccinees than revaccinees: 1,253.8 per million versus 108.2 per million, respectively. With the exception of PV, all other complication rates were higher in primary vaccinees than

TABLE 104-3

Adverse Events from Smallpox (Vaccinia) Vaccination

Complication	*Number of Events/ Million Vaccinees*		*VIGIV Treatment*[a]
	1968[b]	*2002–2004*[c]	
Accidental infection	234.2	145.2	May be indicated for ocular vaccinia not involving the cornea
Eczema vaccinatum	17.0	0	May be indicated if severe
Erythema multiforme	80.0	1.5	Not indicated
Generalized vaccinia	100.7	64.4	May be indicated if severe or patient has underlying immunodeficiency
Myo/pericarditis	—	155.7	Not indicated
Other	128.6	—	Not indicated
Postvaccinial encephalitis	6.1	3.0	Not indicated
Progressive vaccinia	2.4	0	May be indicated depending on patient immune defect

Monitoring the safety of a smallpox vaccination program in the United States: report of the Joint Smallpox Vaccine Safety Working Group of the Advisory Committee on Immunizations Practices and the Armed Forces Epidemiological Board. *Clin Infect Dis* 2000;46:S258–S270.

revaccinees. Inadvertent inoculation was the most common complication reported in both groups. The "other" complication category was broad in its data capture. Reports ranged from bacterial superinfection, to severe reactions to vaccination, to congenital vaccinia, to melanoma growth in a vaccination scar *(30)*. Data generated from the 2002 to 2003 US civilian and military smallpox vaccination campaigns revealed fewer adverse events than those seen in 1968 (Table 104-3). During this time period, no cases of EV, fetal vaccinia, or PV were noted in either primary or revaccinees (*25*,*31*,32). However, a case of PV was seen in 2009 in a military recruit diagnosed with leukemia shortly after vaccination *(33)*.

Previous surveillance studies, 1960s and earlier, that assessed rates for adverse events following smallpox vaccination did not include cardiac complications. Before 2003, only six cases with cardiac complications had been reported after having received smallpox vaccination. Data gathered from the recent national smallpox vaccination program suggest that myo/pericarditis occurs at a higher rate than previously seen *(34)*. From December 2002 to June 2004, the U.S. Department of Health and Human Services (DHHS) and the U.S. Department of Defense (DoD) vaccinated 667,980 persons. Eighty-three cases of suspected, probable, or confirmed cases of myo/pericarditis were indentified in DoD vaccinees and 21 among DHHS vaccinees. Most cases clustered during the first 7 to 12 days postvaccination. None of these patients had evidence of cardiac damage and <20% of either population reported persistent mild symptoms. Other cardiac events included 26 cases of ischemic cardiac disease resulting in 5 deaths and 7 cases of dilated cardiac myopathy resulting in the need for two heart transplants. While none of the reported ischemic cardiac disease cases clustered temporally with vaccination, a deferral from vaccination was given in 2003 to persons with three or more than three risk factors for ischemic heart disease (Table 104-4) (32). This deferral is still in place today.

The risk of death from smallpox vaccination was estimated at approximately one per million primary vaccinees in mortality data collected from 1959 to 1966 and 1968. The three most common causes were PV, postvaccinial encephalitis, and EV. Of the 68 individuals that died, 70.6% were primary vaccinees, 17.6% were contacts of recently vaccinated individuals, and 11.8% were revaccinees. The most common cause of death in primary vaccinees was postvaccinial encephalitis; in contacts, EV; and in revaccinees, PV. One death in a primary vaccinee was the result of Stevens–Johnson syndrome *(35)*. Five deaths occurred among DoD and DHHS vaccinees from 2002 to 2004—all from ischemic cardiac conditions (32).

