Healthcare-associated transmission of rotavirus has been well documented on pediatric hospital wards; 2% to 24% of children admitted to the hospital with other diagnoses acquire rotavirus in the hospital *(21,30,86–93)*. In several reports, up to 70% of infants in a nursery have healthcare-associated rotavirus *(94–97)*. Hospital surveillance for rotavirus using molecular methods has detected newly emerging strains and the nosocomial transmission of those new strains *(96–100)*. Immunocompromised children acquire rotavirus in the hospital with an infection rate of 12% to 25%. Immunocompromised children have an extended period of virus excretion and may be a source of virus for transmission to others *(101,102)*. Community-acquired symptomatic rotaviral infection in children admitted to the hospital and asymptomatic rotavirus shedding by neonates and other hospitalized infants appear to be the primary reservoirs for nosocomial rotavirus infection in susceptible children *(103–105)*. Fomites may play a role in rotavirus transmission. Rotavirus contamination was detected by PCR in 19% of inanimate objects in a childcare center during an outbreak *(106,107)*. Nosocomial rotavirus infection may cause both outbreaks and endemic diarrheal disease in newborn nurseries; however, infection is usually asymptomatic *(94,105,108–115)*. Asymptomatic rotavirus infection also occurs in older children, with evidence of asymptomatic rotavirus infection occurring in 24% to 50% of the infections in infants younger than 2 years during the rotavirus season *(116–118)*. Asymptomatic excretion of rotavirus by healthcare personnel has been proven (119). The incidence of confirmed nosocomial rotavirus diarrhea in a large pediatric hospital was found to be 0.5 to 0.9 per 1,000 admissions *(120,121)*.

HAIs in developing countries occurred in 12% to 22% of all rotavirus cases with an incidence of 0.024 to 1.6 cases per 1,000 child-days. No HAIs occurred in children older than 4 years (*122,123,*124).

Prospective surveillance for rotavirus gastroenteritis in three Spanish hospitals in the winter of 2006 to 2007 identified nosocomial rotavirus infection in 2.8 cases per 100 inpatients and 0.48 cases per 100 patient days. Rotavirus was the etiology of 59% of healthcare-associated gastroenteritis. G9P[8] and G1P[8] were the predominant serotypes *(15)*.

A review of healthcare-associated rotavirus gastroenteritis in European hospitals made several conclusions. Healthcare-associated rotavirus infections have an incidence from 1.6 to 6.3 cases per 1,000 children younger than 5 years; these infections represent 1.6 to 15.8 cases per 1,000 hospital days and account for 3,000 to 20,000 rotavirus infection cases in children younger than 5 years. Rotavirus gastroenteritis lengthens hospital stay by 1.8 to 5.0 days. Hand washing, and specifically the use of alcohol-based hand sanitizers, is very effective in reducing the number of HAIs (125,126). Unique serotypes that occur in a community will be seen as a cause of HAIs during that season *(127)*.

Breast feeding was protective against both infection and symptoms, whereas 32% of formula-fed and 11% of breast-fed infants acquired rotavirus in the hospital ($p < .005$). No breast-fed infant had symptomatic infection *(128)*.

Rotavirus is detected in stool specimens by EIA, latex agglutination, EM, polyacrylamide gel electrophoresis, and PCR *(129–132)*. Several EIA and latex agglutination assays are commercially available. Detection rates depend on which assay is employed because of their varying sensitivities.

Universal mass vaccination against rotavirus in Austria resulted in a considerable decrease in hospitalization for rotavirus gastroenteritis and a considerable decrease in the number and percentage of healthcare-associated rotavirus infections *(133–135)*. Rotavirus vaccination in the United States has lowered the frequency of severe diarrhea and, therefore, hospitalizations. The impact on HAIs remains to be seen.

Human Parechoviruses Human parechoviruses belong to the family *Picornaviridae*. A retrospective evaluation identified human parechoviruses type 4 to 6 in association with gastrointestinal tract symptoms in addition to respiratory tract symptoms. Twenty of 277 children with the virus detected in fecal samples had gastrointestinal symptoms. The authors describe at least one child who acquired the virus nosocomially, because it was a 3-month-old infant who had never left the hospital. The virus was detected by RT-PCR in nasopharyngeal aspirates, feces, and plasma. It could be detected in fecal samples for up to 40 days after initial detection (136).

Bacteria

Healthcare-associated bacterial gastroenteritis is less common than viral gastroenteritis. In the United States, the majority of information about healthcare-associated bacterial gastroenteritis consists of reports of outbreaks, many of which are food-borne or waterborne. Several prospective studies of healthcare-associated diarrhea in children failed to demonstrate any bacterial etiologies *(14,22)*, although *C. difficile* is common in adults. Bacterial infections are much more common in less-developed countries. A patient with poor nutritional status or an immunocompromised

patient is at particularly high risk for healthcare-associated bacterial gastroenteritis.

Campylobacter Species Twenty-one species have been identified in the family *Campylobacteraceae*, but only 12 cause disease in humans. *Campylobacter jejuni*, *Campylobacter coli*, *Campylobacter upsaliensis*, and *C. jejuni* subspecies *doylei* are the most common species isolated from children. *Campylobacter fetus* is a rare cause of bloodstream and systemic infections occurring mostly in immunocompromised and debilitated hosts, as well as a cause of perinatal infection and abortion. Since *C. jejuni* is the species that usually causes intestinal illness, many laboratories place stool specimens on selective media with incubation temperatures to isolate this species. With this method, several other *Campylobacter* species will be missed as a cause of diarrhea. Therefore, the extent of HAIs involving many of the *Campylobacter* species is not known. Isolation of *Campylobacter* spp. from blood and other sterile body sites does not present the same isolation problem as isolation from feces *(137)*.

Predominant symptoms are diarrhea, abdominal pain, malaise, and fever. Stools may contain blood. *C. jejuni* has been reported as a cause of severe infection in neonates following vertical transmission. Vertical transmission of a microorganism is considered a nosocomial infection in the nursery for purposes of surveillance reporting. Postnatal person-to-person transmission has also been documented with reports of nursery epidemics of *Campylobacter* spp. diarrhea and meningitis *(138)*. The incubation period is 1 to 7 days.

Healthcare-associated transmission of *Campylobacter* spp. is not common. The gastrointestinal tract of domestic and wild birds and animals is the reservoir of infection. A Finnish hospital reported a waterborne nosocomial outbreak of *C. jejuni* gastroenteritis in both patients and hospital staff *(139)*. Several community-acquired outbreaks caused by *C. jejuni* have been reported, usually due to ingestion of contaminated raw milk, water, or food. In addition, infection can occur through person-to-person transmission or contact with infected animals *(140)*. For example, an outbreak involving two very closely related strains of *C. upsaliensis* in four childcare centers implicated person-to-person transmission *(141)*.

Clostridium Difficile Healthcare-associated gastrointestinal tract infection caused by *C. difficile* in adults and children is discussed in Chapter 37. The role of *C. difficile* in antibiotic-associated diarrhea has been more difficult to establish in infants and young children than in adults, since *C. difficile* is commonly recovered from the stools of asymptomatic infants and young children.

The reported incidence of neonatal colonization varies, with isolation rates as high as 90% in neonatal intensive care units (NICUs) and between 2% and 30% in healthy newborn infants. The *C. difficile* toxin has been detected in up to 36% of sick neonates without gastrointestinal tract symptoms. The incidence of *C. difficile* toxin detection in stool specimens declines with age and approaches 1% to 3% in healthy adults *(142)*. Pseudomembranous colitis has been reported in infants and children, but the incidence is difficult to assess. *C. difficile* was described as the etiology of 13% to 16% of healthcare-associated gastrointestinal tract infections *(9,143)*. Outbreaks of diarrhea associated with *C. difficile* have been reported in childcare centers *(144)*. The incubation period is unknown. The virulence and mortality of *C. difficile*-associated disease are increasing (145). This may be associated with hypertoxigenic strains.

C. difficile may be isolated from stool using a selective cycloserine cefoxitin fructose agar in an anaerobic environment. *C. difficile* produces two toxins. The *C. difficile* cytotoxin B may be detected by cell culture cytotoxicity assay or EIA. Some commercially available EIAs will detect both toxins A and B *(146)*. There have been reports of toxin A negative, toxin B positive *C. difficile* antibiotic-associated diarrhea in adults *(147)*. Arbitrarily primed PCR has been used for genotypic differentiation of strains in hospital outbreaks *(148)*.

Escherichia Coli *Escherichia coli* strains that cause acute diarrheal disease may be classified into five groups: enterotoxigenic (ETEC), enteroaggregative (EAEC), enteroinvasive (EIEC), enteropathogenic (EPEC), and enterohemorrhagic (EHEC) *(149)*. ETEC usually infects infants and children in developing countries or adults following travel to developing countries. EAEC produces acute or chronic diarrhea in all age groups, but predominantly infants, by attachment to and effacement of the intestinal mucosa. EIEC infects all ages and causes diarrhea containing blood and mucus as a result of tissue invasion. These infections may occasionally be food-borne or occur as the result of travel to developing countries. EPEC produces acute and chronic diarrhea, generally in infants under 2 years old in developing countries *(150)*. EHEC causes abdominal pain and bloody diarrhea in children and adults, mostly in developed countries. The illness may be complicated by hemolytic uremic syndrome (HUS) in children or thrombotic thrombocytopenic purpura in adults. It is most frequently spread by undercooked contaminated meat, but many other vehicles of transmission have been described.

The reported incidence of healthcare-associated gastroenteritis caused by these five groups of *E. coli* is low. This may be a reflection of the unavailability of detection methods in most clinical microbiology laboratories. The incubation periods range from 10 hours to 6 days.

Reports of healthcare-associated ETEC-associated diarrheal outbreaks in special care nurseries due to heat-stable enterotoxin–producing strains include one report from Spain with six ETEC-associated neonatal diarrheal outbreaks *(151)*. In another report, ETEC was cultured from infants, nurses, family members, infant formula, and surfaces in the nursery *(152)*. This report implicated person-to-person transmission and food-borne transmission by formula. In another report of a hospital outbreak, a rare phage type further differentiated the infected strain *(153)*. *E. coli* has also been reported as a contaminant of expressed human milk, which caused both asymptomatic infections and gastroenteritis in a nursery *(154)*.

A single report described person-to-person transmission of EIEC in students and staff of a school for mentally retarded adults and children: 48% of the students and 28% of the staff were ill. Control of the outbreak was achieved by cohorting and an emphasis on hand washing *(155)*.

Community-acquired food-borne outbreaks of EHEC serotype O157:H7 are well documented. *E. coli* O157:H

phage type 8 caused a hospital outbreak with food brought to a party from the outside *(156)*. Many outbreaks have occurred in nursing homes, and a report of an outbreak in an institution for mentally retarded children and adults demonstrated the devastating effects of this microorganism in an outbreak. Eight of 20 infected residents developed HUS, and four died of complications *(157)*. Twenty-nine children with *E. coli* O157:H7 in nine childcare centers were reported. There was evidence of person-to-person transmission in all nine facilities *(158)*. Spread of *E. coli* O157:H7 from a patient to a nurse in the hospital setting has been reported *(159)*.

EPEC is the strain most commonly associated with HAIs. It was the etiology of 1.3% of gastrointestinal tract infections in a children's hospital in the United States *(10)* and of 6 of 10 nosocomial bacterial gastrointestinal tract infections in a South African hospital *(9)*. Many studies of outbreaks of diarrhea in NICUs have demonstrated person-to-person transmission by the hands of hospital personnel. Premature infants are the most susceptible to severe morbidity and to mortality resulting from these infections *(160–165)*. Detection of EPEC requires a high level of suspicion. Colonies of *E. coli* from a routine bacterial culture must be screened by type-specific antisera. Research methods for identifying related serotypes include adherence of microorganisms in HEp-2 cells, DNA probes, and PCR to detect EPEC strains with the enteroadherence plasmid.

Leuconostoc Species *Leuconostoc* species are members of the family *Streptococcaceae* and commonly found in dairy products, vegetable matter, and in the soil. They are not considered part of the normal gastrointestinal flora. These microorganisms have been described as the etiology of bacteremia and central catheter-associated infections in children with underlying gastrointestinal disease. The most common reports include children with short bowel syndrome receiving enteral feeds and/or total parenteral nutrition. Several of the children had concomitant gastrointestinal symptoms, thereby implicating the gastrointestinal tract as the source of infection (166).

Salmonella Species The genus *Salmonella* is now considered to comprise a single species named *Salmonella enterica* based on DNA structure and biochemical properties. Within this species are seven subspecies with almost all serotypes pathogenic for humans classified into subgroup I (*S. enterica* subspecies *enterica)*. The subspecies can be divided into serotypes based upon their O (somatic) and H (flagellar) antigens. Two main clinical syndromes are associated with *Salmonella*. The first is the protracted bacteremia of typhoid (*Salmonella typhi*) and paratyphoid (*S. paratyphi*) fevers. The second is the predominantly gastrointestinal tract illness caused by animal adapted *Salmonella* strains. *S. typhimurium* is the serotype most commonly reported as the cause of *Salmonella* infections in humans in the United States. Many outbreaks of *Salmonella* gastroenteritis in hospitalized patients due to a variety of serotypes have occurred through various methods of transmission. Person-to-person transmission may occur among patients or from healthcare personnel. Common-source outbreaks have also been traced to diagnostic agents and medications *(167–169). Salmonella* infections have been acquired from reptiles, highlighting the importance of avoiding exposure to pet reptiles in a hospital setting *(170)*. The incubation period for gastroenteritis is from 6 to 12 hours. For enteric fever, the incubation period is from 3 to 60 days but is usually 7 to 14 days.

Food-borne *Salmonella* outbreaks simultaneously may affect patients in multiple hospitals. In 1962 and 1963, a large outbreak of healthcare-associated gastroenteritis caused by *S. derby* occurred among patients, medical staff, and employees of 53 hospitals in 13 states *(171)*. Contaminated eggs that were eaten raw or undercooked were responsible for this and many other outbreaks *(172–175)*. Person-to-person transmission to hospital staff and to other patients has been documented *(174,176,177)*. Food-borne outbreaks have also occurred following the ingestion of improperly cooked and stored poultry *(178,179)*. Food-borne outbreaks may originate in hospital personnel or in patients *(180–183)*. An epidemic caused by *S. kottbus* was traced to contaminated pooled human milk *(184)*. *S. poona* mastitis was the source of infection for a 5-week-old infant. This case was not healthcare associated but indicated the need to consider pumped breast milk as a potential source of infection (185).

Common-source *Salmonella* outbreaks have also been traced to contaminated diagnostic reagents and medications. These types of outbreaks generally do not present as typical common-source outbreaks and, therefore, may be difficult to recognize. An interstate outbreak of *S. cubana* occurred in 1966 due to contaminated carmine dye used as a marker of gastrointestinal tract transit *(167–169)*. Healthcare-associated outbreaks of salmonellosis have also been traced to bile salts, gelatin, pancreatin, pepsin, vitamins, and extracts of various endocrine glands *(186,187)*. Eight cases of *S. enteritidis* occurred in hospitalized patients receiving enteral nutrition containing lyophilized egg albumin (188). These outbreaks appeared to be sporadic and, therefore, required a high index of suspicion to document their association with a common vehicle.

Outbreaks of *Salmonella* gastroenteritis have also been associated with a variety of medical instruments or procedures, including upper gastrointestinal tract endoscopy *(189)*, fiberoptic colonoscopy *(190)*, rubber tubing attached to a suction apparatus *(191,192)*, rectal thermometers *(193)*, and contaminated mattresses *(194)*. Healthcare-associated *S. hadar* infection occurred in laundry personnel at a nursing home following a food-borne outbreak in the nursing home residents. This report implicated the handling of soiled laundry in the absence of person-to-person contact *(195)*.

Outbreaks of *Salmonella* infection have been reported in nurseries. The microorganism is generally introduced to the nursery by an infant recently born to a mother with clinical or asymptomatic salmonellosis *(196)* or a child with community-acquired *Salmonella* infection. In another report, a 12-day-old infant acquired *S. brandenburg* from his visiting mother (197). *Salmonella* is transmitted among the staff and patients through person-to-person contact. The acquisition of multiple resistant microorganisms by premature infants in special care nurseries results in increased rates of morbidity and mortality *(198,199)*. A case–control study of an outbreak of *Salmonella infantis* in a neonatal care unit in Brazil demonstrated protection

by increased birth weight, and peripheral IV catheter use was a risk factor. Overcrowding and understaffing were associated with the outbreak *(200)*.

Extended-spectrum beta-lactamase–producing *S. isanga* of a single pulsed-field gel electrophoresis (PFGE) type was the etiology of a healthcare-associated outbreak in a South African hospital with immunocompromised children *(201)*.

Salmonella can be cultured from stool, rectal swabs, blood, urine, bone marrow aspirates, and other foci of infection. Serotyping with specific antisera provides further identification for epidemiologic investigation. Determining serotypes remains a useful epidemiologic tool for investigations of outbreaks in both the hospital and the community setting. Plasmid profile analysis (PPA) and PFGE are useful methods for determining the relatedness of infecting strains during an outbreak *(179,202,203)*.

Shigella Species Shigellosis occurs worldwide, although its prevalence differs by location. It is largely a disease associated with poverty, crowding, poor levels of personal hygiene, inadequate water supplies, and malnutrition *(204)*. There are four species of *Shigella* (*S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei*), which are differentiated by group-specific polysaccharide antigens of lipopolysaccharides, designated A, B, C, and D, respectively, biochemical properties, and phage or colicin susceptibility. *S. sonnei* is the most common cause of bacillary dysentery in the United States, with *S. flexneri* being responsible for most of the remaining cases. *S. dysenteriae* type 1 and *S. flexneri* are the most common species causing disease in developing countries. Direct fecal–oral transmission can contribute to endemic shigellosis in institutional environments such as mental hospitals, childcare centers, nursing homes, prisons, and outdoor gatherings *(205,206)*. The incubation period is 1 to 7 days. Healthcare-associated outbreaks have seldom been reported despite the low inoculum necessary to cause infection *(207)*. *Shigella* was the etiology of 3% of nosocomial gastrointestinal tract infections among patients in a hospital in a developing country and also caused HAIs among the staff of the clinical microbiology laboratory of a large university-affiliated hospital *(208,209)*.

In one large healthcare-associated outbreak, hospital workers had dysentery caused by *S. dysenteriae* type 2 after eating at the salad bar in the hospital cafeteria. Ninety-five workers were ill, but only three hospital inpatients became ill following person-to-person transmission *(210)*.

Both *S. flexneri* and *S. sonnei* have been reported in newborn infants who acquired the microorganism from an infected mother during labor and delivery. Bacteremia in neonates has been reported but is uncommon *(211,212)*. In one report, 3 of 32 healthcare providers caring for an infected neonate acquired shigellosis *(213)*. *Shigella* is detected by routine microbiologic culture of stool specimens; ribotyping and PPA have been used to differentiate strains.

Vibrio Species *Vibrio cholerae* O1, the etiologic agent of cholera, and *V. cholerae* non-O1 strains, including *V. cholerae* O139, are recognized as important causes of acute, often severe, diarrheal disease in developing countries. A number of other *Vibrio* species have been identified and associated with gastroenteritis including *(214,215)*: *V. parahaemolyticus*, *V. mimicus*, *V. fluvialis (216)*, *V. furnissii (217)*, and *V. hollisae (218)*. *V. parahaemolyticus* is a common marine isolate that has been found in water, shellfish, fish, and plankton. *V. parahaemolyticus* has caused food-borne outbreaks in the United States, but there have been no reports of healthcare-associated gastroenteritis *(214,215)*. Food-borne healthcare-associated *V. parahaemolyticus* has been reported in Asia *(219)*. In countries with endemic cholera, all ages are affected, although children over 1 year old are disproportionately involved. *V. cholerae* O1 is primarily a problem in Asia, Africa, and South America, although there is a focus in the Gulf Coast of the United States, where the microorganism has been associated with undercooked shellfish consumption *(220)*. *V. cholerae* O139 has been reported in several countries in southeast Asia since 1992 in epidemic proportions *(221)*. The incubation period of cholera is usually 1 to 3 days.

Healthcare-associated transmission of cholera has been described in developing countries but not in the United States. Close person-to-person contact and sharing of food was implicated in these outbreaks *(222–225)*. In one hospital in Thailand, the microorganism was isolated from water used for bathing in a pediatric ward *(226)*.

Vibrio spp. may be isolated from stool specimens on thiosulfate-citrate bile salts sucrose agar. Serotyping is performed to distinguish O1 and non-O1 strains. Enterotoxins may be detected by animal or tissue culture assays, EIA, and DNA probes *(214)*.

Yersinia Enterocolitica

Yersinia enterocolitica is associated with a wide spectrum of clinical and immunologic manifestations. The clinical illness caused by this pathogen ranges from self-limited enterocolitis to potentially fatal systemic infection; postinfection manifestations include erythema nodosum and reactive arthritis. *Y. enterocolitica* enterocolitis is characterized by diarrhea with blood-streaked stools, fever, vomiting, and abdominal pain *(227,228)*. Serogroups O:3, O:8, and O:9 are most commonly implicated as a cause of enterocolitis in the United States. *Y. enterocolitica* has been isolated from a variety of animate reservoirs, including birds, frogs, fish, flies, fleas, snails, crabs, oysters, and a wide array of mammals with swine being the major reservoir for human pathogens *(229)*. Animal products including raw milk, whipped cream, ice cream, beef, lamb, and poultry may also harbor the microorganism. Inanimate reservoirs include lakes, streams, well water, soil, and vegetables *(230)*. The most frequent outbreaks in the United States have been associated with the preparation of chitterlings for holiday meals in the south *(231,232)*.

Several mechanisms of healthcare-associated transmission have been described. Transfusion-related yersiniosis has been reported in several countries including the United States and in Europe. In 1987 through 1991, 7 deaths occurred among the 10 reported patients with transfusion-associated *Y. enterocolitica (233)*. Blood donors apparently had low-grade *Y. enterocolitica* bacteremia at the time of donation, and the microorganism replicated at the storage conditions provided for units of red blood cells *(234,235)*. Children and adults with hematologic conditions resulting in iron overload are at greater risk of yersiniosis than healthy individuals *(229)*.

There is a report of an 11-day-old infant with *Y. enterocolitica* enterocolitis acquired either during delivery from an infected mother or postnatally during routine care *(236)*. The incubation period in single-source outbreaks is 1 to 14 days, so either method of transmission was possible in this case. Acquisition and excretion of *Yersinia* spp. has been associated with consumption of pasteurized milk in a pediatric ward *(237)*. The same serotype of *Y. enterocolitica* was isolated from the patients and the pasteurized milk.

Person-to-person spread to both patients and staff within adult and pediatric inpatient populations has also been reported *(238,239)*. In one study, 28% of *Y. enterocolitica*–infected patients acquired the microorganism in the hospital *(240)*.

The detection of *Y. enterocolitica* requires isolation on selective media. Cold enrichment techniques may increase the rate of recovery from stool cultures. Serotyping is performed to identify the most common serotypes in human disease and may be used for outbreak evaluation. Chromosomal DNA restriction fragment length polymorphism *(231)*, PPA, and phage typing have been used to evaluate the relatedness of serotypes during outbreaks.

Parasites

Cryptosporidium Cryptosporidia are small coccidian parasites that infect the microvillus region of epithelial cells lining the digestive and respiratory organs. Since 1982, these microorganisms have been recognized as an important cause of widespread diarrheal illness in humans and some domesticated animals. In immunocompetent persons, *Cryptosporidium parvum* may cause a short-term (3–20 days) diarrheal illness that resolves spontaneously. However, in the immunocompromised patient, cryptosporidiosis usually presents as a life-threatening, prolonged, cholera-like illness *(241,242)*. Nitazoxanide was recently approved for the treatment of cryptosporidiosis in children *(243)*. Highly active antiretroviral therapy has reduced the frequency and severity of cryptosporidiosis in patients with acquired immunodeficiency syndrome (AIDS). Person-to-person transmission is common; and outbreaks of cryptosporidiosis among children in childcare centers have been reported, hospital-acquired infections have been investigated, waterborne outbreaks have been documented, and *Cryptosporidium* is recognized as a cause of traveler's diarrhea. The incubation period is estimated to be 2 to 14 days.

Healthcare-associated *Cryptosporidium* infections have occurred by person-to-person transmission, particularly among immunocompromised patients. Outbreaks have been reported among patients with AIDS, patients on a bone marrow transplant unit, and severely malnourished children in a developing country *(244–247)*. Transmission among patients with AIDS has also occurred following the contamination of an ice machine on a nursing unit by a patient infected with *Cryptosporidium (248)*. There has also been a report of transmission to hospital workers after caring for a patient with chronic cryptosporidiosis *(249)*.

The detection of *Cryptosporidium* is accomplished by microscopic examination of fresh or concentrated stool specimens followed by staining with a modified Kinyoun acid-fast stain *(250)*. The microorganism can also be seen on intestinal biopsies. A monoclonal antibody-based fluorescein-conjugated stain for detecting oocysts in stool and an EIA for detecting antigens in stool are commercially available *(251)*. PCR may be a useful tool for the diagnosis and study of the molecular epidemiology of *Cryptosporidium* infections *(252)*. Outbreak control has been achieved by intensified enteric precautions and cleaning *(244)*.

Cyclospora *Cyclospora cayetanensis* have been associated with diarrhea. It has been reported as an etiology of food-borne diarrhea outbreaks with fresh berries most commonly implicated. Watery diarrhea, abdominal cramping, decreased appetite, and low-grade fever characterize the illness. Symptoms can occur in cycles of remission and exacerbation lasting up to several weeks. A hospital-associated outbreak among staff was associated with stagnant water in a storage tank *(253)*.

Cyclospora are detected by identifying the 8- to 10-μm spherical bodies that auto-fluoresce or by acid-fast staining *(254,255)*. Direct person-to-person transmission is unlikely because *Cyclospora* oocysts require time and favorable conditions to become infectious.

Entamoeba Histolytica Amebiasis is a major health problem in Asia, Latin America, and Africa. Childhood intestinal amebiasis generally presents with diarrhea containing blood and mucus and no fever. Diarrhea without blood, fever, fulminating colitis, appendicitis, and ameboma occur infrequently in children. The cyst form is resistant to environmental stresses and is in the infective stage. Transmission is by the fecal–oral route. The incubation period is variable, ranging from a few days to months or years; commonly, it is 2 to 4 weeks. HAI is rare but has been reported in hospitalized adults in a developing country *(256)*. A colonic irrigation machine was implicated in an outbreak of amebiasis in adults after therapy at a chiropractic clinic *(257)*.

Entamoeba histolytica is detected by the direct examination of fresh stool specimens. *E. histolytica* actually comprise two genetically distinct but morphologically indistinguishable species. *E. histolytica* is pathogenic and causes invasive amebiasis; and *E. dispar* is probably nonpathogenic and is often reported as *E. histolytica* due to the microscopic resemblance of the two species. *E. histolytica* and *E. dispar* have been differentiated using restriction fragment analysis of DNA amplified by PCR, PCR, isoenzyme analysis, and antigen detection *(258,259)*.

Giardia Lamblia *Giardia lamblia* is transmitted directly from person to person by fecal–oral transmission of cysts or, indirectly, by transmission in water and, occasionally, food *(260)*. Travelers often become infected when they ingest contaminated ground water or surface water. The cyst is highly infectious for humans, and infections can occur following ingestion of as few as 10 to 100 cysts *(261)*. Infection by *G. lamblia* may produce flatulence, foul-smelling stools, abdominal cramps, abdominal distention, anorexia, nausea, and weight loss *(262)*. Outbreaks of infection and endemic infections occur in childcare centers and other institutional settings and among the family members of infected children *(263,264)*. The incubation period is usually 1 to 4 weeks. Healthcare-associated hospital outbreaks are uncommon, but outbreaks among children in childcare

centers are well documented *(265,266)*. An outbreak of giardiasis with person-to-person and food-borne transmission in nursing home residents, employees, and children in a combined childcare center with an adopted grandparent program has been reported *(267)*.

G. lamblia may be detected by the microscopic examination of fresh or formalin-preserved concentrated stool or by use of a commercially available EIA. Specific DNA probes for *Giardia* may assist in the diagnosis in the future.

Strongyloides Stercoralis *Strongyloides stercoralis* is a nematode that infects humans and, sometimes, other animals. It has a complicated life cycle that may have both parasitic and free-living phases. Strongyloidiasis has a worldwide distribution. The prevalence of infection varies inversely with socioeconomic level and is highest in warm, moist regions where sanitary practices are poor. The parasite is endemic in certain southern areas of the United States including eastern Kentucky, Tennessee, and elsewhere in southern Appalachia. Most human infections are acquired outdoors when polluted soil containing filariform larvae comes in contact with the skin. The filariform larvae then penetrate the intact skin of the new host, travel through the blood vessels to the lungs, penetrate the alveoli, are coughed up and swallowed, and then establish infection in the mucosa of the small intestine *(268,269)*. There have been no reports of HAIs within a hospital, but human-to-human transmission of *S. stercoralis* has been reported in residents of homes for the mentally retarded *(270–272)*. The incubation period is not known.

Disseminated strongyloidiasis has been reported in two recipients of kidney allografts from a single cadaver donor *(273)*. Neither recipient had previous evidence of parasitic infection or risk factors for strongyloidiasis. Disseminated strongyloidiasis has also been reported as a complication of immunosuppression. Patients with a history of exposure to *S. stercoralis* many years previously have experienced hyperinfection with the parasite during immunosuppression following renal transplantation *(274,275)*.

S. stercoralis is detected by a microscopic examination of fresh stool to identify the rhabditiform larvae. The method of placing stool in an agar plate and observing worms and worm tracks on the agar is an efficient method of detecting the parasite *(276)*. Several immunoassays for the detection of serum antibodies against filarial larvae or larval antigens are available *(277)*.

Isospora Belli *Isospora belli* is an obligate, intracellular protozoan. Humans are the only known host for *I. belli*, and transmission is believed to occur by the ingestion of oocysts contaminating food, water, or environmental surfaces. *I. belli* infection usually has an acute onset with fever, diarrhea, and colicky abdominal pain. The illness may be self-limiting with spontaneous resolution in the healthy host. Prolonged watery diarrhea accompanied by malabsorption, weight loss, and asthenia may occur in immunocompromised patients. The incubation period is 8 to 14 days. Isosporiasis has been encountered in 15% of patients with AIDS in Haiti but is much less frequent in the United States *(278,279)*. There have been no reports of healthcare-associated isosporiasis; in fact, 170 healthy siblings, friends, and spouses of patients with AIDS did not have *I. belli* in their stool specimens *(279)*.

Diagnosis is made by the demonstration of oocysts in feces or duodenal aspirates or by finding developmental stages of the parasite in biopsy specimens of the small intestine. Oocysts can be detected by a modified Kinyoun acid-fast stain and by auramine–rhodamine stains.

Microsporidia *Microsporidia* are ubiquitous, spore-forming, intracellular protozoal parasites that cause disease in a wide range of vertebrate and invertebrate animals. Manifestations of disease in humans range from asymptomatic infections to fulminant cerebritis and/or nephritis; ocular infections are recognized infrequently. Since 1985, enteric microsporidial infections have been reported with increasing frequency in patients with AIDS and chronic diarrhea. *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* are the species associated with diarrhea *(280)*. Common epidemiologic characteristics have not been identified, and the mode of transmission in humans is not known for certain. Fecal–oral transmission is the likely route of infection in humans with intestinal microsporidiosis, but the source of ocular infections is not clear. To date, there have been no reports of HAIs with this microorganism.

Routine histopathologic studies can provide presumptive identification, but diagnostic confirmation requires EM visualization of the microorganism's characteristic ultrastructure *(281)*. *Microsporidia* have been detected from formalin-fixed stool specimens following staining by a chromotrope-based technique and light microscopy *(282)*. PCR has also been used for detection from stools or from a small-intestine biopsy *(283)*.

Other

Candida Species *Candida* spp. have been associated with gastroenteritis in two settings: noninvasive enteritis in healthy persons *(284,285)* and invasive enteritis in patients with underlying diseases *(286,287)*. *Candida* is a saprophyte in healthy humans and is present in approximately 60% of stool specimens *(288)*. Since *Candida* spp. can frequently be isolated from the gastrointestinal tract of healthy individuals, its presence does not necessarily signify disease. Gastroenteritis associated with *Candida* spp. is characterized by intermittent, watery, explosive diarrhea that is not bloody and is rarely accompanied by fever, nausea, anorexia, or vomiting. These symptoms can be chronic and have been reported for up to 3 months *(289)*.

A prospective study of healthcare-associated diarrhea in newborns and infants isolated *Candida* spp. from 5% of stool specimens. *Candida* was the third most common etiology *(290)* and appeared most frequently in premature infants. The causative role of *Candida* in diarrhea was not clear in this study. Healthy patients who develop *Candida* gastroenteritis generally do not develop candidemia and usually respond to either nystatin or clotrimazole within 72 hours *(289)*. Healthcare-associated diarrhea associated with *Candida albicans* is particularly prevalent in immunocompromised or malnourished patients *(291,292)* and in patients receiving antibiotic or antineoplastic drugs *(256,293)*. *Candida* is detected by a routine microscopy of stool specimens or by growth on agar plates.

Necrotizing Enterocolitis NNIS system data showed that NEC occurred in 6 out of 10,000 discharges; that is, 8.7 out of 100,000 patients overall and 60 out of 10,000 infants in high-risk nurseries. Microorganisms associated were *C. difficile* (28%), *E. coli* (19%), *Klebsiella pneumoniae* (15%), coagulase-negative staphylococci (5%), *Enterobacter cloacae* (7%), and enterococci (6%). Gerber and others did not identify a cause in an outbreak of NEC, but nurses caring for infants involved in the outbreak also became ill *(114,294,295)*. A review of several outbreaks included the etiologies above and added viral enteropathogens including coronavirus, adenovirus, rotaviruses, and Echovirus type 22 as isolates during outbreaks *(296,297)*. Further discussion of NEC can be found in Chapter 52.

Potential Healthcare-Associated Gastrointestinal Tract Pathogens

Aeromonas Species Species of *Aeromonas*, including *Aeromonas caviae, Aeromonas hydrophila,* and *Aeromonas sobria* have been associated with acute gastroenteritis *(298–303)*, but other studies do not support this finding *(304)*. *Aeromonas* spp. have been implicated in healthcare-associated diarrhea, but this association is debated. *A. hydrophila* has been described as the etiology of an acute diarrheal outbreak in a geriatric long-term care facility *(305)*. In a study in childcare centers, *Aeromonas* was identified in the stool specimens of 25% of children during an outbreak of diarrheal illness *(306)*. These outbreaks of diarrhea were unusual in that several different *Aeromonas* spp. were involved in each outbreak. In another study, *Aeromonas* spp. were recovered from the stool specimens of 15 hospitalized children, but all were community acquired *(307)*. Surveillance in a French hospital revealed a seasonal variation in nosocomial *A. hydrophila* infection that was correlated with the number of *Aeromonas* microorganisms in the hospital water supply *(308,309)*.

Aeromonas spp. are recovered by culture and identified by biotyping. DNA hybridization has been used to investigate the relatedness of strains in hospital outbreaks *(306,310,311)*. PFGE was useful in the investigation of outbreaks in childcare centers *(306)*.

Klebsiella Species *Klebsiella* spp. are members of the Enterobacteriaceae family. They can cause a wide variety of clinical infections including urinary tract infections, pneumonia, and bacteremia. *Klebsiella* spp. have not been proven to cause enteritis. *Klebsiella* is mentioned here because of a report of an outbreak of *Klebsiella* spp. bacteremia following nasoduodenal feeding of premature infants with human milk contaminated with *Klebsiella (312)*. None of the bacteremic infants had diarrhea. Diarrhea was reported in preterm infants who had *Klebsiella* isolated from stool specimens, but a causal association was not established *(162,313)*.

Pantoea Agglomerans NICU infections caused by *Pantoea agglomerans* were definitely associated with parenteral nutrition. The microorganism colonized a large number of children in the NICU. Investigators hypothesized that gastrointestinal tract colonization may precede septicemia (314,*315*).

EPIDEMIOLOGY

Descriptive Epidemiology

The behavior of infants and children places them at increased risk of healthcare-associated acquisition of enteropathogens compared with adults. The close, frequent contact among children facilitates person-to-person transmission. Infants and children do not wash their hands and frequently place their fingers, toys, and other items in their mouths. Children cared for in childcare centers have a threefold greater risk of acquiring diarrhea than children cared for at home *(316,317)*. Hospitalized children display these same behavior patterns, which place them at a similarly high risk of fecal–oral transmission of enteropathogens. This is particularly true of infants and toddlers who are not toilet trained.

Reservoirs and Sources of Infection

The pattern and timing of an outbreak of diarrhea in a hospital may provide clues about the reservoir or source and mode of transmission. The possible reservoirs and sources of these microorganisms will be considered first (Table 50-2). Patients may act as a reservoir for enteropathogens. As described above, many potential enteropathogens are frequently excreted asymptomatically. If an asymptomatic patient is not isolated because the infection is not suspected, microorganisms may be introduced into the healthcare environment. The second scenario of the patient as the reservoir is a child admitted for management of an acute gastrointestinal tract infection. Enteropathogens may be transmitted to other patients, to hospital personnel, or to hospital visitors. Immunosuppressed patients may become infected with enteric microorganisms that are part of their own normal flora.

Healthcare personnel may act as a reservoir of infection. The same conditions occur as with patients. An employee may be an unknown chronic carrier of an enteropathogen or may be present in the hospital with an acute illness. The enteropathogen may then be transmitted to patients or coworkers by direct person-to-person contact or indirectly through fomites.

Food products may serve as a point source for HAIs if patients, hospital personnel, visitors, or all three groups eat the implicated food items. The food reservoir may originate outside or within the hospital. Several *Salmonella* spp.

TABLE 50-2

Factors Important in the Introduction of Healthcare-Associated Infectious Gastroenteritis

Short-term, asymptomatic carriers of enteropathogens
Colonized, asymptomatic prolonged carriers of enteropathogens
Patient-to-patient transmission via hands of hospital personnel, generally after contact with a child with diarrhea
Contaminated medications, food, or medical instruments
Hospital crowding
Lack of adherence to infection control procedures

outbreaks have been traced to intact and properly stored eggs *(172)*. Improperly stored foods have been implicated in several food-borne diarrheal outbreaks among both patients and employees *(178,318)*. Norwalk virus has been described as a cause of food-borne outbreaks in the hospital setting *(68)*. In addition to prepared foods, enteral feedings and infant formulas have become contaminated during storage *(182)*.

The CDC's definition for surveillance purposes of waterborne disease outbreaks is restricted to illness that occurs after the consumption or use of water intended for drinking. Outbreaks have been associated with private wells, small water systems, and community water systems *(319)*. Reservoirs for waterborne outbreaks may also include drinking water contaminated at the faucet, as occurs with *Aeromonas*, or in ice *(308,309)*. The contamination may occur away from the hospital, as has been reported in outbreaks due to *G. lamblia*, *Cryptosporidium, Cyclospora, microsporidia,* and viruses *(319)*. Various reservoirs exist within the hospital where water-holding units such as whirlpools, storage tanks, or common bathing tanks may be contaminated *(226). C. difficile* spores remain on surfaces in patient rooms after cleaning *(320)*.

All healthcare devices should be considered potential reservoirs. The reservoir may exist as the result of inadequate cleaning and sterilization, as occurred with endoscope-transmitted infections *(189,190)*; lack of proper cleaning, as in the use of common suction traps and tubing *(191,192)*; or inadequate sterilization, as occurred when a breast pump used by several mothers in an NICU became contaminated *(192)*. Some enteropathogens such as *C. difficile*, rotavirus, and norovirus may survive on contaminated fomites (72,321).

Blood products are a well-known risk factor for HAIs such as hepatitis B and C, human immunodeficiency virus (HIV), and cytomegalovirus. The contamination of whole blood units with *Y. enterocolitica* resulted in bacteremia in recipients. It is thought that the blood donors had a mild bacteremia at the time of their donation and that the refrigerated storage supported the growth of *Y. enterocolitica (233–235)*.

Other reservoirs may include animals outside the hospital or pets used in pet therapy programs within the healthcare system (see Chapter 94) *(322)*. There have been no reports of gastrointestinal tract disease resulting from pet therapy, but immunosuppressed patients may be particularly at risk. The association of salmonellosis with reptiles warrants the restriction of reptiles from the healthcare setting.

Modes of Transmission of Infection

The mode of transmission describes how the enteropathogen gets from the reservoir to the host. The pattern and timing of an outbreak may provide clues about transmission. Several cases occurring in a short period may be easy to recognize and trace to a point source such as food or a specific patient or employee. Other point sources such as an endoscope may be more difficult to recognize, because the number of infections may be few and may appear sporadically. Routine surveillance is an important tool in the recognition of these sources.

Person-to-person transmission may occur as the result of many practices. Poor hand washing by personnel results in direct spread to patients or self-inoculation. The patients may secondarily infect *(4)* other family members either as hospital visitors or after returning home. Fomites play a role in patient-to-patient transmission. Many items within a room or within common areas may become contaminated by enteropathogens. Subsequent contact with these items results in transmission. This is particularly important for microorganisms for which the transmission of infection is associated with a low inoculum, such as rotavirus, *Shigella*, *Giardia*, enteric adenovirus, astrovirus, calicivirus, *E. coli* O157:H7, and *Cryptosporidium*. Person-to-person spread also occurs through the vertical transmission of a microorganism from a mother to her newborn at the time of delivery. Several enteropathogens, such as *S. sonnei (211)*, *S. flexneri (212)*, *C. fetus,* and *C. jejuni* have been transmitted to neonates in this manner.

Food-borne transmission results from ingesting contaminated foods, poorly cleaned fresh foods, or nasoduodenal infusion of contaminated nutritional supplements or infant formulas. Nasoduodenal feedings may be a greater risk than nasogastric feedings, since the feeding tube bypasses the normal protective acidic environment of the stomach. Infections have resulted from *Salmonella* spp. *(184)*, *Campylobacter* spp. (*140*,*323*), *Klebsiella* spp. (*312*), and ETEC contamination of milk *(152)*, as well as *Campylobacter* spp. *(140)* contamination of poorly cleaned vegetables. *Salmonella (171–173,176,182)*, *Staphylococcus aureus, E. coli (159)*, and Norwalk virus *(68)* have all been described in food-borne HAIs in the hospital setting.

A gastroduodenal endoscope transmitted *Helicobacter pylori* in adults *(324,325). Salmonella newport* was transmitted by fiberoptic colonoscopy in 8 of 28 patients who underwent the procedure after the colonoscope had been used in a patient with acute disease due to *S. newport (324)*. Transmission resulted from inadequate cleaning and sterilization of the biopsy forceps. Chapter 62 describes HAIs associated with endoscopic procedures.

Transmission of enteric pathogens by hospital instruments occurs most frequently in NICUs. Nursery isolettes have been implicated in the transmission of ETEC and *C. difficile*. Common-use suction tubing and an overflow reservoir were reported to transmit *Salmonella worthington* in an NICU *(192). Klebsiella* was cultured from the tubing of a breast-milk pump following an outbreak of bacteremia in preterm infants receiving donor human milk by nasoduodenal feedings *(312)*. Rectal thermometers have been reported to spread *Salmonella eimsbuttel* among newborn infants *(193)*.

Risk Factors for Infection

The most severely ill patients are at greatest risk for healthcare-associated gastrointestinal tract infections for several reasons. The patients may be immunocompromised by the severity of illness, by poor nutritional status, and/or by therapeutic modalities. The use of antacids and H2 blockers in intensive care units may decrease the protective effect of gastric acidity. Children in intensive care units require frequent manipulation by multiple hospital personnel, which increases the risk of person-to-person transmission.

Neonates, particularly premature infants, are unique in that they are immunocompromised. The incidence of healthcare-associated gastrointestinal tract infection is twice as high in the high-risk nursery as it is in the general pediatric population *(10)*. The types of HAIs of

the gastrointestinal tract that occur in the nursery include NEC, rotavirus, *Klebsiella* spp., *C. difficile*, EPEC, and *Salmonella*. See Chapter 52 for a review of HAIs in hospital nurseries.

Immunocompromised patients constitute a special high-risk group. Patients infected with HIV have an increased risk of infection with microorganisms previously not shown to be enteropathogens. *C. parvum* and Microsporidia have been described as enteropathogens in this population. There have been no reports of healthcare-associated transmission, but such occurrences may occur. Patients with severe combined immunodeficiency disease acquire healthcare-associated enteropathogens and suffer prolonged disease with significant morbidity and often a fatal outcome *(101,326)*. Malnourished persons are at high risk for severe gastrointestinal tract disease. This is particularly evident in the reports of healthcare-associated gastroenteritis from developing countries.

Patients receiving chemotherapy for malignancies or persons who are immunosuppressed after organ transplantation are at a increased risk for infection by microorganisms that are part of their normal flora. *C. difficile* and *Candida*, in particular, have been reported to cause gastroenteritis under these conditions *(327)*. Forty percent of bone marrow transplant patients developed healthcare-associated gastroenteritis in one study, and another unit had a prolonged healthcare-associated astrovirus outbreak *(49,328)*.

Prolonged hospital stay is another risk factor for healthcare-associated gastroenteritis. These children are at risk both because of their underlying medical condition and their continued exposure to a variety of enteropathogens. Children in long-term care facilities have an increased risk of food-borne, waterborne, and person-to-person transmission of enteropathogens *(16, 329–331)* compared with children who receive care at home. In one study, 10% of children with an infected roommate developed healthcare-associated diarrhea. The risk was directly proportional to the number of roommates. Younger hospitalized children were at a greater risk than older ones: 10% of diapered children developed healthcare-associated diarrhea, compared to only 2% of nondiapered children *(22)*. The viral healthcare-associated diarrhea rate decreases with age. The rate at 0 to 11 months was 9%; at 12 to 35 months, 4%; and at 36 months or more, 0.6%. The rate does not significantly increase with the length of hospital stay *(10,22–24,332)*.

PATHOGENESIS

Viral enteropathogens are transmitted by the fecal–oral route. Enteric viruses tend to infect the small intestine, with replication occurring in epithelial cells at the tips of the villi; infection is confined primarily to these cells. The changes include the shortening and blunting of the villi and increased infiltration of the lamina propria with mononuclear cells. Mucosal damage is repaired rapidly, as early as 3 weeks after onset. Many children with acute viral gastroenteritis have lactose malabsorption and intolerance. Loss of fluids and electrolytes in viral gastroenteritis can lead to severe dehydration and even death and requires fluid- and electrolyte-replacement therapy. The severity of intestinal mucosal injury varies among the enteric viruses.

The major virulence properties of bacterial enteropathogens include adherence, enterotoxin production, cytotoxin production, epithelial cell invasion, and translocation. Certain enteropathogens may produce diarrhea by other mechanisms, and enteric pathogens may possess one or several of these virulence properties. Enterotoxins are bacterial products that act on the mucosal epithelium of the small intestine, causing fluid secretion and profuse watery diarrhea without damage to the intestinal mucosa. Functionally similar enterotoxins are produced by *V. cholerae*, ETEC, *Aeromonas*, *C. difficile*, *C. jejuni*, *Salmonella*, and *Y. enterocolitica*. Presumptive evidence indicates that rotavirus nonstructural glycoprotein (NSP4) functions as an enterotoxin *(333,334)*. Cytotoxins kill mammalian cells, usually by the inhibition of protein synthesis. *In vivo,* they cause damage to the intestinal epithelial cells and destruction of the normal absorptive mechanisms, which results in diarrhea containing blood. Fluid loss is probably related to impaired absorption due to intestinal damage; unlike enterotoxins, cytotoxins do not cause active fluid secretion by the gut. Microorganisms such as *Shigella,* EIEC, *C. jejuni*, *Salmonella*, and *Y. enterocolitica* can invade the mucosa of the colon or small intestine and result in an inflammatory host response. This invasion is characterized clinically by fever, abdominal pain, tenesmus, and stools containing blood, mucus, and fecal leukocytes. Adherence, the ability of microorganisms to attach to and colonize gut epithelium, is the least specific virulence property in terms of related clinical findings. The ability of ETEC to adhere to and colonize the upper small intestine, where it causes disease by production of enterotoxin, has been well described.