Vaccinia immune globulin (VIG) contains γ-globulin fractioned from plasma of persons who have been recently vaccinated with vaccinia. VIG is used to treat some adverse reactions associated with the smallpox vaccine. This can include EV, generalized vaccinia, PV, and severe reactions to inadvertent inoculation. VIG is not recommended for the treatment of vaccinia keratitis, myo/pericarditis, mild instances of inadvertent inoculation, erythematous rashes, or postvaccinial encephalitis. The U.S. Strategic National Stockpile at the CDC stores all lots of VIG and distributes them as needed. VIG is currently the only licensed product for treatment of adverse events. Cidofovir has demonstrated antiviral activity against certain orthopoxviruses

TABLE 104-4

Cardiac Contraindication Screening Questions for Preevent Smallpox Vaccination

1. Have you ever been diagnosed by a doctor as having had any of the following:
   a. A previous heart attack (myocardial infarction)?
   b. Angina (chest pain caused by lack of blood flow to the heart)?
   c. Coronary artery disease (disease in the vessels that bring blood to the heart)?
   d. Cardiomyopathy (heart muscle becomes enlarged and does not work as it should)?
   e. Congestive heart failure?
   f. A stroke or transient ischemic attack (a "mini-stroke" that produces strokelike symptoms but no lasting damage)?
2. Do you have chest pain or shortness of breath with activity (such as walking upstairs)?
3. Are you under the care of a doctor for any other heart condition?
4. Do you have three or more than three of the following:
   a. You have been told by a doctor that you have high blood pressure?
   b. You have been told by a doctor that you have high blood cholesterol?
   c. You have a first-degree relative (e.g., mother, father, sister, or brother) who had a heart condition before the age of 50?
   d. Currently smoke cigarettes?

(Adapted from CDC Smallpox Vaccine: What You Need to Know (Vaccine Information Statement [VIS]) (Updated November 15, 2003).)

in vitro and in animal models but can only be obtained through an investigational new drug protocol. Several other antivirals are in clinical trials to determine their efficacy in treating adverse reactions (28).

HOSPITAL INFECTION CONTROL

Variola virus is viable for a considerable amount of time in the environment. As a result, a room occupied by a smallpox patient, including the objects in it, may become contaminated. Centuries ago, separate hospitals were established specifically for smallpox patients. These separate facilities limited the spread of the disease to other patients and healthcare providers. An outbreak in a German hospital resulted in secondary cases of patients on three different floors of the hospital. Transmission likely occurred via the hospital's air duct system *(36)*. However, an airborne outbreak is a rare occurrence likely due to the size of droplet nuclei. Even though droplet nuclei are expelled when a smallpox patient is breathing, talking, or coughing, experiments at the Infectious Diseases Hospital, Madras, India, determined that virus in these larger particles quickly settled closely on the floor, clothing, objects, or other linens. Virus in smaller sized particles could not be readily detected in the air even at a short distance from the patient. Only seven cases of hospital-acquired smallpox occurred in the Madras hospital that saw about 17,000 cases over a 10-year period, despite smallpox and nonsmallpox patients sharing corridors and barely 20 ft separating the wards *(10)*. However, the smallpox wards at this hospital were "open" allowing considerable air movement through them which could possibly dilute excreted virus *(37)*. Traditional hospitals served as a considerable source of transmission in outbreaks. In a summary of smallpox in Europe from 1950 to 1971, more than half of indigenous smallpox cases were acquired in a medical setting *(15)*. Hospitals and other treatment facilities should be cognizant about the risks associated with smallpox infection for staff and other patients. Plans should include comprehensive procedures that ensure the safety of smallpox and other patients and all staff that may come in contact with a smallpox patient.

There are several sources of information with detailed recommendations and instructions on healthcare and community infection control measures. The first is a consensus statement by the Working Group on Civilian Biodefense. This working group was selected to recommend medical and public health measures in the event of a release of variola (13). The second is a series of guides issued by the CDC, "CDC Smallpox Response Plan and Guidelines," and is freely available online at *http://www.bt.cdc.gov/agent/smallpox/response-plan/*. These guides cover a wide range of topics including surveillance and case reporting (Guide A), vaccination guidelines (Guide B), infection control measures for healthcare and community settings (Guide C), specimen collection (Guide D), communication plans (Guide E), and environmental control (Guide F) (38).