Parasitic enteropathogens possess a variety of pathogenetic mechanisms. The spore-forming protozoa (cryptosporidia, microsporidia, isospora, and cyclospora) produce abnormalities in the absorption, secretion, and motility of the small bowel and are associated with inflammatory infiltrates. This may be associated with villus blunting and crypt hyperplasia but not mucosal invasion. Gastrointestinal tract function and morphology relate to the number of microorganisms present. *Giardia* produce disease and malabsorption by producing varying degrees of mucosal injury and by influencing conditions in the intestinal lumen, which could impair digestion and absorption. *Strongyloides* is acquired by the penetration of intact skin by the filariform larvae. All other parasitic enteropathogens are acquired by fecal–oral transmission through ingestion of cysts or oocysts that are resistant to physical destruction.

CLINICAL MANIFESTATIONS

Localized

The approach to hospitalized patients with acute infectious diarrhea begins with a carefully obtained medical history including epidemiologic considerations and a physical examination. Acute diarrhea can be caused by one of the many microorganisms discussed previously. Clinical

manifestations occurring in patients with diarrhea reflect either localized involvement of the gastrointestinal tract or systemic involvement, manifested by generalized symptoms or signs. The presence of a specific clinical manifestation is not pathognomonic of any causative agent; however, some clinical features occur more frequently as a result of infection by certain microorganisms. The most common localized manifestations may occur with varying degrees of severity. These include diarrhea, nausea, anorexia, vomiting, and abdominal discomfort or cramping. The character of the diarrhea may provide a clue as to the associated enteropathogen. Bacterial microorganisms that invade intestinal mucosa often cause abdominal cramps, tenesmus, fecal urgency, and passage of stools containing blood and mucus and fecal leukocytes. Patients with secretory diarrhea have abdominal cramps and pass a low to moderate number of large-volume watery stools that, when passed, may be associated with temporary relief. Patients infected with *E. coli* O157:H7 and *E. histolytica* may have bloody diarrhea without fecal leukocytes and severe cramps. Patients with giardiasis or cryptosporidiosis often have watery, foul-smelling stools associated with nausea and flatulence or chronic diarrhea with malabsorption and abdominal distention. Diarrhea due to viral enteropathogens generally occurs in infants who present with low-grade fever, vomiting, and watery diarrhea.

Generalized

Many enteropathogens present with systemic manifestations of illness. Fever is a common, but not universal, manifestation of these infections. The parasitic enteropathogens that involve the small intestine rarely cause febrile illness, whereas acute infection with many of the enteric viruses and bacteria may result in fever. Dehydration is the most common reason for hospitalization of children with gastroenteritis in the United States. Dehydration occurs as the result of increased fluid losses from vomiting, diarrhea, and increased insensible losses associated with fever. Dehydration may result in shock if not recognized or corrected early. Shock may lead to multiple organ system involvement. Mild to moderate dehydration is most appropriately treated with an oral rehydration solution *(335)*. This has been demonstrated to be effective in developing countries and is the mainstay of therapy in cholera.

Enteric pathogens have extraintestinal manifestations. These include cutaneous involvement by *S. typhi* and strongyloidiasis; bacteremia and other organ system involvement by bacterial and parasitic enteropathogens; the complications of HUS with *E. coli* O157:H7, other EHEC, and *S. dysenteriae* type 1; and pulmonary compromise in immunosuppressed patients with strongyloidiasis. A wasting syndrome of malnutrition occurs in HIV-infected patients with microsporidiosis or cryptosporidiosis. In addition, several immune-mediated conditions can occur following enteric infections including reactive arthritis, Reiter's syndrome, Guillain-Barré syndrome, glomerulonephritis, erythema nodosum, and hemolytic anemia. These manifestations have been associated with *Salmonella*, *Shigella*, *Yersinia*, *Campylobacter*, *Giardia*, or *Cryptosporidium*.

DIAGNOSIS AND EVALUATION OF OUTBREAKS

The evaluation of either endemic infections or outbreaks of healthcare-associated gastroenteritis has two purposes. The first is to identify the enteropathogen and determine the method of transmission. The second is to evaluate isolated strains of the enteropathogens for relatedness. For epidemiologic purposes, the more closely related the strains of microorganisms are, the stronger is the proof that an outbreak is due to a common epidemic strain. Merely proving that several patients are infected with the same species does not substantiate the occurrence of an outbreak. Many techniques are available to evaluate genetic relatedness (see Chapter 95). The identification of microorganisms may be approached in a stepwise fashion. First, nonspecific tests are used to support infection and identify the type of enteropathogens (viral, bacterial, or parasitic). Next, phenotypic techniques are used to identify the microorganism based on characteristics expressed by the microorganism. Finally, genotypic techniques that involve direct DNA-based analyses of chromosomal or extrachromosomal genetic elements are utilized for molecular fingerprinting. In general, these three approaches to diagnosis move from evaluation at the bedside, to routine laboratory evaluation, to testing in research or referral laboratories *(336–338)*. See Table 50-3 for a list of methods and Chapter 8 for further information about outbreak investigations. The techniques generally available will be briefly described, but more detailed descriptions may be found in the listed references.

The timing of the onset of diarrhea in relationship to the admission to the hospital should be used to guide the evaluation. Diarrhea occurring more than 3 days after admission is unlikely to be caused by either bacterial or parasitic etiologies. Viral or *C. difficile*–associated diarrhea is more likely. Therefore, routine bacterial cultures and studies for ova and parasites are not cost-effective for the initial testing of diarrhea occurring more than 3 days after admission *(339–342)*.

The utility of the age-old technique of microscopy permits the evaluation of fresh stool specimens for the presence of fecal leukocytes. This single procedure differentiates inflammatory diarrhea from noninflammatory diarrhea, thereby narrowing the differential diagnosis considerably. Microscopic examination of either fresh or concentrated stool specimens is the mainstay in the diagnosis of parasitic diseases. Trophozoites, cysts, oocysts, or worms can be identified in stool specimens *(279,282)*. Gram stain of a stool specimen may not be useful to identify a specific enteric gram-negative bacterium, but yeast cells can be identified in this manner, as can the spiral-shaped *Campylobacter* microorganisms. Testing a stool sample for occult blood is a simple, inexpensive, and rapid method for evaluating the presence of gastrointestinal tract inflammation or mucosal damage.

The interpretation of a complete blood count and differential cell count also provides nonspecific evidence to determine the etiology. Anemia or hemolysis may occur, particularly with HUS. Leukocytosis is more frequently seen with a bacterial gastrointestinal tract infection. Eosinophilia would support further investigation for a parasitic infection.

TABLE 50-3

Laboratory Tests Used to Evaluate Healthcare-Associated Outbreaks of Infectious Gastroenteritis

Nonspecific tests
Stool fecal leukocytes
Microscopy
Stool occult blood
Complete blood cell count
Stool culture
Electron microscopy
Immunoelectron microscopy
Phenotypic techniques
Biotyping
Antibiograms (antimicrobial susceptibility patterns)
Serotyping
Bacteriophage typing
Immunoblotting
Enzyme immunoassay (EIA)
Multilocus enzyme electrophoresis (MEE)
Genotypic techniques
Electropherotyping
Plasmid profile analysis (PPA)
Restriction endonuclease analysis (REA)
Southern hybridization analysis (SHA) using specific DNA probes
Ribotyping
DNA profiling using pulsed-field gel electrophoresis (PFGE)
Polymerase chain reaction (PCR)
Nucleotide sequence analysis

Several phenotypic methods are used to characterize microorganisms and include biotyping, antimicrobial susceptibility testing, serotyping, bacteriophage typing, immunoblotting, EIA, and multilocus enzyme electrophoresis. The mainstay of the diagnosis of bacterial diarrheal illness is the stool culture. Many of the microorganisms discussed in this chapter are not detected with routine stool culture methods. Selective media and special conditions for growth may be necessary for isolation of many microorganisms. Communication with the clinical microbiology laboratory is essential for identification of these enteropathogens. The microbiologist should be notified about the suspected microorganisms so that appropriate media and techniques may be used for identification. *C. jejuni* and other *Campylobacter* species, *Y. enterocolitica*, *V. cholerae* and other *Vibrio* species, pathogenic *E. coli*, and *C. difficile* all require special procedures for isolation.

EIA is a relatively rapid technique to identify many of the microorganisms and toxins described above. Commercially produced EIAs are available for detection of *Cryptosporidium*, *G. lamblia*, rotavirus, enteric adenovirus, astrovirus, calicivirus, cholera toxin, and *C. difficile* toxins. Other EIAs for detection of other enteropathogens are available in reference or research laboratories.

Evaluation of the molecular structure of enteropathogens is useful for analysis of different strains of the same microorganism. These methods add nothing to the identification of a specific microorganism but are used for comparison of strains based on genetic similarities or dissimilarities. Application of one or more of these methods to various collections of healthcare-associated pathogens has shown that DNA-based typing methods are useful in studying the relationship between colonizing and infecting isolates in an individual patient, distinguishing contaminating from infecting strains, documenting cross-infection among hospitalized patients, and evaluating reinfection versus relapse in patients being treated for an infectious process. Examples of genotypic methods include electropherotyping, PPA, restriction endonuclease analysis, Southern hybridization analysis, ribotyping, PFGE, PCR, random amplified polymorphism of DNA, and nucleotide sequence analysis *(343–350)*.

Biopsy may be the only possible method to identify some of the microorganisms mentioned in this chapter. *Microsporidia* are identified on EM of intestinal biopsy specimens. Microscopic examination of biopsy material may accurately identify *Giardia, Strongyloides, E. histolytica*, EPEC, and EAEC.

PREVENTION AND CONTROL

Healthcare-associated gastrointestinal tract infections are best prevented by surveillance and identification of methods to improve hospital procedures. It is important that infection control methods be based on scientific data, not just speculation. It is difficult to know how many healthcare-associated enteric infections can be prevented. The CDC's Study of the Efficacy of Nosocomial Infection Control project noted that surveillance by infection control practitioners decreased HAIs by 32%, but in this study, gastrointestinal tract infections and pediatric hospital infections were not addressed specifically *(351)*. One study of pediatric healthcare-associated gastrointestinal tract infections indicated that educational intervention programs decreased the incidence of healthcare-associated rotavirus infection (125,*352*). It is accepted universally that effective hand washing is the mainstay of prevention of HAIs including gastroenteritis *(353)*. Observational studies have noted that physicians wash their hands before only 30% to 85% of patient contacts, indicating the need for continuing education for healthcare providers about appropriate infection control procedures including hand washing *(121,354,355)*. Alcohol-based products reduce rotavirus on the hands by approximately 99% in reported studies *(356)*. No antiseptic agents are sporicidal against microorganisms such as *C. difficile*; therefore, the use of gloves is recommended *(356)*. For more information, see Chapter 37.

Cohorting or grouping neonates and their nursing staff was not effective for the prevention of HAIs in an NICU *(357)*. In another study, Klein and coworkers demonstrated that protective isolation of patients in a pediatric intensive care unit using gowns and gloves decreased the HAI rate in that environment *(358)*. Unfortunately, this study did not address gastrointestinal tract infection rates.

Appropriate isolation of patients that are excreting enteropathogens is a necessary part of prevention. Table 50-4 shows diseases transmitted by the fecal–oral route. All patients are to be managed using Standard

TABLE 50-4

Diseases Transmitted by the Fecal–Oral Route

Amebic dysentery
Cholera
Coxsackie virus disease
Diarrhea, acute illness with suspected infectious etiology
Echovirus disease
Encephalitis (unless known not to be caused by enteroviruses)
Enterocolitis caused by *Clostridium difficile*
Enteroviral infection
Gastroenteritis caused by:
- *Campylobacter* species
- *Cryptosporidium*
- *Dientamoeba fragilis*
- *Escherichia coli* (EAEC, ETEC, EPEC, EIEC, or EHEC)
- *Giardia lamblia*
- *Isospora belli*
- *Salmonella* species
- *Shigella* species
- *Vibrio cholerae*
- *Vibrio parahaemolyticus*
- Viruses, including rotavirus, astrovirus, calicivirus (including Noroviruses), and enteric adenovirus
- *Yersinia enterocolitica*
- Unknown etiology but presumed to be an infectious agent

Hand, foot, and mouth disease
Hepatitis, viral, type A
Herpangina
Meningitis, viral (unless known not to be caused by enteroviruses)
Necrotizing enterocolitis
Pleurodynia
Poliomyelitis
Typhoid fever *(Salmonella typhi)*
Viral pericarditis, myocarditis, or meningitis (unless known not to be caused by enteroviruses)

Precautions. Those patients with acute diarrhea with a likely infectious cause or diarrhea in an adult with a history of recent antibiotic use should be managed using additional Contact Precautions (Table 50-5) (see Chapter 90 for more details). Patients in the same room as an index patient should be managed with the same precautions. Exposed patients may be incubating the enteropathogen, and they should not be transferred into a room with unexposed children. Exposed patients may be isolated as a cohort. In addition, gloves should be considered for diaper changing of all hospitalized children. A uniform hospital policy would be advantageous rather than unit-specific guidelines. *C. difficile*–associated diarrhea incidence was decreased among adult bone marrow transplant patients by cleaning the rooms with sodium hypochlorite rather than quaternary ammonium products *(359)*.

Surveillance is integral for the identification of HAIs, their source(s), and modes of transmission. If the source and mode of transmission are not identified, control of an outbreak will be difficult, if not impossible.

TABLE 50-5

Contact Precautions

Use Standard Precautions for all patients
Masks are not indicated
Gowns are indicated
Gloves are indicated
Hands must be washed after touching the patient or potentially contaminated articles and before taking care of another patient
Single room is indicated, if possible

Employee health plays an important role in the prevention of healthcare-associated gastroenteritis. Any staff member with symptoms that suggest infection should be excluded from contact with potentially susceptible persons for at least 2 days after resolution of illness *(83)* (see Chapter 93).

Appropriate antimicrobial agents may be given to patients known to be infected with an enteropathogen. This therapy may shorten the time that a patient excretes the microorganism, although there is concern that treatment of salmonellosis may increase the period of excretion. Table 50-6 lists enteropathogens for which antimicrobial therapy may be useful. Conversely, limiting antibiotic use for other infections may decrease *C. difficile*–associated diarrhea *(360)*.

Immunizations may play a role in prevention and control of HAIs by some enteropathogens, but commercially available enteric vaccines are limited. Typhoid, cholera,

TABLE 50-6

Potential Benefit for Antimicrobial Therapy for Enteropathogens

Potential Benefit	*Enteropathogen or Disease*
No therapy available	Enteric viruses
Established benefit	Necrotizing enterocolitis
	Antimicrobial-associated colitis (*Clostridium difficile*)
	Cholera
	Cryptosporidium parvum
	Cyclospora cayetanensis
	Entamoeba histolytica
	Enterotoxigenic *E. Coli*
	Giardia lamblia
	Isospora belli
	Shigella spp.
	Strongyloidiasis
Absolute	Any bacterium that produces bacteremia (e.g., typhoid fever)
Questionable or unknown	*Aeromonas* spp.

	Candida spp.
	Enterohemorrhagic *E. coli*
	Intestinal salmonellosis
	Microsporidia
	Yersinia enterocolitica

and rotavirus vaccines are available and may be useful for prevention of disease in developing countries.

Human milk decreases the frequency and severity of diarrhea in infants. Therefore, all providers should encourage the initiation and continuation of breast-feeding during the first year of life.

There is increasing support for the use of probiotics for the prevention and treatment of gastrointestinal track infections. These live culture "good" bacteria may be beneficial in both prevention and treatment of diarrhea. Lactobacillus GG was effective in preventing symptomatic infections due to rotavirus in hospitalized infants in a randomized, double-blinded study *(361)*.

Gastrointestinal tract decontamination by giving enteral antibiotics to modify the gut flora and delay gastrointestinal tract colonization has had mixed success. Studies in adults in intensive care units have shown both decreased infection rates and no difference in infection rates *(362,363)*. The studies reported to date have evaluated invasive infections and did not comment on prevention of diarrheal illness.

The CDC lists the following items as necessary steps for the control of an outbreak of viral gastroenteritis. Common sources should be identified and eliminated. Employee transmission of illness should be prevented by use of appropriate gowns and gloves when handling infectious materials. Soiled linens and clothing should be handled as little as possible. Since environmental surfaces in some settings have been implicated in the transmission of enteric viruses, bathrooms and rooms occupied by ill persons should be kept visibly clean on a routine basis.

CHAPTER 51

Healthcare-Associated Measles, Mumps, Rubella, and Human Parvovirus B19

Kathleen M. Gallagher, Preeta K. Kutty, Eileen Schneider, and Jane F. Seward

Healthcare-associated measles and rubella are well recognized and have been the cause of substantial morbidity among both patients and hospital workers. Immunocompromised patients and healthcare personnel (HCP) are particularly vulnerable to severe infections and even death with some of these diseases. Because of highly successful vaccination programs that resulted in an interruption of endemic disease transmission and the elimination of measles and rubella in the United States, measles and rubella are no longer primarily childhood diseases *(1,2)*. However, children may still acquire measles or rubella, particularly if they travel abroad and are unvaccinated or live in communities with lower rates of vaccine coverage and/or pockets of unvaccinated persons *(3,4)*. Because of the severity of measles, patients frequently access medical care and may expose HCP to the disease in emergency rooms or in hospitals. In 2008, the United States experienced the largest healthcare-associated measles outbreak in more than two decades with seven cases acquired in hospital settings, including one case in an unvaccinated HCP following the hospital admission of an adult foreign visitor with measles (5). Healthcare-associated outbreaks of rubella have not been reported in the United States since its elimination was declared; however, HCP in the United States remain at risk for exposure to cases of imported rubella. Mumps outbreaks are not commonly described in hospital settings, probably because of the lower complication rate of mumps compared with measles; nevertheless, during community outbreaks, HCP in hospitals may be exposed to mumps (6). The transmission and impact of parvovirus B19 in hospital settings are less well understood, though outbreaks in hospital settings involving adult patients as well as HCP have been described. Patients with erythema infectiosum are likely to be infectious before, and not after, the onset of clinical manifestations, and persons who are immunocompromised with a chronic B19 infection can be infectious for prolonged periods. Vertical transmission of B19 infection from mother to fetus has also been documented (*178*). Understanding the transmission, infectiousness, and at-risk populations of parvovirus B19 is critical to prevention and control.

HCP are at risk for exposure to each of these viral diseases, and if susceptible, may transmit these infections in healthcare settings. This draws attention to the critical need for comprehensive prevention and control programs. One important component of such programs is providing basic education to HCP on the modes of transmission of these nosocomial pathogens and methods of prevention and control.

Integral to any prevention and control efforts are systematic screening and vaccination programs for HCP, prompt diagnosis and management of potentially transmissible illnesses or exposures among hospital workers, and the implementation of patient management techniques that lower the risks of transmission (Table 51-1).

All medical institutions (inpatient and outpatient, private and public) should ensure that all HCP who work within their facilities (i.e., medical or nonmedical, paid staff, student or volunteer, full time or part time, with or without patient care responsibility) have evidence of immunity to measles, mumps, and rubella (Table 51-2). A comprehensive program of HCP immunization should include screening for evidence of immunity (Table 51-2) of existing staff as well as routine evaluation of incoming staff (see also Chapter 80). Some hospitals require evidence of immunity to some or all of these vaccine-preventable diseases, particularly measles, as a condition of employment.

All hospitals should have standard guidelines and procedures for identifying HCP with or exposed to infectious diseases and for managing situations in which personnel have been exposed or may be infectious. For situations involving measles, rubella, and mumps, these procedures are greatly simplified if the HCP already possess documented evidence of immunity, preferably through rapidly retrievable electronic records. Since the elimination of measles and rubella in the United States, the number of reported cases of these two diseases has declined substantially. Nevertheless, importations continue to occur, and the occurrence of even a single case in a hospital setting requires immediate reporting to the local or state health department and rapid response and control efforts in collaboration with local public health agencies.

Promptly instituting and complying with proper isolation precautions for patients with known or suspected communicable infections protects personnel and patients. In addition, hospital-acquired infections have been demonstrated to spread from patients and hospital personnel to their community contacts, as well as from the community to hospital settings. Transmission of infectious diseases is theoretically possible anywhere in hospitals where individuals, including HCP, patients, volunteers, trainees, and

Measles, Mumps, Rubella and Parvovirus B19 (Erythema Infectiosum): Incubation, Infectious and Isolation Periods

	Measles	*Mumps*	*Rubella*	*Parvovirus B19 Erythema Infectiosum*
Incubation period	10–12 d (range: 7–18 d),	16–18 d (range: 12–25 d)	14–16 d (range: 12–23 d)	7–21 d (range: 4–28 d)
Infectious period	4 d before until 4 d after rash onset	2 d before to 5 d after onset of parotitis	7 d before to 7 d after rash onset	7 d before to onset of rash
Isolation precautions	Standard and Airborne Precautions for 4 d after rash onset. Airborne infection isolation room is required. Respiratory etiquette to be followed.	Standard and Droplet Precautions for 5 d after onset of parotitis. Respiratory etiquette to be followed.	Rubella: Standard and Droplet Precautions for 7 d after the onset of rash. Room doors can remain open and special ventilation is not required. Respiratory etiquette to be followed. CRS: First year of life: Standard and Contact Precautions to be followed. After first year: Standard Precautions if nasopharyngeal and urine cultures are repeatedly negative after 3 mo of age	Standard and Contact Precautions

CRS, congenital Rubella syndrome.

visitors, may come into contact with those diseases. This includes waiting areas, cafeterias, playrooms, and other locations. Because visitors, friends, and relatives of hospital staff (including small children) may be infected or incubating infections, the important relationship between hospitals and their communities must be considered in developing prevention and control programs. Visitors, particularly children, may need to be screened for present or incubating infectious diseases before they are allowed to enter all or some patient care areas.

MEASLES

Epidemiology

Prior to the licensure and availability of a live measles vaccine in 1963, approximately 95% of persons living in urban areas of the United States were infected with measles by the age of 15 years, and 3 to 4 million cases occurred annually *(7,8)*. From 1950 to 1959, an average of 549,000 measles cases and 495 measles deaths were reported annually *(9)*. After vaccine licensure, the incidence of measles declined rapidly with >99% reduction in the reported incidence in the United States by 1988 *(10)*. This was associated with declines in measles-related hospitalizations and deaths.

In 1989, in response to outbreaks occurring in vaccinated school-aged children, two doses of measles, mumps, and rubella (MMR) vaccine were recommended for children (*11,*12). A major resurgence of measles occurred in the United States from 1989 to 1991 with 55,662 cases, 11,000 hospitalizations, and 124 deaths reported; the highest incidence was among preschoolers (<5 years) followed by adolescents (10–19 years)(13,*33*). Implementation of the two-dose MMR vaccine requirement and increased focus on improving vaccine coverage among preschool-aged children resulted in further declines in incidence with <140 measles cases reported annually between 1997 and 2001, an incidence of <1 measles case per million population *(14)*. With this reduced incidence and lack of sustained endemic transmission, measles was declared "eliminated" from the United States in 2000 *(1)*. During the postelimination era (2001–2008), 557 measles cases were reported in the United States (median: 56 cases, range: 37–140 cases per year) of which 232 (42%) cases were imported from 44 different countries, and the majority of the remaining cases were associated with these importations (15). As measles remains endemic in many other parts of the world, importations into the United States will continue to occur (*3*,15,*16*).

Once a disease primarily of childhood, measles may now affect persons of any age in the United States. Although the incidence of measles remains highest in the most susceptible age groups (infants <12 months and children aged 12–15 months, because they have not yet been vaccinated), the highest proportion of cases in the postelimination era has been among adults (40%), followed by preschool children (32%) (15). Measles epidemiology

Measles, Mumps and Rubella: Presumptive Evidence of Immunity and Vaccination Requirements for Healthcare Personnel

	Measles	*Mumps*	*Rubella*
Presumptive evidence of immunity	1. Documentation of administration of two doses of appropriately spaced live measles virus vaccine on or after the first birthday, or 2. laboratory evidence of immunity, or 3. laboratory confirmation of disease, or 4. birth before 1957[a]	1. Documentation of administration of two doses of appropriately spaced live mumps-containing vaccine on or after the first birthday, or 2. laboratory evidence of immunity, or 3. laboratory confirmation of disease, or 4. birth before 1957[a]	1. Documented administration of one dose of live rubella virus vaccine on or after the first birthday, or 2. laboratory evidence of immunity, or 3. laboratory confirmation of disease, or 4. birth before 1957[a] (except women of childbearing age who could become pregnant)
Vaccination requirement			
Routine	Two doses of live, attenuated measles virus or MMR vaccine.	Two doses of live, attenuated mumps virus or MMR vaccine.	One dose of live, attenuated rubella virus or MMR vaccine.
Outbreak	Two doses of MMR vaccine are recommended for HCP who lack evidence of immunity, even if they were born before 1957.	Two doses of MMR vaccine are recommended for HCP who lack evidence of immunity, even if they were born before 1957.	One dose of MMR vaccine is recommended for HCP who lack evidence of immunity, even if they were born before 1957.

[a]For unvaccinated personnel born before 1957 who lack laboratory evidence of measles, mumps, or rubella immunity or laboratory confirmation of disease, health-care facilities should consider vaccinating personnel with two doses of MMR vaccine at the appropriate interval.

is now mainly determined by the characteristics of the imported case and the people they come into contact with.

In addition, in recent years, there has been an increase in the number of measles outbreaks among populations who choose not to vaccinate because of personal beliefs. In the United States in 2008, 140 measles cases were reported—the highest number of cases annually since measles was declared eliminated (15). Of the nine outbreaks that year, six were related to personal-belief exemptors, and almost all these cases were children (15), including two children who were infected while visiting their mother in the hospital (5). In 2009, six of the eight outbreaks were associated with personal-belief exemptors (*CDC, unpublished data*). To maintain measles elimination in the United States, it will be necessary to sustain high MMR vaccine coverage among children and other groups at high risk of exposure and transmission, including HCP.

Measles in Medical Settings Prior to measles elimination in the United States, measles was commonly transmitted to and among patients in outpatient departments, in-patient wards, and emergency departments, and instances of measles transmission and outbreaks in medical settings in the United States and other countries have been well described *(17–20)*. Visiting a hospital emergency room was identified as a risk factor for measles infection during community measles outbreaks in Houston and Los Angeles in 1989 *(21)*. The predominant setting of transmission for 24 (20%) of the 120 measles outbreaks reported during 1993 to 2001 was healthcare facilities *(22)*. Measles outbreaks have resulted in lost productivity and high containment costs for healthcare facilities *(23–25)*. In addition, medical facilities can contribute to the propagation and amplification of community measles outbreaks *(21,26,27)*.

Because of the severity of measles, patients usually seek medical care, and as a result, HCP have a higher risk of being exposed to and acquiring measles. In a study of a measles outbreak in Clark County, Oregon, in 1996, HCP were 19 times more likely to be infected with measles than the general adult population of the county *(23)*. Measles has been reported in persons of virtually all occupations providing patient or ancillary services including nurses, physicians, laboratory and radiology technicians, clerks, nursing assistants, and medical and nursing students *(28)*. Transmission has been reported between patients, between HCP, from patient to HCP, and from HCP to patient. In many instances, the patient contact that led to measles in the HCP did not qualify as direct patient care, which illustrates the extreme transmissibility of measles virus. Visitors were rarely identified as the source for measles transmitted in these settings.

Almost 30% of HCP who acquired measles in medical settings from 1985 to 1991 were born before 1957 (i.e., they were older than the age for routine vaccination) *(28)*. Studies among HCP indicated that up to 5% of HCP born before 1957 lacked measles antibodies *(29,30)*. A recent study on measles seroprevalence among 469 newly

hired hospital HCP born before 1957 revealed that only 1.3% were measles seronegative *(31)*.

In 2008, a measles outbreak occurred in Arizona with 14 confirmed cases, including 7 healthcare-associated-acquired infections—the largest reported healthcare-associated measles outbreak in the United States since 1989 (5). Healthcare-associated transmission included patient-to-HCP, patient-to-patient, patient-to-visitor, and HCP-to-patient. During the screening of 7,195 HCP in two hospitals during this outbreak, 1,776 (25%) were found to lack evidence of measles immunity in their employee health record. Among the 1,583 of these HCP who underwent serologic testing for measles IgG antibodies, 18 of the 506 HCP (4%) born before 1957 and 121 of the 1,077 (11%) HCP born during or after 1957 were found to be seronegative. The two hospitals spent US$799,136 responding to and containing 7 cases in these facilities.

Between 2001 and 2008, 27 reported measles cases were transmitted in healthcare facilities, accounting for 5% of all reported US measles cases; 8 cases occurred among HCP, 6 (75%) of whom were unvaccinated or had unknown vaccine status (15).

Clinical Description

Measles is an acute viral infection that is characterized by a generalized maculopapular rash and high fever. Following an incubation period of 10 to 12 days (range: 7–18 days), the patient typically develops a prodrome consisting of fever and malaise, followed by cough, coryza, and conjunctivitis. The characteristic maculopapular rash usually appears 2 to 4 days after onset of the prodromal symptoms and first appears on the face, and then spreads to the trunk and extremities. The rash lasts 5 to 7 days and fades in order of appearance. An enanthem, characterized by small bluish-white spots on a red background (Koplik's spots), may be seen on the buccal mucosa from 2 days before to 2 days after onset of rash. A person with measles is considered to be infectious from 4 days before until 4 days after rash onset.

Measles may be associated with serious complications. The most common complications of measles are otitis media, diarrhea, and pneumonia. Pneumonia is the most common cause of death and may be caused by the measles virus or by a secondary bacterial or viral infection. Measles encephalitis is reported once in every 1,000 cases and can result in permanent neurologic sequelae or death. The age-specific complication rates are highest among infants, children between 1 and 4 years old, and adults over 20 years, and lowest in children 5 to 19 years old *(32)*. Measles can be severe in immunocompromised patients, particularly in those with abnormalities of cellular immunity. From 2001 to 2008, 23% of reported measles cases in the United States required hospitalization (15). In the United States between 1987 and 2002, the case fatality rate for measles was 2 to 3 per 1,000 cases *(33)*; two deaths due to measles occurred among the 557 reported cases between 2001 and 2008 (15). Another serious complication is subacute sclerosing panencephalitis (SSPE), which is a rare progressive neurologic disorder caused by a persistent infection of the brain with aberrant measles virus. The onset of behavioral and intellectual deterioration usually occurs 6 to 8 years after wild-type measles infection. SSPE is almost universally fatal *(34)*.

Pathogenesis

The measles virus is a single-stranded RNA virus of the *Paramyxovirus* family. The measles virus can survive for at least 2 hours in fine droplets, and airborne spread in medical and other settings has been documented *(35)*. Secondary attack rates of over 90% have been documented among susceptible populations *(36,37)*. Neither a long-term infectious carrier state nor an animal reservoir is known to exist. Infection with measles virus is thought to confer lifelong immunity from clinical measles.

The primary site of measles infection is the respiratory epithelium of the nasopharynx. Generally, primary viremia with infection of the reticuloendothelial system occurs 2 to 3 days after invasion and replication in the respiratory epithelium. A second viremia occurs 5 to 7 days after initial infection, following further viral replication in regional and distal reticuloendothelial sites. During this viremia, there may be infection of the respiratory tract, skin, conjunctiva, and other organs. The characteristic pathologic feature of measles infection is the presence of multinucleated giant cells, which are found in the reticuloendothelial (Warthin–Finkeldey cells) or in the respiratory epithelium. In an immunocompetent person, measles virus is shed from the nasopharynx beginning with the prodrome until 4 days after rash onset. Immunocompromised persons with measles may shed the virus for a longer time.

Diagnosis

Since measles has become a rare disease in the United States, few younger clinicians have ever seen a patient with measles. The key to diagnosing measles is having a high index of suspicion in any patient with a generalized rash, fever and cough, coryza, or conjunctivitis and performing the appropriate laboratory tests. Recent international travel or exposure to persons with recent international travel should increase the diagnostic suspicion of measles. A history of vaccination, even with multiple doses of measles vaccine, does not preclude the diagnosis.

Laboratory testing is critical in confirming the diagnosis of measles. Measles may be confirmed by the presence of measles immunoglobulin M (IgM) antibodies in a single serum specimen, immunoglobulin G (IgG) seroconversion, a fourfold rise in IgG antibodies, isolation or detection of the measles virus by reverse transcriptase polymerase chain reaction (RT–PCR) *(38)*. For IgM testing, enzyme immunoassay (EIA) is the most common assay currently in use and is commercially available. IgM antibodies appear with or soon after rash onset, peak 1 to 2 weeks later, and fall to nondetectable levels 1 to 2 months after the appearance of the rash. Serum specimens for IgM testing should be collected at the first clinical contact with a person with suspected measles. In previously vaccinated persons, the IgM response may be absent or short-lived, and additional testing, particularly viral testing, may be warranted *(39)*.

The measles virus can be cultured from throat swabs, urine, nasal swabs, or whole blood. A throat or nasopharyngeal swab collected from first day of rash through 3 days following onset of rash is the preferred specimen for viral testing, although swabs collected up to 7 days after rash onset may still yield virus. Isolation of measles virus in culture or detection of measles virus by RT–PCR confirms

the diagnosis of measles *(38)*. As most measles cases in the United States are currently associated with importations, the genotyping of viral specimens is of importance since this allows for a better understanding of the measles viruses being imported into or detected in the United States and the global epidemiology of the disease.

Prevention and Control

Because of the ease of transmission of measles, the fact that cases may present in medical facilities before onset of rash and recognition of measles as the diagnosis and because measles cases are frequently misdiagnosed, particularly during the prodrome, prevention of healthcare-associated measles transmission is challenging. However, a number of strategies will lower the risk. These include strategies to (a) maintain a high awareness among staff that a measles case could enter the facility, (b) assess the presumptive evidence of immunity of HCP, (c) maintain high vaccine coverage in the health facility staff, (d) promptly identify and isolate HCP and patients with febrile rash illness clinically compatible with measles, (e) identify and vaccinate potentially exposed patients, (f) exclude potentially infectious HCP from duty in the healthcare facility, (g) observe appropriate procedures for standard and airborne isolation in separate waiting areas, (h) inform health authorities promptly of suspected and confirmed measles cases, and (i) administer immune globulin as needed to selected immunocompromised patients and HCP where live viral vaccines, such as measles vaccine, are contraindicated (12,*38,40,41*,42).

Routine Vaccination Recommendations Live, attenuated measles vaccine is now available in the United States only as combined MMR vaccine. The Advisory Committee for Immunization Practices (ACIP) and Hospital Infection Control Practices Advisory Committee (HICPAC) recommend that all HCP should have documented immunity to measles. Vaccination with two doses of live, attenuated MMR vaccine is recommended for all HCP who lack evidence of immunity (see below) unless otherwise contraindicated (Table 51-2).

Presumptive Evidence of Immunity to Measles All HCP should have documented evidence of immunity to measles (Table 51-2). Adequate presumptive evidence of immunity to measles is defined as (a) documentation of administration of two doses of appropriately spaced live measles virus vaccine on or after the first birthday, (b) laboratory evidence of immunity, (c) laboratory confirmation of disease, or (d) birth before 1957 (43). Although most persons born in the United States before 1957 are likely to have been infected with measles naturally, ACIP and HICPAC suggest that healthcare facilities should consider vaccinating personnel without laboratory evidence of immunity or disease born before 1957 because of the potential for measles exposure in healthcare facilities and disruption that may result if an outbreak does occur. For HCP who have two documented doses of MMR vaccine or other acceptable evidence of immunity to measles, postvaccination serologic testing for immunity is not recommended. In the event that an HCP who has two documented doses of MMR vaccine is serologically tested and found to have negative or equivocal measles titer results, it is not recommended that the individual receive an additional dose of MMR vaccine. Documented age-appropriate vaccination is acceptable evidence of immunity irrespective of the results of subsequent serologic testing.

Management of Patients and Healthcare Personnel with Measles Patients with suspected or confirmed measles should be placed on Airborne Precautions for 4 days after the onset of rash (42). If airborne infection isolation rooms are not available, the patient should be placed in a room with the door closed and asked to wear a surgical mask (44). Only HCP with adequate presumptive evidence of immunity should provide care to a person with suspect or confirmed measles. Immunocompromised persons with measles (e.g., persons with acquired immunodeficiency syndrome) may shed virus for extended periods and should be kept on Airborne Precautions for the duration of their hospitalization for the acute illness.

If an HCP is suspected of having measles, they should be excluded from work until a diagnosis of measles can be ruled out. An HCP with confirmed measles should be excluded from duty for 4 days from the day of onset of rash.

Management of Measles Exposures and Outbreaks in Healthcare Settings If measles exposures occur in a healthcare facility, all contacts (those exposed during the infectious period) should be immediately evaluated for evidence of measles immunity.

Exposed HCP who cannot document evidence of measles immunity should be offered the first dose of MMR vaccine immediately and be excluded from work from the 5th through the 21st day following exposure (12). The second dose should be administered 28 days after the first. Those with documentation of one vaccine dose may remain at work and should receive the second dose. During an outbreak, HCP born before 1957 without laboratory confirmation of immunity or disease should receive two doses of the MMR vaccine; the first dose should be immediately followed by the second dose at least 28 days later. Serologic testing of HCP before vaccination is not recommended during an outbreak because arresting measles transmission requires rapid vaccination of HCP who lack evidence of measles immunity. The need to screen, wait for results, and then contact and vaccinate seronegative persons can impede the rapid vaccination needed to curb the outbreak. Serologic testing performed prior to vaccination may be used to guide the need for a second dose. HCP without evidence of measles immunity, for whom MMR vaccine is contraindicated, should receive immune globulin and should be excluded from work, and observations should continue for signs and symptoms of measles for 28 days after exposure, because immune globulin might prolong the incubation period.

Exposed patients without evidence of immunity should be offered the first dose of MMR vaccine or measles immune globulin (if vaccine is contraindicated) and should be discharged from hospital, if feasible. If they remain in the hospital, they should be quarantined from the 5th through the 21st day following exposure and should receive their second MMR vaccine 28 days after the first dose. If they have received immune globulin, they should be excluded for 28 days.

Other contacts (e.g., visitors, persons exposed in emergency rooms) should be identified, and information about them should be provided to local and state health departments so that these contacts can be followed up for evidence of measles immunity, need for vaccination or immune globulin, and for development of signs and symptoms of measles.

Any hospital contact who develops measles-compatible symptoms should be evaluated, isolated/excluded from work (as appropriate), and appropriate infection-control measures should be implemented to prevent further spread.

MUMPS

Epidemiology

Prior to the availability of mumps vaccine, epidemics of mumps occurred in the United States approximately every 3 years with peak incidence during the winter and spring *(45)*. The infection largely occurred among children aged 5 to 9 years; by age 14, approximately 90% of children living in urban areas had already been infected with mumps *(46)*. The epidemiology of the disease significantly changed following the licensure of a mumps vaccine in 1967. After that, reported cases of mumps in the United States began to decline steadily from 152,209 cases reported in 1968 to 2,982 cases reported in 1985 (*47,*48). Between 1986 and 1991, the United States experienced a resurgence of mumps, particularly among 10- to 14-year-olds and 15- to 19-year-olds, caused initially by a failure to vaccinate older cohorts of children and later characterized by one-dose vaccine failures *(49,50)*. The recommendation for a routine two-dose schedule for MMR to improve measles control in 1989 likely contributed to further declines in the incidence of mumps throughout the 1990s, and in 2003, a record low of 231 cases was reported nationally (48); this number represented a >99% decline from the 152,209 cases reported in 1968—the year after the live mumps vaccine was licensed.

During 2006, the United States experienced a large mumps outbreak with 6,584 cases—the largest number of cases reported since 1987 (51). The outbreak primarily affected college students from the Midwest, many of whom had already received two doses of the MMR vaccine. Mumps incidence again declined after this outbreak with 800 cases of mumps reported in 2007 and 454 cases reported in 2008 *(52,53)*. Again in 2009 to 2010, a large outbreak of mumps occurred in orthodox Jewish communities, primarily in the northeastern United States. The majority of cases (61%) occurred among persons aged 7 to 18 years; 75% of cases, where vaccine status was known, had previously received two doses of MMR vaccine *(54)*. In 2006 and 2009–2010 outbreaks, crowded social, religious, educational, or living environments appeared to be fueling the transmission of mumps. Although the effectiveness of the mumps component of the MMR vaccine is lower than that of the measles and rubella components, it appears sufficient to maintain mumps control and prevent outbreaks in most community settings. Estimates of the effectiveness of the mumps vaccine using the Jeryl Lynn or derived strains have varied in previous studies, ranging from 62% to 91% after one dose and from 79% to 95% after two doses (*55–57,*58).

Although most cases of mumps in HCP may be community acquired, sporadic transmission of mumps within hospitals to patients and staff is well documented (6). Cases of mumps in HCP and patients have been reported following healthcare-associated exposure, particularly in long-term care facilities housing adolescents and young adults. Outbreaks of mumps within hospitals, however, have only rarely been reported *(59,*60*)*. Presumably, the rare occurrence of healthcare-associated mumps outbreaks is because mumps virus is less communicable than measles and many other viruses, and mumps results in hospitalization less commonly. The level of mumps transmission in the surrounding community may also affect the risk for introduction into hospitals (6). During the 2006 mumps outbreak, a single healthcare institution experienced ongoing transmission of mumps for 1 month, affecting seven employees and two inpatients (60).

Clinical Description

Mumps is an acute viral illness, classically characterized by the presence of unilateral or bilateral parotitis. Onset of the disease usually occurs with nonspecific prodromal symptoms such as anorexia, myalgia, malaise, headache, and low-grade fever lasting up to several days. Parotitis, the predominant clinical feature, usually develops an average of 16 to 18 days (range: 12–25 days) after exposure. However, mumps infection may present only with nonspecific, primarily respiratory, symptoms or may be a subclinical infection *(56)*. Parotitis may be accompanied by earache and pain on chewing and may involve other salivary glands, including the submaxillary and sublingual glands. Parotitis is usually accompanied by moderate fever, but temperature may range from normal up to 40°C (104°F). Symptoms tend to decrease after 1 week and are usually gone by 2 weeks.

Complications of mumps include orchitis, affecting up to 37% of postpubertal males *(61)*, and mastitis, affecting up to 31% of females older than 15 years *(62)*. Oophoritis occurs in 5% of postpubertal females. Sterility or long-term infertility is thought to be a rare sequelae associated with orchitis and oophoritis. Meningeal signs may appear in up to 15% of cases, and pancreatitis, usually mild, may be present in up to 4% of cases *(63)*. An association between maternal mumps infection during the first trimester of pregnancy and an increase in the rate of spontaneous abortion or intrauterine fetal death has been reported in some studies but not in others *(64,65)*.

Serious complications of mumps are rare. Encephalitis occurs in <0.3% of apparent mumps infections *(66,67)*. Permanent sequelae are rare, but the reported encephalitis case fatality rate has averaged 1.4% (*67a*). Transient high-frequency deafness may occur in up to 4% of mumps cases *(63)*. Permanent deafness may occur at a rate of 1 case per 15,000 to 20,000 cases of mumps.

Pathogenesis

The mumps virus is single-stranded RNA virus in the *Paramyxovirus* family. The mumps virus is transmitted in saliva and respiratory secretions *(63,68)*. Mumps is acquired through the nose or mouth by direct contact with infected

droplets, saliva, or contaminated fomites but appears to be less efficiently transmitted than some other infectious diseases such as measles and chickenpox; the secondary clinical attack rate in susceptible household contacts <15 years was estimated to be 31%, 61%, and 76% for mumps, chickenpox, and measles respectively *(69)*. Primary viral replication occurs in the epithelium of the respiratory tract and possibly in regional lymph nodes. This is followed by viremia, which persists for 3 to 5 days, disseminates mumps virus throughout the body with localization in glandular tissue, and terminates with the development of humoral antibody *(70)*. Mumps virus has been isolated in saliva from 7 days before parotitis to 8 days after onset of disease; cessation of viral shedding coincides with the appearance of virus-specific secretory immunoglobulin A *(63,68,*71*,72,73*). However, viral shedding and therefore transmission risk are highest 1 to 2 days prior to and following parotitis onset, and most transmission likely occurs before and within 5 days of parotitis onset. During viremia, virus may be disseminated to the salivary glands, meninges, kidneys, testes, and other organs. Viruria is frequent and may last 10 days or more. Virus can be isolated from breast milk of infected women *(74)*. Parotitis accounts for most of the observed elevation of serum and urine amylase. Development of measurable neutralizing antibodies appears to correlate best with immunity to mumps.

Diagnosis

When parotitis is present, the clinical diagnosis of mumps is generally apparent. Although parotitis may be caused by other agents such as parainfluenza and coxsackievirus, bacterial infections, systemic diseases such as lupus and sarcoid, and certain drugs, mumps virus is the only known cause of epidemic parotitis. Because mumps is now a rare disease in the United States, diagnostic testing for persons with parotitis with no other apparent cause is recommended *(75)*. Laboratory diagnosis of mumps requires either detection of mumps IgM antibodies, a significant rise in serum IgG antibody titers between acute and convalescent phase sera, IgG seroconversion from negative to positive, isolation of mumps virus, or detection of virus by RT–PCR *(76)*.

Laboratory diagnosis of mumps in highly vaccinated populations may be challenging, and the timing of specimen collection and the utility of testing depend on the vaccination history of the person suspected of having mumps. In general, sera for IgM testing or as the acute specimen for examining seroconversion should be collected as soon as possible after onset of parotitis. In unvaccinated persons, IgM antibody is detectable within 5 days of onset of symptoms, peaks in about 1 week, and remains elevated for up to several months; for persons who have been previously vaccinated, the IgM response may be absent, and a negative result should not be used to rule out the diagnosis of infection. The IgM-capture EIA is the most sensitive method for detecting antibodies but has limited commercial availability. Other IgM test methods are more variable in their sensitivity and specificity.

The convalescent specimen for IgG detection should be collected approximately 2 to 3 weeks after the acute specimen. In unvaccinated individuals, mumps IgG antibody rises early after the onset of symptoms and is long-lasting. Previously vaccinated individuals may already have high levels of IgG present at the time that the acute specimen is collected. Oral or buccal swab samples should be collected as soon as mumps disease is suspected. Samples collected when the patient first presents with symptoms, usually within 3 days of parotitis, have the best chance of having a positive result by RT-PCR.

Prevention and Control

Because viral shedding occurs before clinical symptoms begin and because mumps may occur as a nonspecific respiratory illness or as an asymptomatic infection, effective methods to reduce mumps transmission can be challenging. Preventing mumps through an effective vaccination program is the best approach to controlling this disease. Strategies for mumps prevention and control should be applied in all healthcare settings and include (a) assessing the presumptive evidence of immunity of HCP, (b) vaccination of those without evidence of immunity, (c) exclusion of HCP with mumps as well as those lacking presumptive evidence of immunity who are exposed to persons with mumps, (d) isolation of patients in whom mumps is suspected, and (e) implementation of Standard and Droplet Precautions.

Routine Vaccination Recommendations Live, attenuated mumps vaccine is now available in the United States only as combined MMR vaccine. The ACIP and HICPAC recommend that all HCP should have documented immunity to mumps. Since 2006 (77), vaccination with two doses of MMR vaccine has been recommended for all HCP who lack evidence of immunity (see below) unless otherwise contraindicated (Table 51-2).

Presumptive Evidence of Immunity to Mumps All HCP should have documented evidence of immunity to mumps (Table 51-2). Acceptable presumptive evidence of immunity to mumps is defined as (a) documentation of administration of two appropriately spaced doses of live mumps-containing vaccine on or after the first birthday, (b) laboratory evidence of immunity, (c) laboratory confirmation of disease, or (d) birth before 1957 (43). Most persons born before 1957 are likely to have been infected naturally and generally may be considered to be immune even if they may not have had clinically recognizable mumps. However, a recent serosurvey conducted in 488 HCP born before 1957 showed that 3.7% of persons tested did not have serologic evidence of mumps antibody *(31)*. ACIP and HICPAC suggest that healthcare facilities should consider vaccinating personnel without laboratory evidence of immunity or disease born before 1957 because of the potential for mumps exposure in healthcare facilities and disruption that may result if an outbreak does occur.

Management of Patients and Healthcare Personnel with Mumps To prevent transmission, Standard and Droplet Precautions are recommended for patients with mumps, including a private room and use of masks for those providing care to the patient (42). These precautions should be maintained for 5 days after onset of parotitis. HCP with mumps should be excluded from work for 5 days after onset of parotitis (71).

Management of Mumps Exposures and Outbreaks in Healthcare Settings If mumps exposure occurs in a healthcare facility, all contacts (those exposed during the infectious period) should be evaluated for evidence of mumps immunity.

Exposed HCP without evidence of mumps immunity who are exposed to a person with mumps should be offered the first dose of MMR vaccine and should be excluded from duty from the 12th day after the first unprotected exposure through the 25th day after the last exposure. They should receive the second dose 28 days after the first dose. HCP with documentation of one vaccine dose may remain at work and should receive the second dose. During an outbreak of mumps, unvaccinated personnel born before 1957 who lack laboratory evidence of mumps immunity or laboratory evidence of disease should be vaccinated with two doses of MMR vaccine, 28 days apart. Serologic testing of HCP before vaccination is not recommended during an outbreak. The need to screen, wait for results, and then contact and vaccinate seronegative persons can impede the rapid vaccination needed to curb the outbreak. Serologic testing performed prior to vaccination may be used to guide the need for a second dose.

Exposed patients without evidence of immunity should be offered the first dose of MMR vaccine and should be discharged from the hospital, if feasible. If they remain in the hospital, they should be quarantined from the 12th day after the first unprotected exposure through the 25th day after the last exposure.

Other contacts (e.g., visitors, persons exposed in the emergency rooms) should be identified, and information about them should be provided to local and state health departments so that these contacts can be followed up for evidence of mumps immunity, the need for vaccination, and development of signs and symptoms of mumps.

Any hospital contact that develops mumps-compatible symptoms should be evaluated, isolated/excluded from work (as appropriate), and appropriate infection-control measures should be implemented to prevent further transmission.

RUBELLA

Epidemiology

During the global rubella pandemic that occurred between 1962 and 1965, an estimated 12.5 million cases of rubella occurred in the United States, resulting in considerable morbidity and mortality, including 11,250 therapeutic or spontaneous abortions, 2,100 neonatal deaths, and 20,000 infants born with congenital rubella syndrome (CRS) *(78,79)*. The licensure of rubella vaccine in the United States in 1969 *(80)*, and its use, primarily in children, led to dramatic declines in the number of reported rubella cases in the United States from 57,686 cases in 1969 to 12,491 cases in 1976 *(81)*. CRS cases also decreased dramatically from 68 in 1970 to 23 in 1976 *(82)*. A resurgence of rubella from 1977 to 1978, primarily among older adolescents and young adults (12,*83*), led to a modification of the rubella vaccination strategy to target additional groups for vaccination including susceptible postpubertal girls and women, military recruits, college students, and persons in certain work settings (e.g., healthcare) *(83–86)*. These recommendations resulted in a decrease in rubella cases in these age groups in the 1980s. During the mid 1990s to 2000, the majority of cases in rubella outbreaks were among foreign-born Hispanic adults from countries without a history of routine rubella vaccination programs *(87–89)*. Between 2000 and 2004, the median number of rubella cases reported annually was 18 (range: 7–176 cases) *(90)*. In 2004, rubella was declared eliminated from the United States on the basis of data showing that the virus was no longer circulating endemically within the country's borders *(2)*.

During the post-elimination era (2005–2009), 54 cases of rubella were reported for an average of 11 rubella cases reported annually (range: 3–16 cases); the majority of the cases occurred among individuals aged 20 years and above. Of the reported cases, 23 (43%) were imported or associated with importations; only two outbreaks of rubella were reported during this time and both were small ($n = 3$) (*CDC, unpublished data*). Since 2005, reported cases of CRS have remained low, and most infections were acquired overseas, with two cases reported in 2009 (*CDC, unpublished data*).

Although the virus has been eliminated in the United States since 2004 *(2)*, a national survey where specimens were collected between 1999 and 2004 indicated that approximately 12% of adults aged 30 to 39 years remain susceptible to rubella *(91)*. In 2011, these adults are now approximately a decade older. Although not as infectious as measles, rubella can be transmitted effectively whenever a large number of susceptible persons congregate in one place, and outbreaks continue to be a possibility in these settings, which include hospitals. Because rubella remains endemic throughout most of the world, the likelihood of future importations of rubella into the United States is high.

Rubella in Medical Settings

Although healthcare-associated outbreaks of rubella have not been reported in the United States since elimination was declared, U.S. HCP remain at risk for exposure to cases of imported rubella. In the decades prior to rubella elimination, healthcare-associated transmission of rubella was well documented (*92–95,*96). Transmission of rubella has occurred from HCP to susceptible coworkers and patients, from patients to HCP, and from patient to patient. Medical and dental students have been sources of infection and have facilitated transmission in rubella outbreaks *(95,97)*. Outbreaks have resulted in serious consequences including therapeutic abortions, disruption of hospital routine, time loss from work, costly control or containment measures, adverse publicity, and the potential for legal action.

Clinical Description

Rubella is generally a mild viral illness characterized by a generalized erythematous maculopapular rash, lymphadenopathy, and fever. Approximately 50% of infections may be subclinical or inapparent *(98)*. The incubation period ranges from 12 to 23 days *(99,100)*, with most persons developing a rash 14 to 16 days after exposure. In adults, a prodrome frequently occurs. It precedes the rash, lasts 1 to 5 days, and consists of malaise; low-grade fever; postauricular, occipital, and posterior cervical adenopathy;

and upper respiratory infection. The maculopapular erythematous rash begins on the face and spreads rapidly to the chest, abdomen, and extremities. Lymphadenopathy is a major clinical manifestation of rubella, and in addition to the characteristic suboccipital and postauricular nodes, there can be generalized involvement as well. Transient polyarthralgia and polyarthritis sometimes accompany or follow rubella, particularly among adult women (up to 70%). Rubella virus has been recovered from the synovial fluid of patients with acute disease *(101)* and, in some instances, from individuals with chronic arthritis in the absence of clinical rubella *(102,103)*, although the overall risk of persistent arthritis appears to be low. Central nervous system complications (encephalopathy or encephalomyelitis) and thrombocytopenia have been reported at rates of 1 per 6,000 cases and 1 per 3,000 cases, respectively. Hemorrhagic manifestations occur with an approximate incidence of 1 per 3,000 cases, occurring more often in children than in adults.

By far the most important consequences of rubella are the abortions, miscarriages, stillbirths, and multiple anomalies in infants that result from maternal infection in early pregnancy, particularly in the first trimester. The most commonly described anomalies associated with CRS are auditory (sensorineural hearing impairment), ophthalmic (cataracts, microphthalmia, glaucoma, chorioretinitis), cardiac (patent ductus arteriosus, pulmonary artery stenosis, atrial or ventricular septal defects), and neurologic (microcephaly, meningoencephalitis, developmental delay). Preventing fetal infection and the consequent CRS is the primary objective of rubella vaccination programs.

Pathogenesis

Transmission of rubella virus, an RNA virus in the *Togavirus* family, is from person to person via droplets shed from the respiratory secretions of infected persons. The disease is most contagious when the rash is erupting, but the virus may be shed from 7 days before to 7 days after the rash onset (infectious period). The mucosa of the upper respiratory tract and the nasopharyngeal lymphoid tissue are the primary portals for virus entry and the initial sites of viral replication. Virus spreads via the lymphatic system, or viremia may seed regional lymph nodes. The appearance of the rubella rash coincides with the detection of rubella-specific antibodies. Immunity is generally long lasting, but reinfection may occur following either naturally acquired rubella or vaccine-induced immunity *(104,105)*. Although some individuals have antibody levels that are not detectable by Hemagglutination Inhibition antibody testing following previous vaccination or infection, the clinical significance of such low-level antibody has not been well documented. Limited data suggest that reinfection with the rubella virus may occur in persons with low antibody levels. During reinfection, there is limited viral replication in the nasopharynx, and viremia and systemic manifestations are uncommon.

In fetal infection, transmission occurs during maternal viremia when the placenta is seeded with the virus followed by development of inflammatory foci in the chorionic villi, granulomatous changes, and necrosis *(106,107)*. CRS following maternal reinfection has been documented, although such instances have been rare *(108,109)*.

Diagnosis

Clinical diagnosis of rubella is difficult in the post-elimination era because of absence of disease and nonspecificity of clinical features. Laboratory confirmation is required for diagnosis. Although suboccipital and postauricular lymphadenopathy are characteristic, enlargement of these nodes can occur in adults with other conditions such as infectious mononucleosis, acquired toxoplasmosis, and *Mycoplasma pneumoniae* infection. Serologic diagnosis can be made by demonstrating IgM antibody in an acute specimen, by IgG seroconversion, or by demonstrating a fourfold rise in antibody titer between acute and convalescent serum samples. Because of its sensitivity, availability, and ease to perform, EIA is the most commonly used diagnostic testing for the detection of rubella IgM and IgG antibodies.

Rubella virus grows slowly in tissue culture. The preferred clinical specimens for culture of rubella virus and detection of rubella virus RNA are throat swabs or nasal aspirate secretions. Viral specimens should be collected as soon after symptom onset as possible and no later than 10 days postonset. Virus can also be recovered from the blood and urine.

Prevention and Control

An effective vaccination program is the best approach to preventing and controlling rubella. Strategies for rubella prevention and control should be applied in all healthcare settings, including outpatient facilities and long-term care facilities and should include (a) assessing the presumptive evidence of immunity of HCP, (b) vaccination of those without evidence of immunity, (c) exclusion of HCP with rubella as well as those lacking presumptive evidence of immunity who are exposed to persons with rubella, (d) isolation of patients in whom rubella is suspected or confirmed, and (e) implementation of Standard and Droplet Precautions.

Routine Vaccination Recommendations Live rubella vaccine is now available in the United States only as a combined MMR vaccine. The ACIP and HICPAC recommend that all HCP should have documented immunity to rubella. Vaccination with one dose of MMR vaccine is recommended for all HCP who lack evidence of immunity (see below) unless otherwise contraindicated (Table 51-2).

Women of childbearing age should receive rubella-containing vaccines only if they state that they are not pregnant and only if they are counseled not to become pregnant for 3 months after vaccination (12,*110*). Women without evidence of rubella immunity from whom vaccine is withheld because they state they are or may be pregnant should be counseled about the potential risk for CRS and the importance of being vaccinated as soon as they are no longer pregnant (111).

Presumptive Evidence of Immunity to Rubella All HCP should have documented evidence of immunity to rubella (Table 51-2). Adequate presumptive evidence of immunity to rubella is defined as (a) documented administration of one dose of live rubella virus vaccine on or after the first birthday, (b) laboratory evidence of immunity, (c) laboratory confirmation of disease, or (d) birth before 1957 (except women of childbearing age who could become pregnant) (43). For unvaccinated personnel born before

1957 who lack laboratory evidence of rubella immunity or laboratory confirmation of disease, healthcare facilities should consider vaccinating personnel with one dose of MMR vaccine.

Persons born before 1957 are generally considered to be immune to rubella. However, in a recent study among 477 newly hired HCP at a hospital in North Carolina, who were born before 1957 serologic testing, revealed that 14 (3.1%) lacked IgG antibodies to rubella *(31)*. Because rubella could occur in persons born before 1957 and because congenital rubella and CRS can occur in the offspring of women infected with rubella virus during pregnancy, although pregnancy is now expected to be a rare occurrence in this age group, birth before 1957 is not considered acceptable evidence of rubella immunity for women who could become pregnant.

Management of Patients and Healthcare Personnel with Rubella Patients diagnosed with rubella should be isolated for 7 days after rash onset and Droplet Precautions and respiratory etiquette should be followed (42). Isolation with Contact and Standard Precautions are also recommended for infants diagnosed with CRS, including placement in a private room and use of gowns and gloves when soiling is likely or for touching infective material. These Precautions should be maintained during any admission for the first year after birth unless nasopharyngeal and urine cultures, obtained at least 1 month apart, after the age of 3 months are negative for rubella virus.

HCP diagnosed with rubella should be excluded from work for 7 days after the onset of rash (43,112).

Management of Rubella Exposures and Outbreaks in Healthcare Settings The primary strategy for responding to rubella exposures and for controlling rubella outbreaks should be to ensure that persons without evidence of rubella immunity are vaccinated rapidly (or excluded from work if a contraindication exists).

Exposed HCP without evidence of rubella immunity should receive one dose of MMR vaccine and be relieved of direct patient contact from the 7th day after the first exposure through the 23rd day after the last exposure (43). All unvaccinated HCP born before 1957, who lack laboratory evidence of rubella immunity or laboratory confirmation of disease, should receive one dose of MMR vaccine during an outbreak of rubella. Serologic screening before vaccination is not recommended because rapid vaccination is necessary to halt disease transmission (12). Mandatory exclusion and vaccination of HCP who cannot document rubella immunity is recommended in medical settings, because pregnant women may be exposed.

Exposed patients without evidence of immunity should receive a dose of MMR vaccine and should be discharged from the hospital, if feasible. If they remain in the hospital, they should be quarantined from the 7th day through the 23rd day following the exposure.

Other contacts (e.g., visitors, persons exposed in the emergence rooms) should be identified, and information about them should be provided to local and state health departments so that these contacts can be followed up for rubella immunity, the need for vaccination, and development of signs and symptoms of rubella.

Any hospital contact that develops rubella-compatible symptoms should be evaluated, isolated/excluded from work (as appropriate), and appropriate infection-control measures should be implemented to prevent further transmission.

HUMAN PARVOVIRUS B19

Overview

Parvoviridae are small nonenveloped, single-stranded DNA viruses that infect invertebrates (subfamily: *Densovirinae*) and vertebrates (subfamily: *Parvovirinae*) *(113,114)*. Within the subfamily *Parvovirinae*, there are five genera, and viruses within these genera are known to infect many vertebrates, including cats (feline panleukopenia virus), dogs (canine parvovirus), pigs (porcine parvovirus), nonhuman primates (e.g., simian parvovirus), and humans. Currently, at least four different parvoviruses have been detected in humans (adeno-associated viruses, PARV4, human bocavirus, and human parvovirus B19). B19, the best characterized, is classified within the genus *Erythrovirus* and was discovered in the mid-1970s while evaluating a hepatitis B assay among human blood donors (plate B, position 19) *(115)*. It was not until 1981 that B19 was linked to a disease—transient aplastic crisis among children with sickle cell anemia *(116)*. Since then, B19 has been definitively linked to a number of diseases including erythema infectiosum (fifth disease), B19 arthropathy, transient aplastic crisis, chronic anemia, and hydrops fetalis and has been implicated in several others (e.g., autoimmune disorders, hepatitis, myocarditis, thyroiditis, and vasculitis).

Epidemiology

Prevalence B19 infections are common worldwide, demonstrating seasonal and year-to-year variations, occurring as sporadic cases or as community-wide outbreaks *(113,117)*. In temperate climates, most cases of erythema infectiosum occur during winter and early spring, with epidemics following a cyclical pattern every 3 or more years *(118–121)*. School outbreaks of erythema infectiosum may be protracted, often beginning in winter or spring and frequently lasting until the school year ends months later *(122)*. Prevalence of B19-specific antibodies rise steeply during childhood from 2% to 15% among children 1 to 5 years old to 35% to 60% at 11 to 19 years old *(118,123,124)*. This rise in prevalence is consistent with the fact that B19 infection is most commonly diagnosed in school-age children. The seroprevalence of IgG antibodies continues to increase during adulthood, reaching 75% to 90% among persons over 50 years old. In the absence of community outbreaks, the annual incidence of B19 infection in HCP is approximately 1% *(125)*.

Transmission Transmission for B19 parvovirus is primarily through contact (i.e., direct, droplet) with respiratory secretions, but it may also be transmitted transplacentally (*in utero*) or via fomites, blood components, and transplantation (e.g., stem cell, solid organ). Respiratory secretions are known to contain parvovirus B19 DNA, suggesting that they are likely to be important in viral transmission *(126–128)*. Fomite transmission is facilitated by the

stability of parvoviruses on environmental surfaces (129). Parvoviruses can also be transmitted via the administration of contaminated blood and plasma-derived products *(130–133)*; since they are small and very stable, they are resistant to common inactivation or removal methods (e.g., heat, solvents, detergents, filtration).

Transmission is very efficient in household settings in which half of susceptible exposed household members can become infected *(127,128,134)*. Although 25% to 50% of students in a school outbreak can have clinical or serologic evidence of infection, adult staff in schools and childcare settings generally have less-pronounced seroconversion rates of 5% annually *(125)*; however, in one outbreak, 20% of staff had serologic evidence of acute infection *(122)*.

Healthcare-associated transmission of parvovirus B19 among hospitalized patients and hospital staff has been described *(135–139)*, but in such cases, an index viremic patient is often not identified *(135,140–142)*. Based on the presence of B19 DNA in blood and respiratory secretions, the capacity to transmit B19 virus varies by the clinical syndrome of the index patient: patients with erythema infectiosum are likely to be infectious before, and not after, the onset of the typical clinical manifestations associated with erythema infectiosum (e.g., rash, arthralgias) *(126–128)*; however, patients with transient aplastic crisis can be infectious a week after onset of illness *(136,143)*, and immunocompromised patients with chronic B19 infection can be infectious for prolonged periods *(144–147)*. Some outbreaks of B19 infection that were initially presumed to be of nosocomial origin were, on careful evaluation, more likely to have been manifestations of community outbreaks (129,*138,146*). Therefore, the possibility of a community-based outbreak should be evaluated before attributing hospital-associated cases of B19 to healthcare-associated transmission.

B19 viral transmission has also been documented in other settings. As determined by serologic testing, vertical transmission of B19 infection occurs in 25% to 50% of infants born to mothers with B19 infection during pregnancy *(148–150)*, and fetal B19 infection is the cause of an estimated 5% to 20% of nonimmune hydrops fetalis *(151–153)*. Laboratory workers have also become infected following exposure to specimens from viremic patients *(154,155)*.

Disease transmission by transfusion of blood components is uncommon. B19 antigen has been found in 1 of 20,000 units of blood for transfusion, and B19 DNA has been found in 1 of 100 to 1 of 3,000 units, depending on the detection assay used *(130–132)*. However, units positive by DNA assays are frequently also positive for B19 antibodies, presumably reducing the likelihood of transmitting infection. B19 can also contaminate a variety of plasma-derived products *(133)*. Transmission of B19 infection to recipients of heat or solvent-treated blood products has been described *(156–159)*; and the seroprevalence of B19 is also higher among persons receiving plasma-derived products for treatment of chronic medical conditions *(130,152–156,160)*.

B19 viral transmission or suspected transmission by transplantation (e.g., stem cell, solid organ) has been documented in the literature, although it is considered an uncommon event *(161–167)*. Transplant recipients may present with mild symptoms that are consistent with erythema infectiosum or with more significant complications, including refractory or severe anemia and allograft dysfunction.

Clinical Description

In outbreaks of erythema infectiosum, the incubation period before the onset of rash is most commonly 1 to 2 weeks but can be as long as 3 weeks. Outbreak investigations have shown nearly half of infected persons do not report a rash, and one-quarter report no symptoms *(125,127,168)*. When illness does occur, it is often biphasic. An initial phase of nonspecific systemic symptoms (fever, malaise, and myalgias) develops at 1 to 2 weeks and correlates with the onset of viremia at 5 to 7 days *(126)*. The level of B19 DNA in blood during the acute phase of viremia may be $>10^9$ to 10^{12} genome copies per mL *(169)*. The second phase of illness begins 2 to 5 days after viremia is cleared and is associated with the appearance of antibodies and the onset of rash and arthralgias—the classic symptoms of B19 infection (170,*171–173*).

The most commonly recognized clinical condition associated with B19 infection, the rash illness—erythema infectiosum—was well characterized (as fifth disease) centuries before the discovery of the etiologic agent *(143)*. This illness is defined by a bilateral, intensely erythematous, maculopapular facial rash affecting the cheeks but sparing the bridge of the nose and circumoral region. Patients with this rash are often described as having a "slapped-cheek" appearance. In addition, a lace-like rash can concurrently affect the trunk and extremities but usually spares the palms and soles. Vesicles, papules, purpura, and desquamation have also been reported in some cases. The rash normally fades over a period of 2 weeks, but for several weeks afterward, the rash may reappear transiently following nonspecific stimuli, such as changes in ambient temperature, exposure to sunlight, exercise, or stress. Fever, if noted, is usually low grade; other symptoms may include sore throat, headache, and pruritus. Because there is variability between individuals in the intensity and distribution of the rash, sporadic cases of erythema infectiosum cannot be distinguished on the basis of clinical criteria alone from other exanthemas caused by rubella, enteroviruses, and other viruses or from some drug rashes. Adults may also develop erythema infectiosum, but the facial rash is usually less prominent; consequently, the diagnosis of B19 in adults is difficult to make if there is no laboratory confirmation or epidemiologic link to a child with typical erythema infectiosum.

A self-limited symmetric peripheral polyarthropathy particularly affecting the hands, wrists, and knees has been reported with B19 infection of children and adults, but it is most often found in adult women. The arthropathy can occur with or without a rash. Joint manifestations frequently include arthralgias or stiffness and less commonly include swelling or other signs of inflammation. These signs and symptoms usually improve within a few days or weeks but occasionally last for months and, rarely, for years and can mimic rheumatoid arthritis. B19-associated joint disease cannot be distinguished clinically from other arthropathies without B19-specific laboratory testing.

Persons with underlying hematologic disorders characterized by decreased red cell production (e.g., thalassemia) or increased red cell destruction (e.g., sickle cell disease

and hereditary spherocytosis) can acutely develop severe symptomatic anemia (e.g., fatigue, pallor, tachycardia, and congestive heart failure) because of the red blood cell aplasia. This transient aplastic crisis can be complicated by bone marrow necrosis or stroke and can lead to death. Hematologic recovery generally occurs within 7 to 10 days of presentation. Medical management of the patient may necessitate hospitalization and supportive care including red cell transfusions. Prior to hematologic recovery, the patient is viremic and should be considered infectious. Erythema infectiosum and arthropathy are usually not observed in persons with transient aplastic crisis. In some cases, by precipitating transient aplastic crisis, B19 infection may serve to unmask a previously undiagnosed, preexisting condition such as autoimmune hemolytic anemia.

Immunocompromised patients may develop chronic B19 infection and chronic anemia. This complication of B19 infection has been identified most often in children undergoing treatment for leukemia, in persons infected with human immunodeficiency virus (HIV), and in some cases, following transplantation (e.g., solid organ and stem cell) *(144,172–177)*. The clinical course varies. In leukemic patients, completion, modification, or interruption of chemotherapy may lead to spontaneous viral clearance. In persons with HIV infection, viral clearance can be achieved by administering intravenous immunoglobulins (IVIGs), but relapse can occur. Chronic B19 infection has rarely been documented in patients without recognized immunodeficiency.

Maternal B19 infection during pregnancy is associated with a risk for fetal anemia, nonimmune hydrops fetalis, spontaneous abortion, and fetal death (*117,171–181,*182). These conditions are dependent on several factors including maternal susceptibility to B19 infection, the prevalence of B19 infection (e.g., epidemic years, seasonality), and the timing of maternal infection relative to gestation age. The fetus is particularly susceptible to severe anemia with B19 infection owing to its expanding red cell volume, increased erythrocyte turnover, and immature immune system that often cannot control infection. Vertical transmission of B19 infection from mother to fetus can lead to chronic fetal anemia with high-output congestive heart failure with fetal death *(150,178,183,184)*. However, the natural history of fetal B19 infection is varied: approximately 30% to ~50% of maternal infections may lead to fetal infection *(145,150)*, with most neonates being born normal *(145,148,149,178,185,186)*. Fetal death appears to be highest in association with infection between the 10th and 20th weeks of gestation (*178–181,*182). This may be due to increased transplacental transfer of maternal antibody during the second trimester. Chronic red cell aplasia in infancy has been reported as a complication of intrauterine B19 infection in a few cases *(187)*. Infants born to women with B19 infection during pregnancy do not have a significantly increased incidence of congenital anomalies *(117,148,150,185,186)*. Rare case reports have presented findings of congenital anomalies following intrauterine B19 infection, but no associations have been proven *(148,188–191)*.

In addition to the well-established disease associations described above, acute and chronic B19 infections have been reported in sporadic cases of hemophagocytic syndrome, peripheral and central neurologic disorders, autoimmune conditions, hepatitis, thyroiditis, myocarditis, systemic vasculitis, and a variety of other conditions that are reviewed elsewhere (*113,117,*170,*171–173,192–195*). Etiologic links between B19 and many of these conditions have not been confirmed in controlled studies or by histopathologic criteria, and for some of these conditions, B19 infection may be coincidental or represent an opportunistic pathogen in an abnormal host. Associations with these less common conditions is often prompted by the identification of B19 DNA via PCR in patients' blood or tissues. B19 DNA has been found in asymptomatic healthy patients months after infection—the significance of this is currently not well understood *(196)*.

Pathogenesis

There is one serotype of B19 and three currently recognized genotypes *(113–115,197–200)*. B19 binds to the blood group P-antigen (globoside) *(201)* and infects and replicates in human erythroid progenitor cells *(202)*. Bone marrow is the primary tissue for viral replication, but as a result of extensive extramedullary hematopoiesis, fetal liver is also an important site of infection *in utero (203)*.

The natural history of B19 infection has been evaluated through human volunteer studies *(204,205)*. Viremia is usually detectable at day 6 after intranasal inoculation, peaks between 6 to 12 days, and resolves by 11 to 16 days. Viremia is associated with cessation of new red cell production and reticulocytopenia along with nonspecific signs and symptoms including fever, headache, myalgia, and chills. During the peak of the viremia, B19 DNA can also be detected in respiratory secretions (170,*204*). In immunocompromised patients with chronic B19 infection, such as pure red-cell aplasia, viremia persists in the absence of or low antibody production. In immunocompetent persons, the humoral immune response is best characterized with the production of specific immunoglobulin antibodies (IgM, IgG) (*143,144,*170,*204*). IgM antibody response is first detectable at 10 to 14 days after infection. The timing of the IgM response correlates with clearing of the viremia and onset of immune-mediated rash and arthralgias. IgM can be typically detected 2 to 3 months or longer after initial infection. High levels of IgM antibodies usually denote acute infection. An IgG response is detectable several days after the appearance of the IgM response and persists long term in immunocompetent persons and presumably confers lifelong protection against disease and reinfection. The importance of IgG in protection is emphasized by the efficacy of IVIG in controlling and sometimes curing B19 infection in immunocompromised patients *(144)*.

Lytic infection of red cell progenitors and arrest of hematopoiesis lead to the anemia commonly associated with B19 infection. Anemia is not clinically significant in persons without underlying illness primarily because of the brief interruption of hematopoiesis and the long lifespan of the red blood cell. However, among persons with underlying medical problems resulting in increased demand or turnover of red blood cells, including sickle cell disease, hereditary spherocytosis, thalassemia, and acquired hemolytic anemias, B19 infection can lead to a transient aplastic crisis, with hemoglobin levels falling 30% or more. In such cases, a hypoplastic or aplastic erythroid and normal myeloid series are seen in the patient's

bone marrow. A brisk reticulocytosis is seen with the onset of host immune response and termination of viremia. Some patients with an impaired immune response cannot control infection and develop chronic hypoplasia or aplasia of the erythroid series in the bone marrow.

Laboratory Diagnosis

Virus Isolation Although erythroid cell lines have been developed that support B19 cultivation *(206,207)*, these are not efficient virus isolation tools and therefore have not been used for clinical diagnosis.

Antibody Detection Antibody assays are currently the cornerstone of laboratory diagnosis for most B19 infections. Acute B19 infection in the immunologically normal patient can be diagnosed by detection of B19 IgM antibodies that develop within 10 to 12 days after infection and can remain present for months. B19 IgG antibodies usually become detectable several days after the appearance of IgM; IgG can persist for years and perhaps for life. Over 90% of patients with erythema infectiosum or arthropathy will have both B19 IgM and IgG antibodies at the time of presentation with acute onset of rash. IgM antibody is present in 80% of patients with transient aplastic crisis *(123,208)*; however, serologic studies can be misleading for persons presenting in the early stages of anemia prior to the rise of B19-specific antibody. Serologic studies of mother and infant can also be of use in diagnosing acute B19 fetal infections.

Unless removed, high levels of B19-specific IgG can compete with and block detection of IgM antibodies, and since rheumatoid factors or nonspecific binding of IgM antibodies can yield false-positive reactions, indirect IgM assays tend to have lower sensitivity and specificity than IgM-capture assays *(209)*. Acute infection can also be evaluated using non–IgM-based assays designed to detect either a high frequency of low-avidity antibodies *(210)* or antibodies recognizing antigens indicative of acute or early convalescent infection *(211–213)*. Antibody assays are not useful for diagnosing B19 infection in immunodeficient patients who may not have a normal antibody response to the infection. In such situations, immunohistology and nucleic acid detection are more appropriate diagnostic tools.

Antigen Detection Current antigen detection assays (enzyme-linked and radioimmune assay) are not sensitive enough to reliably diagnose acute infection *(123,208)*. Immunohistologic techniques have been useful for detection of B19 antigens in fetal tissues and bone marrow samples *(123,213)*.

Nucleic Acid Detection Polymerase chain reaction (PCR) assays are highly sensitive and specific tests that are commonly used to detect both acute and chronic B19 infections, as well as to perform the screening of blood products for the presence of B19 parvovirus. Sensitivity and specificity of these assays can vary greatly between laboratories *(214)*. Qualitative and quantitative PCR assays have both been used in clinical diagnoses *(215–217)*. Quantitative PCR assays can detect as few as 10^2 genome copies per mL and are used to measure viral load in blood components. Results from B19 PCR assays must be carefully interpreted because of the potential for false–positive results from amplicon contamination and because low viral loads may not be indicative of acute B19 infection or associated with disease.

Prevention and Control

Currently, no vaccine is approved for B19 infection. Although the majority of B19 infections are mild and self-limiting, a vaccine would be beneficial, particularly in specific populations such as pregnant women, immunocompromised persons, and those with underlying hemolytic disorders or increased erythropoiesis where B19 infection can cause significant morbidity. Preliminary results from a randomized, double-blinded, phase 1 trial were promising—adult volunteers receiving a recombinant parvovirus B19 vaccine developed neutralizing antibody titers *(218)*. The public health intervention of a vaccine for a high-risk population has prompted the investigation into the relationship of B19 infection and severe anemia among children in areas endemic for malaria *(219–222)*.

Because B19 infection is primarily transmitted through respiratory secretions and close contact (e.g., droplet and fomite), attention to handwashing and not sharing food or drinks should be effective for preventing spread of the virus. However, since the classic signs and symptoms of B19 infection (e.g., rash and arthralgias) are not apparent until after the patient has been viremic, good hygienic practices, particularly during outbreaks, need to be universally applied to be effective at prevention.

Parvoviruses, in general, are highly resistant to disinfection procedures and can remain infectious in the environment for prolonged periods of time; the virus is stable in lipid solvents such as ether and chloroform. There are no specific data about the viability of B19 in the environment, but on the basis of properties exhibited by other members of the *Parvoviridae* family, surfaces contaminated with bodily fluids containing B19 should be considered infectious. In one case, vaginal delivery of a B19-infected fetus resulted in widespread contamination of environmental surfaces in the patient's room with B19 DNA (129).

Patients and staff with the classic signs of erythema infectiosum or B19-associated arthropathy are past the infectious period and therefore do not require special precautions (42,44,*223*). Patients with transient aplastic crisis and patients with chronic B19 infection may be viremic for up to a week after presentation and do pose a risk of healthcare-associated transmission. Little is known about the risk for transmission from immunodeficient patients. The HICPAC recommends maintaining Droplet Precautions for the duration of hospitalization when chronic disease occurs in an immunocompromised patient; for patients with transient aplastic crisis or red-cell crisis, Droplet Precautions should be maintained for 7 days (42). Most patients with transient aplastic crisis will mount an effective immune response that cures the infection; isolation precautions can be removed after hematologic recovery, which usually occurs 7 to 10 days after presentation. For chronically infected patients treated with immunoglobulins, isolation precautions can be removed if hematologic recovery occurs and if available virologic surveillance (e.g., PCR testing) demonstrates that the B19 viremia has been cleared. In pregnant women with suspected or proven intrauterine B19 infection, amniotic

fluid and fetal tissues should be considered infectious, and Contact Precautions should be used in addition to Standard Precautions if exposure is likely (129).

B19 community outbreaks, particularly those associated with schools and day-care centers, are often associated with heightened concern about infection of persons at risk for complications, particularly pregnant women. Depending on the community and on the assay used, 40% to 60% of women of childbearing age test positive for B19 IgG antibodies and therefore are not thought to be susceptible to infection. The risk of fetal death in pregnancy can be estimated to be 0.4% to 3% after exposure to B19 in the household and 0.16% to 1.2% after exposures associated with working in a school or childcare setting with a B19 disease outbreak. The American College of Obstetrics and Gynecology (ACOG) recommends that pregnant women exposed to B19 parvovirus should have serologic testing for B19 performed to determine susceptibility and possible evidence of acute B19 infection (182). Pregnant women with evidence of acute B19 infection should be closely monitored (e.g., serial ultrasound examinations) by their healthcare provider. The CDC recommends that persons be informed of potential exposures to B19 and that efforts to lower the risk of exposures (e.g., avoiding the workplace or school environment) be made on an individual basis after consultation with family members, healthcare providers, public health officials, and employers or school officials *(223)*.

Many HCP already have B19 IgG antibodies from prior infection and are believed to be at low risk of becoming reinfected or of transmitting B19 to patients or other staff (44). Serologic screening of asymptomatic HCP to identify susceptible staff is not currently recommended by the CDC. HCP should be advised that they are at risk of B19 infection after exposure in the hospital or in the community and that there may be a risk for further transmission to patients. Routine infection control practices, particularly hand washing, should minimize the risk for transmission. Pregnant personnel should be advised about potential risks of B19 infection to the fetus and advised to consult with their healthcare providers; the CDC and ACOG do not recommend that pregnant personnel routinely be excluded from caring for patients with B19 infection (182,*223*).

In July 2009, the U.S. Food and Drug Administration issued guidance for nucleic acid testing (NAT) to reduce the possible risk of human parvovirus B19 transmission by plasma-derived products *(224)*. The goal was to identify and prevent the use of plasma-derived products containing high levels of parvovirus B19. Parvovirus B19 viral loads in manufacturing pools should not exceed 10^4 IU/mL. B19 NAT should also be performed on minipool samples to screen plasma units intended for manufacturing into plasma-derived products.

Treatment

No specific antiviral drugs are currently available for treatment. Most cases of erythema infectiosum or B19-associated arthropathy are mild and self-limited and require no treatment other than supportive care. Transient aplastic crisis can be a life-threatening event, but if diagnosed early, it can be managed with red cell transfusions to relieve signs and symptoms associated with anemia. Chronic B19 infections in immunosuppressed patients have been successfully controlled and sometimes cured with IVIG *(225,226)*. Relapses of anemia have been successfully treated with additional IVIG doses. Use of immunoglobulins to prevent or treat other types of B19 disease has not been studied. HIV-infected persons with chronic B19 infection can benefit from optimizing antiretroviral therapy to improve immune status. There are no definitive or established guidelines for clinical management of pregnancies complicated by intrauterine B19 infection and fetal hydrops *(117)*; however, ACOG has published guidelines to aid practitioners with decisions concerning diagnosis and clinical management, including serologic testing and serial ultrasound examinations (182). Intrauterine blood transfusions can be considered for treatment of B19-associated hydrops. However, since fetuses can survive free of sequelae without treatment and since transfusions can be associated with fetal death, it is not possible to determine when the benefits of this procedure outweigh the risks.

CHAPTER 52

Healthcare-Associated Infections in Newborn Nurseries and Neonatal Intensive Care Units

Kristina Bryant

The neonate is a vulnerable host. While advances in newborn intensive care have permitted the survival of low-birth-weight and sick infants, life-saving, invasive therapies and prolonged hospitalizations place these infants at risk for infection. The immunologic immaturity of the newborn infant, particularly the infant born prematurely, increases this risk. Healthcare-associated infections (HAIs) contribute substantially to morbidity and mortality in hospitalized neonates *(1–3)*.

EPIDEMIOLOGY

In general, infections not present or incubating at the time of admission are considered healthcare-associated. A practical adaptation of this definition for newborns has been to define HAIs as those that present after 48 hours of age. This convention may result in misclassification of some infections, as some that result from perinatal exposure to maternal genital flora may not manifest until ≥48 hours. Likewise, failure to use aseptic technique for invasive procedures such as umbilical catheter placement may result in HAIs that manifest in <48 hours. Because of the difficulty in correctly classifying infections, the Centers for Disease Control and Prevention (CDC) has defined all neonatal infections, whether acquired during delivery or during hospitalization, as healthcare-associated unless evidence indicates transplacental acquisition *(4)*.

Rates of HAIs in well newborn nurseries are low, ranging from 0.3 to 1.7 per 100 newborns *(5–7)*. Short hospital stays and exposure to few invasive devices or procedures account for the low rates of infection. The difficulty of performing postdischarge surveillance for infection may lead to underrecognition of HAIs such as conjunctivitis and pustulosis. Outbreaks in newborn nurseries have been linked to vertical transmission from a mother to her infant with subsequent transmission to other infants, or occasionally sick healthcare workers *(8)*.

Reported rates of HAIs in neonatal intensive care units (NICUs) have ranged from 6% to 25% *(9–12)*, while a multicenter study in Europe reported rates of 7% *(13)*. Lack of consistent definitions, heterogeneous patient populations, and variable exposure to invasive devices make comparison of these studies difficult. A national point-prevalence survey conducted in the United States by the Pediatric Prevention Network identified HAIs that met CDC definitions in 11.4% of NICU patients (14). National prevalence studies from Spain *(15)* and Norway *(16)* yielded similar results, with reported rates of 16.7% and 14%, respectively.

Rates of healthcare-associated neonatal infections are 3 to 20 times higher in resource-limited countries *(17)*. A 10-year prospective surveillance study of six NICUs in Brazil identified HAIs in 69% of admitted infants *(18)*.

Prematurity and low birth weight are consistently identified as a significant risk factors for infection. According to data reported by the National Institute of Child Health and Human Development (NICHD) National Research Network over a 2-year period, 21% of very low birth weight (VLBW) infants developed late-onset sepsis. Rates of infection were inversely related to birth weight and gestational age *(19)*.

An overall infection rate is of limited use, because it is influenced by hospital or nursery type, patient mix, referral patterns, whether or not newborn surgery is performed, the infections targeted for surveillance, and the definitions used for these infections *(20–22)*. Also, total infections must be distinguished from the numbers of infected patients, because many patients have more than one infection. Infection rates expressed per admission or per patient-day may be useful for following infection rates in a specific NICU over time or for interhospital comparison, provided that the rates are adjusted for severity of illness or are expressed by risk group.

Birth weight is commonly used as a marker for severity of underlying illness in the NICU. Goldmann et al. *(23)* found a strong correlation between infection and low birth weight, with a mean birth weight of 1,581 g for infants with major HAIs versus 2,607 g for those without infections. Use of invasive devices may be an even more relevant marker for average severity of illness and for the type of NICU. NICU infection rates vary with intensity of device use. In a study involving 35 hospitals, assessment of device use (central or umbilical lines and ventilators) by total device-days and calculation of device-associated infection rates by device-days controlled for this variation. Stratification

by birth weight did not eliminate the need to control for device use.

The National Nosocomial Infection Surveillance (NNIS) system was established by the CDC in 1970 as a voluntary, national surveillance system for HAIs. NNIS utilized standardized definitions and developed risk-adjusted infection rates for different kinds of intensive care units, including NICUs. Participating NICUs could report data on all HAIs at all body sites. In 2006, NNIS and two other national surveillance systems administered by the CDC were replaced by the National Healthcare Safety Network (NHSN), a secure, Internet-based surveillance system. Between 2006 and 2008, more than 1,500 hospitals, including 150 NICUs, contributed data about device-associated and procedure-associated infections (24). Definitions of HAI in the newborn are based on those for older children and adults with modifications for children <12 months of age *(4)*, and device-associated infections in NICU patients are stratified by birth weight.

RISK FACTORS FOR INFECTION

Immunologic Immaturity

Immaturity of the newborn immune system and defects in structural defenses make the neonate, especially the neonate born prematurely, uniquely susceptible to infection. The skin, for example, normally provides a mechanical barrier between the host and the environment. In infants born before 32 weeks of gestation, the stratum corneum is poorly developed, and the skin is fragile, very permeable, and easily traumatized by routine procedures such as cleansing or removal of adhesive tape. Injured skin provides a portal of entry for infectious agents. Similar defects are seen in the alimentary tract, where low levels of mucosal immunoglobulin A, high gastric pH, and short gastric emptying times increase the susceptibility of the newborn to gastrointestinal infections.

Immune function in the newborn has been extensively reviewed elsewhere *(25)*. Term and preterm newborns have functioning B cells, but there is little antibody synthesis *in utero*. Postnatally, the B cells make antibodies to protein antigens but respond poorly to polysaccharide antigens, including the bacterial capsular polysaccharides of group B streptococcus (GBS) and *Haemophilus influenzae*. In the first weeks of life, the newborn depends on passively transferred maternal antibody and the repertoire of antibodies received depends on maternal exposure. Because placental transfer of antibody occurs in the third trimester, infants born at <34 weeks have low levels of immunoglobulin G antibody.

The newborn has a high total T-lymphocytic count, but phenotypic surface markers differ from those in the older child. Cytotoxic T-cell activity is decreased, as is T-cell helper function. The T-cell-dependent antigen-specific response is delayed, and there is limited production of several cytokines. These maturational defects in T cell function enhance the susceptibility of the newborn to intracellular pathogens such as *Listeria, Toxoplasma,* and *Salmonella*. Natural killer cell activity, important in control of herpes group viral infections, is also decreased.

Reduced numbers and activity of alveolar macrophages in the lungs of term and preterm infants increase the risk for pulmonary infection. The newborn has a decreased granulocyte storage pool and defective neutrophil and monocyte chemotaxis. Neutrophil phagocytosis and antimicrobial activity are largely intact but may be decreased when bacterial density is high or when opsonins are limited. Although production of complement proteins begins early in gestation, mature activity of the complement system may be delayed until 6 to 10 months of age.

Sources of Infectious Agents and Modes of Transmission

The newborn may develop infection as a result of exposure to maternal flora during labor or delivery, or postpartum from maternal, hospital, or community sources. Postnatally, the hands of healthcare workers are the most common vehicles for transmission of potential pathogens in neonatal units *(26,27)*. Nursery outbreaks of *Staphylococcus aureus*, enterococcus, a variety of gram-negative bacilli, and viruses have been attributed to hand transmission *(1,28–35)*. In one study, gram-negative bacilli were found on the hands of 75% of NICU personnel *(36)*. Usually, hands are transiently contaminated, and hand washing removes the microorganisms and interrupts transmission *(37)*. A few outbreaks have been linked to microbial contamination of hand washing agents *(38,39)*.

Occasionally, personnel who are persistent carriers of potential pathogens such as *S. aureus* or group A *Streptococcus* (GAS) have been implicated in nursery outbreaks *(40,41)*. Artificial fingernails may lead to increased hand carriage of gram-negative microorganisms, and healthcare workers with artificial nails have been linked to transmission of *Pseudomonas aeruginosa (29,30)* and *Klebsiella pneumoniae (42)*.

Patient care equipment may also serve as a vehicle for transmission. Multiple outbreaks have been associated with contaminated respiratory care equipment including ventilator circuits *(43,44)* laryngoscopes *(45)*, balloons used for manual ventilation *(46)* and suction devices *(47–49)*. Inadequate disinfection of rectal thermometers contributed to nursery outbreaks of *Salmonella eimsbuettel (50)* and *Enterobacter cloace (51)*.

Infusion of contaminated intravenous fluids, including total parental nutrition solutions and lipid emulsions, may result in bacteremia or meningitis *(52–60)*. Exposure to contaminated topical preparations and medications, including contaminated eyewash *(61)*, umbilical cord wash *(62)*, and glycerin *(63)* may also result in invasive infections. Use of contaminated ultrasound gel resulted in an outbreak of pyoderma in hospitalized neonates *(64)*, while bathing practices have been linked in clusters of listeriosis *(65)* and *Stenotrophomonas* infections *(66)*.

Blood transfusions may be a source of viruses such as hepatitis A virus, hepatitis B virus (HBV), and hepatitis C virus (HCV) *(67–69)*. Before current screening practices, blood products were also a source for perinatal cytomegalovirus (CMV) transmission *(70,71)*. Neonatal transfusion-acquired malaria has been rarely reported *(72,73)*.

Hospitalized neonates are at risk for food-borne infection. Powdered formula is not sterile, and feeding of reconstituted formula has been associated with gram-negative

bacteremia and meningitis *(74)*. Expressed breast milk may be contaminated during collection *(75–77)* and both breast milk *(78–80)* and formula *(81,82)* may be contaminated during storage and handling. Feeding practices may also contribute to infection. Pathogens may be acquired during insertion or handling of nasogastric tubes used for feeding *(35,83,84)*. Feedings administered though nasogastric tubes by continuous infusion remain at room temperature for several hours, creating the potential for microbes to proliferate in the reservoir or tubing during infusion *(77)*.

Infected personnel and visitors may introduce pathogens into the nursery, especially during community outbreaks of viral infections *(85)*. Both symptomatic healthcare providers *(86)* and visitors have been the source of healthcare-associated pertussis in the NICU.

Environment

Infection rates in the NICU increase with overcrowding and understaffing. In one report, a 16-fold increase in outbreaks of *S. aureus* infection was observed when the infant-to-nurse ratio exceeded 7 and there was a sevenfold increase when the nursery was crowded *(87)*. Increasing rates of endemic methicillin-resistant *S. aureus* (MRSA) were also linked to overcrowding and understaffing, with eradication of MRSA when these conditions improved *(88)*. An outbreak of *E. cloacae* infection was associated with understaffing and overcrowding in another report *(89)*.