Designated Facilities

Preparedness for a smallpox outbreak must include plans to identify appropriate facilities to limit transmission and treat patients, including confirmed variola infections and febrile contacts. The CDC Response Plan outlines three types of facilities that should be identified, C, X, and R (Table 104-5). Type C facilities are designated for confirmed and suspect cases of smallpox; Type X facilities house febrile contacts of smallpox cases; and Type R facilities house asymptomatic contacts for observation. Guide C, Part 1 of the Response Plan has facility details and procedures for isolation and transportation of known or suspect cases (38).

Type C (C = contagious) facilities are characterized by nonshared air or ventilation systems and high particulate air filtration. Type C facilities must be equipped to maintain daily living and provide complex medical care. Type C facilities also can house vaccinated febrile contacts with a rash and atypical suspect smallpox cases. If a patient is admitted to a hospital, the ill patient should be quarantined to a negative pressure room with high particulate air filtration and transferred as soon as possible to a designated Type C facility. *All persons* entering a Type C facility must be vaccinated due to the risk of exposure. This includes suspect cases because diagnosis errors can occur. Varicella testing is recommended prior to admission to a Type C facility because varicella infection can be confused with variola (38).

TABLE 104-5

Facilities for Use in a Smallpox Emergency

Facility Type	*Purpose*	*Individuals Housed*	*Requirements*
Type C	House confirmed and suspect cases; limit exposure of susceptible individuals	• Vaccinated confirmed cases of smallpox • Vaccinated febrile contacts with rash • Vaccinated atypical suspect cases of smallpox	• Nonshared air conditioning, heating, and ventilation system • Exhausts 100% of air to the outside through a HEPA filter *or* is ≥100 yards from an occupied building or area • Has water, electricity, heating, cooling, and closed-window ventilation to maintain daily living and medical care activities • Has a telephone or intercom system • Ability to provide complex medical care • Controlled access
Type X	House febrile contacts during observation period	• Vaccinated febrile contacts without rash	• Nonshared air conditioning, heating, and ventilation system • Exhausts 100% of air to the outside through a HEPA filter *or* is ≥100 yards from an occupied building or area • Has water, electricity, heating, cooling, and closed-window ventilation to maintain daily living and medical care activities • Has a telephone or intercom system • Ability to provide basic medical care
Type R	House asymptomatic contacts for fever observation	• Asymptomatic contacts for 18 d postexposure or 14 d postvaccination • Contacts who refuse vaccination	• No strict requirements; may be person's residence

(Adapted from CDC Smallpox Response Plan and Guidelines, Guide C, Part 1.)

Type X (X = uncertain diagnosis) facilities are characterized by the same ventilation and filtration systems, but they are required to provide basic medical care rather than complex medical care. Type X facilities are designed to observe febrile contacts to see if they develop any further symptoms, particularly a rash. All febrile contacts should be treated as suspect cases, even if the fever is likely due to recent smallpox vaccination. If a rash develops in a patient housed in a Type X facility, the patient should be moved to a Type C facility for further evaluation. Fever surveillance can continue at the patient's residence (Type R facility) 5 days after being held at a Type X facility (38).

Type R (R = residential) facilities are designated for asymptomatic contacts under fever surveillance for 18 days postexposure or 14 days postsuccessful vaccination. Type R facilities are residential facilities such as the patient's home or a designated hotel. Asymptomatic contacts are permitted to continue their daily activities within 20 mi. of their residence while maintaining daily contact with a health department. Asymptomatic contacts that develop two successive fevers ≥101°F should be transported to a Type X facility (38).

Should a larger outbreak occur, patients can be cared for under home isolation and confinement. This will not be the best option for all patients, however, and the working group recommends that public health officials designate a specific hospital or standalone building for smallpox patient care, containment, and isolation from the general population (13).

Healthcare Personnel Precautions

There is a high probability for multiple transmission events before a patient is diagnosed with variola because transmission can occur at all stages of the rash illness. A patient may not be diagnosed with smallpox for 12 to 14 days postexposure; the delay in time is due to an asymptomatic period, a flu-like prodromal period, and several days to accurately recognize and diagnose the disease. Hemorrhagic smallpox, a rare form of smallpox, is particularly worrisome, as the duration of illness is very short and death often occurs within 5 or 6 days of rash onset. The hemorrhagic form may not be recognized or diagnosed until the patient is close to death and highly contagious; therefore, in the event of an outbreak, all hospital staff must be alerted to the possibility and identification of any

severe illness. Transmission may occur within a hospital by contact with respiratory droplets, and there is the likelihood, albeit lower, of transmission via contact with linens and bedding (13).