Invasive Procedures

Any procedure that disrupts the normal barriers to infection may predispose the newborn to infection. Scalp electrodes, for example, provide a portal of entry for maternal genital microorganisms. Although infectious complications occur in <1% of infants and most are benign abscesses, occasionally severe cellulitis, bacteremia, osteomyelitis, and disseminated herpes simplex virus (HSV) occur *(90,91)*. Osteomyelitis has resulted from infected toe and heel punctures and femoral venipunctures. Surgical-site infections (SSIs), as well as device-associated infections including catheter-associated bacteremia, bladder catheter-associated urinary tract infection, and ventilator-associated pneumonia (VAP), are discussed in detail below.

INFECTIONS AT SPECIFIC SITES

Skin, Subcutaneous Tissues, Mouth, and Eyes

Pustules, cellulitis, subcutaneous abscesses, lymphadenitis, and infections at sites of percutaneous punctures are most often due to *S. aureus*, or less commonly to streptococci and gram-negative bacilli and other microorganisms *(92)*. Microbes causing infections at scalp monitor sites are more diverse and include maternal genital microorganisms such as HSV *(90,91)*.

Omphalitis is uncommon, occurring in 0.5% of term and 2% of preterm infants in one report *(93)*. The presentation varies from mild erythema or serous drainage to purulent discharge, cellulitis, and acute necrotizing fasciitis of the abdominal wall. *S. aureus* is most often isolated, but GAS, coagulase-negative staphylococci (CONS), enterococci, gram-negative rods, and anaerobes may also be involved *(94)*. A mortality rate of 7% was reported in a series, with fatalities associated with rapidly progressing cellulitis or necrotizing fasciitis *(95)*.

Mastitis, characterized by redness, swelling, or induration of the breast, is seen occasionally in term infants in the first 3 weeks of life *(96)*. *S. aureus* is the most common pathogen, although disease due to gram-negative microorganisms such as *Escherichia coli* and *Proteus mirabilis* is also reported *(97)*.

Circumcision is the most common surgical procedure performed in the newborn, although NHSN considers circumcision infections with skin and soft-tissue infections rather than with SSIs. Reported infection rates are low, at 0.06% to 0.4% *(98,99)*. Most are simple skin infections, but more serious complications, including necrotizing fasciitis, have occasionally been reported *(100)*. An outbreak of neonatal pustulosis due to a community-associated MRSA strain in one newborn nursery was attributed in part to circumcision practices *(101)*.

Healthcare-associated conjunctivitis is common in NICUs *(102,103)*. The conjunctivae of neonates may become colonized with nasopharyngeal and skin flora during routine care. The immature lacrimal system of preterm neonates facilitates pooling of bacteria and other debris on the surface of the eye, leading to conjunctival infection. The most common bacterial pathogens associated with healthcare-associated conjunctivitis include CONS, *S. aureus*, *Klebsiella* species, *Pseudomonas aeruoginosa*, *Serratia marscescens, H. influenzae,* and *E. coli (102)*. Viral conjunctivitis also occurs. Risk factors for conjunctivitis include low birth weight and the need for respiratory support, including nasal CPAP and mechanical ventilation. *P. aeruginosa* conjunctivitis in particular has been associated with contaminated resuscitation equipment *(47)*, and infection in intubated patients has been related to endotracheal tube colonization and eye contamination during suctioning *(104)*. Opthalmalogic exam for retinopathy of prematurity has been associated with the development of conjunctivitis, including outbreaks of adenoviral conjunctivitis *(105,106)*.

Bloodstream Infections

Bloodstream infections (BSIs) are the most common HAI in hospitalized neonates, and most are related to central venous catheters (CVCs) *(13*,14,*22)*. While there is significant variability in infection rates among NICUs, higher rates of device-associated bloodstream infection are consistently reported among the smallest, most premature infants (24). The pooled mean rates of umbilical catheter-associated BSIs in Level II/III NICUs that reported data to NHSN from 2006 to 2008 ranged from 1/1,000 catheter days in infants with birth weights of >2,500 g to 5.7/1,000 catheter/days in infants with birth weights ≤750 g. Central line–associated BSIs (CLABSIs) for the same time period ranged from 1.2/1,000 catheter days for the largest infants to 4.9/1,000 catheter days in infants in the smallest birthweight category. Even higher rates of catheter-associated BSIs are reported by NICUs in resource-limited settings *(107)*. NHSN does not further stratify CLABSIs by type of catheter, but some data suggest lower rates of infection with percutaneously inserted central catheters (PICCs) compared with tunneled catheters *(108)*, while a multicenter study showed no difference *(109)*.

Coagulase-negative staphylococci, *S. aureus*, enterococci and *Candida* species are the most common causes of CLABSIs *(110)*. Among neonates with PICCs, 75% of CLABSIs are caused by CONS (111), although differentiating true CONS bacteremia from culture contamination is challenging. Increasingly, *S. aureus* CLABSIs are due to MRSA. From 1998 to 2008, the rates of MRSA CLABSIs reported to NHSN rose 49% *(112)*.

In additional to low birth weight and gestational age, mechanical ventilation *(113,114)* and total parenteral nutrition *(114)* are risk factors for the development of CLABSIs. In one study involving 3,470 catheter days, sampling of blood through the central line and disconnection of the catheter increased the risk of CLABSIs *(115)*. The importance of catheter location on the incidence of infection remains controversial. One study identified a higher rate of catheter-related sepsis in VLBW infants with femoral PICCs compared to those with nonfemoral PICCs (22.5% vs. 12 or 10.9 vs. 6.8 episodes/1,000 catheter days) *(116)*. Another study found no difference in infection rates when PICCs placed in an upper extremity were compared to those placed in a lower extremity, although the pathogens associated with infections did vary by site *(117)*. Coagulase-negative staphylococcal infections were more common in infants with upper extremity catheters, while more gram-negative infections were diagnosed in children with lower extremity catheters.

Some (118) but not all studies have demonstrated that the risk of infection increases with the duration of catheter use. Umbilical catheterization for more than 5 days is recognized as an independent risk factor for sepsis *(113)*. In one study, catheter duration of 10 to 21 days was associated with a 40-fold risk of gram-negative BSIs in VLBW infants, while the risk was 90-fold with catheter duration of >21 days (119). In a retrospective cohort study in a single NICU, the incidence rate of CLABSIs increased by 14% by day during the first 18 days after PICC insertion. The trend reversed from days 19 to 35 after insertion, but after day 36, the incidence rate of CLABSIs increased by 33% per day.

Healthcare-associated BSIs can also occur in the absence of a central venous catheter. When all causes of late-onset sepsis are considered, the pathogens are similar to those observed with CLABSIs *(19,114)*. Although gram-positive infections still account for the majority of infections, the proportion of BSIs caused by gram-negative microorganisms is higher. In patients with short gut syndrome, enteric gram-negative bacilli and yeast predominate, probably because of translocation of bacteria from the gastrointestinal tract and subsequent seeding of the catheter *(120)*. Nasal cannula continuous positive pressure airway use and H_2 blocker/proton pump inhibitor therapy are also risk factors for gram-negative BSIs in VLBW infants (119).

Central Nervous System Infections

The burden of healthcare-associated meningitis in NICU infants is difficult to quantify, as not all infants with symptoms of infection undergo lumbar puncture. In a study of 9,641 VLBW infants born at NICHD Neonatal Research Network Centers, only 1.4% infants who survived at least 3 days developed meningitis, representing 5% of infants who underwent lumbar puncture (121). Notably, only half of the infants who had a blood culture obtained because of suspected sepsis also had a lumbar puncture performed, suggesting that some cases of meningitis could have been missed. One-third of infants with meningitis had negative blood cultures.

The most frequent pathogens isolated in VLBW infants with healthcare-associated meningitis include CONS (29%), *Candida* species (14%), and enterococci (13%). In the NICHD study, gram-negative microorganisms, including *E. coli*, *Klebsiella,* and *Serratia* species, accounted for 19% of episodes. Multiple NICU outbreaks of gram-negative meningitis have been reported *(56,122,123,124–127)*, some of which have been linked to feeding practices. A cluster of *Elizabethkingia meningosepticum* (formerly *Flavobacterium meningosepticum*) was linked to contamination of the formula preparation area and bottle stoppers *(128)*. Cases of *Chronobacter sakazakii* (formerly *Enterobacter sakazakii*) have been linked to contaminated powdered infant formula *(129)*.

Risk factors for gram-negative meningitis include underlying urinary tract anomalies and hydrocephalus *(130)*. Meningitis may also occur as a complication of ventricular drain and shunt placement *(131)*. In a study of shunt placement for hydrocephalus in newborns weighing <2,000 g, the shunt infection rate was 25% after primary placement and 36% after revision *(132)*. Common causes of shunt infection include CONS, *S. aureus,* and gram-negative bacilli *(133)*. Young age, prematurity, and the presence of intraventricular hemorrhage, a known complication of prematurity, are associated with an increased risk of shunt infection. In one study, prematurity increased the risk for shunt infection nearly fivefold. Proposed reasons for this increased infection risk may include a high density of CONS on the skin of preterm infants and colonization with more virulent CONS strains. Strategies for the prevention of ventriculoperitoneal (VP) shunt infections are similar to those proposed for the prevention of other SSIs. The use of antibiotic-impregnated shunt systems reduced infections in one small case series of premature infants and deserves further study *(133)*.

Respiratory Tract Infection

Early-onset pneumonia is usually related to intrapartum exposure and is most often due to GBS *(134)*. Maternally transmitted *Ureaplasma urealyticum* infection occasionally causes pneumonia or respiratory distress in VLBW, premature infants *(135)*.

Most cases of late-onset pneumonia are device-related *(134)*. VAP is common in preterm infants, many of whom require prolonged ventilatory support. In a prospective study, nearly 30% of infants born at <28 weeks of gestation developed VAP; infection was significantly associated with mortality (136). Not surprisingly, the rates of VAP reported through NHSN are consistently highest in infants of <1,000 g birth weight and are similar to those reported in pediatric intensive care units and adult medical intensive care units (24). Pooled mean rates of VAP for level II/III NICUs reporting data to NHSN from 2006 to 2008 ranged from 0.6/1,000 ventilator days in infants of >2,500 g birth weight to 2.7/1,000 ventilator days in infants of ≤ 750 g birth weight.

The true burden of VAP may not be known, because the diagnosis is difficult in NICU infants. While NHSN surveillance definitions for VAP include criteria for infants <1 year of

age, these definitions have not been validated in premature neonates. Comorbid conditions such as bronchopulmonary dysplasia may mimic the clinical and radiographic features of VAP *(137)*. Ultimately, many infants are treated empirically for presumed pulmonary infection.

Gram-negative microorganisms are thought to cause at least 30% of VAP episodes, but a specific microbiologic diagnosis is often difficult unless there is secondary bacteremia (14,*22*). Endotracheal cultures are rarely useful in the diagnosis of VAP because the respiratory tract of the intubated newborn rapidly becomes colonized with mixed gram-positive flora by the second week of mechanical ventilation, and gram-negative microorganisms after the fourth week *(138,139)*. The presence of purulence in a specimen suctioned from the endotracheal tube of a mechanically ventilated neonate has a poor positive predictive value for respiratory tract infection, including pneumonia and tracheitis *(139)*. Risk factors for VAP in NICU patients include duration of mechanical ventilation, reintubation, treatment with opiates, and endotracheal suctioning *(140)*. Other modes of assisted ventilation, including nasal continuous positive airway pressure, have been associated with the development of healthcare-associated pneumonia, albeit at lower rates than those associated with mechanical ventilation *(141)*.

Gastrointestinal Infections

Gastrointestinal infections account for ~1% of infections in NICUs. Microorganisms that cause community-associated outbreaks of gastrointestinal infection can also cause sporadic infections or clusters of infection in the NICU. Rotavirus is most commonly identified *(142)*, although outbreaks of norovirus and adenovirus have also been reported.

Outbreaks of bacterial enteritis are occasionally reported. *Salmonella* outbreaks in neonatal units may be prolonged, in part due to the prolonged incubation period of this microorganism, a high proportion of asymptomatic infants, and prolonged shedding by carriers *(143,144)*. Widespread contamination of the environment and equipment may also facilitate ongoing transmission *(145)*. The newborn with *Salmonella* gastroenteritis is at risk for bacteremia and focal infections are often seen. Symptomatic *Shigella* infection in the newborn is rare and transmission to other newborns is unusual; transmission to nursery personnel has been reported *(146)*. *Campylobacter jejuni* is an uncommon newborn pathogen and is usually of maternal origin, but healthcare-associated outbreaks have been described *(147,148)*.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) occurs in 1% to 8% of all NICU admissions *(149–151)*. It is a disease of prematurity, with preterm infants comprising 90% or more of all cases *(92)*. Rates of NEC are highest in infants born at 30 to 32 weeks of gestation and disease is most common in the second week of life *(152,153)*. The etiology of this disorder is not well understood but is thought to involve vascular compromise, bacterial invasion, and release of inflammatory mediators in the setting of a substrate such as enteral feedings.

While NEC is not strictly an infectious process, it is included in the CDC definitions of HAIs. Outbreaks in nurseries have been temporally associated with the isolation of a number of different microbes, including *Klebsiella* species; *Clostridia* species; *E. coli* species; *Serratia* species; *Pseudomonas* species; *Staphylococcus epidermidis*, *Salmonella* species, toxigenic *E. coli*, and *S. aureus* *(154–156)*. Because these microorganisms are commonly found in patients without NEC, proving a causal association has been difficult and association of specific microorganisms with clusters of NEC may reflect patterns of intestinal colonization rather than actual outbreaks of infection. The role of viruses in the pathogenesis of NEC is not well understood. Adenovirus *(157)*, norovirus *(158)*, coronavirus *(159)*, and rotavirus *(160,161)* have been recovered in infants with NEC but causality remains uncertain.

Prematurity is the principal risk factor for NEC, along with several factors related to infant feeding. The risk of NEC is 6 to 20 times higher in formula-fed infants than in breast milk-fed infants. While breast milk is generally protective, consumption of dry powdered human milk fortifier has been identified as a risk factor for NEC *(162,163)*. One study of >15,000 infants that utilized administrative data identified exposure to antenatal steroids as a risk factor for NEC independent of birth weight *(151)*.

A number of strategies have been evaluated for the prevention of NEC. Enteral probiotic supplementation reduces the risk of severe NEC and death in preterm infants with birth weights of at least 1,000 g *(164)*. In one study, oral immunoglobulin containing immunoglobulin A and immunoglobulin G was protective when fed to low-birth-weight infants for whom breast milk was not available *(165)*. Prophylactic oral vancomycin protected VLBW infants against NEC and may be indicated in specific situations, but routine use may increase the risk of colonization with resistant microorganisms *(166)*. Outbreaks of NEC, even those not temporally associated with isolation of a particular microbe, have been aborted with typical infection control interventions such as cohorting, environmental cleaning, and enhanced hand hygiene *(167)*.

Urinary Tract Infection

Some studies suggest that healthcare-associated urinary tract infections (HA-UTIs) are uncommon in NICU patients. In a national point prevalence survey of NICU HAIs in the United States, urinary tract infection occurred in only 10/827 patients (14). Most infections occurred in infants with birth weights of ≤1,000 g or >2,500 g. Similar rates were reported from a multicenter trial in Europe: only 0.3% of infants developed HA-UTIs *(13)*. Single center studies report rates of HA-UTIs ranging from 11.6 to 19/1,000 admissions *(168–170)*. Higher rates are reported in infants undergoing surgery *(170)* and in VLBW infants *(171)*. In a retrospective review of NICU infants weighing ≤1,500 g at birth, HA-UTIs developed in 8.1%.

The most common bacterial pathogens causing HA-UTIs in NICU patients include *E. coli*, *Enterobacter,* and *Klebsiella* species. In one 6-year retrospective study, *Candida* species were the most common cause of HA-UTIs *(169)*. Compared to bacterial UTIs, candidal UTIs occurred in less mature and younger (34 vs. 97 days) infants, and were more likely to be associated with bloodstream infection.

Most infants who develop HA-UTIs do not have underlying renal anomalies or vesicoureterial reflux. Exposure to

intermittent or indwelling urinary catheters is a well-described risk factor in pediatric patients *(168)*. Although catheters are used less frequently in newborns than in older children and adults, they carry a high risk of infection. This may be because of the use of feeding tubes, which are not well stabilized for bladder drainage rather than the balloon-tipped catheters used in older children *(172)*.

Surgical-Site Infections

Neonates are at increased risk for SSIs compared to children and adults *(173,174)*. In a study involving 1,094 neonates and 1,433 surgical procedures, 17% of patients developed a wound infection *(175)*. Staphylococci were most commonly isolated. Increased incision length, increased duration of surgery, and contamination of the operative site were all associated with an increased risk of infection but gestational age and birth weight were not. Rates of SSI are likely to vary by patient population, type of surgery, surgical site infection risk, severity of illness, and duration of operation. At present, NHSN does not provide risk-stratified, comparative data for neonates who develop SSIs, but such data are needed.

Guidelines for the prevention of SSI have been published. Although details of SSI prevention in pediatric surgical practice are not addressed in these guidelines, it is noted that SSI prevention measures effective in adult surgical care are indicated in pediatric surgical care *(176)*. Use of prophylactic antibiotics was associated with a lower infection rate after potentially contaminated surgery but not after clean surgery *(177)*. Unfortunately, there are few data on the efficacy of antibiotic prophylaxis for surgical procedures in the neonate *(175)* and detailed recommendations that address issues unique to this population are lacking. The current wound classification system used for determining the need for antibiotic prophylaxis (clean, clean contaminated, contaminated, and dirty or infected) was created based on adult surgeries, and it is unclear how these guidelines apply to neonatal operations *(178)*. The American Academy of Pediatrics (AAP) recommends systemic antibiotic prophylaxis "when the probability or morbidity of postoperative infection is high and the benefits of preventing wound infection outweigh potential risks for adverse drug reactions and emergence of resistant microorganisms" *(179)*. Specifically, prophylaxis is indicated for some clean wound surgeries and most clean contaminated wound surgeries (Table 52-1). Surgeries that involve contaminated wounds or dirty and infected wounds require treatment rather than prophylaxis. Ampicillin and gentamicin are recommended agents for surgical prophylaxis in all neonates <72 hours of age. For older neonates, prophylaxis is targeted to colonizing microorganisms, healthcare-associated microorganisms, and the operative site. Unfortunately, there is little consensus among pediatric surgeons about how these recommendations apply to specific neonatal surgical procedures, which agents should be used, and what duration of therapy is appropriate *(180)*.

Bone and Joint Infections

Neonatal osteomyelitis and septic arthritis are uncommon manifestations of HAI, with only one to three cases reported per 1,000 admissions to intensive care nurseries *(181)*. Both are usually hematogenous in origin and, as such, are most often caused by the same agents that cause neonatal sepsis, including GBS, *S. aureus,* a variety of gram-negative bacilli, and *Candida* species *(182)*. Osteomyelitis may also occur as a result of direct trauma related to heel puncture *(183)*, femoral venipuncture *(184)*, and fetal monitoring electrodes *(185)*. Most cases of bone and joint infection are sporadic, although outbreaks have been reported *(186)*.

TABLE 52-1

Indications for Surgical Antimicrobial Prophylaxis in Neonates

Clean wound surgeries[b]
Open heart surgery for repair of structural defects
Implantation of intravascular prosthetic material
Body cavity exploration in neonates
Neurosurgical procedures[a]
Clean-contaminated wound surgeries[b]
Gastrointestinal tract procedures involving obstruction
Gastrointestinal tract procedures when permanent foreign body in place
Biliary tract procedures involving obstruction
Urinary tract procedures in the setting of obstructive uropathy or bactiuria

[a]Most procedures.
[b]Includes but not limited to surgeries listed here.

INFECTIONS CAUSED BY SPECIFIC MICROORGANISMS

Staphylococcus aureus

S. aureus causes a wide spectrum of disease in neonates, from superficial skin infections to severe invasive disease including bacteremia, meningitis, osteomyelitis, and SSIs. Colonization is common; from 20% to 90% of newborns acquire the microorganism in the first week of life *(187)*. In NICUs, healthcare worker hands are implicated in transmission. In one study, 20/37 infants handled by a caregiver for 10 minutes through the portholes of incubators acquired that caregiver's strain of *S. aureus (27)*. Transmission may be reduced by hand washing *(26,188)*. Less commonly, outbreaks have been traced to nasal carriage by a healthcare worker, or the so-called cloud phenomenon *(40,41)*.

Increasingly, staphylococcal infections in NICUs are due to MRSA. According to data reported to NHSN, late-onset MRSA infection in US NICUs increased 300% from 1995 to 2004 (189). In units that conduct active surveillance, up to 40% of infants may be colonized *(190)*. Infants with MRSA colonization have a significantly higher rate of MRSA infection than those without colonization. In one study, the risk of infection in colonized infants was 26% versus 2% in non-colonized infants ($p < .001$; odds ratio 19.86). Other risk factors for infection include low birth weight and prematurity *(190,191)*.

The clinical manifestations of MRSA in neonates are similar to those seen with methicillin-susceptible *Staphylococcus*

aureus (MSSA). Bloodstream infections and skin and soft tissue infections (including postoperative wound infections) predominate, although in one report, infants with MRSA infections were younger at presentation than infants with MSSA infection (23 vs. 32 days, $p < .03$) *(192)*.

As with MSSA, transmission of MRSA within NICUs is most often ascribed to transient hand carriage on the unwashed hands of healthcare workers *(88,193,194)*. Overcrowding and understaffing may facilitate the MRSA spread *(87,195)*. Other sources include colonized or infected healthcare workers *(196)*, an infected or colonized family member *(197)*, or contaminated breast milk *(198)*. Rates of maternal vaginal or rectovaginal MRSA colonization in pregnant women range from 0% to 10% *(199–202)*. Nevertheless, maternal to child transmission with subsequent early-onset MRSA infection is rare *(200,201)*. Community-acquired MRSA chorioamniotitis with subsequent transmission to a premature neonate who developed MRSA sepsis has been described *(203)*.

MRSA has become endemic in some neonatal units, with ongoing introduction and transmission of multiple, distinct molecular strains over time *(204)*. Nevertheless, several centers have eradicated transmission using a multimodal approach to infection prevention (88,*205*,206,*207*). Active surveillance cultures, aggressive implementation of Contact Precautions with monitoring of compliance, cohorting, and decolonization of patients and healthcare workers eradicated MRSA from one 18-bed NICU in a community hospital for 2.5 years *(205)*. Creation of distinct nursing cohorts to care for MRSA-colonized or -infected infants, MRSA-exposed infants, and newly admitted infants contributed to the control of MRSA outbreaks in centers in the United States and France (206,*208*).

Decolonization of MRSA carriers, including colonized infants, is controversial. The optimal decolonization regimen remains unknown. In two, small observational studies, application of mupirocin to the anterior nares of colonized infants did not reliably eradicate colonization or prevent infection (206,*208*).

A working group composed of infection prevention experts at Chicago-area hospitals has published consensus recommendations for the control of MRSA in NICUs (209). Key features of the recommendations include ready availability of hand hygiene products with monitoring of hand hygiene compliance, cohorting and Contact Precautions for colonized or infected infants, periodic active surveillance culture of patients' anterior nares, molecular analysis of MRSA isolates, and communication between regional NICUs to prevent spread between institutions with patient transfers. Notably, screening of healthcare workers to detect MRSA colonization is recommended only to corroborate or refute epidemiologic data that link a particular HCW to transmission.

Coagulase-Negative Staphylococci

CONS are the most common cause of HAIs in NICU infants. They cause 35% of late-onset sepsis in neonates *(19,210)* and are a common cause of CLABSIs (14,111). A syndrome of persistent bacteremia accompanied by thrombocytopenia has been described in neonates, even in the absence of CVCs *(211)*. Endocarditis, abscesses, omphalitis, SSIs, and meningitis occur occasionally, and a mild form of NEC has been described. The role of CONS as a cause of neonatal pneumonia is suggested by the isolation of microorganisms in the blood of infants with pulmonary infiltrates. CONS are also the major cause of ventricular shunt and drain infections *(212)*. The virulence of these common skin commensals in neonates may relate in part to their ability to adhere to catheter surfaces and proliferate to form a multilayered biofilm *(213,214)*. Production of slime may also help the microorganism evade host defenses *(214a)*.

Low birth weight, low gestational age, and procedures that interfere with skin or mucosal integrity, including placement of intravascular catheters, endotracheal tubes, and feeding tubes, increase the risk for CONS infection *(19,215,216)*. Receipt of intravenous lipids is also a risk factor; lipids may enhance the growth of CONS in colonized catheters *(217,218)*. CONS infections prolong the hospital stay of infected newborns and increase healthcare costs but are not associated with increased mortality *(219,220)*.

Effective measures for the prevention of CONS infection include limiting the use of invasive devices and aseptic technique for insertion and handling of intravascular and other prosthetic devices. Addition of vancomycin to intravenous fluids has been shown to reduce the incidence of CONS bacteremia in neonates but is not recommended for routine use because of potential for inducing vancomycin resistance *(221)*. Transmission of CONS with heteroresistance to vancomycin in NICU has been reported *(222)*.

Group B Streptococci

GBS is a leading cause of neonatal sepsis and meningitis among newborns. Approximately 10% to 30% of pregnant women are colonized with GBS, 50% of these women will transmit the bacteria to their newborns, and 2% of colonized infants will develop disease. Early-onset disease usually presents on the first day of life with septic shock, pneumonia, and severe multiorgan failure. Intrapartum prophylaxis of GBS-colonized women has decreased the incidence of disease in infants in the first 72 hours of life *(223)*.

In contrast, late-onset disease is seen in infants up to 3 months of age or older and may manifest as bacteremia, meningitis, or focal infection such as osteomyelitis. The risk factors for late-onset disease are not well described, but only 50% of cases are attributable to maternal colonization *(224)*. Infection may result from a colonized healthcare worker or occasionally as a result of cross-transmission from other infants in the nursery. Healthcare-associated transmission has been reported, especially in crowded nurseries with a high rate of maternal colonization *(225)*.

Enterococci

Enterococci, including *Enterococcus faecalis* and *Enterococcus faecium*, are common commensals of the gastrointestinal tract and the vagina. Maternally acquired infection can result in sepsis during the first week of life, although symptoms are generally less severe than those observed with GBS *(226)*. Late-onset infection commonly manifests as bacteremia, often in the setting of NEC or other gastrointestinal tract pathology *(227)*. Bacteremia is often polymicrobial. Enterococci may also cause focal infections such as abscess, urinary tract infection, or meningitis.

Not long ago, vancomycin-resistant enterococci (VRE) were rarely encountered in hospitalized neonates (14), but

recent reports suggest that the incidence of VRE, like other MDRO, is increasing (228,*229*) Clinical cultures identify a minority of patients harboring VRE. In the setting of active surveillance cultures, the prevalence of colonization has ranged from 2% to >40% (228,*229*,*230*). Risk factors for VRE acquisition include low birth weight and exposure to antimicrobials *(229,230)*. Clonal spread in one NICU was linked to a contaminated electronic thermometer (228). Routine infection control measures, including Contact Precautions, cohorting, hand hygiene, and environmental cleaning, have been successful in terminating VRE outbreaks (228,*229*).

Group A Streptococci

GAS infections may be acquired vertically from colonized mothers or from colonized or infected healthcare personnel *(231–235)*. Most infants described in reports of nursery outbreaks developed mild, indolent omphalitis *(232–234)* although severe disease, including sepsis and necrotizing cellulitis, also occur *(235)*. Treatment of the umbilical stump with bacitracin *(233)*,triple dye *(234)*, or chlorhexidine *(236)* may reduce colonization and disease. Identification and treatment of GAS carriers is essential for the control of outbreaks. Administration of Penicillin G has been effective in some outbreaks. In other reports, eradication of colonization required clindamycin treatment *(235)*.

Other Gram-Positive Bacteria

Listeria is usually maternally acquired *(237)*. Maternal infection is food borne, and clusters of infection in newborns usually indicate community outbreaks. Early-onset disease, often associated with maternal symptoms, presents with pneumonia and rash and multisystem disease. Meningitis is the major form of late-onset disease. Control measures include advising pregnant women to avoid unpasteurized milk products and foods epidemiologically associated with an outbreak and diagnosing and treating infection in pregnancy. Nursery transmission is reported but rare *(238)*. Contaminated resuscitation equipment *(239)* and mineral oil used to bathe infants *(65)* have been implicated.

Streptococcus pneumoniae is an unusual cause of neonatal sepsis. Early-onset infection may be associated with maternal sepsis and has a poor prognosis *(240)*. Healthcare-associated transmission has been reported *(241)*.

Leuconostoc species may cause sepsis and meningitis in premature infants *(242)*. Case reports describe underlying gastrointestinal tract disease and central venous catheter use in infants diagnosed with this uncommon, vancomycin-resistant pathogen.

From 2% to 70% of infants may be asymptomatically colonized with *Clostridum difficile*, including toxigenic strains *(243,244)*. Rates of colonization decrease with age, falling in the second year of age to 6%. Rates of colonization in children >2 years of age are similar to those in adults (~3%).

Infants may acquire colonization early in the first week of life *(245)*. Studies examining the risk factors for *C. difficile* have failed to show a consistent association between acquisition of the organism and the mode of delivery or receipt of formula versus breast milk. However, healthcare acquisition of the microorganism is well described in NICUs and *C. difficile* contamination of the NICU environment has been demonstrated *(246)*.

Most studies have failed to show an epidemiologic association between colonization and disease in infants <1 year of age, including NICU patients. *C. difficile* toxin was recovered from the stools of 55% of patients in one NICU, but signs of enteric disease, including NEC, occurred with equal frequency in both toxin-positive and toxin-negative infants *(247)*. Data from neonatal rabbits suggest that the lack of disease in colonized infants may be related to the absence of a receptor for toxin A in immature enterocytes *(248)*.

Sporadic case reports suggest that severe *C. difficile* infection occasionally occurs in infants, especially those with underlying intestinal pathology. For example, *C. difficile* pseudomembranous colitis has been identified at autopsy in infants with Hirshprung's disease *(249)*. Fatal *C. difficile*–associated pseudomembranous colitis has also been described in a premature infant with NEC *(250)*. The impact of the emergence of the BI/NAP1 strain of *C. difficile* on disease in neonates is not yet known.

Enterobacteriaceae

The Enterobacteriaceae, including *E. coli, Enterobacter, Klebsiella* and *Citrobacter* species, and *Serratia marcescens*, are increasingly recognized as important causes of endemic and epidemic HAI in NICUs *(22,251)*. Transmission is usually person to person via hands, although contaminated patient care items have also been involved.

Early-onset *E. coli* disease is usually of maternal origin, but neonates may rapidly acquire nursery strains of *E. coli (252)*. Healthcare-associated *E. coli* infections commonly manifest as bacteremia, SSI, or infection of the gastrointestinal or urinary tracts *(22)*. Some reports suggest that cases of late-onset *E. coli* sepsis are increasing *(253)*. Prolonged NICU stay is a risk factor for the acquisition of extended-spectrum beta-lactamase (ESBL)-producing strains *(254)*.

Hospitalized newborns readily become colonized with *Klebsiella* species; the gastrointestinal tract is the major reservoir *(255)*. These microorganisms are the most commonly reported cause of outbreaks in NICUs; the mortality associated with *Klebsiella* outbreaks exceeds 11% *(251)*. Commonly identified sources include enteral feeding *(83)* and infusion therapy practices *(256)*. Increasingly, outbreaks associated with ESBL-producing strains are reported *(132*,*257*,*258*,*259*).

Like *Klebsiella* species, *Enterobacter* species are commonly in the fecal flora of hospitalized infants. Low birth weight and prematurity *(59)*, as well as prolonged hospital stay, are risk factors for the acquisition of *Enterobacter* colonization. Receipt of total parental nutrition and bladder catheterization are risk factors for the development of bacteremia *(260)*. Outbreaks have typically been associated with intravenous fluids *(52*,*59*).

Citrobacter koseri (previously *C. diversus*) is part of the normal gastrointestinal flora. Infection in the newborn most often manifests as meningitis, ventriculitis, and focal brain abscess *(261,262)*. Non–central nervous system infection is rare, although neonatal septic arthritis and osteomyelitis have been reported *(263)*. Most cases of *C. koseri* infection are sporadic, but outbreaks have been recognized in normal newborn nurseries as well as NICUs *(127,261,264*,). Outbreaks are characterized by large numbers of colonized infants with small numbers of symptomatic infants over extended periods *(*127,*264)*. Single strains differing from one hospital to another may be implicated *(264)*, or

several strains may be present in one outbreak, suggesting multiple introductions *(261)*. Hand or gastrointestinal carriage in healthcare workers has been implicated in transmission. Infants infected by vertical transmission are more likely to be premature than infants infected by horizontal transmission in the NICU *(265)*.

Long considered a commensal with little pathogenic potential, *S. marcescens* is now recognized as a frequent and often devastating cause of infection in NICU infants *(266)*. In a multicenter European study, 15% of HAIs in neonates were caused by *S. marcescens,* including 5% of BSIs. Other manifestations of *Serratia* infection include sepsis *(267)*, meningitis *(267,268)*, brain abscess *(269)*, and conjunctivitis *(39)*.

Sources of *Serratia* outbreaks include contaminated intravenous fluids *(56)*, delivery room equipment *(48)*, laryngoscopes *(270)*, breast pumps *(76)*, prepared infant formula, and soap *(39)*. Transient hand carriage of the microorganism has been considered a likely mode of transmission in outbreaks in which no point source has been identified (271). Infants with asymptomatic gastrointestinal tract colonization may act as reservoirs, facilitating both endemic and epidemic transmission *(272)*.

Other Gram-Negative Bacilli

Chronobacter sakazakii (formerly *Enterobacter sakazakii*) is a coliform that causes sepsis and meningitis often complicated by ventriculitis, brain abscess, and cerebral infarcts *(273,274)*. The microorganism has also been linked to NEC *(275)*. Mortality rates as high as 80% have been reported; 94% of meningitis survivors experience neurologic sequelae.

Prematurity, low birth weight, and age <28 days have been identified as risk factors for *C. sakazakii* infection *(276–278)*. Powdered infant formula has been implicated as the source of infection in both sporadic cases and clusters of disease. Intrinsic contamination resulting in manufacturers' recall of powdered formula *(279)* and extrinsic contamination of blenders *(82)* used in formula preparation have been reported. Strategies for the prevention of *C. sakazakii* infection have focused on infant feeding practices.

Carriage of *P. aeruginosa* has become endemic in some NICUs, with nearly 25% of infants colonized *(280)*. This microorganism is ubiquitous in the environment and proliferates in water *(281)*. It readily colonizes skin, gastrointestinal tract, and respiratory tract, especially when antibiotics are used *(47)*. Clinical manifestations of infection include sepsis, pneumonia, and urinary tract infection *(29,280, 282*). It is also an important cause of healthcare-associated conjunctivitis *(47,104)* and the leading cause of neonatal endophthalmitis *(283)*. Outbreaks have been associated with contaminated equipment *(282)*. Low-birth-weight infants are particularly at risk, and the case fatality rate is high *(284). Burkholderia cepacia (285)*, *Ralstonia pickettii (286),* and *Stenotrophomonas maltophilia (66)* may also be acquired from environmental water sources. A national outbreak of *Ralstonia mannitolytica* infection/colonization that involved primarily premature infants was epidemiologically linked to contamination of a respiratory gas humidification device *(287)*. Although the cause of the contamination was not identified with certainty, water was used to manufacture the device and its filter cartridge. The outbreak resulted in a national recall of the device and changes in the recommended procedures for cleaning and reprocessing. Outbreaks of neonatal meningitis caused by *B. cepacia (125)* and sepsis and meningitis caused by *S. maltophilia (123,288)* have been described.

Acinetobacter (Ab) species, including *A. baumannii*, *A. cacloaceticus*, and *A. lwoffii*, inhabit soil and water and frequently colonize the skin and the gastrointestinal tracts of adults. Ab species are common causes of HAIs, particularly bacteremia and VAP, in intensive care units and burn units (289). Outbreaks of bacteremia *(31,58,290,291)*, meningitis *(126)*, and pneumonia *(43)* have been described in NICUs. Most infections have occurred in low birth weight neonates.

Because Ab species can survive for prolonged periods on dry surfaces, contaminated environmental surfaces have been implicated in healthcare-associated spread. Healthcare-associated transmission has been linked to inadequate hand hygiene by healthcare workers, intravenous catheters, contaminated hydroscopic bandages used to secure endotracheal tubes and umbilical catheters, contaminated aerosols from an air conditioning unit, contaminated suction catheters, and contamination of the humidification chamber of ventilatory devices *(292,293)*.

Multidrug-resistant (MDR) Ab (MDR-Ab) is increasingly described as a cause of HAIs in adults and is emerging as a pathogen in neonates *(294,295)*. Simmods et al. described a clonal NICU outbreak of MDR-Ab that involved seven infants *(295)*. Three infants had bacteremia, and one had a positive pleural fluid culture. All infected or colonized infants were born at <26 weeks of gestation, weighed <750 g at birth, and had a positive culture in the first 7 days of life, leading the authors to speculate that invasive Ab has an affinity for damaged or nonkeratinized immature skin. Effective control measures were similar to those employed for other MDR microorganisms and included cohorting, reinforcement of Standard and Contact Precautions, and the use of dedicated personnel and equipment for colonized or infected infants.

Pertussis is an unusual HAI in the newborn, but when it occurs, it is often severe. Newborns may acquire the disease from visitors *(296)* or personnel *(8,297)* with unrecognized infection.

Only sporadic cases of *Legionella* infections have been described in neonates, but reported cases are usually healthcare-associated *(298)*. Infection has been linked to water used in an oxygen nebulizer and for heating feeding bottles and to postoperative contamination of a sternal incision with tap water *(299)*. Pneumonia has been reported after water birth *(300)*. Risk factors for infection include prematurity, immune deficiency, or congenital heart or lung disease *(301)*.

Mycobacteria

Congenital or perinatal tuberculosis may be acquired from an infected mother. It is rare, and diagnosis may be delayed. Infants are unlikely to transmit infection by coughing, but suctioning may generate infectious aerosols. Tuberculin skin test conversions have occurred in healthcare workers exposed to infected neonates *(302,303)*.

Candida

Candida species, most commonly *C. albicans* and *C. parapsilosis* (304,*305*,*306*), are important causes of HAIs in NICU infants. In a national point prevalence study conducted by

the Pediatric Prevention Network, *Candida* species were identified as the third most common cause of healthcare-associated bloodstream infection in NICU infants (14). Disseminated *Candida* infection also occurs and most commonly involves the kidneys; the heart, lungs, central nervous system, eyes, liver, spleen, bones, or joints may also be affected *(307)*. Although there is evidence that the incidence of infections due to *Candida* in NICUs is decreasing (304), invasive candidiasis remains an important cause of morbidity and mortality. The attributable mortality of invasive candidiasis is 11.9% in extremely low birth weight (ELBW) infants, and disease increases length of stay and hospital charges in older infants *(308)*. Neurodevelopmental impairment occurs in more than 50% of ELBW infants who survive an episode of candidemia *(309)*.

The highest rates of invasive candidiasis are in the smallest infants, and rates decline with increasing birth weight *(310)*. In a study of 4,579 infants, 11.4% of ELBW infants (birth weight 401–750 g) developed *Candida* infection *(309)*. Higher rates of disease are also seen in infants with gastrointestinal tract pathology, including congenital anomalies and NEC *(311)*. Central venous catheter use, intubation, and hyperalimentation are risk factors for invasive candidiasis *(306,312,313)*. Medications that increase the risk of *Candida* infection include third- and fourth-generation cephalosporins *(306,314,315)*, carbapenems (315), histamine-2 blocking agents *(306)*, and intravenous hydrocortisone *(316)*. Petrolatum ointment skin care increased the risk of invasive disease in neonates with birth weight of <1,000 g *(317)*. *Candida* colonization typically precedes disease. Endotracheal colonization in the first week of life identified VLBW infants at high risk to develop systemic disease *(318)*. While most *Candida* infections in NICUs are sporadic, common-source outbreaks have been associated with contaminated pressure transducers *(319,320)*, syringes *(57)*, and glycerin suppositories *(63)*.

Prevention of *Candida* infection in the NICU is a challenge. Antibiotic therapy is one modifiable risk factor, yet it is often impossible to withhold empiric antibiotic therapy in sick premature infants when bacterial infection cannot be excluded. Fluconazole prophylaxis decreases the rates of invasive candidiasis in premature infants. In one randomized, controlled trial, 100 infants of <1,000 g birth weight were randomized to fluconazole prophylaxis or placebo. Fluconazole was dosed at 3 mg/kg every third day for 2 weeks, every other day during weeks 3 and 4, and daily during weeks 5 and 6. Fungal infections decreased from 20% in the placebo group to 0 in the treatment group ($p = .008$) *(321)*. Similar results were achieved in a multicenter study that compared fluconazole dosing regimens to placebo. In infants weighing <1,000 g at birth, the incidence of invasive fungal infections was 2.7% in infants dosed with 6 mg/kg of fluconazole, 3.8% in infants dosed with 3 mg/kg of fluconazole, and 13.2% in placebo recipients (322). Individual centers have successfully implemented fluconazole prophylaxis for infants weighing <1,000 g at birth, reducing the incidence of *Candida* infections and essentially eliminating *Candida*-related mortality *(323)*. Recently published guidelines from the Infectious Diseases Society of America recommend that fluconazole prophylaxis be considered for neonates with birth weights of <1,000 g in nurseries with high rates of invasive candidiasis *(324)*. Although "high rates" are not specifically defined, it is noted that the incidence of invasive candidiasis in most NICUs is <5% in infants weighing <1,000 g, and ~1% in infants weighing 1,000 to 1,500 g.

Malassezia Species

Malassezia furfur, a dimorphic lipophilic yeast that causes tinea versicolor in older children, is an uncommon cause of fungemia in the NICU *(325)*. Receipt of intravenous lipids is the primary risk factor for invasive disease as lipids serve as a growth factor for this microorganism.

Malassezia pachydermatis, an animal pathogen, can also colonize infants in the NICU and cause fungemia in association with intravenous administration of lipids. Disease is generally mild *(326)*, but meningitis has been reported *(327)*. One NICU outbreak was associated with healthcare workers' pet dogs *(327)*.

Filamentous Fungi

Invasive infections with filamentous fungi are rare in the newborn, but sporadic cases of aspergillosis and zygomycosis have been reported. Spores may be inhaled as a result of environmental contamination with dust containing fungal spores such as may occur during hospital renovation or with faulty cleaning practices *(328)*. Alternately, puncture sites or wounds may be inoculated with the microorganisms. Contamination of nonsterile medical equipment, including adhesive tape and wooden tongue depressors used as splints to stabilize intravenous catheters, has been implicated *(329,330)*. Aspergillus infections in neonates present as cutaneous or disseminated disease. Gastrointestinal infections account for more than 50% of reported cases of zygomycosis in neonates; some cases mimic NEC, although pneumatosis intestinalis is absent *(331)*. Cutaneous and disseminated infections also occur. Extreme prematurity, acidosis, renal failure, and treatment with steroids are risk factors for invasive mold infections. Mortality rates are high, and diagnosis is often made only at autopsy.

Neonatal infection with dermatophytes is also rare. Healthcare providers with unrecognized infections were the sources of two nursery outbreaks of *Microsporum canis* skin infection *(332)*. In another outbreak, nurses were infected by contact with an infected newborn *(333)*.

Viral Infections

Up to 6% of all HAIs in the NICU are caused by viruses (334,*335*). In one prospective study, 1% of all NICU patients developed a viral infection (334). Outbreaks tend to reflect viral activity in the community. As with bacterial infections, vertical transmission may occur from an infected mother and contact with an infected healthcare worker, a visitor, or another infant may result in horizontal transmission. The symptoms of healthcare-associated viral infections can mimic those seen with bacterial sepsis. Symptoms include apnea, lethargy, feeding difficulties, and pulmonary infiltrates on chest radiograph.

Respiratory syncytial virus (RSV) outbreaks are common and have sometimes included large numbers of infants *(336–340)*. In one outbreak, 35% of newborns in the NICU for more than 6 days and 34% of the staff were infected *(336)* and in another, infections occurred in 84% of newborns in

the NICU for more than 3 weeks *(340)*. Pseudo-outbreaks have also been reported. The use of a rapid immunoassay led to an erroneous diagnosis of RSV in seven premature infants in one NICU, highlighting the need to employ confirmatory tests when viral outbreaks are suspected in a population expected to have low disease prevalence *(341)*. The false-positive results were attributed to cross-reactivity between the immunoassay and pulmonary surfactant that had been administered prophylactically at birth.

Concurrent outbreaks of RSV and rhinovirus *(337)* and RSV and parainfluenza virus *(339)* have been described. There is significant overlap in the symptoms seen with these three viruses, making respiratory virus testing important in the investigation and management of outbreaks. Crowding and understaffing may contribute to outbreaks of respiratory illness *(342,343)*, with attack rates of 63% in infants and 25% in personnel *(343)*.

Healthcare-associated influenza infections in neonates also occur. As with RSV, symptoms may be mild or may resemble bacterial sepsis. In two reported outbreaks, attack rates in neonates were 35% and 32% *(344,345)*. Low influenza immunization rates among healthcare providers may have contributed to the outbreaks. In one report, most nursery personnel had not received influenza vaccine, and 16% were symptomatic *(344)*. Immunization of healthcare personnel is an effective strategy for the prevention of disease in hospitalized neonates.

Healthcare-associated adenovirus infections may present as mild respiratory tract infections, conjunctivitis and gastroenteritis, or as severe pneumonia, sepsis syndrome, and death (334,*346*,*347*). Symptomatic maternal infection may result in severe neonatal disease, presumably because the newborn lacks passively transferred maternal antibody *(346)*. An outbreak of conjunctivitis and pulmonary disease was associated with ophthalmologic examination *(106)*. Healthcare-associated respiratory adenoviral infections may contribute to the development of bronchopulmonary dysplasia in premature infants *(347)*.

Enteroviruses

Neonatal enteroviral infections, including echovirus and Coxsackie B virus infections, occur in both newborn nurseries and NICUs and are commonly associated with community outbreaks *(348)*. Maternal infection may result in perinatal transmission. During a community outbreak, 3.4% of mothers were shedding enterovirus in the stool at delivery and reported transmission rates from mother to infant have ranged from 29% to 57%. Horizontal transmission occurs in the nursery by fecal–oral contamination.

Infants may be symptomatic within the first day of life. Personnel may also become infected and contribute to horizontal spread. Mild febrile illness and aseptic meningitis are the most frequent presentations, but disease may resemble bacterial sepsis. Severe hepatic necrosis or myocarditis may also occur.

Rotavirus

Rotavirus infections are common in hospitalized neonates. During a 25-month-long surveillance period, 12% of neonates hospitalized in six Brazilian special care nurseries were found to have rotavirus infection *(349)*. Viral excretion varied by season, with infection rates rising to 21% during "epidemic" periods. In another study, 53% of infants hospitalized in a special care nursery were found to excrete rotavirus; stools from more than half had detectable virus by the fifth day of life *(350)*. Others have demonstrated neonatal infection by 48 hours of life, suggesting a role for perinatal infection *(351–353)*.

The spectrum of disease associated with rotavirus infection in hospitalized neonates ranges from asymptomatic excretion of virus to severe, hemorrhagic diarrhea with dehydration *(354)*. Fever may occur with or without typical gastroenteritis symptoms *(355)*. Symptomatic disease is more common in infants who develop disease after 7 days of age *(355)*. Preterm infants infected with rotavirus are less likely than term infants to experience watery diarrhea and more likely to exhibit bloody mucoid stools, abdominal distention, and intestinal dilation *(356)*. Rotavirus has also been associated with an attenuated form of NEC *(356)*.