Given the transmission potential in a highly immunologically naive healthcare personnel population, the working group has recommended immediate vaccination of all hospital staff as well as patients in the event of an outbreak (13). Only healthcare workers that are vaccinated should care for suspect or confirmed smallpox patients. If there are no vaccinated healthcare workers, then a limited number of unvaccinated workers should wear N95 masks while caring for the patient (38). Vaccination should also be offered to mortuary and morgue workers who may come into contact with dead bodies. Prophylactic VIG treatment should be considered for individuals who are immunocompromised or have contraindications to live vaccinia vaccination (13).

Any person caring for smallpox patients must adhere to standard, contact, and airborne precautions. These precautions may require use of disposable gloves, gowns, masks, eye protection, and N95 respirators. These items should be discarded in biohazard waste immediately after caring for the patient (38,*39*).

Environmental Control

Variola virus has a lipid envelope and is remarkably stable when in a proteinaceous milieu. Poxviruses show high resistance to drying and have an increased temperature tolerance—a feature enhanced depending on the material in which it is found, such as crust, blood, or other excretions. When compared to other enveloped viruses, poxviruses have a lower lipid content in their envelope and a smaller quantity of carbohydrates. Although poxviruses are remarkably sensitive to commercial chemical treatment and disinfection, the reduction of lipid content makes them less sensitive to organic solvents *(40)*. The disinfectants listed in Table 104-6 are sufficient for decontamination of surface areas in smallpox patient care areas (38). In addition, quaternary ammonium compounds have been proven effective in disinfection of objects contaminated with poxviruses. A summary determining the efficacy of commercially available disinfectant formulations against poxviruses has been described elsewhere *(40)*. Reusable medical instruments and patient-care devices should be cleaned after use using previous standardized protocols then sterilized or treated with high-level disinfection depending on their reuse. Reusable medical instruments should be cleaned and sterilized (38).

Low- to intermediate-level disinfection with Environmental Protection Agency–registered chemical germicides can clean environmental surfaces frequently touched with hands, as well as floors and tabletops. Routine hospital cleaning and disinfection procedures are adequate for sanitizing nonporous surfaces such as the interior surfaces of ambulances. Fumigation is not indicated for environmental containment of variola virus. There are no special procedures or schedules for cleaning carpeted floors or furniture. A high efficiency particulate air (HEPA) filtered vacuum or commercially available furniture cleaner are adequate. Vacuum waste should be disposed of as routine solid waste (38).

Bedding and linen should be handled carefully as to not disperse any particles that may contain viable virus. A water-soluble bag is recommended for transport of linen that will be laundered in an effort to minimize environmental contamination and exposure. Personnel handling laundry should do so with appropriate personal protective equipment (PPE), including N95 respirators. Laundry should be done in an area with negative air pressure and physically separate from the area where clean laundry is dried, sorted, and folded. Standard laundry protocols may be followed. The inclusion of a chlorine bleach with hot water and a hot airdry may provide additional levels of protection (38). Alternatively, bedding and linen can be discarded in biohazard waste to be autoclaved or incinerated.

Medical waste from smallpox patients should be contained, subjected to decontamination treatment, and then discarded in accordance with currently approved methods. Human remains are often not considered anatomical or pathological waste. Barrier precautions, safe handling and disposal of embalming chemicals, proper ventilation, and environmental surface disinfection can protect mortuary personnel preparing bodies for burial or cremation.

TABLE 104-6

Chemicals Used on Environmental Surfaces for Disinfection[a]

Chemical	*Concentration*[b]
Ethyl alcohol	40%
Isopropyl alcohol	30%
Benzalkonium chloride	100 ppm
Sodium hypochlorite	200 ppm
*Ortho*phenylphenol	0.12%
Iodophor	75 ppm

[a]Inactivation after 10 min contact time at room temperature.
[b]Minimum concentration.