Hospital outbreaks of rotavirus are well described *(357)*. Rotavirus can survive on hands for at least 4 hours and on environmental surfaces for many days, factors that facilitate healthcare transmission *(358,359)*. Improved hand hygiene by healthcare personnel has been shown to decrease healthcare-associated transmission of rotavirus in children *(360)*.

Herpes Simplex Virus

The frequency of neonatal HSV infection varies from 1/12,500 to 1/6,000 live births *(361)*. Most infections result from exposure to the virus in the maternal genital tract at the time of delivery, with 50% to 80% of infected infants born to mothers with newly acquired disease *(362,363)*. The use of fetal scalp monitors may increase the risk of transmission.

Transmission of HSV in the nursery is rare, but small outbreaks have been described *(364)*. Infection has been transmitted to an infant suctioned by a healthcare worker with orolabial lesions *(365)* and during ritual circumcision that involves oral suctioning of the wound *(366)*.

Varicella-Zoster Virus

Varicella is transmitted by the airborne route, and transmission may occur before onset of the rash. Fortunately, varicella is rare in newborns, because most adults are immune and most infants are protected by maternal antibody. The newborn is at risk for severe perinatal disease when acquired from a mother who has onset of varicella lesions from 5 days before to 2 days after delivery, presumably because virus but no antibody is transmitted to the fetus *(367,368)*. Prophylactic varicella-zoster immune globulin or intravenous immune globulin (IVIG) is recommended for these newborns. Varicella may still occur despite the administration of prophylaxis. Airborne and Contact Precautions are recommended for infants born to mothers with acute varicella and should be continued for hospitalized infants for 21 days (or 28 days if varicella immune globulin or IVIG is given). Infants with varicella embryopathy from *in utero* exposure to varicella zoster virus do not require isolation unless they have active lesions.

Varicella may be introduced into the nursery by mothers, employees, or visitors with unrecognized infection *(369,370)* or by an infant with perinatal varicella *(371)*.

Hospitalized premature infants exposed to varicella are at risk for severe disease. Prophylaxis with varicella immune globulin or IVIG is recommended for exposed infants born at ≥28 weeks of gestation to mothers who lack a reliable history of chickenpox or serologic evidence of protection against varicella, and for all infants born at <28 weeks of gestation or with birth weights of <1,000 g (*367*,*368*). Airborne and Contact Precautions are indicated from 8 to 21 days after exposure; when varicella-zoster immune globulin or IVIG is given, precautions are continued for 28 days.

Parents and healthcare workers who receive live-attenuated varicella vaccine need not be excluded from the newborn nursery or NICU unless a rash develops after immunization. Transmission of vaccine-associated virus is rare and has occurred only when the immunized individual developed a rash *(367)*.

Cytomegalovirus

Approximately 1% of all newborns are infected with CMV *in utero*, but 85% to 90% are asymptomatic at birth *(372)*. Severe disease occurs when the mother has primary CMV infection in pregnancy *(373)*. Perinatal transmission of CMV, either as a result of exposure to the virus in maternal cervical secretions at the time of delivery or through receipt of CMV-containing breast milk, is usually asymptomatic. Some infants present with mild self-limited pneumonia or hepatitis at 1 to 4 months of age *(374)*. Severe disease may occur in premature infants with birth weight of <1,500 g, presumably because they receive little maternal antibody (*375*,376).

Severe disease in low birth weigh infants was described with transfusion-related CMV. Infants developed a sepsis-like syndrome with hepatomegaly, respiratory deterioration, and atypical lymphocytosis, and some died *(70)*. Transfusion-related CMV is of historical interest, but unlikely when leukoreduced or CMV-negative blood products are used. Transmission of CMV between infants in the NICU has been reported *(377)* but is extremely rare *(378)*.

Hospitalized infants with congenital or perinatal CMV infection are managed with Standard Precautions *(367)*. Transmission of CMV to healthcare personnel is unlikely if hand hygiene is performed after contact with urine or saliva.

Human Immunodeficiency Virus

Mother-to-child transmission of human immunodeficiency virus infection may occur *in utero*, at delivery, or postnatally through breast milk. A comprehensive strategy to reduce transmission, including universal HIV testing of all pregnant women, prophylaxis of infected women during pregnancy, labor, and delivery, prophylaxis of exposed infants during the first 6 weeks of life, elective cesarean section for women with viral loads of >1,000 copies/mL, and complete avoidance of breast-feeding, may reduce mother-to-child transmission from 25% to 30% to <2% *(379)*. Unfortunately, transmission continues to occur, even in locales with the infrastructure and resources to implement these strategies *(380)*.

In countries with resources for antiretroviral treatment, screening for HIV should be part of routine prenatal care, and all pregnant women with HIV infection should be offered antiretroviral therapy. All normal newborn and special care nurseries should have protocols in place to identify HIV-exposed infants, even if the mother's HIV infection was unrecognized prior to delivery *(381)*. For neonates born to mothers whose HIV serostatus is unknown, rapid HIV antibody tests should be performed on the mother or the infant so that antiretroviral prophylaxis may be provided to HIV-exposed infants within 12 hours of birth. Consent for such testing should be obtained in accordance with local laws. Prophylaxis is continued for 6 weeks, during which time infants should be monitored for drug-related, hematologic toxicities. Mothers known to be HIV-infected should not breast-feed if safe alternatives to breast milk are available.

Hepatitis B and C

The newborn may acquire HBV from a mother with chronic or acute infection in pregnancy. Infection is almost always asymptomatic at birth, but 90% of infants infected perinatally develop chronic HBV infection and are at risk for the development of hepatocellular carcinoma or cirrhosis. Administration of hepatitis B hyperimmune globulin and vaccine at birth prevents infection in the newborn, and neonatal units should have procedures in placed to ensure that all exposed newborns receive appropriate prophylaxis *(367)*.

Approximately 5% of infants born to women seropositive for HCV acquire infection *(367)*. Whether transmission occurs *in utero* or intrapartum is not known, but increased rates of transmission have been associated with increased maternal HCV viral load and coinfection with HIV. Although HCV has been detected in colostrum, breast-feeding does not appear to increase the risk of transmission. Infection in the newborn is usually asymptomatic, but 50% to 60% develop persistent infection. Prophylaxis for HCV exposure is not available *(367)*.

PREVENTION AND CONTROL OF INFECTIONS

The foundation of an infection prevention program in the NICU is similar to those for other at-risk patients. The program will identify infection risks through active surveillance, implement evidence-based practice to mitigate those risks, and monitor compliance. Appropriate infrastructure, encompassing both physical design and staffing, is crucial. Routine care practices for the neonate should promote healthy growth and development while minimizing the acquisition of pathogenic microorganisms.

Elements of an Infection Control Program

Surveillance Surveillance for HAIs is essential for infection prevention. Surveillance permits early detection of infection trends and clusters and identification of new risks, provides information on which to base empiric antibiotic therapy, and is one measure of quality of care (382). Targeted surveillance is generally more feasible and potentially of greater value than surveillance for all infections. A risk-assessment provides useful information to guide targeted surveillance.

Surveillance in the normal newborn nursery should concentrate on infections likely to be associated with

nursery outbreaks such as staphylococcal or streptococcal skin infections, gastroenteritis, and other viral infections. Because many of these infections manifest only after discharge, communication with community healthcare providers is essential. In intensive care settings, targeted surveillance may include device-associated infections such as CLABSIs or VAP, rates of colonization or infection with MDR microorganisms such as MRSA or VRE, or cases of healthcare-associated viral transmission. The use of standard definitions, such as those endorsed by NHSN, allows for accurate comparison of rates over time and benchmarking with similar institutions. Effective surveillance requires collection of appropriate denominators, including device utilization days and patient days stratified by birth weight.

Routine surface cultures from the skin and mucous membranes of hospitalized neonates are generally not helpful, because colonization is not a good positive predictor of infection and correlation of isolates from surveillance cultures and invasive infections has been poor *(138,383,384)*. Targeted surveillance for MDR microorganisms such as MRSA may be helpful when routine infection control procedures fail to control transmission *(385)*. Screening cultures of all intensive care unit patients to detect MRSA colonization is now required by law in some states *(386)*. In outbreaks, surveillance cultures may be indicated to identify colonized infants for purposes of cohorting or isolation or for assessment of risk factors for acquisition of the microorganism (382).

Hand Hygiene Hand hygiene before and after each patient contact reduces the incidence of HAIs in NICUs and other settings *(387)*. Compliance, however, is difficult to monitor and enforce, and studies show poor compliance with this procedure in the NICU *(388–391)*.

Guidelines for Hand Hygiene in Healthcare Settings were published in 2002 by the Healthcare Infection Control Practices Advisory Committee at the CDC (392). Additional recommendations for hand hygiene are included in the Guidelines for Perinatal Care published by the AAP and the American College of Obstetricians and Gynecologists. Before handling neonates for the first time on a work shift, personnel should scrub their hands and arms to above the elbows with an antiseptic soap. Hands should be rinsed thoroughly after washing and dried on paper towels. Watches, rings, and bracelets should be removed. Nails should be trimmed short, and no false fingernails should be worn (382,392). The Guidelines for Perinatal Care recommend a 10-second wash with soap and vigorous scrubbing before and after each patient contact and after touching objects in the patient's environment, while Healthcare Infection Control Practices Advisory Committee guidelines recommend use of an alcohol-based hand rub unless hands are visibly soiled. Use of alcohol-based products has been associated with increased hand hygiene compliance in neonatal units *(391)*. Neonatal units should have a program in place to monitor healthcare provider compliance with hand hygiene, and provide feedback to personnel.

Isolation Precautions Revised guidelines for isolation precautions for hospitalized patients were published by CDC in 2007 and are discussed in detail in Chapter 90 *(393)*. These guidelines include a comprehensive review and detailed recommendations for the prevention of infections due to MDR microorganisms in healthcare settings including NICUs *(385)*. Standard Precautions refer to precautions to be taken with all patients to reduce transmission from recognized and unrecognized sources of infection. Additional transmission-based precautions (Airborne, Droplet, and Contact) are used when caring for patients infected or colonized with microorganisms transmitted by these routes. Implementation of isolation precautions in neonatal units may pose unique challenges.

Although single rooms are recommended with Droplet and Contact Precautions, they are not mandatory and may not be available in all NICUs. Separate isolation rooms are not considered to be necessary for newborns if the following conditions are met: (a) the infection is not transmitted by the airborne route, (b) there is sufficient space for a 4- to 6-ft aisle between infant stations, (c) there are an adequate number of nursing and medical personnel and they have sufficient time for hand hygiene, (d) an adequate number of sinks are available for hand washing, and (e) continuing instruction is given to personnel about the ways that infections are spread (382). When multiple infants require isolation precautions for the same symptoms or colonization with the same MDR microorganism, an isolation area can be defined in the nursery or NICU by curtains, partitions, or other markers. Infants on Droplet Precautions should be separated from one another by at least 3 ft. A closed incubator may be helpful in maintaining barrier precautions, but because incubator surfaces and entry ports readily become contaminated with the microorganisms carried by the infant, the outside of the incubator should be considered contaminated and the boundaries of the isolation area should extend beyond the incubator itself. Forced-air incubators cannot be substituted for isolation rooms when Airborne Precautions are required, because of the discharge of unfiltered air into the nursery. Infants with suspected measles, varicella, or tuberculosis should be cared for in a negative pressure isolation room.

The necessary duration of Contact Precautions for infants colonized with MDR microorganisms such as MRSA and ESBL-producing gram-negative bacilli remains unknown. Some infants remain hospitalized for months to >1 year, and the potential adverse effects of prolonged isolation have not been studied in this population. Close contact between infants and their parents, as well as other caregivers, promotes bonding and is important for normal infant development. The need for parents to wear personal protective equipment when interacting with infants on isolation precautions is an unresolved issue and requires further study *(393)*.

Antimicrobial Stewardship Because hospitalized neonates are at risk for HAIs, they are frequently exposed to both empiric and therapeutic courses of broad-spectrum antibiotics *(394,395)*. In one point-prevalence study involving 29 US NICUs, 43% of NICU patients were receiving antimicrobials with a median number of two agents. While few studies have assessed the appropriateness of antimicrobial prescribing in this population, a study involving four NICUs characterized 25% of antibiotic courses and antibiotic days as inappropriate based on CDC guidelines. Inappropriate use of both vancomycin and carbapenems was noted (396).

Antibiotic exposure is a risk factor for colonization and infection with *Candida* and MDR bacteria. Antimicrobial stewardship interventions are needed to improve antimicrobial prescribing for NICU patients and reduce the emergence of MDR microorganisms (see also Chapters 86 and 87).

Prevention of Device-Associated Infections

Technologic advancements in neonatal care have given rise to new and sometimes unexpected infection risks. As a general principle, whenever a new invasive procedure or device is introduced, the potential risk for HAI should be considered, protocols established to minimize this risk, and surveillance initiated to monitor for infection. Exposure to an invasive device is a prerequisite for a device-associated infection. The need for any invasive device should be assessed daily, and use should be discontinued promptly when no longer essential. Bundled implementation of evidence-based infection prevention strategies is thought to be more effective than implementation of any single intervention.

Central Line–Associated Bloodstream Infections Guidelines have been published for the prevention of CLABSIs in adults and children *(397,398)*. Recommended strategies include (a) education and training for healthcare personnel who insert and maintain catheters; (b) use of maximal sterile barrier precautions during central venous catheter insertion and use of an insertion checklist; (c) 2% chlorhexidine gluconate (CHG) for skin antisepsis before catheter insertion in infants at least 2 months of age; (d) replacement of administration sets not used for blood products, lipids or propofol no more frequently than every 96 hours but at least every 7 days; and (e) avoidance of routine catheter replacement as an infection prevention strategy. Additional recommendations for the management of umbilical arterial and venous catheters, devices used exclusively in neonates, are listed in Table 52-2. The use of "bundled" strategies for catheter insertion and maintenance is emphasized, although the recommended components of such bundles are not provided.

Modifications to these recommendations may be indicated for NICU patients. Evidence-based guidelines recommend CHG-based products for skin antisepsis before central line insertion and with dressing changes. Notably, use of CHG as part of an insertion bundle has been demonstrated to reduce CLABSI rates in adults *(399)*. However, CHG is not currently approved by the U.S. Food and Drug Administration (FDA) for use in children <2 months of age, because safety and efficacy data are lacking in this population.

Modified strategies may be needed for NICU patients. For example, use of chlorhexidine gluconate (CHG) as part of an insertion bundle has been demonstrated to reduce CLABSI rates in adults *(399)*, and evidence-based guidelines recommend CHG-based products for skin antisepsis before central line insertion and with dressing changes. However, the U.S. Food and Drug Administration has not approved CHG for use in children <2 months of age, because safety and efficacy data are lacking in this population.

The Association of Women's Health, Obstetric Nurses and Neonatal Nurses (AWHONN) has acknowledged the benefits of CHG for skin antisepsis and has suggested that it can be used in neonates if applied judiciously, without splashing or excess solution and if removed after the procedure is complete *(400)*. Because of concerns about skin irritation, AWHONN skin care guidelines recommend aqueous CHG rather than an alcohol-containing preparation for infants <34 weeks of gestation.

Published data about CHG use for central venous catheter care in neonates are limited. In one study, 48 infants ≥1,500 g birth weight (BW) and at least 7 days of age were randomized to 2% CHG or 10% povidone-iodine for preparation of catheter insertion sites and for use with dressing changes *(400a)*. Severe dermatitis did not occur in the CHG group. Cutaneous absorption of CHG was documented but was not associated with systemic toxicity. This small study was underpowered to show a difference in CLABSI or clinical sepsis. The enrolled infants were relatively mature (mean BW of 2,000 g and 32–33 weeks of gestation) and whether the results can be generalized to younger or more premature infants is unknown.

A study in less mature neonates did demonstrate CHG-related dermatitis. When an Australian NICU employed 2% aqueous CHG for central line insertion and maintenance, 4/26 infants <1,000 g BW and <48 hours of age developed severe skin irritation (redness = 3; skin breakdown = 1) *(401)*. Use of a chlorhexidine-impregnated dressing has been associated with dermatitis in low birth weight neonates *(402)*.

Nevertheless, a recent survey of neonatology training program directors confirms that off-label use of CHG is common in NICUs. Sixty-one percent of survey respondents reported using CHG in their NICUs *(403)*. Prospective trials are needed to identify the safest CHG preparation for neonates as well as the optimal application technique. CHG

TABLE 52-2

Recommendations for the Management of Umbilical Artery Catheters

Remove and do not replace umbilical artery catheters if any of the following are present:
CLABSIs
Vascular insufficiency in lower extremities
Thrombosis
Remove and do not replace umbilical vein catheters if either of the following are present:
CLABSIs
Thrombosis
Replace umbilical venous catheters only in the setting of catheter malfunction
Cleanse umbilical insertion site with antiseptic before catheter insertion
Avoid tincture of iodine because of the potential effect on the neonatal thyroid
Avoid topical antibiotics or creams at the catheter insertion site
Add low doses of heparin (0.25–1 U/mL) to fluids infused through umbilical artery catheters
Remove umbilical artery catheters after 5 d (or sooner if they are no longer needed)
Remove umbilical vein catheters after 14 d (or sooner if they are no longer or have not been managed aseptically)

is applied to the skin of older children and adults, using a scrubbing motion, but this may not be ideal for neonates because of their fragile skin.

Individual centers and statewide collaborative groups *(404)* have reported decreases in NICU CLABSI rates coincident with adoption of central catheter insertion and maintenance bundles. Although variation exists in the components of these bundles, core strategies were similar to those implemented by a group of 22 NICUs in California (Table 52-3). This collaborative also developed auditing tools for monitoring critical processes such as central line set-up and entry and investigated all possible CLABSIs concurrently with bedside interviews and observation. CLABSI rates fell 25% during the first year of the project.

When rates of CLABSIs remain elevated despite consistent, documented compliance with evidence-based practices for catheter insertion and maintenance, additional interventions may prove beneficial. Lock therapy is a promising strategy for the prevention of CLABSIs. Filling the lumen of a catheter with a supraphysiologic concentration of an antibiotic or agent such as ethanol may prevent or eliminate the bacterial colonization that ultimately results in CLABSIs. Current guidelines suggest that lock therapy could be useful in certain high-risk patients or those with recurrent infections. However, few studies have evaluated lock therapy in neonates.

TABLE 52-3

Sample Insertion and Maintenance Bundles for the Prevention of Central Line-Associated Bloodstream Infections in the NICU

Insertion
Maximal sterile barrier precautions
Skin disinfection with chlorhexidine or povidone–iodine
Dedicated team for catheter placement and maintenance
Availability of all supplies at the bedside at start of procedure
Hand hygiene standards met
Insertion checklist used
Staff empowered to stop nonemergent procedure if sterile technique is not followed
Maintenance
Daily assessment and documentation of catheter need[a]
Daily review of dressing integrity, cleanliness
Closed systems for infusion, blood draws, and medication administration
Infusion tubing assembled and connected aseptically or sterilely
Scrub of needless connecters with friction for at least 15 s before line entry[b]
Clean for all line entries (hand hygiene before and after glove use)
Use of prefilled, flush-containing syringes when feasible

[a]When catheter used primarily for nutritional purposes, catheter removal considered when infant receiving ≥120 mL/kg/d enteral nutrition; discontinuation of intravenous lipids considered when infant receiving >2.5 g/kg/d enteral fat.
[b]Alcohol or chlorhexidine used.

Vancomycin–heparin locks were studied in a prospective randomized double-blind trial in NICU patients. When definite and probable BSIs were considered, there were significantly fewer infections in the lock group (2.3 vs. 17.8/1,000 catheter days; relative risk 0.13: 95% confidence interval: 0.01–0.57) (111). Similar results were observed in an Italian trial of a fusidic acid–heparin lock in neonates *(405)*. To date, however, few centers employ antibiotic lock therapy for primary prevention of CLABSIs in NICU patients.

Ventilator-Associated Pneumonia Recommendations for the prevention of VAP in children and adults have been published, although not all of the recommended strategies are applicable for NICU patients *(406)*. For example, elevation of the head of the bed to 30 to 45 degrees is not feasible in a 1,000-g infant. Moreover, the optimal products and regimens for oral care in ventilated newborns are not known.

Few published data inform VAP prevention strategies in neonates. A closed endotracheal suction system did not prevent the development of VAP or bacterial airway colonization in a study of 133 ventilated NICU patients. However, the majority of nurses involved in the study (40/44) found the system easier to use than an open suction system and better tolerated by infants *(139)*. In a study involving 60 relatively mature infants (mean birth weight 2,100 g), mechanically ventilated patients were randomized to supine or lateral positioning. Although rates of VAP *per se* were not reported, infants positioned on their sides were less likely to have new or persistent infiltrates on chest radiographs (20% vs. 67%; $p < .01$) or positive endotracheal tube cultures after 5 days of mechanical ventilation (30% vs. 87%; $p < .01$) *(407)*. In one NICU with high rates of VAP, increasing hand hygiene compliance before and after patient contact was temporally associated with a decrease in infections from 16.9/1,000 ventilator days to 6.4/1,000 ventilator/days ($p = .37$) (408). The Institute for Healthcare Improvement has made recommendations for the prevention of VAP in pediatric patients (409). An example of a VAP bundle for neonates is presented in Table 52-4.

Infrastructure

Design Nursery design should provide adequate space for appropriate care of the infant and for the necessary equipment and sufficient numbers of strategically placed sinks. Specific recommendations include a space of 30 net square feet per neonate with at least 3 ft between bassinets in the normal newborn nursery *(410,411)*.

For continuing care of low-birth-weight infants who are not ill but require more nursing hours than term infants, 50 square feet per infant with 4 ft between bassinets is recommended. Intermediate-care nurseries should have 120 square feet per patient station if subspecialty care is required, with at least 4 ft between incubators or bassinets. Five-foot-wide aisles are recommended in multiple bed rooms and 8-foot-wide aisles in single patient rooms, or fixed-cubicle partitions should have 150 square feet per infant with at least 6 ft between incubators and 8-foot-wide aisles. There should be one sink for every six to eight patients in the normal newborn nursery and one sink for every three or four patients in intermediate- and intensive-care nurseries. Each nursery should have access to at least one negative pressure

TABLE 52-4

Sample Bundle for Ventilation-Associated Pneumonia Prevention in the NICU

Elevate the head of the bed 15 to 30 degrees to prevent aspiration
Age-appropriate comprehensive mouth care
Meticulous hand hygiene before handling ventilator circuit
Drainage of ventilator circuit condensate away from patient every 2–4 h
Daily assessment of extubation readiness
Use heated ventilator circuits
Change ventilator circuits and in-line suction devices only when soiled
Store oral suction devices in clean, nonsealed plastic bag

isolation room, with exhaust air vented to the outside, to accommodate newborns with airborne infections (382,*411*).

Nursery design has the potential to impact rates of HAI. One NICU noted a decrease in catheter-associated BSIs (10.1/1,000 device days to 3.3/1,000 device days) coincident with the adoption of single patient rooms for the care of critically ill neonates *(412)*.

Staffing Staffing should be sufficient to allow for adequate care of infants with sufficient time for hand hygiene between patient contacts. For normal newborn nurseries, recommendations are one nurse for every six to eight infants or for every three to four mother–infant pairs. A ratio of one nurse for every two to three patients is recommended in intermediate-care units and of one nurse for every one to two patients in NICUs *(410)*. Understaffing has been linked to increased rates of BSIs, as well as the transmission of MRSA and gram-negative pathogens *(413)*.

Employee Health Healthcare personnel can serve as sources of infection for infants in newborn and neonatal intensive care nurseries *(410)*. At hire, personnel should be screened for immunity to rubella, measles, mumps, varicella, and HBV *(414)*. Susceptible workers should be offered vaccination. Annual influenza vaccine is indicated for all healthcare providers and either inactivated, injectable vaccine or live-attenuated, intranasal vaccine is appropriate for personnel who work with neonates. Tuberculin reactivity should be determined on employment and periodically; the frequency of testing is based on local epidemiologic data *(414)*. Because adults including healthcare workers can transmit pertussis to susceptible infants, a single dose of tetanus–diphtheria–acellular pertussis vaccine is recommended for all healthcare workers *(415)*. Although Tdap vaccines are licensed for individuals <65 years of age, in January 2011, the ACIP recommended a single dose of Tdap for all adults 65 years and older, including healthcare providers, who anticipate having close contact with an infant <12 months of age *(415a)*.

It is important that employees understand the risks of transmitting infections to newborns and report acute infections for assessment. Employee health policies should encourage reporting of symptoms and not penalize workers who stay away from work because of illness.

Decisions to furlough workers should be made on an individual basis, taking into consideration the mode of transmission of the particular infection and the ability of the employee to comply with preventive measures.

Individuals with active tuberculosis should be excluded from patient care until adequate treatment is completed and the noninfectious status has been verified. Employees with exudative or herpetic hand lesions should not have direct patient contact or handle patient care equipment. Personnel with herpes labialis are unlikely to transmit infection but should avoid touching the lesions during patient care and cover any external lesions (382). Nonimmune persons exposed to varicella, measles, or rubella should not work during the latter part of the incubation period, because these diseases may be transmitted for a few days before eruption of the rash *(367)*.

Personnel should take precautions to minimize the risk of potential infection with blood-borne viruses and should be familiar with hospital protocols for postexposure prophylaxis after occupational exposures to blood (382) (see also Chapters 73 and 74).

Special Attire In general, special attire is not required for routine care of most infants in newborn nurseries or intensive care units. Most nurseries provide scrub suits or dresses that are laundered by the hospital for personnel spending most of the day in the nursery. This practice may prevent soiling of personal clothing and may be reassuring to parents in providing easy recognition of personnel but should not be considered an infection control measure. Several studies have shown that wearing of cover gowns over scrubs suits or street clothes has no effect on colonization or infection rates in the newborn nursery or the NICU *(389,416–419)* and does not improve hand hygiene compliance. Cover gowns need not be worn for entry to the NICU or for provision of routine care unless an infant is on Contact Precautions. Additional recommendations from the AAP are for a long-sleeved gown to be worn by personnel holding newborns outside of the bassinet or incubator (382).

Decontamination and Cleaning The nursery should be kept clean and dust free by daily cleaning using cleaning methods that minimize dust dispersal. Quaternary ammonium, chlorine, and phenolic compounds are satisfactory low-level disinfectants for nursery cleaning (382). These do not sterilize but reduce the concentration of microbes to an acceptable level. Phenolic compounds should be used with caution, because inappropriate use has been associated with absorption by the newborn resulting in hyperbilirubinemia *(420)*.

NICU equipment should be maintained free of dust, because fungal spores from dust may result in serious infections. Responsibility for the cleaning of delicate equipment, especially monitoring equipment, radiant heaters, or infant care units in constant use, must be clearly assigned, because these items are often not handled by the regular cleaning personnel *(20)*. Incubators, open care units, and bassinets should be cleaned between infants and changed and cleaned periodically for those infants with prolonged stay (382).

Humidifier reservoirs in incubators are potential sources of *Pseudomonas, Legionella,* and other water-borne microorganisms. During periods when the incubator humidifier is in use, the reservoir should be drained, cleaned, and refilled with sterile water every 24 hours (382). When humidification is required, use of a humidifier external to the incubator may facilitate appropriate cleaning.

Nebulizers and attached tubing and water traps should be replaced regularly with equipment that is sterile or has undergone high-level disinfection (382). Only sterile water should be used in these devices, and residual water should be discarded when they are refilled.

New garments and linens should be laundered before use. Linen for newborns does not need to be autoclaved as this has not been shown to reduce infections in hospitalized neonates (382). Clean linen should be transported to the nursery or NICU in covered carts and stored in closed cabinets to prevent dust contamination. Used linen should be handled as little as possible to avoid hand contamination and aerosolization of microorganisms.

Care of the Hospitalized Neonate

Skin and Cord Care Once the newborn's temperature has stabilized, blood and meconium should be removed with sterile cotton sponges (not gauze) and warm water. Alternately, the newborn can be bathed with a mild, nonmedicated soap followed by careful rinsing with water. Soap should be supplied in a single-use container or reserved for use with one infant. Because of potential exposure to blood-borne viruses, personnel should wear gloves when handling the neonate until this has been done (382). Localized skin care using warm water and a mild soap for the diaper area and other soiled areas may be sufficient throughout the nursery stay. Whole-body bathing and antiseptic agents are not necessary for routine newborn care but may be indicated in outbreaks if the benefits outweigh the risks. In the 1970s, bathing infants with hexachlorophene effectively reduced staphylococcal disease in some settings *(421)* but reports of neurotoxicity led to a discontinuation of this practice *(422)*.

Care should be taken to avoid damage to the newborn skin from excessive drying, manipulation, exposure to irritating chemicals, or other trauma *(423)* The skin of the premature infant is especially fragile, and minor trauma such as removal of adhesive tape or oxygen probes may remove the outer layer of the epidermis. Prophylactic application of topical ointments to the skin of neonates to improve barrier function has been shown to increase the risk of coagulase-negative staphylococcal infection as well as any HAI *(424)*. Routine use of topical ointments is not recommended.

The optimal regimen for umbilical cord care remains controversial. A recent Cochrane review examined the use of topical antibiotics and antiseptics for umbilical cord care *(425)*. Twenty-one studies involving 8,959 participants were included, the majority of which were from high-income countries. Neither the use of antibiotics nor antiseptics for cord care reduced the incidence of local infection, although there was a trend to reduced colonization with antibiotics. Antiseptics prolonged the time to cord separation.

Eye Care The eyes of the neonate should be cleaned with sterile cotton to remove secretions and debris. Topical prophylaxis against gonococcal opthalmia neonatorum is mandatory for all infants immediately after birth. Acceptable agents include 0.5% erythromycin ophthalmic ointment or 1% tetracycline opthalmic ointment; either agent causes less chemical irritation than silver nitrate *(179)*. Single-dose containers should be provided. Topical prophylaxis appears to be ineffective against neonatal *Chlamydia* conjunctivitis. Strategies for the prevention of healthcare-associated conjunctivitis include scrupulous hand hygiene, protection of the eyes of infants during respiratory care, proper disinfection of ophthalmologic instruments, and use of eye drops only from single-dose vials whenever feasible *(102)*.

Infant Feeding Human milk is optimal for infant feeding *(426)*. Human milk provides immunologic and nutritional benefits and has been reported to reduce the risk of sepsis in premature infants *(427,428)*. When the sick newborn cannot suck, the mother may express and store breast milk. Routine microbiologic monitoring of milk expressed by a mother for her infant is not necessary or cost-effective *(410)*. Nevertheless, improper expression or storage of milk can result in contamination with a variety of bacteria, including *S. aureus* and gram-negative bacilli. Mothers should therefore be instructed about proper collection technique, including the performance of hand hygiene, to minimize bacterial contamination. Milk should be expressed into sterile containers and if a breast pump is used, part components in contact with milk should be washed with hot soapy water, rinsed thoroughly, and allowed to dry after each use *(444)*.

Freshly expressed milk should be refrigerated promptly and used or frozen within 48 hours. Fortified human milk should be used within 24 hours. Milk stored in the freezer compartment of a refrigerator should be used within 3 months; milk stored in a deep freeze at –20°C can be stored for 6 to 12 months. Frozen milk should be thawed in the refrigerator or quickly under running or fresh warm water, because standing water may become contaminated. Milk should not be subjected to excessive heat from hot water or a microwave oven. Thawed milk should be used promptly or stored in the refrigerator for up to 24 hours. Human milk is not sterile and bacterial growth can occur when expressed milk is held for several hours at room temperature, as occurs with continuous feeding. The hang time for human milk should not exceed 4 hours and continuous feeding is employed, the syringe and tubing must be changed every 4 hours. There is no evidence that any healthcare worker has acquired a viral infection from handling human milk and as such, the Occupational Health and Safety Administration does not consider unprotected contact with human milk to be an occupational exposure. Nevertheless, many experts recommend that healthcare workers wear gloves when handling human milk.

Not all mothers are willing or able to provide breast milk for their infants. Banked human milk is an acceptable alternative provided that donors are appropriately selected and screened and donated milk is carefully collected, processed, and stored. Donor milk banks that belong to the Human Milk Banking Association of North America voluntarily follow guidelines drafted in consultation with the CDC and the FDA. Donors are screened for hepatitis B surface antigen (HbsAg) and

antibodies to HIV-1, HIV-2, human T-lymphotrophic virus 1 (HTLV-1), HTLV-2, hepatitis C, and syphilis. Donated milk is heat treated at 62.5°C (144.5°F) for 30 minutes and is released only if bacterial cultures yield no pathogenic microorganisms. Fresh human milk from unscreened donors is not recommended because of the risk of transmission of infectious agents.

Inadvertent administration of stored breast milk to the wrong infant occasionally occurs and may result in exposure to infectious agents *(429,430)*. Therefore, accidental exposure to breast milk is treated in the same manner as accidental exposure to other potentially infectious body fluids. Counseling is necessary for both the mother who provided the milk (donor mother) and the mother of the infant who mistakenly received the milk (recipient mother). Confidentiality must be maintained for both families. Both should be screened for hepatitis B and HIV; some experts would also test for HTLV. Evaluation and treatment of the exposed infant must be individualized based on the results of this screening *(431)* (Table 52-5). Processes and procedures that reduce medication errors may have applicability to the prevention of human milk misadministration *(432)*.

Detailed guidelines for aseptic preparation of infant formula have been published by the American Dietetic Association *(433)*. Powdered infant formula is not sterile and should be avoided in infants at high risk for invasive disease *(129)*. Since powdered formulas are not sterile, they should be used only when no commercially sterile liquid products are available. Formula made from liquid concentrates or powders must be prepared with chilled, commercially sterile water using aseptic technique. If commercially sterile water is not available, water may be boiled for 1 to 2 minutes and then cooled before use. Because blenders may be difficult to clean, the use of stainless steel mixing bowls and electric beaters or whisks are preferred for formula preparation. Formula should be bottled in quantities for individual feeds or for 4 hours continuous feeding, refrigerated for a maximum of 24 hours, and used within

TABLE 52-5

Sample Plan for Managing Inadvertent Exposure to Hepatitis B and HIV through Human Milk[a]

Donor Mother[b]	*Recipient Mother*	*Treatment of Infant Recipient*
Management of Potential Hepatitis B Exposure		
Hepatitis B surface antigen negative	Hepatitis B surface antigen negative	Hepatitis B vaccine given according to the routine infant immunization schedule
	Hepatitis B surface antigen positive	Administer hepatitis B vaccine and hepatitis B immune globulin (HBIG) if not yet given
Hepatitis B surface antigen positive	Hepatitis B surface antigen negative	Administer hepatitis B vaccine (if not yet given) and HBIG
Hepatitis B surface antigen positive	Hepatitis B surface antigen positive	Administer hepatitis B vaccine and HBIG if not yet given
Management of Potential HIV Exposure		
Negative	Negative	Standard infant care
	Positive	If receiving AZT and standard therapy for infants born to HIV-positive mother, no additional therapy
Positive by ELISA with Western Blot confirmatory test	Negative	No standard for AZT prophylaxis but could be considered in high-risk situations. Consultation with expert in HIV care recommended
	Positive	Standard prophylactic treatment for infant born to HIV-positive mother. Consultation with expert in HIV care recommended

[a]Treatment options should be discussed with the family and care individualized.
[b]When the donor mother refuses or is not available for testing, treatment with hepatitis B vaccine is given. Some experts would treat with HBIG.
(Compiled from recommendations by the Human Milk Banking Association of North America. *Best practices for expressing, storing and handling human milk in hospitals, homes and child care settings*, 2005; and American Dietetic Association. *Infant feedings: guidelines for preparation of formula and breast milk in health care facilities*, 2005. Readers may wish to consult the latest ADA Guidelines: Pediatric Nutrition Practice Group. Infant feedings: Guidelines for the preparation of human milk and formula in health care facilities, second edition. Robbins ST, Meyers R, eds. Chicago, IL: American Dietetic Association, 2011.)

4 hours of opening. Any formula remaining after the 4-hour "hang time" should be discarded. The American Dietetic Association recommends that tubing and feeding reservoirs also be changed every 4 hours. Formulas containing probiotics should not be feed by continuous infusion.

All facilities should have a Hazard Analysis and Critical Control Point (HACCP) plan for human milk, infant formula and enteral feeding. This plan should include all aspects of the feeding process, including preparation, storage, delivery and administration, and be integrated into a facility's overall performance improvement program.

Blood Development of guidelines for administration of blood products to hospitalized neonates and strict adherence to these guidelines in order to limit exposure to blood products is the best way to prevent transmission of bloodborne pathogens. Nevertheless, many premature or ill newborns receive blood products *(434,435)*. All cellular blood products given to low-birth-weight infants should be from CMV-seronegative donors or leukoreduced to remove CMV. Some centers use these products for all newborns.

Family-Centered Care The family-centered care model recognizes the importance of parents and families in the care of sick newborns. Active engagement and participation in care is encouraged, and while a number of benefits have been described, the associated infection risks have not been well studied.

The kangaroo care model was initially described in Colombia in the 1970s as a model for home care of low-birth-weight infants. The key components include 24-hour skin-to skin contact with the infant positioned upright on the mother's chest, and exclusive or nearly exclusive breast-feeding. The original model is still employed in resource-limited settings, and several studies have suggested a benefit for infant outcomes, including decreased infections *(436)*. In more affluent settings, kangaroo care has been implemented as skin to skin contact that lasts at least 1 hour per day, is thought to promote bonding and improved physiologic and is not typically associated with an increased risk of infection *(437)*. In one small study in Japan, kangaroo care increased the risk of developing an MRSA infection (odds ratio 3.82; $p = .033$) *(191)*.

Even when kangaroo care is not employed, most neonatal units promote physical contact between mothers and their infants. Transmission of maternal flora to the newborn usually occurs during delivery, and postpartum separation of the mother and the newborn is rarely desirable or necessary, even when the mother has an active infection. Most maternal postpartum infections are urinary or gynecologic infections that arise from endogenous flora. The mother with a communicable infection should perform hand hygiene before handling the infant and take measures to prevent contact of the infant with potentially contaminated clothing, bedclothes, tissues, and other fomites (382).

When a mother has untreated pulmonary tuberculosis, separation is necessary until both mother and baby are receiving antituberculous therapy. When MDR tuberculosis is suspected, the infant should be separated from the mother and neonatal immunization with Bacille Calmette-Guérin vaccine should be considered. The newborn who has received varicella immune globulin or IVIG may remain with the mother with varicella infection (382). Separation should be considered if a mother has extensive *S. aureus* infection with drainage not contained by dressings or if a mother has a GAS infection until she has received antibiotic therapy and the infection is no longer communicable (382). Rooming-in has traditionally been encouraged for infants born to mothers with acute seasonal influenza infection, although when mothers and infants are not interacting, infants should be placed in isolettes positioned at least 3 ft from the mother's bed. Mothers are advised to wear a surgical mask and to perform hand hygiene before each feeding or other contact with the infant for at least 5 days after the onset of infection *(438)*. Concerns about the virulence of a novel H1N1 influenza virus that circulated in 2009 and 2010 prompted more stringent recommendations for postpartum women known or suspected to be infected with this virus. Temporary separation of the mother and the infant was recommended until the mother had been treated with antiviral medication for at least 48 hours, was afebrile without antipyretics for at least 24 hours, and could control her cough and secretions *(439)*. The efficacy of this strategy relative to the one usually employed with seasonal influenza is unknown.

There are relatively few infection-related contraindications to breast-feeding. Human immunodeficiency virus can be transmitted via breast milk; in the United States and in other settings where safe, affordable, and sustainable alternatives to breast milk are available, HIV-infected mothers should not breast-feed their infants *(445)*. Likewise, mothers in the United States known to be seropositive for HTLV-1 and HTLV-2 should not breast-feed. Women with tuberculosis who have been treated with at least 2 weeks of antituberculous therapy and who are not considered contagious may breast-feed. Breast-feeding by HSV-infected mothers is permissible as long as there are no lesions on the breast and other cutaneous lesions can be covered. Although HBsAg has been detected in the milk of women infected with HBV, breast-feeding does not increase the risk of transmission to the infant. Hepatitis B vaccine and hepatitis B immune globulin are recommended for all infants born to HbsAg-positive mothers, including those who will be breast-fed. Although hepatitis C RNA has been detected in human milk, transmission of hepatitis C by breast-feeding has not been documented. Although HCV infection is not a contraindication to breast-feeding, infected mothers should be counseled about the theoretical risk of transmission and counseled not to breast-feed with cracked or bleeding nipples.

Cytomegalovirus can be transmitted by breast milk, although clinically significant disease is uncommon in term and near-term infants. Conversely, severe CMV disease has been associated with breast milk transmission in infants born at less than 28 to 30 weeks of gestation (*375,440)*. CMV-seropositive mothers who deliver VLBW infants should be counseled about the potential risks and benefits of breast-feeding. Pasteurization of milk may be considered. Freezing milk at -20°C (-4°F) decreases but does not reliably eliminate CMV.

Mothers with mastitis may continue to breast-feed. Conversely, breast abscesses may rupture into the ductal system and release large numbers of pathogenic bacteria into the milk. Interruption of breastfeeding on the affected breast for 24 to 48 hours after surgical drainage and appro-

priate antimicrobial therapy has been suggested *(441)*. Breast-feeding may continue on the unaffected breast.

Co-bedding is the practice of placing multiples (i.e., twins) in the same crib or isolette. Proposed physiologic advantages include improved weight gain and decreased episodes of central apnea *(442,443)*. The infection risks associated with this practice have not been well studied, although in one randomized study of 82 infants, the incidence of HAI and NEC were similar in co-bedded infants and controls *(443)*. Infants in the co-bedded group who developed infections did not transmit infections to their twin.

The AAP encourages sibling visits for both healthy and sick newborns, including those in NICUs *(444,445)*. The benefits of visitation are thought to outweigh the risk that a sibling may harbor and transmit an infectious disease in the NICU. Few studies have systematically evaluated sibling visitation in NICUs, but limited data suggest that neonatal colonization and infection are not increased with such visits *(446)*.

In the normal newborn nursery, visiting in the mother's room or a special visiting room reduces the exposure of other newborns. NICUs should establish policies that minimize infectious risks associated with sibling visitation (Table 52-6). Some facilities restrict sibling visitation during community outbreaks of RSV and other respiratory viral illnesses, but this is not necessarily evidence-based.

Immunizations Premature infants generally respond well to protein antigens *(447)*. All infants with birth weights of at least 2,000 g should receive monovalent hepatitis B vaccine at birth. Newborns remaining in the NICU should receive diphtheria, tetanus, acellular pertussis, *H. influenzae* B conjugate, pneumococcal conjugate, and inactivated polio vaccines, as well as subsequent doses of hepatitis B vaccine, at full dose at the usual chronologic age *(448)*. Diminished immune responses to hepatitis B vaccine have been noted in infants weighing <2,000 g who are vaccinated before 1 month of age. The immunization strategy for these infants depends on the HBsAg status of the mother. When the maternal HBsAg status is positive or unknown, hepatitis B vaccine is administered within 12 hours of birth, but this dose is not counted in the three-dose series. Routine hepatitis B immunization should begin at 1 month of age. For infants <2,000 g born to HBsAg-negative mothers, the first dose of hepatitis B vaccine is postponed until 1 month of age or hospital discharge.

Premature infants are at increased risk of hospitalization for rotavirus gastroenteritis during the first year of life and should be immunized with live-attenuated rotavirus vaccine. However, because vaccine virus is shed in the stools of immunized infants and a theoretical risk exists for transmission to other infants who are acutely ill, the vaccine should be administered only at or after discharge from the nursery or NICU *(449)*. If an infant immunized with rotavirus vaccine requires readmission to the NICU within 2 weeks after receipt of vaccine, Contact Precautions should be implemented and maintained for 2 to 3 weeks after vaccine administration.

Infants should receive inactivated influenza vaccine at 6 months of age *(450)*. Influenza vaccine is also recommended for all pregnant women. In a randomized study in Bangladesh, administration of trivalent, inactivated influenza vaccine to pregnant women reduced proven influenza infection in their infants by 63% for up to 6 months of age *(451)*. Immunization during pregnancy to protect the newborn against other pathogens is an approach that is being explored *(452)*.

A "cocoon strategy" has been advocated for the protection of young infants against vaccine preventable diseases. Vaccinating an infant's close contacts against diseases such as influenza and pertussis may, in fact, protect the infant who is too young to be immunized himself. Both the Advisory Committee on Immunization Practices and the AAP recommend influenza vaccine for all household and other close contacts of infants <6 months of age, but compliance with the recommendation is low. One NICU was able to vaccinate 95% of NICU parents by offering education and free vaccine at the infants' bedsides *(453)*.

Similarly, tetanus–diphtheria–acellular pertussis vaccine is recommended for contacts of infants <12 months of age to protect infants against pertussis *(415)*. Routine immunization of postpartum women before hospital discharge is recommended and standing order protocols may result in immunization of most women *(454)*. Immunization of both mothers and fathers may be achieved by offering the vaccine in the NICU *(455)*.

Immunotherapeutic Agents Prophylactic administration of IVIG to preterm or low birth weight infants results in modest decreases in sepsis and other serious infections but does not decrease mortality *(456)*. Routine use of IVIG as an infection prevention measure is not recommended. Immunoglobulin preparations with sufficient concentrations of antibodies against common neonatal pathogens may be more effective. Monoclonal anti-RSV antibody (palivizumab) protects against RSV disease and is recommended for selected high-risk infants at hospital discharge to prevent community-acquired RSV disease *(457)*. However, routine use in hospitalized infants is not recommended nor is its use recommended in the setting of nursery outbreaks of RSV. Several antistaphylococcal immunoglobulin preparations have been developed but to date, these have not been more effective than placebo in reducing staphylococcal infections in preterm and VLBW infants and their use is not recommended *(458)*.

TABLE 52-6

Guidance for Sibling Visitation

Prepare child in advance of visit
Perform screening health interview for each sibling outside the unit
Document screening results in patient record
Verify that immunizations are current, including influenza vaccine
Defer visitation for any child with fever, symptoms of acute illness, or recent exposure to communicable disease[a]
Teach and observe compliance with recommended hand hygiene practices
Prohibit visitation with any patient other than child's own sibling
Require supervision of child by parents or other responsible adult

[a]Aymptomatic siblings who have recently been exposed to varicella but have been previously immunized are considered immune and may visit.

Lactoferrin, the major whey protein in mammalian milk, exhibits antimicrobial activity and is thought to play an important role in innate immune host defenses. In one randomized, placebo-controlled trial, orally administered bovine lactoferrin given with or without the probiotic *Lactobacillus rhamnosus GG* reduced the incidence of a first episode of neonatal sepsis in infants with birth weights of <1,000 g *(459)*. Further advances in the understanding of immune function in the newborn may lead to new strategies to strengthen neonatal defenses.

CHAPTER 53

Healthcare-Associated Infections Acquired in Childcare Facilities

Andi L. Shane and Larry K. Pickering

Group childcare facilities continue to be a major source of care for almost 10 million preschool aged children who spend at least 10 hours per week in one of these settings. According to the National Association of Childcare Resource and Referral Agencies (NACCRA), there were 119,174 childcare centers and 238,103 home-based childcare programs in the United States in 2008 (http://www.naccrra.org/randd/docs/2008_Child_Care_Capacity.pdf). Of the 9.6 million (40%) children from birth through 4 years of age in (nonrelative) childcare identified in the 2007 National Survey of Children's Health, 11% received childcare in their own home, 22% received childcare in someone else's home, and 72% were enrolled in center-based childcare. Children in out-of-home childcare tend to have higher rates of infectious diseases and antimicrobial use than children cared for at home, and their illnesses were transmitted to their care providers and family members. The burden of illness associated with group childcare depends on the age, developmental stage, immunization, and immune status of childcare enrollees, as well as environmental characteristics of the facility where care is provided as well as seasonal factors. Adult providers and school-aged siblings also may have an impact on the direct and indirect introduction and propagation of infectious microorganisms to children in group childcare. A reduction in antimicrobial use due to an increased awareness of appropriate use by providers with a corresponding emergence of antimicrobial resistant pathogens has influenced the epidemiology of many common childhood infectious diseases (1,*2*).