CONSIDERATIONS FOR A BIOTERRORISM PLAN

Preparedness for a bioterrorism outbreak requires extensive planning by hospitals and other public health institutions. Early recognition and identification of smallpox patients is one of the first defenses a hospital has against the spread of smallpox within its walls. The last outbreak and cases of smallpox in the United States occurred in 1949 in the Lower Rio Grande Valley of Texas. The origin of the outbreak remained unknown although several cases were thought to have contracted smallpox while in the hospital from a patient admitted originally with a febrile illness. In all, eight cases and one death were reported. Smallpox was not suspected in six of the cases until the death of the fourth identified case. Several cases of smallpox were missed likely because of the prevalence of chicken pox at the time *(41)*. Similar outbreaks were seen in 1947 in New

York City and in 1950 in Glasgow, Scotland, in which a single case infected multiple people in a hospital setting before being correctly identified *(42,43)*.

Identification of smallpox today may prove even more difficult given that the majority of practicing clinicians have never seen a case of smallpox. The development of the algorithm *Evaluating Patients for Smallpox: Acute, Generalized Vesicular or Pustular Rash Protocol* by CDC was designed to help clinicians evaluate patients with suspicious rashes (*http://emergency.cdc.gov/agent/smallpox/diagnosis/evalposter.asp*). A multicenter study conducted on hospital admissions for rash or rash-like illness over a 12-month period beginning in late 2003 assessed if smallpox risk was accurately classified. Of those eligible and classified, CDC and physicians within the hospitals were in agreement 84% of the time. Discrepancies in classification were mainly due to the characteristics assigned to a patient's rash—deep seated, firm, well circumscribed, and in same stage of development. This same issue has been noted in inquiries reporting possible smallpox cases to CDC's Emergency Operations Center. Physicians may describe lesions as firm, deep seated, and in the same stage of development but evaluation of images submitted by the physicians to CDC often are interpreted otherwise. Education of physicians, other healthcare, or public health providers about the correct description of dermatological terms, smallpox diagnosis, and management may decrease this discrepancy *(44)*. To further strengthen clinician awareness on diagnosing smallpox, training efforts should be undertaken and may encompass lectures, handouts, posters, and reliable Internet resources.

The capabilities to detect and swiftly respond to a release of a biological weapon include measures that are often used to respond to naturally occurring infectious diseases or emerging infections *(45)*. This typically includes the ability to provide airborne isolation and other appropriate infection control measures. Healthcare workers with contact to patient skin, respiratory secretions, or other bodily fluids may accidently infect themselves or other patients. To prevent the spread of smallpox, and other infectious agents, healthcare workers should comply with Healthcare Infection Control Practices Advisory Committee guidelines and wear PPE such as gloves, gowns, masks, head and shoe covers, and eye protection if recommended. Regular exercises in proper donning and safe removal of PPE and healthcare worker understanding of the route of transmission can increase adherence to regulations *(46)*. Infection control measures for managing a patient with smallpox in a non–smallpox-designated facility can be found in Table 104-7.

Multiple groups and agencies must work together efficiently and effectively to isolate and contain the spread of smallpox. Hospitals, public health departments, and law enforcement agencies at local, state, and federal levels will be involved and integrated into an outbreak response. Communication across all jurisdictions will facilitate a coordinated response. There are several preevent preparedness items that are recommended by the CDC Response Plan (Table 104-8). A response plan should also include a directory of public health authorities and these resources should be readily available. This may include public health facilities, such as local or state health departments and laboratories, law enforcement at all levels, CDC Emergency Operations Center, or other resources *(47)*.