While funding for childcare-associated activities has increased over the past decade, the majority of these resources have been directed toward policy development and regulatory compliance activities. Support for understanding transmission of infectious microorganisms and for assessing the effectiveness of interventions to reduce infections has declined, without a corresponding decline in the incidence of childcare-associated outbreaks. The threat of propagation of infectious pathogens, accentuated by the 2009 novel H1N1 influenza pandemic, resulted in numerous discussions by policy makers and healthcare providers regarding efforts to contain and reduce transmission of infections. Although pandemic response planning focused on all members of communities, preschool aged children in group settings inherently pose a risk for transmission of respiratory and enteric pathogens due to the frequent contact of secretions directly with other children and indirectly through exposure to contaminated environmental surfaces and toys. Guidance for childcare and early childhood programs during outbreaks of novel H1N1 and seasonal influenza were outlined as part of a community response (www.cdc.gov/h1n1flu/childcare/technical.htm). Universal immunization of eligible people with influenza vaccination, decreasing exposure of ill and well attendees and staff, age-appropriate hand hygiene and respiratory etiquette, medical evaluation and treatment, and consideration of selective program closures were strategies proposed in the technical report. Consideration of a pandemic and response of childcare providers heightened awareness of the role of group childcare for preschool aged children in the containment of a community outbreak.

The national interest in promoting better childcare has been augmented by the planned publication of the third edition of *Caring for Our Children: National Health and Safety Performance Standards: Guidelines for Out-of-Home Childcare* by the American Academy of Pediatrics (AAP), the American Public Health Association (APHA), and the Health Resources and Services Administration (HRSA) (3), (*http://www.nrckids.org/*). As with previous editions, this comprehensive document is a compendium of best practices and policies developed by committees of experts in childcare and childcare health and safety.

TYPES OF CHILDCARE SETTINGS

Definitions

The U.S. Census Bureau classifies regular preschool childcare arrangements by provider (relative vs. nonrelative) and location of care. Nonrelative care may be further divided into provision of care in an organized care facility or childcare center and into other nonrelative care in the child's home or in the provider's home, (*http://www.census.gov/population/www/socdemo/child/ppl-2005.html*) *(4)*. Types of facilities also may be classified by size of enrollment, age of enrollees, and environmental characteristics of the facility. Grouping of children by age varies by setting but in organized care facilities infants and children usually are separated by age into infants

(6 weeks through 12 months), toddlers (13 through 35 months), preschool (36 months through 59 months), and school-aged children (5 through 12 years). The classification of group childcare settings has relevance to infectious disease epidemiology with regard to regulation and monitoring. Most nonrelative care provided in an organized care facility is subject to state licensing and regulation, whereas relative care in a child or provider's home may not be subject to state regulations and monitoring. The terms *caregiver* and *childcare provider* are used interchangeably to identify people providing direct care to children.

Alternative Childcare Arrangements

Employer-Sponsored Childcare Employer-sponsored childcare and onsite childcare have become prevalent and are often selected as an option for families who are unable to utilize relative or other forms of nonrelative childcare. An advantage of employer-sponsored or onsite childcare is that the child or the children are located in close physical proximity to the parent. For young infants, this proximity may facilitate breastfeeding, and for older children, transportation to and from work/ childcare activities as well as proximity to after school activities offer opportunities for increased parent–child interactions. Financial benefits including direct payroll deduction and increased productivity by parents who may be able to devote time saved to their jobs. Additionally, an employed parent may be less likely to be absent if he or she is in close proximity to a mildly ill child in an employer-based childcare arrangement. Accessibility and observation of a child in employer-based care may be an incentive to keep the child in the employer-based care arrangement and continue with employee obligations.

Ill Childcare Ill childcare is defined as the provision of care for a child who is mildly ill and who does not meet criteria for exclusion from childcare. However, some childcare facilities may not be able to accommodate a mildly ill child, translating into parental absences, ranging from 5 to 29 days annually and a corresponding cost to employees ranging from $2 to $12 billion annually (*http://nascd.com/index.htm*). Following a 1998 needs assessment for ill childcare, a collaboration of childcare providers formed the National Association for Sick Child Daycare (NASCD), a nonprofit educational organization that serves as a resource for ill childcare programs. Arrangement for the provision of ill childcare may vary with the needs and the structure of the center. Considerations affecting the choice of an appropriate alternative include the need to ensure the child's health and well-being, increased costs of alternative arrangements, the desire to reduce parental absenteeism from work, disruption of the child's routine, and the potential for spread of infection to children or adults in the alternative setting *(5)*.

Models include temporary or permanent arrangements for the care of ill children and dedicated locations within a facility or a separate facility in which ill care is provided. Temporary arrangements may best be suited for a local or community outbreak of a communicable disease, while a permanent ill childcare location may serve the needs of a higher volume facility or a community where ill childcare cannot be provided effectively within an existing childcare center.

Although ill childcare raises concerns about children's emotional and medical needs and the risk of transmission among children in such settings *(6)*, few studies have addressed these issues. A comparison of 118 children who attended a center providing short-term care for children with mild illnesses with an age-matched cohort of ill children who received care from a home care provider in their own homes indicated no increased risk of subsequent illness in the former group *(7)*. The provision of ill childcare may require additional training of staff including availability of facilities to maintain segregation of children with a variety of illnesses. Providers of care for ill children should be well versed in strategies to prevent transmission of potentially infectious microorganisms, both among attendees and staff, and should be able to maintain vigilance for changes in conditions of children who are mildly ill. Hospitals that provide employer-based childcare may be uniquely situated to provide ill childcare and may provide a sense of reassurance to parents due to their proximity to the availability of medical care services, if needed. While these facilities are not intended to replace evaluation by a healthcare provider, childcare providers with training and experience related to provision of care for mildly ill children may result in appropriate care for mildly ill children.

Backup Childcare Care of children who receive care from an individual provider may be interrupted when the provider becomes ill or is unable to provide care for another reason. In these situations, availability of backup childcare is beneficial. One of the challenges to providers of intermittent care is that the need for these services is variable and the care provided is frequently transient, lasting only for the duration of the incapability of a regular provider. Although backup childcare arrangements facilitate continuation of care for children and sustainability of employment for parents, settings that provide urgent childcare should be evaluated prior to their need to ensure that they meet local licensing requirements.

Sibling Childcare When children are hospitalized for acute and chronic conditions, a need has developed to provide care for their siblings while their parents spend time with the hospitalized child. In certain inpatient units, such as intensive care or transplant units, age and developmental limitations may not be conducive to sibling visits. Additionally, care for well siblings of hospitalized children may be a challenge for families who reside at significant distances from the hospital. Therefore, the provision of childcare for well siblings of hospitalized children provides a service to families of pediatric inpatients and optimizes compliance with visitation policies. Hospitals or medical centers that provide employer-based care could extend care of employee children to that of temporary care for siblings of hospitalized children.

MAGNITUDE OF CHILDCARE HEALTH ISSUES

Children attending out-of-home childcare generally have higher rates of infectious diseases and antibiotic use than children in home care. Among preschool children

in the United States, 9% to 11% of all upper respiratory tract infections (URIs), 10% to 14% of all otitis media episodes, and 19% of all clinic visits for diarrheal disease are attributable to childcare attendance *(8–10)*. Despite variations in study methods and definitions, the increased burden of illness associated with childcare compared with illness among children in home care has been demonstrated fairly consistently. In a study of children enrolled in a Memphis healthcare maintenance organization, children in out-of-home childcare had 2.5 to 3.1 physician-diagnosed infections during a 7-month study period compared with 2.0 infections among children in home care *(11)*. These differences were statistically significant. Results from the National Institute of Child Health and Human Development Study of Early Childcare suggest that these differences still exist for children younger than 2 years of age but by 3 years of age, illness experiences among children in out-of-home childcare are comparable to illness episodes in children cared for at home (12).

The risk of illness associated with family childcare usually has been found generally to be intermediate between the risks associated with center care and risks associated with home care *(11–21)*. However, some studies have indicated that provider-reported illness rates in children attending childcare homes were greater than those among children in centers *(22,23)*. As many previous studies obtained data through retrospective telephone interviews with parents, these differences in results suggest that comparisons of illness rates from various types of childcare facilities may be influenced by the information source.

In 1989, childcare-associated illnesses were estimated to cost the U.S. economy at least $1.8 billion annually *(24)*. Two-thirds of that cost was due to lost employee time due to parental care of an ill child. In one survey conducted in 1990, almost 18% of mothers interviewed had missed an average of 2.2 days of work during the month before the study interview to care for an ill child *(25)*. During a similar period, the mean monthly costs of medical care incurred by children in home care and center care in Memphis, TN, were $19.78 and $32.94, respectively *(11)*. After including lost income for parents who missed work, the mean monthly cost of illnesses ranged from $29.50 for families with children in home care to $61.64 for families with children in center care. Total parental- and societal-adjusted average costs for illness among toddlers in Quebec childcare facilities over a 6-month period were U.S. $260.70. The costs of medical care ($47.47 for medication and $49.10 consultation) may have underestimated actual costs. However, this assessment included an estimate of $35.68 for a previously overlooked cost of care by family members *(26)*.

By amplifying the prevalence of pathogens already present in the community, childcare patterns have influenced the epidemiology of a number of illnesses, including cytomegalovirus (CMV) infection, hepatitis A, shigellosis, giardiasis, and cryptosporidiosis. A concerning issue is the widespread use of antimicrobial agents among children attending childcare and the increased likelihood of isolation of antibiotic-resistant bacteria from children in out-of-home childcare (*27*,*28*,29,*30–35*,36,*37–42*).

INFECTION CONTROL CONSIDERATIONS

The concept of infection control, as applied in the hospital or other healthcare venues, can serve as a model for understanding the epidemiology of infectious diseases in the childcare setting. Although differences between the childcare and inpatient settings are significant, some common elements can be found. Very young children, like hospitalized patients, have an increased susceptibility to infections. Like many patients in hospitals and nursing homes, young children depend on care providers for the most basic functions, including nourishment and personal hygiene. Care providers inadvertently may transmit microorganisms between children and are themselves at risk for contracting infections through occupational exposures. Prevention methods focus on increased recognition of the risks of transmission and on interrupting the chain of transmission within the institutional setting *(43–49)*.

EPIDEMIOLOGY OF INFECTIOUS DISEASES IN CHILDCARE

The incidence of illness within a childcare facility is determined by factors influencing both the rate of introduction of pathogens into a facility and the rate of transmission once a pathogen has been introduced *(50)*. Aspects influencing the rate of introduction are often beyond the control of the facility and include the prevalence of the illness in the community, the age and health status of children served by the facility, and facility size (usually expressed as the total number of children enrolled). One model suggests that the geographic distribution of the homes of children attending the facility may influence morbidity and that facilities with more widely distributed homes of attendees were less likely to experience major epidemics than those with clustering of homes *(50,51)*.

Characteristics influencing the rate of transmission once a pathogen has been introduced can often be addressed and modified. These factors include practices and policies concerning hygiene and disinfection, including hand hygiene, staffing patterns and education of staff, isolation or exclusion of ill children, mixing of children of various ages in the same classroom, and diaper type and use of overclothing with diapers. A simple scheme depicting the mode of spread of enteric bacteria within childcare centers has been devised *(49)*. This model has been developed further and probably applies, with some modification, to nonenteric pathogens as well *(52)* (Table 53-1).

Factors Related to Increased Transmission among Children

Young children have an increased susceptibility and high age-specific attack rates for numerous diseases. Infections in childcare settings are transmitted primarily by person-to-person spread of pathogens through body substances, including feces, saliva, nasal secretions, and urine; through direct contact; or by hands of children and care providers. Children, especially toddlers, in childcare have frequent person-to-person contact and often have poor personal hygiene with regard to contact with and disposal

TABLE 53-1

Modes of Transmission of Organisms in Childcare Settings

Usual Route of Transmission[a]	*Bacteria*	*Viruses*	*Other*[b]
Fecal–oral	*Campylobacter* organisms, *Clostridium difficile*, *Escherichia coli* O157:H7, *Salmonella* organisms, *Shigella* organisms	Astrovirus, norovirus, enteric adenovirus, enteroviruses, hepatitis A virus, rotaviruses	*Cryptosporidium species*, *Enterobius vermicularis*, *Giardia intestinalis*
Respiratory	*Bordetella pertussis*, *Haemophilus influenzae* type b, *Mycobacterium tuberculosis*, *Neisseria meningitidis*, *Streptococcus pneumoniae*, group A *Streptococcus*, *Kingella kingae*	Adenovirus, influenza virus, human metapneumovirus, measles virus, mumps virus, parainfluenza virus, parvovirus B19, respiratory syncytial virus, rhinovirus, rubella virus, varicella-zoster virus	—
Person-to-person contact	Group A *Streptococcus*, *Staphylococcus aureus*	Herpes simplex virus, varicella-zoster virus	Agents causing pediculosis, scabies, and ringworm[c]
Contact with blood, urine, and/or saliva	—	Cytomegalovirus, herpes simplex virus	—
Blood-borne	—	Hepatitis B virus	—

(Used with permission of the American Academy of Pediatrics. Children in out of home care. In: Pickering LK, Baker CJ, Kimberlin DW, et al., eds. *Red Book: 2009 report of the committee on infectious diseases*. 28th ed. Elk Grove Village, IL: American Academy of Pediatrics.)
[a]The potential for transmission of microorganisms in the childcare setting by food and animals also exists (see Appendix IX, Clinical Syndromes Associated With Foodborne Diseases, p 860, and Appendix X, Diseases Transmitted by Animals, p 864, and Diseases Transmitted by Animals [Zoonoses]: Household Pets, Including Nontraditional Pets, and Exposure to Animals in Public Settings, p 198).
[b]Parasites, fungi, mites, and lice.
[c]Transmission also may occur from contact with objects in the environment.

of potentially infectious body substances (*43,46*,53,*54*). Frequent hands-on contact by staff, often in hectic circumstances, provides additional opportunity for person-to-person spread via the care providers' hands both to other children and to other care providers *(49,52,55,56)*. The lack of fecal continence in children who are not toilet trained and the tendency for children to explore their environment with their hands and mouths lead to frequent sharing of oral secretions and fecal–oral spread of infection *(46,52,54,57–59)*.

Children also share secretions and excretions via fomites; contaminated toys and environmental surfaces are important in the epidemiology of childcare-associated infections. These areas, especially surfaces in classrooms of non–toilet-trained children, are often contaminated with enteric microorganisms *(52,59–63)*. Many microorganisms associated with childcare related infections can survive on environmental surfaces for considerable periods of time. Some, including CMV, rotavirus, and *Giardia*, have been isolated from environmental surfaces in childcare facilities *(58,64–66)*. The concentration of microorganisms recovered from surfaces and air samples in childcare center classrooms is inversely related to the age of the children in the room *(67)*. Environmental levels of fecal coliforms in childcare classrooms often increase during outbreaks of diarrheal illness *(49)*. Group A *Streptococcus* was isolated from plastic toy food during an investigation of two cases of invasive GAS infections in a childcare facility *(68)*. Although mouthing behavior is uncommon among children 3 and 4 years of age, such as the children involved in this outbreak, food replica toys encourage mouthing behavior and are examples of the types of fomites that contribute to transmission.

Airborne transmission also contributes to spread of pathogens. Respiratory tract infections, transmitted through respiratory aerosols and droplets, are the most common infections associated with childcare attendance (12,*19,22,23,48*,69). Studies in crowded homes and childcare settings have shown that risk of respiratory tract infections, including otitis media, increases as the number of children per room increases *(8,70,71)*. Results from a series of longitudinal studies suggest that a positive association exists between frequency of respiratory tract illness and childcare among preschool children. These results also suggest that this association is related to the number of children in the group, may be moderated by length of time in childcare, and is reversed to a protective effect in school-aged children, with the differences disappearing by 13 years of age (12,*72*).

Common source and food-borne transmission rarely are reported causes of outbreaks in childcare settings *(73–77)*. However, unhygienic food-handling practices have been shown to be a risk factor for illness spread by fecal–oral transmission in childcare facilities *(14,55)*, and clinicians may not have recognized fully the significance of food-borne transmission in this setting.

Other Persons and Groups at Risk

Childcare Providers Childcare providers, like healthcare providers, are at risk of occupational exposure to infectious microorganisms *(78,79)*. The majority of childcare providers are women; many of whom are of childbearing age *(80–82)*. Childcare providers have an increased endemic risk for a number of infections including CMV, parvovirus B19, and *Giardia* and an increased epidemic risk for infections with other agents such as *Shigella*, hepatitis A, and *Cryptosporidium*. Infections caused by pathogens, such as varicella, parvovirus B19, and CMV, which are common in childcare settings, pose a significant risk of adverse consequences for pregnancy outcomes. However, few studies have focused on infections among childcare providers, and the actual risk of maternal or fetal infection or of specific adverse pregnancy outcomes as a result of these likely exposures has not been well defined.

Childcare providers experience annual rates of CMV seroconversion ranging between 8% and 20%, compared with hospital employees who experience annual rates of seroconversion of 2% (*58,80,83*,84,*85,86*). During community outbreaks of erythema infectiosum, childcare providers were found to be among the most affected occupational groups, with seroconversion rates ranging from 9% to 31% *(87–90)*. In a prevalence study of hepatitis A antibodies among childcare providers employed in 37 randomly selected childcare centers in Israel during 1997, 90% (402 of 446) of the childcare providers had antibodies to hepatitis A. The authors concluded that childcare providers are at high risk of occupational exposure to hepatitis A, and postulated that seronegative employees may have a twofold chance of acquiring hepatitis A *(91)*. Since the recommendation for universal immunization of children over 12 months of age in 1995, the risk for infection with hepatitis A after occupational exposure in a childcare setting may be reduced. However, the risk of exposure to unimmunized children and international adoptees may warrant hepatitis A immunization of childcare providers *(92)*.

Childcare providers compared with nonproviders have a significantly higher risk of at least one infectious disease and lose more work days due to infectious diseases *(79,93,94)*. Childcare providers should receive all immunizations routinely recommended for adults, as shown on the adult immunization schedule, which is updated annually (*www.cdc.gov/vaccines*).

During outbreaks of diarrhea in childcare centers, 40% of care providers developed diarrhea *(95)*. During a multicommunity outbreak of shigellosis, the overall median attack rate among employed staff of childcare centers was 6%, with a range of 0% to 17% *(96)*. In outbreaks of group A streptococcal (GAS) infection and echovirus 30 infection *(97,98)* in childcare centers, both microorganisms have been shown to infect and cause disease in adult providers and parents. A cross-sectional study of 477 childcare staff revealed a seroprevalence for parvovirus B19 IgG antibodies of 70%. Seropositivity was associated with age, and among staff <40 years of age, with length of group childcare contact *(89)*. A concern is that an infected pregnant woman could transmit the virus transplacentally, leading to fetal hydrops, intrauterine growth retardation, isolated pleural and pericardial effusion, and death, but congenital malformations have not been linked to prenatal parvovirus B19 infection. Estimates of the risk of fetal loss when a pregnant woman of unknown antibody status is exposed are 2.5% for fetal death after household exposure and 1.5% after occupational exposure in a school *(87)*.

Family Members Family members of both providers and children may be infected by pathogens transmitted in childcare settings. Parents of children who attend a childcare facility and persons who provide care to these children have increased risk of acquiring infections such as CMV (*58,80,82,83*,84,*86,99*), parvovirus B19 *(87–90)*, hepatitis A virus (HAV) *(91,93)*, and diarrhea *(95,96,100)*. Mothers of children in childcare are at increased risk of acquiring childcare-associated infections *(83,87,101–103)*. Preschool children often introduce infections into their families *(9,54,87,101,102,104)*. Secondary attack rates among household contacts are often high (53,*74,79,103,105*), especially for highly communicable diseases such as shigellosis. In the case of hepatitis A, clinical illness among older household contacts may be the first indication of transmission within a childcare facility *(101)*. Older siblings, secondarily infected at home, may spread infections to other children through school and play contact.

The Community Childcare-associated infections generally reflect agents circulating in the community. Transmission within childcare facilities amplifies the prevalence of pathogens in the community, including *Giardia*, *Cryptosporidium*, *Shigella*, hepatitis A, and CMV. Interrupting disease transmission in childcare settings may lead to a reduction in the disease burden within the community and to a reduction in expenditures associated with infectious diseases outbreaks.

The economic burden of illness associated with group childcare was estimated at $1.5 billion annually adjusted to 2005 U.S. dollars *(106)*. Precise mechanisms for estimating illness burden and for evaluating effectiveness of infection control interventions are rare due to challenges associated with performing such assessments (107). Economic evaluations of outbreaks occurring in the school setting and modeling of vaccine prevention efficacies have been described frequently in the literature, but few economic analyses of outbreaks of infections associated with group childcare have been published. In order to perform an economic analysis, information required for the analysis must often be collected concomitantly with an outbreak investigation. Due to numerous variables, computerized models must often be created to perform these evaluations. Attributing an outbreak to group childcare is challenging, because although these settings may promote transmission of infection, childcare attendees and staff interact with household contacts external to the childcare arrangement, thus facilitating secondary spread. An economic analysis of a childcare-associated outbreak of *Shigella sonnei* in southwestern Ohio in 2001 incurred an overall cost of $821,725 to contain the outbreak of over 1,600 infections, which was the equivalent of $514 per culture confirmed case *(96)*. A prospective evaluation of 208 families with at least one childcare enrollee, conducted from November 2000 to May 2001 in the Boston area, documented 2,072 viral illnesses over 105,352 person days. Among the 834 subjects,

1,683 URIs and 389 gastrointestinal tract illnesses (GI) were reported during the study period with a total mean cost of $49 per URI and $56 per GI episode. Decreased parental productivity during missed days of work to care for a child who was not in childcare accounted for a significant proportion of the nonmedical costs *(106)*.

Future investigations of outbreaks of illness associated with group childcare could utilize computerized models and paradigms to assess the economic impact of outbreaks. In an era of limited funding, an understanding of expenses and allocation of resources will be important information to justify utility of interventions.

Antimicrobial Resistance and Antimicrobial Use

Emergence of antimicrobial-resistant strains of bacteria resulting from inappropriate use of antimicrobial agents is a serious public health issue. While antimicrobial use among all preschool aged children is notable, children enrolled in out of home childcare generally receive more antimicrobial treatments than children in home care *(21,34,41,108)*. During an 8-week period of observation of 270 children, antimicrobial agents were used by 36% of children in childcare centers compared to 7% and 8% of children in childcare homes or in home care, respectively ($p < .001$). The mean duration of antimicrobial therapy prescribed for children in childcare centers (20 days) differed significantly ($p < .001$) from children in childcare homes (4 days) and children in home care (5 days). The estimated annual rates of antimicrobial treatment ranged from 2.4 to 3.6 times higher for children in childcare when compared with children in home care *(41)*.

As a result of this increase in antimicrobial use, an association of childcare center attendance with colonization or infection with resistant bacteria has been documented. Outbreaks of illness due to resistant *Streptococcus pneumoniae* (29,*30,40,109–115*,116,*117–120*) and *S. sonnei (96,121,122)*, as well as colonization due to resistant *Haemophilus influenza (123)*, *Escherichia coli (42,94,124)*, and methicillin-resistant *Staphylococcus aureus (32,37)* have been described. In a written survey of 135 licensed childcare directors in Pennsylvania in 2007 to assess opinions of antimicrobial use for childhood illnesses, approximately one-half (52%) of respondents agreed that children are prescribed antimicrobial agents unnecessarily and 89% believed that parents pressure physicians to prescribe unnecessary antimicrobial agents. However, policies requiring receipt of antibiotics prior to returning to the childcare center were notable. Most directors reported that children with conjunctivitis with white or yellow discharge, conjunctivitis with watery discharge, or diarrhea were excluded from the childcare center until antibiotics were prescribed. Although receipt of antibiotics prior to the child's return to a childcare center was not always required in other scenarios, including clear rhinorrhea and afebrile cough, directors frequently reported that antibiotics were sometimes required. In centers with larger enrollments, directors were more likely to exclude children with ear pain until the child receives antibiotics (125). Educational campaigns including the AAP's Healthy Childcare America (HCCA) Campaign, (*http://www.healthychildcare.org/index.html*) and the Centers for Disease Control and Prevention's (CDC's) Get Smart Campaign, (*http://www.cdc.gov/getsmart/*) provide targeted information to parents, childcare, and healthcare providers to assist with choices for judicious use of antimicrobial agents. Efforts should disseminate information that most illnesses acquired in the childcare setting are attributable to viruses, for which supportive care is optimal and for which antimicrobial therapy is economically and scientifically disadvantageous. Additionally, immunization against common viral and bacterial pathogens is an effective means of reducing the prevalence and severity of infections with these microorganisms *(126)*. The current recommended immunization schedule for children can be found at www.cdc.gov/vaccines. This schedule is updated annually in January.

EPIDEMIOLOGY, ETIOLOGY, AND PREVENTION OF DISEASE SYNDROMES

Respiratory Tract Infections

Upper and Lower Respiratory Tract Infections Infections of the upper respiratory tract are the most common illnesses involving children in both home and childcare settings *(127)*. Studies have documented the association between childcare attendance and increased risk of URIs especially in children <3 years of age *(127)*. Using different methods, the risk of contracting a respiratory tract infection was found to be 2 to 3 times higher among children cared for at home *(8,127,128–130)*.

Respiratory tract symptoms were involved in 45% to 85% of illness episodes reported among children attending childcare facilities in various geographic locations *(19,22,23)*.

Respiratory tract infections that have been studied in the childcare setting include pharyngitis, sinusitis, otitis media, the common cold, bronchiolitis, and pneumonia *(20,131–133)*. Microorganisms responsible for illness in the childcare settings are similar to microorganisms that circulate in the community. Depending on the season, these microorganisms include parainfluenza, influenza, respiratory syncytial virus, adenovirus, rhinovirus, coronavirus, metapneumovirus, parvovirus B19, and *S. pneumoniae*. Infections due to *Haemophilus influenzae* b and pertussis have experienced dramatic declines in the United States although cases and outbreaks continue to occur *(134)*. In a group childcare setting, adolescents or adults may serve as the index case for pertussis outbreaks or tuberculosis infections *(135–140)*, particularly when children or adults are not appropriately immunized against pertussis *(134,135)*.

Person-to-person transmission of *Chlamydophila pneumoniae* among children in the childcare setting has been reported without occurrence of disease *(141)*. *Kingella kingae* colonizes the oropharynx and respiratory tracts of young children and has been associated with invasive disease *(142–146)*. Invasive *K. kingae* osteomyelitis/septic arthritis has been reported in two children in a childcare center with nine other children in the same class found to be colonized. Matching pulse-field gel electrophoresis (PFGE) patterns supported child-to-child transmission *(142)*. GAS infection among children and adult staff in the childcare setting has been reported *(68,147)* but is not common *(68,147)*. Following a fatal case of invasive disease, 25% of 258 children and 8% of 25 providers had GAS isolated from throat cultures *(147)*. In Israel, a study

conducted in childcare centers showed the prevalence of GAS to be 3% in infants and 8% in toddlers. Carriage was not associated with respiratory tract symptoms *(148)*.

Respiratory tract infections contribute to the burden of otitis media, antibiotic use, and absenteeism experienced by children in out-of-home childcare. Approximately 29% of respiratory tract infections among young children are complicated by otitis media *(20)*. Children with respiratory tract infections in Seattle childcare facilities were absent for an average of 0.9 days per illness episode; these infections accounted for 3,558 days of absence, representing almost half of the total 7,635 days of illness-related absences among these children *(22)*. Among children in San Diego childcare facilities, illness episodes involving rhinitis accounted for 2,335 days of absence (1.6 days per child year), an average of 0.3 days absent per illness episode *(23)*.

Children who have been enrolled in group childcare for some time may have no greater risk of respiratory tract infections than their same-aged peers who stay at home (*9*,12,*44,149*). Results from the National Institute of Child Health and Human Development Study of Early Childcare support this finding and suggest that, although childcare was associated with increased illness in children younger than 2 years of age, the difference was negligible by 3 years of age (12). Children who first entered out-of-home childcare after 3 years of age experience more illness than their classmates who were in childcare before 3 years of age *(150)*. However, the excess respiratory tract illness among children in childcare centers may protect those children against respiratory infections during the early school years *(72)*.

Although results of the few studies assessing the impact of childcare attendance on lower respiratory tract infections are not definitive, they suggest an increased risk among children in childcare *(151–155)*. After other risk factors were controlled, children hospitalized with lower respiratory tract infections at one of four Atlanta area hospitals were more likely than control patients to have been in out-of-home childcare *(152)*. Center care posed a greater risk for hospitalization than care in a childcare home. However, other studies have found no association between lower respiratory tract illnesses and childcare *(108,155)*.

Most authorities agree that children with mild to moderate symptoms of viral upper respiratory infection, such as rhinitis, cough, pharyngitis, or otitis media, may continue in their usual childcare arrangement unless they meet other criteria for exclusion (3,*43*,156). Care should be taken to clean objects, including toys, and surfaces contaminated with oral or nasal secretions. Tissues, towels, or other material used to wipe children's noses and mouths should be handled as contaminated items (3,*43,48,158*). Hand hygiene protocols must be followed carefully (3,*43,48*,156,159).

Immunization of healthy people 6 months of age and older, including adults, with influenza vaccine is encouraged to reduce the impact of influenza on the health of both the children and their contacts (156,*160*). Influenza and other respiratory tract infections predispose children to otitis media. Immunization against influenza may provide some protection against otitis among vaccines and may even reduce respiratory illness among household contacts *(161–164)*.

Invasive Bacterial Infections The risk of developing invasive bacterial infections, especially meningitis and bacteremia caused by *H. influenzae* type b (Hib) before routine use of Hib vaccine in the United States, was higher among children attending childcare centers than in children cared for at home *(109,165)*. The incorporation of conjugated Hib vaccine into the routine immunization schedule to prevent invasive Hib disease has dramatically decreased the frequency of invasive Hib infections. Since use of conjugated Hib vaccine in infants beginning at 2 months of age in October 1990 *(166,167)*, the average annual rate of invasive Hib infections has declined from over 20,000 cases per year to <100 cases of known serotype b *H. influenzae* per year from 2003 through 2008 *(168)*. The prevention of invasive Hib infections in childcare settings today requires ensuring appropriate immunization of all enrolled children, complete reporting to allow the characterization of suspect vaccine failures, standardized serotyping procedures, and serotype tracking for all invasive *H. influenzae* infections *(169)*.

Household contacts of people with *Neisseria meningitidis* infections are at increased risk of disease, but the magnitude of risk for childcare contacts is uncertain. Reports from outbreaks suggest that childcare contacts of cases are at increased risk *(170–172)*. However, from 1998 to 2008, the incidence of invasive meningococcal disease has reached a historic low in the United States *(173)*. From 1993 to 2001 in the Netherlands, clustering of *N. meningitidis* cases beyond chance occurred at a rate of 3% (CI: 2–4%) and concluded that this rate was likely the result of direct transmission *(174)*. Childcare center attendance was reported as the likely exposure for 8/40 (20%) of clusters, accounting for 13/82 (16%) cases of invasive disease with multiple serotypes. Childcare attendees who develop clinical disease while enrolled in group care often result in the need for administration of chemoprophylaxis to family and childcare centers.

In the event of a case of invasive *N. meningitidis* disease in a facility, rifampin prophylaxis generally should be given to childcare contacts (both children and adults) (3,*43*,156,*165*). It is often not necessary to administer rifampin to all center attendees as they may not have had at-risk contact with the case. Public health authorities and healthcare providers should be involved in evaluating the significance of exposure on an individual basis. Routine immunization of healthy preschool aged children with a meningitis vaccine is not recommended unless the child is 2 years of age or older and has an underlying, predisposing condition, anatomical or functional asplenia, persistent complement deficiencies or human immunodeficiency virus (HIV), or plans to travel to a country with highly endemic or epidemic disease (156,175). Immunization may be useful in controlling outbreaks caused by serogroups to which the vaccine confers immunity.

Childcare attendance was shown to be a risk factor for primary invasive pneumococcal disease *(111,112,120)*, for nasopharyngeal carriage of *S. pneumoniae*, and for carriage of antibiotic-resistant strains for children in childcare centers (29,*30,110,112,114,115,120,176–178)*. Secondary spread of *S. pneumoniae* in the childcare setting has been reported, but the exact risks are not known *(40,111,112)*.

Incorporation of a conjugated pneumococcal vaccine into the routine childhood immunization schedule in the United States in 2000 has resulted in a dramatic reduction in the frequency of invasive pneumococcal disease *(179)*. With expansion of coverage of pneumococcal serotypes by six with the recommendation for routine use of PCV13, further disease reduction may occur *(177,178)*.

The emergence of antibiotic-resistant strains of pneumococci is a matter of both clinical and public health concern. Israeli investigators reported that the risk of resistant pneumococcal infections in children who attended childcare centers and who had received at least one course of antimicrobial treatment in the previous 3 months was 12.9 times that of children who had neither of these risk factors *(180)*. In studies among children attending four Houston childcare centers, *S. pneumoniae* was recovered from 40% of 140 children younger than 3 years *(181)*. Intermediate penicillin resistance was found in 11% of isolates; none was highly resistant. During a 7-year prospective study, upper respiratory tract cultures were collected monthly from 72 children *(39)*. Each child had an average of 2.1 episodes of *S. pneumoniae* colonization; 68% had resistant pneumococci isolated at least once. In another study, multiply resistant strains were isolated from nasopharyngeal cultures from 9 of 47 children in a center attended by two toddlers hospitalized with invasive pneumococcal infections *(40)*. After isolation of resistant *S. pneumoniae* from the middle ear fluid of a child with otitis media, researchers found that 52 of 250 exposed children were carriers of a resistant pneumococcus *(118)*. Carriage was associated with receipt of antimicrobial agents, especially at prophylactic doses. This association has been demonstrated previously *(110,182)*. Studies in an Omaha childcare center suggest that decreasing antibiotic use may control the spread of resistant pneumococci *(110)*. Resistant pneumococci may persist among children in centers. Although treatment with rifampin or rifampin and clindamycin can reduce the prevalence of carriage temporarily *(112)*, it may not eliminate carriage or reduce spread *(40,181)* and is not recommended.

Group A Streptococcal Infections Outbreaks of GAS infections among children and adult staff in the childcare setting have been reported *(39,147,183)*. A study of prevalence of GAS in a childcare center after a fatal case of invasive disease showed that 25% of 258 children and 8% of 25 providers had GAS isolated from throat cultures *(147)*. Risk of carriage was similar in children housed in the same room as the index case. GAS infection associated with varicella also has been reported *(68)* as has an outbreak associated with toxic shock *(184)*. A program of aggressive intervention that involves culturing and treating symptomatic contacts and environmental sanitation measures has been recommended for outbreaks of symptomatic GAS disease with a high attack rate *(185)*. However, the relative benefits of this approach in comparison to less aggressive interventions have not been evaluated *(131,132)*.

Tuberculosis The principal risk of tuberculosis in the childcare setting is transmission from infected adolescents or adults to children *(137,140,186,187)*. Child-to-child transmission occurs infrequently. Transmission of tuberculosis in childcare is uncommon and generally results in multiple cases. In England, a community outbreak involving 12 children in a play group was traced to one child's infected mother. Investigators were unable to identify a source of infection for two infected children in a Kentucky childcare center *(186)*. In an outbreak of tuberculosis associated with a private home childcare facility, 9 of 11 outbreak cases occurred in children <7 years of age, all of whom had extensive contact with the private-home childcare facility where the adult index case was present for long periods of time *(137)*. Transmission of tuberculosis has been reported to occur in an adult day care facility *(187)*.

Current recommendations call for preemployment screening of all childcare providers with a tuberculin skin test or an interferon-gamma release blood assay and chest radiograph follow-up of all positive reactors. Because the risk of transmission from infected children to other children is low, children do not need routine screening before entry into childcare.

Care providers or children with active disease who are infectious should be excluded from childcare and treated in accordance with the appropriate protocols. After initiation of therapy, public health authorities should determine that the patient is noninfectious before the caregiver or child is readmitted (156).

Otitis Media Otitis media is associated with viral respiratory tract infections and respiratory tract colonization or infection with bacteria including *H. influenzae* or *S. pneumoniae (129,183)*. Childcare attendance, with increased risks of both respiratory tract infections and exposure to pathogenic bacteria, also is associated with an increased incidence of otitis media *(19,20,129,133,183,188–193)*.

Children 6 to 24 months of age in Swedish childcare centers and family childcare homes (caring for one to four children) had 2.5 to 3 times the mean number of episodes of otitis media per child compared with children in home care *(18)*. Older children in childcare were not at increased risk of otitis media. Neither the facility's policy concerning exclusion of ill children nor the number of children enrolled in the facility influenced the risk of illness. A telephone survey of families of 575 children in Atlanta found that children in full-time childcare (>40 hours per week) had 3.8 times the risk of developing an ear infection compared with children in home care *(8)*. The risk was greatest among children younger than 36 months. For children younger than 2 years of age with URIs, attending childcare for at least 20 hours per week resulted in a 1.6- to 1.7-times higher likelihood that the URI would be complicated by an episode of otitis media. The risk was not increased significantly among children older than 2 years of age *(194)*.

Other studies have suggested that the incidence of otitis media among children in out-of-home childcare increases as the number of children present in that setting increases (e.g., in a childcare center rather than family childcare home) and decreases with increasing age at entry into childcare *(11,71,195–197)*. Results from the Child Health Survey of the National Health Interview Survey suggest that children in childcare have 1.5 times the risk of repeated ear infections compared with children in home care *(71)*. Attending a facility with more than six children significantly increases the risk of repeated otitis media in children younger than

3 years of age. Childcare attendance also is associated with an increased risk of recurrent and more severe otitis media, including persistent effusion and complications such as a need for tympanostomy tube placement *(71,191,196–198)*. Otitis media is responsible for most antibiotic use in children younger than 3 years of age in the childcare settings.

Enteric Infections

The childcare setting has been associated with infection caused by a wide variety of enteric pathogens, including *Shigella (14,55,96,100,199–205)*, *Salmonella (75,76,206,207)*, *E. coli (208–217)*, *Campylobacter (55,100,202,218–220)*, *Clostridium difficile (221)*, *Aeromonas (221,222)*, rotavirus *(55,100,223–232)*, coxsackievirus *(233,234)*, calicivirus *(235–237)*, astrovirus *(238–242)*, adenovirus *(238,243,244)*, *Giardia (245–256)*, *Cryptosporidium (234,257–260)*, *Dientamoeba fragilis (251)*, and *Blastocystis hominis (261)*. A study of childcare-associated diarrhea in Maricopa County, Arizona, showed that specific pathogens could be identified from stools of 18% of sporadic cases and 26% of outbreak-associated cases *(55)*. Other investigators have obtained similar results *(74,247,262)*. During outbreak investigations, multiple pathogens frequently are recovered from stools *(55,204,205,253,254)*, suggesting that diarrhea caused by one agent may facilitate transmission of other pathogens.

The risk of diarrhea among children in childcare centers is 1.6 to 3.5 times that of children in homecare settings *(13,55)*. The risk may be much greater for certain pathogens such as *Shigella*, *Giardia*, rotavirus, and *Cryptosporidium* with a low infectious dose, and among subgroups of children, such as infants or toddlers in diapers *(74,95,202)* or those recently enrolled in the facility *(55,262,263)*. Studies based on clinic visits or information from parents have suggested that children in childcare homes have a lower risk of diarrhea than those in centers *(10,13,14)*. However, results of studies comparing illness incidence in childcare homes and centers may be biased by the source of information. Data obtained from childcare providers in Seattle and San Diego showed that the incidence of illness (including diarrhea) among children in childcare homes was greater than that among children in centers *(22,23)*.

Rotavirus, *Giardia*, *Cryptosporidium*, and *Shigella* appear to be the most common causes of diarrhea in childcare settings. Rotavirus appears to cause disease more commonly in infants, and *Giardia* and *Cryptosporidium* appear to cause disease more commonly in toddlers *(55,100,262)*. *Shigella* infections generally occur in outbreaks and are more likely to involve adults and children older than those at greatest risk for the other three common infections *(100,202,203)*. *Giardia*, *Cryptosporidium*, rotavirus, and *Shigella* are more frequent causes of infectious diarrhea in childcare settings because of their low infectious dose *(74,202)*. Outbreaks of these infections are often associated with high rates of asymptomatic infection and prolonged excretion by both asymptomatic and convalescent people who no longer have diarrhea *(40,204,205,223,253)*. These people may pose difficulties in management including exclusion and cohorting to control transmission.

Secondary attack rates are often quite high among family members of children with childcare-associated diarrheal illness. These rates have ranged from 12% to 47% for *Giardia*, 24% to 62% for *Cryptosporidium*, 17% to 79% for rotavirus, and 22% to 29% for *Shigella (74,100,202,205,247,258,259)*. Childcare-associated outbreaks, especially cases of shigellosis, may spread beyond the center and play an important role in the epidemiology of community-acquired infections.

Outbreaks of diarrheal disease occur primarily among children who are incontinent. Other risk factors associated with an increased incidence of diarrheal disease in childcare settings include age of child, duration of attendance in a particular childcare facility, type of setting, and levels of environmental sanitation and adherence to good hygienic practices *(49,55,56,263)*.

Children who are incontinent generally have the highest attack rates during childcare center outbreaks of many diarrheal agents, including *Cryptosporidium*, *Giardia*, and rotavirus *(100,105)*. In a 2-year prospective study of diarrheal illness among children in Houston childcare facilities, the risk of diarrheal illness in children younger than 3 years was 17 times that of children 3 through 5 years of age; the mean incidence of diarrheal illness in facilities that accepted children in diapers was significantly greater than in facilities that did not *(95)*.

The principal means by which enteric diseases spread in childcare facilities is by the fecal–oral route, direct interactions between toddlers, or contamination of caregiver hands or the environment *(43,48,74)*. Low scores on assessments of hygiene and environmental sanitation in Maricopa County, Arizona, childcare facilities were associated with an increased risk of outbreaks of diarrheal illness *(55)*. Practices linked to outbreaks included inadequate hand hygiene, especially by staff with diaper-changing and food-handling responsibilities *(55,56,95)*. Studies in Atlanta childcare centers have shown that a rigorously monitored hand washing program can reduce the incidence of diarrheal illness, especially among children aged 6 through 18 months *(263)*. However, training of childcare staff, without monitoring compliance, has been shown to be ineffective in reducing diarrheal incidence *(264)*. The impact of even subtle reinforcement of hand hygiene protocols is suggested by decreases in both diarrhea and environmental contamination rates among facilities participating in research projects *(61,263)*.

Levels of environmental contamination with fecal coliforms are associated with the incidence of diarrheal illness *(49,52)*. The proportion of cultures from hands and environmental surfaces positive for fecal coliforms increases when cases of diarrhea occur in a classroom *(49,52,62,63)*. One study demonstrated an association between the incidence of diarrhea and the recovery of fecal coliforms from hands of children and staff and from moist environmental surfaces, including sinks and faucet handles *(52)*. Because many enteric pathogens are relatively stable in the environment and some, such as *Cryptosporidium*, are resistant to many commonly used disinfectants, addressing this potential environmental link in the transmission of enteric diseases requires careful adherence to cleaning and disinfection protocols *(58,59,265)*.

Children newly enrolled in childcare centers have a greater incidence of diarrheal illness than those who have attended for at least 3 months *(55,262,263)*. This was first recognized during a hand hygiene intervention study where

researchers noted a peak incidence in diarrhea among children enrolled in centers for 2 to 4 weeks. Although the peak was somewhat smaller in intervention facilities with handhygiene programs than in control facilities, it was present in both groups *(263)*. Children enrolled in Phoenix childcare centers for <3 weeks not only had an increased risk of sporadic diarrhea but were also significantly more likely to be ill during an outbreak of diarrhea than other children *(55)*. Children with a previous history of group childcare attendance who were newly enrolled in Houston childcare centers had an incidence of diarrheal illness comparable to that of newly enrolled children with no previous history of group childcare attendance *(262)*. This phenomenon, coupled with the large influx of children into childcare facilities in the early fall, may explain the increased incidence of *Giardia* and *Cryptosporidium* infections during the late fall and winter months.

Strategies for controlling diarrheal illness focus on preventing fecal–oral transmission (*43,48*,156). Childcare providers should ensure that their own hands and the child's hands are washed after diapers are changed (3,*63*,156). Diapers should be of a type that contains feces without leaking; clothing should be worn over diapers (3,*63*,156). Appropriate environmental sanitation must be maintained, especially in places likely to be contaminated with feces, such as diaper-changing areas. Proper handling of soiled diapers and other contaminated items such as disposable wipes must be ensured (3,*43*). Exclusion of children with diarrhea is controversial. Some authorities maintain that incontinent, symptomatic children need to be excluded (3,156). Readmission criteria for asymptomatic persons excreting enteropathogens depend on the pathogen (3,156,*204,266,267*). As public health laws frequently call for isolation of people with enteric diseases, local health authorities should be contacted regarding criteria for readmission.

Hepatitis A Hepatitis A is spread principally by the fecal–oral route. Therefore, childcare settings offer many opportunities to spread this virus. Several childcare-associated outbreaks of hepatitis A have been reported; some of these may have led to community-wide epidemics *(50,101,268–276)*. The early recognition of outbreaks in childcare facilities is complicated by the high proportion of asymptomatic or mild infections among young children. In a follow-up study of 28 outbreaks of hepatitis A in Maricopa County childcare centers, 84% of cases in children 1 through 2 years of age were asymptomatic, compared with 50% of cases in children aged 3 and 4 years and 20% in older children *(273)*. Children with hepatitis A infections who are symptomatic may be only mildly ill and these infections may not be accurately diagnosed; fewer than 10% show evidence of jaundice *(274,276)*. Outbreaks are usually recognized when cases begin to appear among the children's adult contacts *(101)*. In one study of a community-wide outbreak, household contacts of children in Maricopa County childcare facilities accounted for the largest number of outbreak-associated hepatitis A cases (204 of 342 cases) reported to the health department *(101)*. The attack rate among childcare workers (12%) was greater than that among household contacts (4%). The remainder of reported cases involved the children themselves and other adult contacts such as child sitters. Similar patterns have been reported in other outbreaks associated with childcare facilities *(275,276)*.

The distinction between factors influencing introduction of pathogens into a facility and those influencing transmission within the facility after introduction was first applied to hepatitis A *(50,275)*. Increasing hours of operation and enrollment was associated with hepatitis A introduction. Once hepatitis A is introduced, its transmission is more likely in centers that enroll younger incontinent children. Infection appears to be spread by contact between children and possibly by contamination of care providers' hands *(50,273,275,276)*. Fomites and environmental contamination may also play a role; the virus is relatively stable and can survive on environmental surfaces for up to 1 month *(265)*.