In addition to strengthening the emergency response system, hospitals should be aware of possible treatment options, create vaccine stockpiles, and maintain laboratory capabilities for diagnostic testing. There is no proven treatment for clinical smallpox. Medical management is mainly supportive and may include fluids, electrolytes, and antibiotics. Informational material about the smallpox

TABLE 104-7

Infection Control Precautions for Suspected or Confirmed Infectious Smallpox Patients in a Non–Smallpox-Designated Facility

1. Select route to transport the patient through the hospital to an airborne infection isolation room. Choose the most direct route to the room, consider ease of decontamination if required, and consider isolation from other people including use of nonpublic elevators if possible.
2. Cover patient with linen sheet and place a surgical mask (or N95 respirator) on the patient during transport through the hospital to the isolation room, or from the isolation room to other areas within the hospital, to decrease the chance of contaminating objects in the area and droplet exposure to other individuals.
3. Place the patient in an airborne infection isolation room to prevent airborne transmission to other parts of the facility.
4. Follow standard, contact, and airborne precautions while patient is isolated at the facility.
   a. Wear disposable gowns and gloves to enter contaminated areas; discard used gowns and gloves before leaving area.
   b. Wear fit-tested N95 masks.
5. All protective clothing, including sheet covering patient, should be disposed of in biohazard bags before leaving the airborne infection isolation room.
6. Restrict the number of people entering the patient's room to only those needed for patient care, investigation, and facility maintenance.
   a. Log/register all persons who enter and leave the patient's room.
7. Vaccinate all personnel caring for patient.
   a. If nonvaccinated personnel are needed to provide patient care before they are vaccinated or until vaccination is successful, temperature recordings should be taken twice daily.

(Adapted from CDC Smallpox Response Plan and Guidelines, Guide C, Part 1.)

TABLE 104-8

Preevent Preparedness Activities

Public health and law enforcement

a. Review local and state legal statutes that allow public health intervention and implementation of isolation and quarantine measures.
b. Identify personnel at local and state levels who are responsible for coordination of public health interventions.
c. Identify law enforcement personnel to enforce isolation and quarantine orders.

Facilities and maintenance

a. Identify facilities used to isolate and treat smallpox patients and febrile contacts.
b. Establish procedures to activate facilities for smallpox patients.
c. Establish procedures for controlling access to facilities.
d. Establish procedures for disposal of medical waste.
e. Establish procedures for handling and disposal of laundry.
f. Plan for food service for patients and building occupants.

Personnel

a. Identify personnel that will treat patients.
b. Identify personnel that will maintain facilities where smallpox patients will be housed.
c. Ensure that all staff who will care for smallpox personnel have been vaccinated.
d. Establish procedures to monitor the health of all personnel.
e. Establish plans for care of ill personnel.

(Adapted from CDC Smallpox Response Plan and Guidelines, Guide C, Part 1.)

vaccine should be readily available for personnel when the need arises. While orthopoxvirus testing is reserved for LRN laboratories, hospitals can rapidly rule out other causes of rash illness in low-risk patients. Specimens from high-risk patients should immediately be referred to a LRN laboratory capable of variola-specific testing prior to any other diagnostic assay. High-risk patient specimens require special collection, handling, and transport procedures. The outer surface of specimen containers should be properly decontaminated and packaged and transported within International Air Transport Association regulations. Successfully vaccinated personnel (within the last 3 years) wearing appropriate barrier protection should be involved in specimen collection before giving consideration to using unvaccinated personnel. If unvaccinated personnel must be used, they should wear a fit-tested N95 mask and have no contraindications to vaccination.

CONCLUSION

Preparations for a smallpox release should involve a coordinated effort among public health officials, state and local governments and law enforcement, treatment facilities, and healthcare personnel. Preparations require thoughtful consideration, and planning must take into account alternative responses. These include action items specific to public health and law enforcement, facilities and maintenance, and personnel who are at high risk of exposure to a smallpox patient. Given the marked decline in the number of healthcare workers receiving smallpox vaccination since 2003, hospitals must be prepared to vaccinate their personnel within a limited amount of time once a smallpox case has been detected. Additional public health control measures will incorporate surveillance, vaccination, and isolation of smallpox cases. Isolation measures may reintroduce the establishment of C, X, or R facilities to house selected groups of individuals. Hospitals and public health officials can never be overprepared for a release of variola; and existing outbreaks of other infectious diseases, particularly respiratory diseases, can be used to strengthen control practices and other response strategies.