The principles for preventing hepatitis A infections in childcare facilities are similar to those for other infections transmitted through the fecal–oral route and include hand hygiene, environmental sanitation, and exclusion of ill children *(43,273)*. Universal hepatitis A immunization of children ≥1 year of age will decrease acquisition and transmission among childcare attendees and their providers and is recommended by the Advisory Committee on Immunization Practices (ACIP), *(277)*. Hepatitis A vaccine is also the preferred postexposure prophylaxis for vaccine-eligible children and adults 1 through 40 years of age who have been exposed to hepatitis A due to the longer-term protection and availability compared with hepatitis A immunoglobulin. Passive prophylaxis with immunoglobulin should be administered to individuals in whom hepatitis A vaccine is contraindicated and children and adults outside the recommended age range for postexposure prophylaxis *(278)*. Decisions to administer immune globulin and/or hepatitis A vaccine should be made in conjunction with local health authorities and the children's and care providers' physicians (3,*43*).

Blood-Borne Infections

Hepatitis B The transmission of hepatitis B virus (HBV) between people in close daily contact, such as in households and facilities for the developmentally disabled, has raised concern about transmission in childcare settings *(273,275,279,280)*. Suspected potential routes of transmission include bites and inoculation of infectious blood or body fluids onto mucous membranes or broken skin *(273,275,281)*.

Reports of HBV transmission in childcare settings in the United States are rare *(273)*. A case of apparent child-to-child transmission in a center has been reported; no specific exposure episode could be identified in that case *(281)*. In another report, a childcare provider was infected after exposure to the blood of an infected child *(282)*. Other cases of apparent transmission related to childcare have been reported from outside the United States. In Japan, where HBV is endemic, 15 of 269 children younger than 5 years who attended a nursery school were hepatitis B surface antigen (HBsAg) positive in the absence of any apparent household exposure, suggesting that transmission may have occurred in the school *(283)*. However, two different studies of separate instances in which a HBsAg-positive and hepatitis B e antigen-positive child was attending a childcare facility showed that the mere attendance of such children does not necessarily result in transmission

of infection *(281,284)*. In each instance, the child had been in the facility for more than a year before the infection was recognized and no special infection control precautions had been taken. Contact screening showed no transmission to other children or staff. Reviews of national surveillance data have not demonstrated an excess proportion of cases linked to childcare exposure *(273,281)*. Although HBV transmission can occur in childcare settings and appropriate precautions must be observed, the risk appears to be very low. Widespread compliance with recommendations for universal infant HBV immunization has significantly reduced the risk of transmission *(280,285)*.

Current guidelines recommend that children who are chronic HBV carriers may be admitted to a childcare facility if they have no behavioral or medical conditions that could facilitate transmission of HBV (3,156), including aggressive behavior (e.g., biting or scratching), dermatitis, bleeding problems, or open skin lesions that cannot be appropriately covered (3,156,*273*).

The decision to admit or not admit a child with the previously mentioned risk factors who is a chronic carrier of HBV should be made in conjunction with the child's healthcare provider, the facility's health consultant, and local public health authorities (3,*273*). Information regarding a child's HBV carrier status should be available to care providers who regularly provide care to the child; however, the confidentiality of the child and the child's family must be respected and this information must be appropriately limited to those persons who need to know to protect the child's health and the health of others (3,*273*). The child should be observed for development of any behaviors that could increase the likelihood of transmission. If a bite or other exposure places a susceptible staff member or child at risk, the exposed person should be promptly referred to his or her healthcare provider and to the health department for evaluation of the need for post exposure prophylaxis (3,156,*273*).

As symptomatic undiagnosed HBV carriers may be enrolled in childcare, all staff members should be appropriately trained and educated regarding specific precautions to avoid exposure to potentially contaminated blood and body fluids *(280,285,286)*. Asymptomatic staff members infected with HBV may be allowed to work as long as they are without dermatologic conditions that may facilitate transmission, have received necessary training, and are compliant with methods to prevent transmission of HBV (3,156).

The ACIP recommends universal immunization of infants, nonimmune children and care providers in the childcare setting with the hepatitis B vaccines series *(280,285)*.

Human Immunodeficiency Virus Initial concerns regarding the presence of children and providers with HIV in childcare facilities have not been supported. The possibility that HIV-infected individuals may be susceptible to more severe manifestations of infections transmitted in the group childcare setting and the transmission of HIV infection to others has not been observed *(287–289)*. Although immunosuppressed children may be at increased risk for severe complications from infections, including those caused by varicella, herpes simplex, CMV, *H. influenzae*, *Mycobacterium tuberculosis*, *Cryptosporidium*, and measles, information is limited on the risk that any one child with HIV will acquire a specific infection. In one study, the prevalence of intestinal parasites among children attending a hospital-affiliated childcare center for HIV-infected children was lower than the prevalence typically reported in other childcare facilities *(290)*. Rigorous prevention procedures were followed; by nature of the location, resources available to this center may have been greater than those available to most childcare facilities.

Although HIV has been isolated from several body fluids, including saliva, urine, and tears, only blood, semen, cervicovaginal secretions, and human milk have been implicated in the transmission of infection *(287,291,292)*. Extensive studies of household contacts of HIV-infected children and adults indicate a very low risk of transmission *(287)*. Only a single case of child-to-child transmission (not involving percutaneous or intravenous exposure) among preschool-aged children living in the same home has been reported *(287,293,294)*.

Transmission of HIV in childcare settings via biting is rare and probably involves exposure to blood from the biter or bitten person rather than saliva *(294,295)*. Post exposure follow-up of both parties when biting results in blood exposure should occur (156,*295*).

Skin exposure resulting from spills of human milk or vomitus is unlikely to result in HIV transmission (156).

Children who enter childcare should not be required to be tested for HIV or to disclose their HIV status. Restriction of HIV-infected children without risk factors for transmission of blood-borne pathogens in childcare facilities is not indicated. Decisions regarding the attendance of a HIV-infected child should be made on a case-by-case basis by knowledgeable individuals, including the child's physician, the child's parents or guardian, public health authorities, and the childcare facility operator or director (3,156,*288,294–296*). As is true for any child exposed to a potentially serious infection, the child's parents or guardian should be notified promptly of exposure to communicable illnesses (156). Ongoing involvement of parents, childcare providers, the child's healthcare provider, and local health officials will help to ensure appropriate care. Immunization protocols for HIV-infected children have been published by the ACIP; compliance with these protocols should be ensured (*289*,297). Updates to the recommended childhood immunization schedule occur annually and can be found at *www.cdc.hov/vaccines*.

Asymptomatic HIV-infected care providers should be allowed to provide childcare if they are without conditions that might facilitate contact between potentially contaminated body fluids and children or other adults (3,156,*288*). The potential for and management of exposures of such care providers to other infectious diseases should be addressed as recommended for HIV-infected children (3,156,*288*).

Precautions that apply to the prevention of hepatitis B are relevant to HIV-infected children and care providers. Standard precautions, including careful attention to the handling of potentially contaminated body fluids in both everyday care and as a result of less common events (e.g., blood spills or injuries) should be implemented routinely (3,*79*,156,*286,295*).

Vaccine-Preventable Diseases

Routine immunization is recommended for children and adolescents against 15 infectious diseases: measles, mumps,

rubella, diphtheria, pertussis, tetanus, poliomyelitis, Hib, hepatitis A, hepatitis B, varicella, rotavirus, human papilloma virus, influenza, and pneumococcal infections. Both the adult and childhood immunization schedules are updated annually in January, *http://www.cdc.gov/vaccines/pubs/acip-list.htm* (175). Preschool-aged children continue to have the highest age-specific attack rates of measles, rubella, pertussis, and Hib infections and can suffer more severe sequelae than older children if they become infected *(54,298)*. Most states require immunization before attendance in licensed childcare facilities, which has resulted in more complete immunization histories than children not in licensed childcare establishments *http://nrckids.org/STATES/states.htm.* Children's attendance in out-of-home childcare offers healthcare providers and the public health system an opportunity to ensure that children have received appropriate immunization.

Other Infections

Cytomegalovirus CMV infection is the most common congenital infectious disease in the United States *(102,299)*. Most congenitally infected infants are asymptomatic at birth, but, within the first few years of life, 10% to 20% of these children will experience developmental delay, sensorineural hearing loss *(300)*, cerebral palsy, and visual impairment from chorioretinitis or optic atrophy*(102,299)*. Contact with children in childcare is a well-documented risk factor for adult infection with CMV; childcare providers and family members of children in childcare are at risk *(58,78,80,82,83,85,86,99,102,103,301–309)*. When the exposed adult is pregnant, the fetus may be at risk for congenital infection. Transmission of CMV among children in out-of-home childcare is common; virus excretion rates as high as 69% have been reported, compared with lower excretion rates of 8% among similarly aged children cared for at home *(83,103,302,303)*. Restriction endonuclease patterns of CMV DNA have demonstrated transmission between children in childcare settings; infected children in the same childcare facility have been shown to share identical CMV strains *(83,301,302)*.

Children enrolled in childcare before their first birthday are more likely to be infected; mixing children younger than 18 months with children older than 18 months also appears to increase the risk of transmission. The likelihood of excretion is age dependent, with the highest excretion rates in children between 1 and 3 years of age *(103,299,301,304,306)*. More than three quarters of children aged 12 through 18 months excreted CMV in saliva or urine at the time of assessment *(308)*. One cohort of uninfected children experienced an annual acquisition rate of 3% per year *(306)*. Excretion began between 11 and 59 months after entering childcare; the duration of excretion ranged from 3 through 28 months, with excretion in the urine lasting longer than excretion in the saliva *(306)*.

High rates of transmission and excretion among children in out-of-home childcare pose an infection risk for pregnant women contacts. Baseline rates of seropositivity of CMV antibody among childcare providers ranged from 38% to 63% in one surveillance study; annual seroconversion rates among initially seronegative workers are from 8% to 20% *(80,82,308)*. In comparison, the annual seroconversion rate among 229 seronegative female healthcare providers was 2% *(80)*. Seropositivity is associated with a history of contact with children younger than age 2 years *(80,308)*; seroconversion is associated with providing care for children younger than age 3 years *(80)*.

The risk of long-term sequelae from congenital CMV infection should be communicated as part of employee counseling and education to all providers who may be at risk (3,*43*,*79*). Care providers should be given information regarding prevention through the use of appropriate hygienic precautions (3,156).

Parvovirus B19 Parvovirus B19, the etiologic agent of erythema infectiosum (fifth disease), has been linked with several conditions, including fetal hydrops and fetal death, arising from intrauterine transmission and infection *(310)*. As with CMV, concern exists regarding the risk of exposure and infection of pregnant childcare providers and exposure of mothers of childcare enrollees. The seroprevalence of immunoglobulin G (IgG) antibodies to parvovirus B19 among 122 childcare providers in Virginia was 25%, whereas that among 68 mothers of children in childcare was 29% *(311)*. The annual seroconversion rate among providers and parents of children in childcare was 1.5%. Higher prevalence and incidence rates were reported from studies during a large outbreak in Connecticut in 1988 *(87,89)*. Teachers and childcare providers were assessed using serum immunoglobulin G (IgG) as a marker for preoutbreak seroprevalence and serum immunoglobulin M (IgM) as an indicator of recent infection. The preoutbreak seroprevalence (IgG) among 50 childcare providers was 68%; 5 of 16 (31%) susceptible providers exposed to children with erythema infectiosum showed evidence of recent infection (IgM). The number of classroom exposures to children with a rash was significantly correlated with risk of infection *(89)*. In a second study during the same outbreak, the highest rates of seroconversion were among teachers (16% of susceptible persons), childcare providers (9%), and homemakers (9%) *(89)*. Teachers and childcare providers who were exposed to erythema infectiosum at work and who also had children living in their homes had higher infection rates (13%) than occupationally exposed teachers and childcare providers who did not live with children (10%) (see also Chapter 51).

Herpes Simplex Virus By 5 years of age, 42 of 115 children (37%) attending a North Carolina childcare center had evidence of primary infection with herpes simplex virus *(312)*. Children 1 year of age had the highest incidence; 20.5 infections occurred per 100 children per year. During the 12-year study, most primary viral isolates (55%) were recovered during outbreaks.

Children with mild herpes simplex virus disease and good control of oral secretions may be admitted to childcare after consultation with their healthcare providers and after staff have been reminded of the importance of avoiding contact with infected secretions (3).

INFECTION CONTROL IN CHILDCARE FACILITIES

Several excellent sources of detailed recommendations on health and safety practices in out-of-home childcare include

publications from the HCCA program, coordinated by the AAP, Early Education and Childcare Initiatives (the Section on Early Education and Childcare), and partly funded by the Childcare Bureau (CCB), Office of Family Assistance (OFA), Administration for Children and Families (ACF), and the Maternal and Child Health Bureau, HRSA, U.S. Department of Health & Human Services, *http://www.healthychildcare.org/*. The National Association for Education of Young Children http://www.naeyc.org/ offers a selection of resources and guidance documents for providers of care to young children. The National Resource Center for Health and Safety in Childcare and Early Education publishes *Caring for Our Children: National Health and Safety Performance Standards: Guidelines for Out-of-Home Childcare*. The second edition, published in 2002 is accessible at *http://nrckids.org/CFOC/index.html*, and is currently undergoing revision with a third edition expected to be available in 2011. During the increase in 2009 novel H1N1 influenza infections, the CDC developed guidance for parents, childcare providers, and healthcare professionals to reduce the transmission of influenza in childcare and school settings, *http://www.cdc.gov/flu/professionals/infectioncontrol/childcaresettings.htm*.

In addition to these reference materials, childcare facilities should have access to a health consultant, usually a clinician with expertise in pediatrics, from whom care providers can obtain advice and assistance when making decisions on health issues (3,*313*). Public health authorities and infection preventionists (IPs) may serve as consultants to childcare facilities in the community and to those facilities managed by the IPs' healthcare institution *(314)*.

General Recommendations

Many general principles of infection control in childcare settings are similar to those in healthcare settings: interruption of transmission through hand hygiene and proper handling of contaminated material, management of the environment, surveillance, limitation of the potential for exposure of susceptible persons, and adherence to recommendations for immunization of children and adolescents. As in healthcare settings, hand hygiene is considered to be the single most important step in preventing and controlling infectious diseases in childcare settings (3,*43,47,48,57*,156,*157*,159,*263*). Careful attention by providers to hand hygiene practices, both their own and those of the children, can reduce the incidence of infectious diseases *(55,57,263)*. Guidelines stress both frequency and timing of hand hygiene and use of proper technique (3). The use of alcohol-based hand sanitizers widely used in healthcare settings (159) has the potential for use in childcare settings. The use of alcohol-based hand disinfection in addition to traditional hand washing significantly reduced the rate of absenteeism by 12% compared with a child using traditional hand washing only, in an evaluation in Swedish childcare centers *(315,316)*. In an observational prospective cohort study of families with ≥1 child enrolled in out of home childcare conducted in Boston, the use of alcohol-based hand gels was protective against respiratory virus transmission in the home setting *(317)*. A school-based, cluster-randomized controlled trial involving the use of alcohol-based hand sanitizers and quaternary ammonium wipes in classrooms of third through fifth graders for 8 weeks reduced absenteeism attributable to gastrointestinal illness in elementary school students *(318)*. The use of alcohol-based hand gels was shown to be safe without the absorption of significant amounts of alcohol, despite mouthing behaviors (319). Alcohol-based hand gels may have a role in prevention of outbreaks of infectious pathogens associated with childcare settings and among children involved in activities such as petting zoos where traditional hand washing with soap and water may be impractical *(320)*. Further evaluations of hand hygiene strategies, and educational interventions would assist with allocation of resources to the most effective prevention regimens.

Attention to environmental sanitation also is an important infection control measure in childcare settings, especially in facilities with incontinent or nearly continent children. Younger children often explore by mouthing objects in their environment, resulting in contamination with feces, saliva, and other body fluids. Several of the most common pathogens causing disease among children and providers have been found on environmental surfaces and objects in childcare settings (3,*42,52,58,59,61, 226,314,321*).

Food is often prepared and served in childcare settings. Written policies should enforce meticulous care involving storage, handling, and preparation of all enterally consumed items. Policies should specify procedures for sanitization of all food preparation areas. Adherence to segregation of location and staff involved in preparation and service of food and those involved in toileting activities should be maintained (3,156). The importance of hand hygiene before preparing and serving nutrition must be stressed in training, reinforced, and monitored to ensure compliance (3).

Surveillance of Childcare Infections

As in the hospital setting, effective surveillance is central to preventing and controlling communicable diseases in childcare facilities. Although the major purpose of surveillance is to detect potential problems or outbreaks within facilities, surveillance data also can contribute to the understanding of specific risk factors for infection. The information derived from surveillance can contribute to the design of prevention and control measures and can aid development and conduct of training programs for childcare providers and parents (3,*322*,*323*). Implementation of surveillance has been associated with decreases in diarrheal illness in childcare facilities *(264)*; surveillance in childcare settings can serve as a sentinel system for illness in the community *(314,322)*.

In addition to education of childcare providers, directors, and parents, a relationship with a healthcare consultant may facilitate surveillance activities as well as reporting of infections. Frequent positive interactions between public health officials and the childcare community in the form of training sessions and educational materials may reduce concerns about confidentiality and encourage a collaborative response to potential problems. Maintenance of current lists of licensed providers by public health authorities facilitates notification of reporting requirements and is invaluable in rapidly disseminating information to childcare facilities during public health emergencies. The National Resource Center for Health and Safety in Childcare and Early Education in collaboration with the AAP and APHA, developed a comprehensive source, *Caring for Our*

Children: National Health and Safety Performance Standards: Guidelines for Out-of-Home Childcare Programs that lists over 700 health and safety practices. Updates posted to an internet-based site, *http://nrckids.org/CFOC/updates.htm* are designed to keep providers up to date with the latest guidelines for quality childcare. Additionally, the AAP has appointed Chapter Childcare Contacts (CCCCs) in each of its State Chapters to provide a network of pediatric childcare experts who can mobilize efforts to improve the health and the safety of children in childcare and engage parents in discussions about quality care and their options. Each volunteer is a member of the Section on Early Education and Childcare and is appointed by the AAP Chapter to serve as a liaison between their chapter and stakeholders regarding early education/childcare topics and initiatives.

Role of the Health Department

State and local health departments play an important role in monitoring the health status of children in childcare. For example, they routinely ask about childcare contacts in case investigations of notifiable diseases and generally intervene quickly to interrupt transmission when they learn of an outbreak (3,*314,324,325*). Health departments are often a principal resource for information, training, and education for childcare providers and parents. Public health officials often serve as consultants to childcare licensing and regulatory agencies. Some communities have model programs in which health departments serve as a focus for developing community-wide programs for child health and safety (3,*314,324,325*).

Training and Education

Staff Training Successful childcare infection control programs require high levels of staff training and education. Childcare providers are less likely to receive infection control training than healthcare providers; however, when childcare providers understand the rationale for guidelines and practices, they are more likely to translate education into practice *(326)*. Studies have shown that care providers need and are interested in receiving training, independent of licensing requirements *(81,327)*. This curriculum should cover basic infection control principles, and providers should understand the potential risks of infections that may be acquired in childcare settings (3,*79*). Additional topics to address include techniques to control those risks, including hand hygiene, environmental sanitation, avoidance of exposures to blood and body fluids, and personal protection including immunizations *(55,60,81,86*,156,*326*). Educational efforts in which childcare providers may actively participate in are self-directed learning, and opportunities for periodic updates may be received and accepted with retention.

Health Education for Parents The childcare setting offers unique opportunities to provide health education to parents and to care providers (3). Tailored to the specific setting, educational programs could provide information about immunization, signs of illness requiring medical consultation, fluid replacement for diarrheal disease, proper use of antipyretics and judicious use of antimicrobial agents.

Exclusion and Inclusion

Among the more difficult problems in the childcare setting is establishing and implementing appropriate criteria for excluding ill children from the facility. Parents of excluded children must either seek alternative forms of childcare or miss work to care for an excluded child. Much of the economic burden of childcare-associated illness is due to parental absenteeism (Table 53-2).

TABLE 53-2

General Recommendations for Exclusion of Children in Out-of-Home Childcare

Symptom(s)	*Management*
Illness preventing participation in activities, as determined by childcare staff	Exclusion until illness resolves and able to participate in activities
Illness that requires a need for care that is greater than staff can provide without compromising health and safety of others	Exclusion or placement in care environment where appropriate care can be provided, without compromising care of others
Severe illness suggested by fever with behavior changes, lethargy, irritability, persistent crying, difficulty breathing, progressive rash	Medical evaluation and exclusion until symptoms have resolved
Rash with fever or behavioral change	Medical evaluation and exclusion until illness is determined not to be communicable
Persistent abdominal pain (2 h or more) or intermittent abdominal pain associated with fever, dehydration, or other systemic signs and symptoms	Medical evaluation and exclusion until symptoms have resolved
Vomiting two or more times in preceding 24 h	Exclusion until symptoms have resolved, unless vomiting is determined to be caused by a noncommunicable condition and child is able to remain hydrated and participate in activities
Diarrhea or stools containing blood or mucus	Medical evaluation and exclusion until symptoms have resolved
Oral lesions	Exclusion until child or staff member is considered to be noninfectious (lesions crusted and dry)

(Used with permission of the American Academy of Pediatrics. Children in out of home care. In: Pickering LK, Baker CJ, Kimberlin DW, et al., eds. *Red book: 2009 report of the committee on infectious diseases*. 28th ed. Elk Grove Village, IL: American Academy of Pediatrics.)

Overly strict exclusion policies can create tension between parents and care providers and encourage parents to enroll, or "drop in," an ill child at other facilities without notifying the new facility of the child's health status; this may introduce an infection into a new group of susceptible children *(43)*. Failure to exclude ill children when it is appropriate to do so may increase the risk of transmission to other children in the facility, childcare providers, household contacts of enrollees, and thus the community at large. Ill childcare alternatives for conditions that do not require exclusion may offer parents an opportunity to maintain childcare while fulfilling their work obligation. Open communication between parents and providers will facilitate the provision of optimal care for a child and his or her contacts.

In a telephone survey evaluation of the rate of unnecessary exclusion decisions by childcare directors in a state that endorses AAP/APHA guidelines, directors reported that they would have unnecessarily excluded 57% of children. More than 62% of directors were unaware of AAP/APHA guidelines. Regression analysis demonstrated fewer exclusion decisions by experienced compared with less experienced directors and among larger enrollment centers compared with smaller enrollment centers. This evaluation supports the premise that focused initial and ongoing training of directors regarding AAP/APHA guidelines may help to reduce high rates of unnecessary exclusions (328).

Cohorting and Ill Childcare

In the event of an illness outbreak, the benefits of closing a facility to prevent additional spread of disease should be weighed against the possibility of infected children being sent to other facilities *(44,199,205)*. Cohorting—separating infected and uninfected children into different groups—has been proposed as an alternative to excluding children who are well enough to attend childcare but who may have a transmissible infectious disease. Although this strategy is feasible, it requires careful monitoring to determine which children are and are not infected and to ensure that this separation is maintained. Cohorting may be resource intensive for an individual childcare center, frequently requiring additional staffing and rearrangements of existing or additional physical space. Although the initial increased use or reallocation of resources may be significant, in certain situations, these efforts may interrupt transmission of an outbreak. Small centers with skeleton staff may not be able to accommodate the increased resources of cohorting *(203,267)*. The involvement of local and state health authorities may facilitate cohorting efforts by more than one childcare facility in a community promoting the sharing of resources and maintaining childcare arrangements.

Role of the Healthcare Provider

Guidelines for exclusion of infants and children from group childcare settings exhibiting signs and symptoms consider the prevalence of mild illness among children, frequent transmission of infection before recognized symptoms, and the infectious potential of asymptomatic children. Most children do not need to be excluded from childcare when they have mild respiratory tract illnesses. However, children in obvious discomfort, those whose symptoms interfere with their ability to participate comfortably in childcare activities, and those whose illness requires a level of attention by staff that may interfere with the care of other children, should be excluded from a group childcare setting (3,156). Most states have regulations requiring isolation of people with various types of communicable diseases, including those common among childcare attendees. These regulations vary by region and take precedence over recommendations from other entities. Local or state health departments should be contacted for information about these regulations, their interpretation, and enforcement.

Healthcare professionals may perform a significant service as advisors or consultants to childcare providers. In return, the professional will become more knowledgeable regarding the composition and structure of group childcare options. This partnership may be especially beneficial in situations involving cohorting or exclusion of children or staff in an outbreak setting. Furthermore, if a childcare center enrolls children or staff with special medical or social needs, the contributions of a childcare consultant may be instrumental to the childcare center's provision of care. In addition to providing advice regarding inclusion and exclusion criteria, childcare consultants may serve as sources for information on a range of topics including medication administration, immunization, and optimizing infection control practices. Furthermore, their input as educators for enrollees, staff, and parents may provide additional expertise based on their training. Additional resources for locating a childcare consultant may be found through the HCCA Campaign *www.healthychildcare.org* and the National Training Institute for Childcare Health Consultants, *http://nti.unc.edu/*.

Environmental Control

Disinfection An overriding principle in environmental control of infectious diseases is good physical cleaning using a detergent or detergent-germicide solution. Many difficulties in recommending the use of specific products or formulations for hospital disinfection also apply to the childcare environment *(265)*. In addition, because children crawl on the floor and mouth objects or furnishings, children in childcare, unlike hospitalized patients, are at risk for exposure to toxic substances used for cleaning and disinfection. Thus, disinfectants may need to be assessed in ways not always relevant to the hospital setting (e.g., the potential for chemical residue to remain on environmental surfaces such as floors, walls, and furniture and the risk that chemical agents may be accidentally ingested). The U.S. Environmental Protection Agency registers specific products as detergent-disinfectants for cleaning and disinfecting various settings and materials. The APHA/AAP standards recommend a diluted bleach solution for disinfection in childcare settings (3).

Physical Facilities The design of the environment in and around the facility can directly affect the risk of infectious diseases *(67)*. Ideally, areas for different activities that may affect health risks—diaper changing, play, and food preparation and handling—should be physically separated. Diaper-changing areas, accessories, and receptacles

should be arranged to facilitate appropriate hygiene while changing, handling, and disposing of soiled diapers (3). Sinks should be easily accessible, preferably within arm's reach of the changing area. Children of different age groups should be separated to decrease exposure of older children to environmental fecal contamination. Environmental surfaces, including furnishings and other objects in childcare facilities, should be easy to clean and disinfect (3,*67*). Toys that are shared by children should be cleaned and disinfected daily and removed from circulation when obviously contaminated with saliva or other body fluids (3).

Personnel Health Issues

All staff should have a health appraisal before initiation of childcare activities (3). This evaluation should include documentation of receipt of recommended immunizations or immunity to vaccine preventable diseases for adults, *www.cdc.gov/vaccines/recs/schedules/adult-schedule.htm#print*, or for adolescent volunteers and providers, *www.cdc.gov/vaccines/recs/schedules/child-schedule.htm#printable*. All adolescents and adults with anticipated child contact should undergo tuberculosis screening and appropriate management if indicated before care-giving activities are initiated (3). Annual screening may be indicated based on the risk of acquiring a new infection and on local and state health department recommendations. Additionally, adolescents and adults who are not considered to be staff, but who spend a significant amount of time in a location where care is provided to infants and children, should undergo annual tuberculosis screening. All people over 6 months of age should receive influenza immunizations annually, unless contraindicated. Orientation and periodic refresher courses reinforcing strategies for prevention of infectious diseases, including hand and respiratory hygiene as well as effective diapering and food-handling practices should be provided to maintain competence. Although infections with pathogens including CMV, parvovirus B19, and novel H1N1 influenza may have implications for susceptible pregnant women, Standard Precautions should be routinely practiced despite a provider's or a child's infectious disease status. Childcare providers should practice the same criteria for inclusion and exclusion of themselves as for the children to whom they provide care.

Recommendations for Prevention of Specific Infections

The spread of infectious diseases in childcare settings is best prevented by careful adherence to routinely recommended precautions: hand hygiene; environmental sanitation; and care in handling potentially contaminated material such as tissues, diapers, eating utensils, and mouthed toys (3,*265*). Special care should be taken with exposures to blood or blood-containing body fluids. Children and care providers should be appropriately immunized, and access to immunization records should be available to the facility operator or director (156). Public health officials and parents should be notified if a child or caregiver is exposed to a communicable disease; exposed persons should be referred, as appropriate, to both the health department and healthcare providers for chemoprophylaxis or immunoprophylaxis. Persons who could transmit infection may need to be excluded from the childcare setting (3,156).

Vaccine-Preventable Diseases All children enrolling in childcare should have written documentation of age-appropriate immunizations (297). Depending on local public health and licensing regulations, unimmunized children may be allowed to attend childcare if the appropriate immunization series has been initiated within 1 month of enrollment and completed according to recommended schedules. Unimmunized children, or those who are exempt from routine childhood immunizations for medical or other reasons, should be excluded if the facility has cases of a vaccine-preventable disease to which they may be susceptible. These children may be permitted to return to the center after the risk of exposure no longer exists or they have been appropriately immunized.

THE NEED FOR ONGOING RESEARCH

The increasing number of infants and children enrolled in group childcare has resulted in an increased awareness of infections associated with these settings. Recommendations for practices with regard to transmission, inclusion and exclusion criteria, and personal hygiene are based on clinical and epidemiological studies performed in previous decades. A need to reevaluate the findings and recommendations from these studies is indicated. Updated recommendations based on evaluations using newly developed laboratory molecular techniques could improve our understanding of transmission as well as identification of pathogens. These evaluations would have clinical, social, and economic impact on the growing number of infants and children, parents, and providers who are stakeholders in group childcare. Resource allocation to perform innovative clinical and molecular epidemiological studies in childcare centers would facilitate practices with current guidelines and recommendations.

SECTION VII

Epidemiology and Prevention of Healthcare-Associated Infections in Special Patient Populations

CHAPTER 54

Healthcare-Associated Infections in Dental, Oral, and Maxillofacial Surgery

Cynthia J. Whitener

Dental and oral surgical procedures are some of the most frequently performed minor surgical procedures in the United States. Because these procedures rarely occasion admission to hospital, either for the initial procedure or for the care of a complication, data on incidence rates for procedure-related infections in this setting are limited. Maxillofacial surgery is more commonly performed in an inpatient setting, especially surgery for reconstructive purposes after trauma or that involving major restructuring of bones for cosmetic surgical reasons. Therefore, more information exists concerning risks of procedure-related infection for maxillofacial procedures. Because of the recognition of human immunodeficiency virus (HIV) transmission in one dentist's practice, national attention has been focused on infection control practices in dentistry (1). This chapter discusses the infections seen in these settings, their recognition, and measures for their prevention.

MICROBIOLOGY

Infections after surgery to the gums or teeth or involving mucosal incisions made in the mouth are caused by a combination of the aerobic, facultatively anaerobic, and anaerobic microorganisms found in the saliva and the gingival crevices *(2,3)*.

The number and variety of bacteria found in the oral cavity of each person increase as he or she matures, the dentition erupts, and the flora of the gingival crevice establishes itself. Cross-sectional surveys have suggested that a few anaerobes are present in the mouth of young children before the eruption of their first deciduous teeth *(4,5)*. Older children have a microbial flora closely approximating that of the mature dentulous adult.

In recent years, the breadth of bacterial diversity in the mouth has been appreciated due to the availability of advanced molecular and bioinformatic tools. Numerous formerly uncultivable species have been recognized. Although it is likely that not all oral flora have been identified yet, well over 500 bacterial species are now thought to coexist in the mouth, of which an estimated 50% are uncultivable *(6–8)*. While the variety in any individual is less, studies suggest there still may be more than 50 to 70 species present *(6,9)*. The composition of the oral flora is dynamic, partly because of its connection with the external environment. The microbiome of the mouth is influenced by numerous factors, including genetics, illness, hospitalization, age, diet, hormones, medications, salivary gland secretions, chemotherapy, radiation, dentures, and artificial devices, and, importantly, by oral hygiene (*9*,10,*11*,*12*). Species that generally constitute >80% of the total cultivable oral flora are *Streptococcus, Peptostreptococcus, Veillonella, Lactobacillus, Corynebacterium*, and *Actinomyces* (10). Facultative gram-negative bacilli are infrequent in healthy adults but are common in hospitalized and seriously ill patients.

Within the mouth, bacterial biofilm microcosms are present on the mucosal surface of the tongue, buccal mucosa, tooth surfaces, gingival crevices, and artificial surfaces such as appliances and prostheses, each site with a unique constitution *(13)*. A group of 20 to 30 predominant species are found in each niche, though *Streptococcus* is the predominant species found in nearly all sites *(6)*. While

most studies have focused on bacterial biofilms, fungi, specifically *Candida albicans* and *Saccharomyces cerevisiae*, also can be found in some periodontal niches *(14)*. Most salivary flora are aerobic and facultatively anaerobic, whereas many microorganisms in the gingival crevice are anaerobic. In addition, there are generally many more microorganisms per gram in the latter location. There appears to be no relationship between the appearance of the tongue (presence of white coating or not) and salivary bacterial load *(15)*. Table 54-1 lists the predominant cultivable microorganisms in the saliva and gingival crevice of adults (10,*16–19*).

Using standard culture techniques, studies in the 1990s suggested that key periodontopathogens were eliminated after full teeth extraction. However, a more recent study utilizing qPCR methodology in nine patients before and 6 months after full mouth tooth extraction observed a reduction in, but not eradication, of potential pathogens. A 3-log reduction of *Porphyromonas gingivalis* and *Tannerella forsythia* and lesser reductions of *Aggregatibacter actinomycetemcomitans* and *Prevotella intermedia* were seen. It is unclear if residual lower concentrations have clinical relevance *(20)*.

Although no studies have documented transmission of oral flora from one patient to another in the dental operatory, Genco and Loos *(21)* reviewed several studies using molecular epidemiologic techniques to demonstrate the transmission of *Streptococcus mutans* by vertical transmission from mother to infant and intrafamilial transmission of *A. actinomycetemcomitans*. These studies are the first to document the spread of oral microorganisms and raise the possibility of whether oral bacteria can be transferred in a medical setting from one patient to another.

TABLE 54-1

Common Cultivable Flora of the Oral Cavity

Saliva	*Gingival Crevice/Plaque*
Streptococci	Streptococci
S. salivarius group	*S. mutans* group
S. mitis	*S. mitis*
S. sanguis	*S. sanguis*
Peptostreptococcus	*Peptostreptococcus*
Lactobacillus	*Lactobacillus*
Staphylococcus aureus	*Treponema*
Corynebacteria	*Eikenella corrodens*
Neisseria	*Neisseria*
Branhamella	*Branhamella*
	Actinomyces
	Eubacterium
Veillonella	*Veillonella*
	Leptotrichia
Herpes simplex	*Bacteroides*
Candida albicans	*Porphyromonas*
	Prevotella
Entamoeba gingivalis	*Capnocytophagia*
Trichomonas tenax	*Fusobacterium*
	Aggregatibacter actinomycetemcomitans

Many aerobic bacteria transiently colonize or infect the pharynx and posterior nasopharynx. Recognition of these agents depends either on characteristic clinical symptoms, such as the chancre of syphilis or the adherent membrane of diphtheria, or on culture to demonstrate the presence of group A β-hemolytic streptococci or *Neisseria meningitidis*.

The viruses frequently present in saliva are those agents causing latent infection, particularly the herpes group and less commonly hepatitis B virus (HBV), hepatitis C virus (HCV), or HIV *(22)*. Herpes simplex virus (HSV) has been recovered from the saliva of approximately 1% of asymptomatic children and between 0.75% and 5% of asymptomatic adults. Serial sampling of the saliva from normal adults over time has demonstrated that HSV can be recovered from oral secretions in over 50% of adults in the absence of clinical lesions. More than 50% of seropositive patients undergoing organ transplantation will shed oral HSV asymptomatically *(23)*. Acyclovir prophylaxis results in a decreased incidence of viral excretion after bone marrow transplantation *(24)*. Not surprisingly, HSV is a recognized occupational hazard for dentists, oral surgeons, and dental technicians.

Cytomegalovirus (CMV) has been isolated from salivary glands, adenoid tissue, and pharyngeal secretions. The prevalence of antibody to CMV increases with age and is further increased among people from lower socioeconomic groups. In seroprevalence studies performed in the 1970s, between 40% and 80% of adults had serologic evidence of infection with CMV by the age of 40 *(25)*. CMV excretion is increased in the presence of transplantation and immunosuppression. No transmission to dental workers or medical staff has been shown *(26)*.

Epstein–Barr virus (EBV) is another herpes virus that causes acute infectious mononucleosis followed by a chronic infection of lymphocytes. It is also associated with oral hairy leukoplakia. The prevalence of infection as indicated by the presence of antibody is higher at early ages in the tropics and in underdeveloped countries. Prevalence progressively increases with age in developed countries *(27)*. Saliva is the primary vehicle for EBV transmission from person to person, though no transmission to dental workers or medical staff has been demonstrated. EBV has been implicated in the pathogenesis of periodontitis, but more studies are needed to determine its true significance *(28,29)*.

Herpesvirus 6, herpesvirus 7, and herpesvirus 8 have been identified in up to 29% of gingival biopsies of HIV-seronegative adults with periodontitis, suggesting that the periodontium might constitute a reservoir for these viruses *(30)*.

The blood-borne viruses, including HBV, HCV, and HIV, may be present in the saliva of persons with chronic infection. Small cuts and abrasions in the oral cavity, especially when made acutely during dental or intraoral surgery, serve as the primary sources for seeding the saliva with virus. These viruses are addressed in the epidemiology section of this chapter.

Many other viral agents can be recovered from oropharyngeal secretions during or after acute infection. These agents include polioviruses, coxsackieviruses and echoviruses, influenza viruses A and B, rhinoviruses, and coronaviruses. Despite the occasional isolation from saliva and nasal secretions of these viruses and the childhood

respiratory pathogens rubeola (measles), mumps, and rubella, no occupationally proven transmission of any of these viral agents to a dental worker has been documented, except one case of coxsackievirus infection *(22)*. However, seroprevalence studies have shown a higher prevalence of antibodies to influenza A and B viruses, respiratory syncytial virus, and adenovirus among dentists compared with controls *(31)*. Dental procedures should be avoided in patients suspected of having active severe acute respiratory syndrome, which is caused by a coronavirus and is likely transmitted by droplet and contact routes.

Yeasts and fungi also are part of the normal flora of the oral cavity. *C. albicans* can be isolated from the mouths of approximately 55% of healthy people. Many other species of *Candida* are found less frequently. The dorsum of the tongue has the greatest density of yeast. Carriage rates for yeast are increased among hospitalized patients, people with dentures, persons who are blood type O or nonsecretors, solid organ transplant recipients, and in HIV-positive populations *(32–35)*. Transient carriage of filamentous soil fungi such as *Aspergillus* spp. and zygomycetes can be shown.

Protozoa are also normal inhabitants of the mouth. *Entamoeba gingivalis* and *Trichomonas tenax* are the most common commensals recovered *(36)*.

TYPES OF INFECTIONS

Infections of the oral cavity and maxillofacial regions can be grouped loosely into the categories of localized infection, infection by direct extension, and distant infection.

Localized infections can be classified as dentoalveolar, periodontal, infections of the salivary glands or tonsils, and cellulitis from tissue injury. Dentoalveolar infections are also known as odontogenic infections and include carious teeth with resulting infections of the dental pulp and periapical dental abscess. Infections involving the gingiva, periodontal ligament, and other tissues supporting the teeth are known as periodontal infections. These infections include gingivitis and acute necrotizing ulcerative gingivitis (ANUG). Periodontal disease has been shown to be a risk factor or marker for coronary heart disease *(37,38)*. Parotitis and sialoadenitis are infections of glands.

Infections resulting from the direct extension of one or more of these localized infections include osteomyelitis of the mandible or maxilla, infection of the deep fascial spaces (e.g., submandibular, canine, and retropharyngeal), maxillary sinusitis, noma (necrotizing infection of the cheek), posterior mediastinal infection, and anaerobic pulmonary infection. The anatomy of the deep fascial spaces is beyond the scope of this discussion but is well treated in standard texts *(2,4,19)*.

Distant infections that may develop secondary to oral infection include cerebral, spinal, and liver abscesses, and septic arthritis *(39–44)*. Remote spread of bacteria from the oral cavity to implanted prosthetic devices via the bloodstream is well documented *(45,46)*. Herpetic gingivostomatitis is occasionally complicated by secondary bacteremia, and there are numerous reports of septicemia related to mucositis and/or gingivitis, particularly in immunocompromised patients *(47,48)*. The risk of bacteremia may rise with increasing severity of gingival inflammation.

PATHOGENESIS OF INFECTION

Localized Infection

Infection of the dental pulp may result from microbial penetration directly through the dentin secondary to dental caries, dental drilling, or tooth fracture or by hematogenous spread. The most common cause of pulpal infection is from dental caries that begins with the formation of dental plaque. Regular oral care is needed to prevent plaque buildup. Plaque is composed of a large number of bacteria ($>10^8$ colony-forming unit [CFU]/mm^3), including *S. mutans*, which firmly adhere to the enamel of the tooth. These bacteria secrete enzymes that progressively dissolve away the tooth enamel and dentin, permitting the bacteria to access the pulp *(49)*. Microbial infection of the pulp (pulpitis) results and manifests clinically with pain and temperature sensitivity in the tooth. If the infection is not recognized and treated, the bacteria may then migrate through the pulpal foramen at the apex of the tooth into the alveolar bone at the root of the tooth, forming a periapical abscess, or extend beyond into the medullary space of the mandible, resulting in osteomyelitis.

Gingivitis is a periodontal process. Mild inflammation of the gums is present in almost all adolescents and in most American adults *(50,51)*. Acute and chronic gingivitis begin with the formation of plaque below the gumline. Swelling and hyperemia of the free gum margin occurs, and the gums may bleed easily with brushing. Gingivitis is increased in frequency or severity in certain patient groups such as HIV-positive patients, cancer patients undergoing chemotherapy, and young patients with type 1 diabetes mellitus *(52)*. Cessation of dental oral hygiene results in the appearance of gingivitis within 10 to 21 days.

Periodontal infections usually begin with gingivitis. As the infection becomes chronic, it extends deeper into the junction between the tooth and gingiva. This leads to loss of the connective tissue attaching the tooth to the bone (the periodontal ligament) and resorption of the bone. The resulting periodontitis causes a pocket to form between the tooth and the gingiva. This space is ideal for the growth of anaerobes due to the very low reduction oxidation potential. Spirochetes, of many morphotypes, some uncultivable, appear to be one of the predominant bacteria in advanced lesions *(53,54)*. The chronic infection that occurs causes loosening and then loss of teeth. Periodontal abscesses result from infection of deep periodontal gingival pockets *(55,56)*. Needle aspiration and appropriate culture of pus from dentoalveolar abscesses reveal a polymicrobial flora with a predominance of facultatively anaerobic streptococci together with obligately anaerobic gram-positive cocci and gram-negative rods *(57)*. Over 60% of these infections include aerobic microorganisms, whereas approximately one third have purely anaerobic isolates. In an analysis of apical abscess aspirates from 42 persons using reverse capture checkerboard hybridization assay, the most prevalent microorganisms were *Fusobacterium nucleatum, Parvimonas micra, Porphyromonas endodontalis*, as well as streptococci, *Olsenella uli, Eikenella corrodens*, and other anaerobes such as *Prevotella (58)*.

The most extreme form of gingivitis is ANUG. ANUG represents tissue invasion and destruction by mixed anaerobes and facultatively anaerobic bacteria. Data suggest an important role for spirochetes and for *Fusobacterium* spp. *(59)*. In HIV-seropositive patients, yeasts and herpes viruses may also contribute *(60)*. ANUG manifests as a loss of the papillae between adjacent teeth and results in exposure of the roots of the tooth. There is bleeding of the gingivae with blunting and necrotic punched-out lesions of the interdental papillae. The disease is characterized by the sudden onset of pain and tenderness of the gums associated with increased salivation and a peculiar metallic taste, and it is accompanied by systemic symptoms. ANUG most frequently occurs in adolescents and young adults. Risk factors include poor oral hygiene, infrequent dental care, poor nutrition, and possibly diabetes *(61)*. Prevalence studies have demonstrated that 4% of students using dental services at Harvard University and 6.7% of 9,203 adolescents in Chile have this condition *(61,62)*. *Stenotrophomonas* bacteremia associated with ANUG in a young girl with leukemia has been reported *(63)*.

Acute suppurative parotitis is a healthcare-associated infection that occurs after surgery or in patients who are predisposed because of malnutrition, immunosuppression, or dehydration or in whom drugs have been used that decrease salivary flow *(64,65)*. Such drugs include anticholinergic agents, antihistamines, and tranquilizers. The pathogenesis of this infection is presumed to be retrograde movement of mouth microorganisms up the parotid duct in patients with diminished rates of salivary flow. The condition is unilateral in 80% to 90% of cases and presents clinically as the acute onset of unilateral facial swelling with pain. Physical examination demonstrates purulent fluid, which can be expressed from the parotid duct. The microbial causes reported in the older literature were *Staphylococcus aureus* in the vast majority *(64)*. Newer studies using proper anaerobic culture methods demonstrate anaerobes in most patients *(66)*. The microorganisms are the same as those recovered from the gingival sulcus. Methicillin-resistant *S. aureus* has been reported as the cause of one outbreak in a nursing home *(67)*.

Acute tonsillitis is rarely an institutionally related infection unless an outbreak of acute group A β-hemolytic streptococcal infection is spreading through the population. Although group A β-hemolytic *Streptococcus* is the most commonly recognized cause of tonsillitis, the significance of recovery of other microorganisms such as mycoplasma, chlamydia, and anaerobes from inflamed tonsils has been debated *(68–72)*. The pathogenic role of these bacteria is not known. Microbiologic studies of the core of tonsils removed from 150 children with recurrent tonsillitis due to group A β-hemolytic *Streptococcus* during three periods beginning in 1977 and ending in 1993 revealed mixed flora (8.1 microorganisms per tonsil) in all tonsils and an increased rate of recovery of β-lactamase–producing bacteria with time *(73)*.

Erysipelas, a soft tissue infection of the cheek due to direct extension of bacteria from the mouth, is often due to group A or C streptococci. This rare complication follows 2 to 3 days after oral surgery and represents bacterial entry into soft tissues injured by instrumentation.

Noma (gangrenous stomatitis) is an acute, fulminant, necrotizing infection of the cheek and facial tissue that destroys the oral and para-oral structures and is found predominantly in malnourished children, particularly in sub-Saharan Africa. Certain groups of patients in developed countries may develop noma-like lesions that are slowly progressive. These persons are malnourished or have underlying illnesses such as leukemia *(74)*. The antecedent lesions to noma are believed to be oral herpetic ulcers, necrotizing gingivitis, or a buccal abrasion due to the rubbing of a tooth or from surgery *(75,76)*. Infection of these precursor lesions with synergistic bacteria, such as *Fusobacterium necrophorum* and *Prevotella*, causes progressive full thickness necrosis of the cheek, leaving a large open defect through which the mandible and tongue can be seen *(76–78)*.

Cervicofacial actinomycosis is a rare disease most commonly caused by *Actinomyces israelii*. The portal of entry is through disrupted mucosal barriers after trauma, dental manipulations, or oral and maxillofacial surgery *(79,80)*. The infection often appears as a chronic, slowly progressive induration or soft tissue mass in the mandibular–preauricular area and is sometimes accompanied by fistulous tracts to the skin that release sulfur-like granules. Systemic signs usually are absent *(81)*.

Primary oral tuberculous lesions are seen rarely *(82–84)*. Primary lesions usually occur in younger patients, are painless, and are associated with cervical lymphadenopathy. Secondary oral tuberculous lesions are more common and are seen mainly in older persons. Although the lesions are variable in appearance, the ulcerative form is the most usual, occurring on the tongue base or gingiva. These lesions are often painful. Most of these patients have accompanying active pulmonary tuberculosis *(85,87)*.

There are many oral complications from cancer therapy, one of the most prominent of these being infection. As a result of treatment effects on the mouth and immunosuppression, the oral cavity has the potential to become a reservoir for opportunistic microorganisms. *Candida* microorganisms are the primary cause of opportunistic fungal disease in patients who are immunocompromised. As many as 60% of cases of fungal septicemia in cancer patients are associated with prior oral infections *(88)*. The most common oral manifestation of a candidal infection is pseudomembranous candidiasis, manifested by removable white curd-like plaques over an inflamed mucosa. Other forms include leukoplakia-like white plaques that are not removable, referred to as chronic hyperplastic candidiasis, and chronic erythematous candidiasis that appears as patchy or diffuse mucosal erythema. Oral infections can extend to involve the esophagus. Because of the widespread use of azole prophylaxis in leukemia patients, candidiasis has become less common in this population. However, *C. krusei*, a fluconazole-resistant *Candida* species, and *C. glabrata*, an azole dose-dependent *Candida* species, now make up the majority of cases in hematology units *(89)*.

Aspergillosis is the second most frequent fungal infection in cancer patients, particularly patients with hematologic malignancies *(90)*. The paranasal sinuses are the most common sites of *Aspergillus* infection in the facial region, but there have been a few reports of primary oral

aspergillosis *(90–95)*. The oral lesions initially manifest on the gingiva and then develop into necrotic ulcers covered by a pseudomembrane. Spread to the alveolar bone and facial muscles may occur rapidly.

HSV is the most common viral pathogen in patients receiving cytotoxic agents or bone marrow transplants. The vesicular lesions on an erythematous base may appear anywhere on the mucosa and in addition to the mouth can involve the respiratory and gastrointestinal tracts. In immunocompromised patients, the oral mucositis associated with HSV may be particularly painful, severe, and prolonged. The oral HSV ulcerations may act as portals of entry for bacterial and fungal microorganisms *(47)*.

The most frequent viral infection following solid organ transplants is CMV. This infection can develop in high-risk transplant recipients despite ganciclovir or valganciclovir prophylaxis *(96)*. Oral manifestations, when they occur, are nonspecific and require biopsy to confirm the etiology. The infection often consists of a single, large, shallow ulceration *(97)*.

Infections by Direct Extension

An epidemiologic retrospective study of hospitalized patients with maxillofacial infections noted differences between pediatric and adult patients. Upper face infections predominate in children (81%), whereas in adults, lower face infections, mainly odontogenic or peritonsillar, are more common (66%) (98).

Osteomyelitis of the jaw (usually the mandible) most often results from chronic infection of a tooth, either from periapical abscess or from gingivitis. Other risk factors for osteomyelitis of the jaw include compound jaw fractures, diabetes mellitus, treatment with steroids, and surgery. Infection is particularly likely to occur when surgery is performed after irradiation of the mandible for tumor removal or after compound fracture of the mandible through the socket of a molar tooth. The causative agents reflect the broad range of microorganisms in the mouth, but most often seem to be due to streptococci and anaerobes (such as *Actinomyces, Prevotella, Bacteroides, Porphyromonas*, and *Fusobacterium*) in addition to *S. aureus* in persons with underlying illness *(81)*.

Peritonsillar abscesses arise by direct extension from infected tonsils and tonsillar remnants and are rarely healthcare associated in nature. It is critical to recognize and treat this infection to avoid respiratory compromise and other serious complications *(99–102)*.

Maxillary sinusitis caused by mixed aerobes and anaerobes is recognized as a complication of periapical dental abscesses in the upper teeth and following dental/oral procedures in this region of the mouth *(103,104)*. Sinusitis sometimes complicates extraction of the premolars and molars on the upper side, because the root tips of these teeth almost touch the lower border of the maxillary sinuses *(105)*.

Retropharyngeal abscesses arise by direct extension from uncontrolled tonsillar infection or after perforation of the posterior pharyngeal wall by a foreign body. The foreign body may be a bone or another sharp object carried in the mouth. A retropharyngeal abscess presents initially with pharyngeal discomfort, limited neck motion, and nonspecific constitutional symptoms, including fever and chills *(106)*. In its later stages, the abscess can be recognized by forward displacement of the posterior pharyngeal wall *(107)*. A lateral soft tissue film of the neck or computed tomography of the neck is required for diagnosis and will demonstrate air fluid levels or pockets of air in the retropharyngeal space. Clinical differentiation between a retropharyngeal abscess and cellulitis of the retropharyngeal space is difficult and may be accomplished by performing needle aspiration of the area. A return of pus signifies an abscess *(108)*. Prompt recognition and urgent surgical management by incision and drainage are the standard treatment, because the retropharyngeal space directly communicates with the posterior mediastinum and life-threatening complications such as necrotizing fasciitis and carotid artery rupture may occur rapidly *(109–112)*. There are reports of children being treated successfully without surgical intervention *(106)*.

Carotid artery mycotic aneurysm associated with dental surgery procedures have been noted in the literature on several occasions *(113)*. Patients develop fever and a rapidly enlarging neck mass shortly after the procedure. Prompt diagnosis and treatment are essential for an acceptable outcome.

Anaerobic pulmonary infection ("aspiration pneumonia") due to mixed anaerobes and facultatively anaerobic microorganisms occurs after aspiration/microaspiration of oropharyngeal secretions. Clinical evidence suggests that the presence of severe gingivitis and/or oral surgery on the gums is associated with subsequent development of aspiration pneumonia. Clearly, the very large numbers of microorganisms ($>10^{10}$ microorganisms per gram of tissue) found in gingival material provide a large inoculum if aspirated into the lungs. The interplay of local host defenses to clear the bacteria and the frequency of dental procedures on patients with gingivitis suggests that local host defenses usually overcome this inoculum.

Deep fascial space infections in the upper neck and underneath the jaw usually result from direct extension of odontogenic or oropharyngeal infection, and they have been associated with dental extraction *(114–119)*. Ludwig's angina is a diffuse fasciitis and cellulitis with edema of the soft tissues of the neck and floor of the mouth, originating in the submandibular and submental spaces. It is the result of a polymicrobial infection, often related to peritonsillar or parapharyngeal abscesses, mandibular fracture, or oral mucosal injuries. Airway compromise is the leading cause of death *(119)*. Progression of infection upward may involve the whole side of the face, including the eyelids and orbit, whereas downward movement of infection can lead to necrotizing cervical fasciitis or mediastinitis. The anatomic parameters influencing the spread of infection in these areas is beyond the scope of this chapter but is covered in other works *(19,50)*.

Distant Infection

Many distant abscesses have been reported as complications of dental and periodontal infection, including brain abscess, meningitis, paraspinal abscess, liver abscess, suppurative jugular thrombophlebitis (Lemierre's syndrome), septic cavernous sinus thrombosis, septic arthritis, cellulitis, and necrotizing cavernositis of the penis *(39–44,120–124)*. The route of migration is held to be bacteremia.

EPIDEMIOLOGY

The accuracy of published rates of infection for common dental procedures is limited generally by small numbers in the denominator and variable definitions of infection. Even with limited data, infection rates for some common procedures appear to be very low. For example, one 1992 review of the complications of oral surgical procedures commented that of approximately 50 million intraoral injections of local anesthetic each year, a literature search turned up only two case reports of injection-associated infection *(125)*. Even if this represents underreporting by 100 times, the rate is still 1 infection per 10,000 injections.

Risk factors for infection following oral procedures may variably include older age, female gender, oral contraceptive use, surgeon inexperience, site infection at time of procedure, and a mix of procedure dependent anatomic risks. Table 54-2 summarizes available data concerning the frequency of procedure-related infections (*126*,*127*,128,*129–140*).

TABLE 54-2

Healthcare-Associated Infection Rates for Oral and Dental Operations

Reference	*Procedure/Condition*	*Rate (%)*
126	After third molar extraction	5.8
	After partial bony impaction	4.4
	After complete bony impaction	10.1
	After cyst or tumor	17.0
127	After extraction of impacted third molar[a]	21
128	After extraction of impacted third molar	2.2
129	After third molar extraction	1.1
130, 131	After dental implant[b]	1.2
	Periapical infection in implant:	
	If edentulous	1–2
	If partial teeth	3–6
132, 133	With comminuted fracture of mandible	8
	If using fixed rigid internal device	2–9
134	Mandibular fracture involving teeth	25
135	After orthognathic surgery	10–25
	After compound maxillofacial fracture	50
	With antibiotic prophylaxis	10
136	After extraoral osteotomy	1–5
137	After transoral osteotomy	4–15
	After sagittal split osteotomy	1.3
138	After temporomandibular joint (TMJ) surgery	16
139	After TMJ arthroscopy:	
	Surgical site infection	2.5
	Ear infection	2.2
140	ENT surgery:	
	Clean	<1
	Clean—contaminated	18–87

[a]Alveolar osteitis.
[b]Surgical site dehiscence.

Dental caries and periapical abscess usually are not considered healthcare-associated infections because of their long incubation period and their association with poor oral hygiene and dental plaque formation. However, as noted above, the periodontal flora begins to change within 10 days of stopping active oral hygiene. Therefore, these complications could occur in head trauma, burns, and other patients with prolonged periods of unconsciousness or intubation. Insufficient salivary flow in critically ill patients facilitates the development of oral gingivitis, and the presence of endotracheal and feeding tubes promotes the formation of biofilms. Fourrier et al. (141) studied the relationship between dental status and colonization of dental plaque by aerobic pathogens and the occurrence of healthcare-associated infections in 57 intensive care unit (ICU) patients in France. The amount of dental plaque increased during the ICU stay. Colonization of dental plaque was present in 40% of patients, either acquired or present on admission. A positive dental plaque culture was associated with the occurrence of healthcare-associated pneumonia and bacteremia. In 6 of 15 cases of ICU-related healthcare-associated infection, the pathogen isolated from dental plaque was the first identified source of the healthcare-associated pneumonia or bacteremia. The results from this study, and others, suggest dental plaque colonization and oral flora may be a source of healthcare-associated infection (*142*,*143*,144,145).

Several prophylactic oral measures have been tried to decrease healthcare-associated pneumonia. In 1996, a prospective, randomized, double-blind, placebo-controlled trial in a cardiovascular ICU in a tertiary care center evaluating oropharyngeal decontamination with 0.12% chlorhexidine gluconate oral rinse demonstrated that the healthcare-associated respiratory infection rate and the use of nonprophylactic systemic antibiotics in patients undergoing heart surgery were reduced *(146)*. Since that time, numerous other studies have been done, with only some suggesting benefit in preventing healthcare-associated pneumonia. The variability in results may be explained in part by disparate methodologies, including the concentration of the topical chlorhexidine (0.2% vs. 0.12%) used, the number of applications/day employed, the manner in which the chlorhexidine is applied, and the approaches used for the control arms (Listerine vs. standard oral care). Two meta-analyses have examined this topic. The first included four randomized controlled trials that enrolled over 1,200 patients (147). The incidence of healthcare-associated pneumonia was lower in the chlorhexidine group, but it did not reach statistical significance (odds ratio 0.42, 95% confidence interval 0.16–1.06). Seven randomized controlled trials consisting of 1,650 enrolled patients were included in the second meta-analysis (148). This analysis showed that topical chlorhexidine decreased ventilator-associated pneumonia, but the benefit was most marked in cardiac surgery patients. There was no mortality advantage.

Acute suppurative parotitis was frequently reported in the past among patients undergoing general anesthesia for surgery. With better attention to adequate hydration and oral care and the widespread use of antibiotics in surgery,

it is now reported to occur <0.5% of the time after use of a general anesthetic *(125)*.

The prescribing of prophylactic antibiotics before implant surgery is common practice, but remains a controversial academic issue due to lack of supporting evidence in the literature. Dentoalveolar surgeries are Class II procedures (clean-contaminated) since they involve entry through the microbiologically contaminated oral cavity. Despite this classification, endosseous implant procedures generally lead to a lower infection rate (<5%) than what is seen with many Class II major surgical procedures, and serious adverse events are rare. Early studies suggested the risk of implant failure increased two to three times when preoperative antibiotics were not used, but most subsequent trials demonstrated minimal benefit (*149*,150,*151–153*). A 2003 Cochrane Review did not recommend or discourage antimicrobial prophylaxis for routine implant surgery due to lack of evidence (154). It concluded that antibiotics might be appropriate when implant surgery is extensive and prolonged and that antimicrobials should be used when systemic conditions warrant their use (i.e., such as for endocarditis prophylaxis). It is common for antibiotic prophylaxis to be given for periapical surgery, bone surgery, bone grafts, excision of tumors, and extractions of impacted teeth. For many procedures research support justifying the practice is limited.

Osteotomy for correction of maxillary or mandibular deformities is occasionally followed by surgical site infection. One retrospective analysis of 2,049 patients who underwent maxillofacial orthopedic surgery over a 21-year period reported only eight severe infections requiring incision and drainage, with no results compromised because of infection *(155)*. In a prospective evaluation over a 20-year period of 1,000 consecutive patients after LeFort I osteotomy, 1.1% developed significant infections such as abscesses and maxillary sinusitis, and no cases of osteomyelitis occurred (156).

The risk of bacteremia with dental manipulation has been quantified. One such study reported bacteremia in 72% of 183 patients undergoing one or more tooth extractions, and it occurred most frequently when teeth were extracted for inflammatory conditions *(157)*. Seventy-one percent of isolates were anaerobes. Other reports have identified predominantly the viridans *Streptococcus* group *(158)*. Even minor oral manipulation such as periodontal probing leads to bacteremia in as many as 43% of patients and is more frequent in patients with periodontitis than in patients with chronic gingivitis *(159,160)*. Forner et al. *(161)* discovered bacteremia in 15 of 20 patients with periodontitis after scaling. Some authors suggest employing antibacterial mouthwashes preprocedure to reduce gingival bacterial counts, and the incidence of procedure-related bacteremias though supportive evidence is minimal. The frequency of bacteremia during routine incision and drainage of dentoalveolar abscesses has also been examined. In one study, bacteremia occurred in 25% of such abscesses (3 of 12 patients) *(162)*. Blood cultures were positive only during the drainage procedure in two of three patients, and in the third instance, bacteremia was also demonstrated 5 minutes after the procedure ended. When abscesses were aspirated with a needle before incision and drainage, no blood cultures had growth, suggesting that the risk of bacteremia may be reduced by needle aspiration of the abscess contents before incision and drainage.

Oral infections may be an important cause of septicemia in patients with hematologic malignancies. Dens et al. *(163)* noted a marked reduction of the salivary flow rate in patients after bone marrow transplant that was more pronounced if total body irradiation had been included in the pretransplant therapy. A higher concentration of cariogenic microorganisms and a shift toward a lower buffering capacity in saliva were found. These changes may lead to an increased risk of caries and oral complications posttransplant. Some authors have suggested that radiation therapy in the head and neck region may cause long-term alterations in oral flora *(164,165)*.

Bergmann (166) prospectively followed 46 patients with hematologic malignancies through 78 febrile episodes. He estimated that a probable oral focus for septicemia was demonstrable in 10.5% of these individuals and that an oral origin was possible in an additional 21.1%. Other authors have sought a relationship between the mucositis that often follows chemotherapy for leukemia or bone marrow transplantation and the oral flora, as a way to explain the infections seen in these settings. Dreizen et al. *(167)* prospectively studied patients undergoing treatment for acute leukemia and found that 34.2% developed chemotherapy-related oral infection and 16.3% developed chemotherapy-related oral mucositis. Gradually, it has been recognized that cancer-treatment–induced mucosal injury is not limited to the mouth, but causes mucosal damage throughout the length of the gastrointestinal tract. This mucosal barrier injury is a source for bacteremia, particularly during neutropenia. In a European prospective oral mucositis audit of 197 patients with hematologic malignancies, it was found that patients with severe mucositis had a higher incidence of fever and a longer duration of fever than those without this complication *(168)*. Mortality risk has been reported to be increased among hematopoietic stem cell transplant recipients with severe oral mucositis *(169)*.

Ferretti et al. *(170)* demonstrated that antimicrobial mouthwashes such as 0.12% chlorhexidine gluconate protected against these oral complications. Barker et al. *(171)* showed a possible reduction in incidence of β-hemolytic streptococcal sepsis among children receiving myelosuppressive chemotherapy who received prophylactic oral vancomycin paste. Various oral protocols for preventing oral sequelae in immunocompromised patients have been suggested *(172–176)*.

Not all studies show a correlation between the oral cavity and sepsis in patients with hematologic malignancies. A 2002 retrospective study of 77 patients after hematopoietic stem cell and bone marrow transplant showed no relationship between advanced periodontal disease and septicemia within the initial 100 days after transplant *(177)*.

Fortunately, the frequency of fungal and viral oral infections in cancer and transplant patients has been reduced dramatically by the institution of prophylactic agents. However, one of the untoward consequences of this practice is the emergence of resistant microorganisms.

Oral candidiasis and hairy leukoplakia are conditions that should trigger an assessment of HIV infection risk factors. Many oral diseases in persons with HIV infection can be modified presentations of conventional disorders, such

as gingivitis, necrotizing periodontal diseases, and exacerbated periodontitis *(178,179)*. Lower frequencies of oral disease have been seen in those on antiretroviral therapy and in those who receive regular oral health care *(180–182)*. A retrospective review of 101 HIV-infected patients who underwent 314 procedures revealed an overall complication rate of 2.2% and 4.8% after invasive dental procedures. Those who had an invasive procedure had a 2.0% (3 of 147) infection rate, and there were no infections in those who had noninvasive procedures performed. There did not appear to be a correlation between complications and immunologic or virologic status. Preoperative antibiotics were taken by 33.3% of the patients with complications versus 5.9% of those without adverse events, suggesting that routine antibiotic prophylaxis may not be needed for these patients *(183)*. There are no large comparative trials describing the complication rates for HIV-positive patients undergoing invasive dental procedures (184).

Some literature on the risks of tongue piercing has emerged. Reported complications include pain, tongue swelling, tongue abscess, Ludwig's angina, airway obstruction, bleeding, mucosal or gingival trauma or recession, chipped or fractured teeth, granulomatous inflammation and scar tissue formation, nerve damage and paraesthesia, aspiration of jewelry, incorporation of foreign body into site of piercing, and interference with speech, mastication, and swallowing *(185–190)*. Lopez-Jornet et al. *(189)* described gingival inflammation/swelling in 26.8% and dental fractures or fissures/cracks in 20% of 30 intraoral piercings seen in a University Dental Clinic in Spain. There have been reports of endocarditis due to *Neisseria mucosa, Haemophilus aphrophilus*, and methicillin resistant *S. aureus* as well as polymicrobial cerebellar brain abscess subsequent to tongue piercing *(191–194)*. There may be fewer problems associated with lip piercing, though gingival recession of previously healthy tissue has been seen *(195)*.

Viral Agents

HSV is the latent herpesvirus in the oral cavity most commonly expressed during hospitalization. The virus is latent in the trigeminal ganglion and is secreted in saliva from the parotid gland. Reactivation of active labial lesions in a patient is triggered by oral surgical procedures, trauma, ultraviolet light, and major injuries such as burns. Because of the frequency of asymptomatic excretion of the virus in saliva (virus can be recovered at intervals from the saliva of over 50% of adults in the United States), the unprotected hands of dentists, dental hygienists, and oral surgeons, which are bathed in saliva, are exposed to HSV. The most common result of transmission has been herpetic whitlow, which is a painful infection localized to the periungual region of the fingernail. This is recognized as an occupational hazard for dental workers *(196)*. There are also reports of transmission of HSV from dental workers to patients, including an outbreak of gingivostomatitis in 20 patients treated by a dental hygienist with herpetic whitlow who did not use gloves *(197)*. Because acquisition of HSV infection depends on direct contact between saliva or active lesions and an opening in skin, the potential for transmission of HSV has been reduced by the use of gloves for blood-borne disease precautions (see also Chapter 44). Latex and vinyl gloves have also been shown to protect against HSV *(198)*.

Despite their recovery from saliva and associated oral tissues, EBV and CMV have not been recognized as important pathogens for healthcare-associated infections in the dental or oral surgery setting, either for spread to other patients or for transmission to staff. However, a seroprevalence study done in the United Kingdom suggests possible occupational risk of infection with EBV in dentists based on a higher seroprevalence to EBV among clinical dental students and qualified dentists than among preclinical dental students *(199)*. Another seroprevalence study done in England showed a greater prevalence of antibodies to influenza A and B viruses and respiratory syncytial virus in dental surgeons compared with control subjects, suggesting occupational risk for respiratory virus infections *(200)*. Based on questionnaire results, reported donning of masks did not reduce seroprevalence with these viruses.

Blood-Borne Pathogens

HBV may be transmitted both from patients to dentists and oral surgeons and from oral surgeons and dentists to patients *(201–204)*. HBV can cause a chronic latent infection of the liver and is associated with large numbers of virus particles circulating in the blood of chronically infected persons. Because all intraoral surgery and many dental procedures cause breaks in the mucosa of the oral cavity or gums that result in bleeding, the risk of spread of hepatitis B from the patient to the operator is substantial *(205)*. In prevaccine surveys, the annual incidence of HBV was 5 to 10 times higher among physicians and dentists than among blood donors *(204,206)*. Infections occur when blood from the patient enters the body of the dentist through small breaks in the skin. In recent years, gloves have been used routinely as part of Standard/Universal Precautions. However, exposures of breaks in the skin to blood still occur due to glove perforation. Glove puncture occurs in 2.1% to 16% of oral surgery procedures *(207,208)*. Aerosol transmission from high-speed drills used in dentistry with resulting aerosolization of saliva and blood has never been documented to result in occupationally related infections. Transmission of hepatitis B via human bite has been recognized *(209,210)*.

Several outbreaks of HBV infection have been reported among patients who underwent surgery by dentists and oral surgeons chronically infected with HBV *(22,202,205)*. The precise mechanism(s) resulting in transmission of infection has not been determined, but infection was likely transmitted from dental workers to patients rather than from one patient to another. Some outbreaks were terminated after the involved provider began to wear gloves when performing procedures. Prior to 1987, HBV transmission from 9 oral surgeons/dentists and 14 surgeons to patients were reported in the United States, including one outbreak involving 55 patients traced to a single oral surgeon (211,*212*). Since 1987, there have been no reports of transmission of HBV from dentists or oral surgeons to patients, although there has been one case of patient-to-patient transmission in the dental setting (211,213). The disappearance of transmission in the dental setting may be due to adherence to Standard/Universal Precautions, higher compliance with hepatitis B immunization, incomplete reporting, or isolated sporadic cases that are difficult to associate with a dental worker (213).

HCV was identified in 1989 and is the main agent of what was previously termed non-A, non-B viral hepatitis. The virus produces chronic infection of the liver in most infected persons, and HCV is the leading cause of chronic liver disease, cirrhosis, hepatocellular carcinoma, and liver transplants in the United States and Europe. It is estimated that 4.1 million people in the United States are infected with HCV, of whom 3.2 million have chronic infection *(214)*. Injection drug users account for approximately one-half of infected persons *(214,215)*. HCV RNA is variably detected in the saliva of infected persons *(216–218)*. Oral surgery appears to increase the occurrence of HCV in saliva *(219)*. Transmission of HCV through a human bite has been reported *(220,221)*.

Like HBV, HCV is a known occupational hazard for healthcare personnel by contact with contaminated blood, although HCV seems to be transmitted in the occupational setting less efficiently than HBV. To date, no dental worker is known to have acquired HCV occupationally, but the high frequency of sharp injuries occurring in the dental setting places the dental worker at risk of HCV acquisition *(222)*. Despite this risk, the prevalence of HCV infection among dental workers appears to be similar to that of the general population in most studies *(223–227)*. Anti-HCV may be more common in dental workers who are older, have more years of practice, and have serologic markers of HBV infection *(228)*. A review of self-reported and observational studies of occupational blood exposures among US dental workers between 1986 and 1995 suggested that percutaneous injuries steadily declined to an average of three injuries per year (229).

The data on the frequency of transmission of HCV to patients during dental care are very limited. Gingivectomy performed by a dental surgeon of unknown HCV status was identified as the only risk factor for the seroconversion of one patient *(230)*. Sporadic case–control studies demonstrate an association between the receipt of healthcare or dental care and HCV positivity *(231)*.

HIV infection causes a chronic infection of human lymphocytes and many other cell types and generally has a latency period of at least several years before onset of symptoms. The epidemiology of HIV in the medical setting likely is the same as that of HBV, except the risk of transmission of HBV is approximately 100 times the risk of transmission of HIV for comparable exposures (211,*232*). As of December 2006, the Centers for Disease Control and Prevention (CDC) received reports of 57 US healthcare workers with documented HIV conversion temporally associated with an occupational HIV exposure. An additional 140 cases are considered to have possibly been acquired occupationally, but the source of infection cannot be documented with certainty. No dental personnel are among any of the documented cases, but six dental workers are in the group of possible occupational transmissions *(233,234)*. Occupationally acquired HIV infection recognized among healthcare workers most commonly resulted from blood transmitted by hollow-bore needles *(233,234)*. Because hollow-bore needles are used less frequently in dental practice, the risk of occupationally acquired HIV infection for dental workers may be slightly lower than that for some other groups of healthcare workers. In a national survey, Canadian dentists reported an average of 3 percutaneous injuries and 1.5 mucous-membrane exposures per year *(235)*. Orthodontists reported the highest rate of percutaneous injuries (4.9 per year) and oral surgeons reported the greatest frequencies of blood splashes (1.8 per year). A serosurvey combined with a questionnaire administered to 321 oral and maxillofacial surgeons revealed no HIV-seropositive participants despite a mean number of recalled percutaneous injuries within the previous year of 2.4 (most commonly associated with wire) *(236)*. The results suggest a low occupational risk for HIV infection.

In the United States, the only documented transmission of HIV from an operating surgeon to a patient occurred with one cluster of six cases related to a single dentist in Florida *(237)*. The events that resulted in the infection of these patients remain unknown, although the evidence suggests that HIV was transmitted from dentist to patient rather than from patient to patient *(238)*.

PREVENTION AND CONTROL

Infections may be transmitted in the dental operatory through direct contact with blood, oral fluids, or other secretions; via indirect contact with contaminated instruments, equipment, or environmental surfaces; or by contact with airborne contaminants present in either droplet splatter or aerosols of oral and respiratory fluids (213,239). For more comprehensive recommendations on this topic, the author refers the reader to the CDC's "Guidelines for infection control in dental health-care settings—2003" (213).

Strategies to prevent patient dental infections focus on several areas. The first is sterilization of all instruments used in intraoral procedures and disinfection of related equipment. The second is use of good infection control practices in the dental operatory (213). These measures are aimed at preventing the spread of an infectious agent on instruments or dental apparatus from one patient to another. The third is rigid asepsis during intraoral procedures, including the use of preprocedure mouthwashes to reduce the burden of intraoral flora. Local antisepsis with topically applied antiseptic agents should be used particularly for root canal work, endodontic procedures, and gum surgery. The fourth is antibiotic prophylaxis or treatment of infected areas in which work is performed. These measures are directed at preventing the entry of the patient's own resident oral and gingival flora into the operative site in numbers great enough to cause infection.

Instruments used to penetrate soft tissue or bone (forceps, scalpels, bone chisels, etc.) are classified as critical and should be sterilized by heat after each use. Instruments that are not intended to penetrate oral soft tissues or bone such as mirrors and amalgam condensers but may come in contact with oral tissues are classified as semicritical and also should be sterilized after each use. If a semicritical item will be damaged by heat sterilization, the instrument should receive, at a minimum, high-level disinfection. Instruments or devices that come into contact only with intact skin such as external components of x-ray heads are classified as noncritical. These items may be reprocessed between patients with intermediate-level or low-level disinfection or detergent and water washing, depending on the intended use of the patient-care item (213).

All instruments should be processed in a designated area to control quality and safety. The processing area should be divided into separate sections for cleaning/decontamination, preparation/packaging, sterilization, and storage. Before sterilization or high-level disinfection, instruments should be cleaned thoroughly to remove contamination and debris. They should be placed into a presoak solution immediately after use to prevent the drying of saliva or blood on the instruments and to make cleaning easier. The soak contains an antimicrobial agent to reduce the levels of bacteria and viruses. Cleaning is accomplished by scrubbing in a detergent solution or, preferably, to minimize handling and the exposure of workers to sharps injuries, by placing the instruments into a mechanical device, an ultrasonic cleaner. After cleansing, the instruments should be thoroughly rinsed with water while they are still in the cleaning basket, inspected carefully to make sure all visible debris has been removed, and then allowed to dry. Critical and semicritical instruments should be then sterilized. The most common forms of sterilization used in a dental office include steam under pressure (autoclaving) and dry heat. Sterilization processes must be monitored routinely by using mechanical, chemical, and biological parameters (see Chapter 81).

The use of liquid chemical germicides, such as glutaraldehyde, for high-level disinfection of heat-sensitive semicritical instruments may require up to 10 hours of exposure. These agents are extremely toxic. Indications for wet sterilization are very limited. Manufacturers' directions regarding the correct concentration, exposure time, and safety precautions should be followed closely. The process should be followed by aseptic rinsing with sterile water, drying with sterile towels, and delivering in a sterile manner for storage if not used immediately (213) (see Chapter 80).

Because of the transmission of both HIV and HBV in the dental setting, much concern has been expressed over the dental handpieces used to transmit rotary energy to dental drills/bits *(240,241)*. These handpieces are composed of a number of moving parts and typically have many cracks and crevices, which make them difficult to clean. They cannot be adequately disinfected by wet disinfectants because the agent cannot penetrate into the crevices. Studies have shown that residual live bacteria are recoverable from handpieces even after cleaning and wet chemical disinfection. Because all currently manufactured high-speed handpieces and most low-speed handpieces are heat tolerant, these items should be cleaned and lubricated, followed by heat sterilization between successive patients. Handpieces that are not heat tolerant should be modified to make them tolerant to heat. Those that cannot be heat sterilized should not be used (213,*242*).

Another potential concern is with dental unit water systems supplying dental handpieces and air water syringes becoming contaminated with common heterotrophic microorganisms from the incoming water supply and, less often, with oral flora from entry of a small amount of oral fluid into the device during transient negative pressure immediately after the drill stops rotating (*243–246*,247). To minimize the risk of cross contamination, it is recommended to discharge water and air from the unit for minimum of 20 to 30 seconds after each patient, even when an anti-retraction valve is present (213). Although there is no epidemiologic evidence that high microbial counts in dental unit waterlines is a public health problem, in 1995 the American Dental Association requested manufacturers to supply equipment capable of delivering water with ≤200 CFU/mL due to concerns about potential adverse health effects *(248)*.

The physical construction of certain devices such as burs and endodontic files makes them difficult to clean adequately. In addition, the cutting surfaces tend to deteriorate with repeated processing. These factors, coupled with reports of poor sterilization success, lead to the suggestion that these devices be considered single-use devices (213,*249*).

Good infection control practices in the dental operatory are directed at the use of hand hygiene and personal protective equipment as well as attention to reducing the contamination of environmental surfaces by saliva and blood. These measures include the utilization of impervious paper or plastic covers to protect surfaces that may become contaminated during use and that are difficult to disinfect. Such surfaces include x-ray unit heads and light handles. Between patients, all surfaces potentially contaminated with blood or other potentially infectious material should be wiped off with an Environmental Protection Agency–registered hospital disinfectant, also labeled as "tuberculocidal" (213). These intermediate-level disinfectants are effective against most bacteria and viruses. Other methods to reduce salivary contamination of the operatory in the form of aerosols or spatter include patient use of an antimicrobial mouth rinse before the procedure, use of a rubber dam, and use of a high-speed air evacuator during high-speed drilling (213). Not surprisingly, methicillin-resistant *S. aureus* has been recovered from the surfaces of dental operatories, including the air–water syringe and dental chair *(250)*.

Creutzfeldt–Jakob disease (CJD), one of the transmissible spongiform encephalopathies (TSEs), is a rapidly progressive, invariably fatal neurodegenerative disorder believed to be caused by an abnormal isoform of a cellular glycoprotein known as the prion protein. Prions are resistant to conventional decontamination processes. Epidemiologic investigation has not revealed any evidence that dental procedures lead to increased risk of iatrogenic transmission of TSEs among humans. However, studies have shown that infected animals develop infectivity in gingival and dental pulp tissues, and transmission to healthy animals can occur by exposing root canals and gingival abrasions to infectious brain homogenate *(251)*. Somewhat reassuring is the report by Blanquet-Grossard et al. (252) in 2000 showing that there were no prions detected in the dental pulp of eight human patients with confirmed sporadic CJD.

There is lack of consensus regarding the optimal procedures for disinfection and sterilization of instruments potentially contaminated with the CJD prion. The World Health Organization suggests that usual infection control processes are sufficient when treating patients with TSEs during procedures not involving neurovascular tissue, but that extra precautions be considered for major dental procedures *(253)*. The CDC recommends that special precautions in addition to Standard Precautions may be indicated when treating patients with known disease until

more information emerges about the transmissibility of CJD (213). These additional precautions include utilizing single-use items and equipment if possible, and when reprocessing must be done, keeping the instruments moist until cleaning and disinfecting, and then steam-autoclaving at 134°C for 18 minutes. The Society for Healthcare Epidemiology of America categorizes the infectiousness of different body tissues based on animal studies *(254)*. Gingiva, saliva, sputum, whole blood, and peripheral nerves are all ranked as no-risk tissues. Therefore, the semicritical and critical medical devices that have been contaminated with no risk tissues are recommended to be cleaned and either disinfected or sterilized using conventional protocols.

Local antiseptics are intended to reduce bacterial contamination of the operative site. They are applied to the prepared sites of dental fillings for caries, crowns, and root canals before closing the defect. Presurgical rinsing with an antimicrobial mouthwash has not been shown convincingly to decrease the number of microorganisms introduced into the bloodstream *(255,256)*. Also there is little evidence that topical disinfection of the gingiva with antimicrobial mouth rinses before elective gingival surgery prevents clinical infection.

Marten and van Saene *(176)* discuss methods to prevent each of the seven major oral infectious complications of cancer therapy. Four of these complications (caries, osteomyelitis, periodontal disease, and mucositis) may be decreased by strict application of local measures in the mouth. These measures include good oral hygiene to prevent caries and periodontal disease and to reduce the likelihood of osteomyelitis, and topically applied antimicrobials to prevent osteomyelitis and mucositis.

Systemic antibiotics have a limited role in reducing the rate of infectious complications. Converse and McCarthy *(257)* list the following indications for the use of prophylactic antibiotics for surgery on the jaw (mandible): intraoral approach, previous irradiation of the operative field, use of a bone graft, use of an alloplastic implant, and surgery in a patient prone to infection (diabetes mellitus). As demonstrated in Table 54-2, the rate of surgical site infection is increased when a transmucosal or intraoral approach is used or when the socket of a tooth is involved in a fracture. In addition to the situations listed by Converse and McCarthy, systemic antibiotic administration is of demonstrated benefit for transoral procedures over 3 hours in length and for orthognathic or other major maxillofacial surgery. The Infectious Disease Society of America recommends antimicrobial prophylaxis for head and neck procedures that involve entry into the oropharynx *(258)*.

Patients may qualify additionally for antibiotics in an attempt to protect heart valves or other distant foci from bacteremia originating in the mouth. Routine antibiotic prophylaxis for patients undergoing dental procedures to prevent hematogenous prosthetic joint infections is not recommended, although premedication may be warranted in certain patients, including immunocompromised patients with a potential higher bacteremic risk and patients undergoing higher-risk dental procedures within 2 years postimplant surgery *(259)*.

SAFETY FOR DENTAL HEALTH-CARE PERSONNEL

Worker safety is provided by following measures (213):

1. An infection-control program for personnel that includes education and training; immunizations; exposure prevention and postexposure management; medical conditions, work-related illness, and work restrictions; contact dermatitis and latex hypersensitivity; and maintenance of records, data management, and confidentiality. The components should be contained in written policies, procedures, and guidelines.
2. Every dentist, oral surgeon, and assistant within the office with potential occupational exposure to blood or other potentially infectious material should be offered and encouraged to accept hepatitis B vaccination. U.S. Public Health Service/CDC recommendations for vaccination, serologic testing, follow-up, and booster dosing should be followed.
3. Exposures to blood and other potentially infectious material should be prevented by the use of Standard Precautions and engineering and work-practice controls, including regular evaluation and selection of devices with engineered safety features. Gloves should be worn for any work done in or around the mouth and for handling any instruments, surfaces, or substances contaminated with saliva or blood. A surgical mask and eye protection with solid side shields or a face shield should be worn during all procedures. Any visible wounds suffered from sharp instruments should be immediately cleansed and assessed. The assessment should include informed consent for testing the patient for HBV/HCV and HIV according to applicable state and federal laws. Additionally, a postexposure prophylaxis protocol should be followed (260,*261*).
4. Hand hygiene should be performed with soap (antimicrobial or nonantimicrobial) and water or an alcohol-based hand rub (if hands are not visibly soiled). Hand hygiene should be performed before and after caring for each patient, before donning gloves, immediately after removing gloves, after touching objects and surfaces likely to be contaminated, and when hands are visibly soiled.
5. Protective clothing that covers personal clothing and skin should be worn in the office/operatory setting, and the clothing should be changed if visibly soiled. These items should be removed before leaving work.
6. Because many studies have shown widespread salivary contamination of surfaces in the operatory, barrier protection of commonly touched surfaces such as radiographic handles and controls, bucket handles, and light switches should be provided. Clean and disinfect nonbarrier protected clinical contact surfaces with an EPA-registered low- to intermediate-level hospital disinfectant after each patient. An intermediate-level disinfectant should be used if visibly contaminated with blood.
7. The bacterial content of saliva can be reduced by rinsing the patient's mouth with water before any dental examination. Additional reductions can be accomplished by use of a preprocedural antimicrobial rinse.

8. A careful general medical history should be completed for all new patients and at periodic intervals to look for symptoms or signs of pulmonary tuberculosis. Patients with signs or symptoms suggestive of tuberculosis should not undergo elective dental or oral procedures until they have been evaluated by a physician. All dental office workers should receive a yearly test for tuberculosis *(262)*.

These measures are the minimum for providing reasonable protection to dental staff and patients against communicable diseases. Numerous studies demonstrate improved compliance by dental and oral surgery personnel with recommended infection control practices in recent years *(263–268)*. However, the results of these studies suggest that further education and encouragement are needed to attain a more desirable level of understanding and adherence to the recommended practices.

CHAPTER 55

Healthcare-Associated Infections in Obstetric Patients

Amy Beth Kressel and Suzanne P. Goodrich

The hospital obstetric unit is one of the first examples of a specialized hospital unit with a specialized patient population. "Lying-in" or obstetric hospitals were introduced in the 18th century, and some of the first significant studies on the epidemiology of healthcare-associated infections were made on obstetric services (1). Today's hospital is increasingly becoming a collection of specialized units; these units contain unique patient populations undergoing specialized treatments for specific diseases. Patients on these units may be more vulnerable to infection, or characteristics of the unit may facilitate transmission of infections. Obstetric care is unique in that both the primary patient and the newborn infant are at risk.

A survey of postpartum infections reported an overall infection rate of 6% (Table 55-1) (2). Ledger *(3)* pointed out that the frequent empiric use of antibiotics for febrile patients on the obstetric service probably leads to lower reported infection rates and obscures the true frequency of healthcare-associated infections. In recent decades, postpartum women have had shorter hospital stays. Shortened hospital stays may decrease exposure risk for healthcare-associated infections and may result in decreases in infection rates. Unfortunately, shortened hospital stays also make surveillance of infections more difficult; thus, changes in infection rates cannot be confirmed by current data.

TABLE 55-1

Infection Rates (Cases/100 Deliveries) on Obstetric Services by Site of Infection, 1993–1995

Type of Delivery	*Site of Infection*					
	UTI	*SSI*	*Epi*	*End*	*Mast*	*All Sites*
Cesarean	1.1	3.4	NA[a]	0.8	1.7	7.4
Vaginal	2.0	NA	0.3	0.2	3.0	5.5

[a]NA, not applicable.
End, endometritis; Epi, episiotomy; Mast, mastitis; SSI, surgical site infection (excluding endometritis); UTI, urinary tract infection.

HISTORY OF HEALTHCARE-ASSOCIATED OBSTETRIC INFECTIONS

The establishment of obstetric hospitals in the mid-18th century created the setting for epidemics of puerperal infections (1). The epidemics in turn provided the opportunity both to demonstrate that puerperal fever was contagious and to develop prevention methods. Alexander Gordon was one of the first to document this *(4)* and, later, so did Oliver Wendell Holmes *(5)*, but the most famous was Ignaz Semmelweis in Vienna because of his extensive and carefully detailed observations *(6)*.

The "great free Vienna Lying-in Hospital" created a natural epidemiologic experiment that Semmelweis had the insight to appreciate. The hospital had two separate divisions: the first division for teaching medical students and the second division for teaching midwives. The mortality was so much greater in the first division (16% vs. 2% in the second division) that even the patients knew about it and tried to be admitted to the second division. Semmelweis took advantage of this natural experiment to carefully collect data to document and determine the cause of the epidemics. Not only did he evaluate the data on healthcare-associated infections but he also made anecdotal observations that supported his conclusions—the low infection rate in women who delivered in the street on the way to the hospital compared with those who delivered in the hospital.

The medical students in the first division performed autopsies, whereas the midwives did not. Semmelweis noted the similarity between the fatal illness in a pathologist who had been stuck in the finger by a medical student and the fatal infections in the obstetric patients. He concluded that material from the autopsies was being transmitted back to the patients and causing their illnesses. Hand washing with soap was done after autopsies, so Semmelweis concluded that this was inadequate to remove all "cadaveric particles." He added hand rinsing with chlorinated lime water after performing autopsies and after each patient contact *(7)*. The result was a dramatic decrease in mortality in the first division to rates similar to those of the second division.

It took decades for Semmelweis' ideas, stimulated by Lister's concept of antisepsis, to become standard practice.

Even then, obstetric infections and maternal mortality remained major problems into the 1930s. The appearance of the first antimicrobial agents and improvements in other aspects of obstetric care resulted in a major decrease in maternal mortality *(8)*. Presumably, the reason for the persistence of high obstetric infection rates into the 1900s was that even though epidemics of puerperal fever transmitted by cross-infections were prevented by hand washing and antiseptic techniques, infection from patients' endogenous flora remained a problem.

PATHOGENESIS OF OBSTETRIC INFECTIONS

Most obstetric infections are caused by maternal vaginal and cervical flora; thus, infections usually relate to risk factors that allow endogenous flora to cause disease. Hospital pathogens are seldom problems on obstetric services, because obstetric patients have short stays and obstetric units are separated from other hospital units.

As Bartlett and coworkers *(9,10)* pointed out, vaginal flora are a dynamic ecosystem, with some differences between vaginal and cervical flora. Anaerobic bacteria usually outnumber aerobes, with anaerobic and facultative lactobacilli predominating. Other anaerobes include *Peptostreptococcus* species, *Bacteroides* species, and *Prevotella* species. The aerobic gram-positive flora include coagulase-negative staphylococci, streptococci, enterococci, and *Staphylococcus aureus* [including methicillin-resistant *Staphylococcus aureus* (MRSA) *(11)*]; and the gram-negative flora include *Escherichia coli*, *Gardnerella vaginalis*, *Enterobacter* species, *Klebsiella pneumoniae*, and *Proteus mirabilis (12,13)*. Both *Mycoplasma* and *Ureaplasma* are also found in the vagina. Sexually transmitted diseases may add *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, or herpes simplex virus (HSV) to this flora. Vaginal flora may change during pregnancy. Some studies suggest that lactobacilli increase in pregnancy and that other anaerobes decrease *(14)*. Antibiotics also change the flora, and the use of multiple doses of cephalosporins for prophylaxis has been reported to increase enterococci and perhaps *Enterobacter* species *(15)*.

As would be expected, most obstetric intrauterine infections are polymicrobial, representing contiguous spread from the vagina *(16)*. Ascending infection is demonstrated by both the presence of routine cervicovaginal flora in endometritis and surgical site infections (SSIs) and the ability to predict postcesarean infections by intraoperative lower uterine cultures *(17)*. Although a significant proportion of postcesarean SSIs are caused by staphylococci, as in other SSIs, most postcesarean infections are caused by endometrial contamination *(18)*.

Many risk factors have been proven or suggested to be associated with endometrial infection, including those that increase entry of vaginal flora such as prolonged rupture of the membranes, frequent vaginal and rectal examinations, or intrauterine monitoring; those that result in tissue injury such as soft tissue trauma, midforceps delivery, or inexperienced surgeons; and host factors that are associated with increased infections such as maternal age, lower socioeconomic status, diabetes mellitus, or obesity. Understanding these risk factors may become important in evaluating infection rates on specific obstetric units.

OBSTETRIC INFECTIONS (INFECTIONS RELATED TO PREGNANCY AND DELIVERY)

Postpartum Endometritis

The classic obstetric infection is postpartum endometritis. The postpartum patient develops fever that may be associated with abdominal pain, uterine tenderness, malaise, or foul-smelling discharge. In most cases the patient is started on antibiotics without obtaining cultures *(16)*. Endometritis can occur after either vaginal delivery or cesarean section but is more common after cesarean section. Infection has been reported to occur after fewer than 3% of vaginal deliveries and 5% to 95% of cesarean sections (2,*16*,*19*). The variation in infection rates results from the variation in risk factors in the population studied and patient's management. Endometritis after cesarean section occurs earlier than after vaginal delivery, as shown by hospital readmissions for postpartum endometritis. Most women who were readmitted for endometritis had delivered vaginally *(20)*.

Endometritis may be caused by either a single bacterial species or multiple microorganisms *(21)*. Common etiologic agents include the gram-positive cocci, such as streptococci and enterococci; gram-negative bacilli, such as *E. coli*, *K. pneumoniae*, and *P. mirabilis*; and anaerobes, such as *Bacteroides bivius* and peptostreptococci *(16,21,22)*. Some studies have distinguished between early and late postpartum endometritis *(23,24)*; late infection is a milder disease that occurs after vaginal delivery. It has been suggested that genital *Mycoplasma* and *Chlamydia* are important etiologic agents in late endometritis.

The most important risk factor for postpartum endometritis is cesarean section, and the risk of infection is greatest when it is a nonelective procedure after rupture of the membranes and the onset of labor *(16,19,25)*. General anesthesia, long duration of surgery, intraoperative problems, and poor surgical technique may all be risk factors. Currently patients undergoing both elective and nonelective cesarean sections are routinely given prophylactic antibiotics as they are shown to decrease postpartum endometritis and wound infections by 50% to 75% *(26)*. Administration of intravenous antibiotics is done before skin incision as it has been shown to be more effective than administration at cord clamping, the previous practice (27,*28*). In vaginal deliveries, prolonged rupture of the membranes, midforceps delivery, and soft tissue trauma increase the risk. With many other risk factors for postpartum endometritis, it is difficult to separate out relative risks, because the factors are interrelated. This applies to risk factors such as prolonged labor, frequent vaginal examinations, and internal monitoring. Host factors that increase risk include bacterial vaginosis, human immunodeficiency virus (HIV) infection, anemia, low socioeconomic status, maternal age, and obesity *(25,29,30)*.

Infection of the endometrium may extend into the myometrium and parametrial tissue, causing abscess formation

or sepsis. Septic pelvic thrombophlebitis (SPT) should be suspected in a patient who does not respond to antibiotic therapy *(31)*. If the workup fails to identify another infection, computed tomography should be performed to look for pelvic thrombophlebitis. Past treatment included the addition of heparin to broad spectrum antimicrobial therapy. However, a large randomized trial of SPT showed no benefit from adding heparin to antimicrobial therapy when compared to those receiving antimicrobial therapy alone *(32)*.

Evaluation of the febrile postpartum patient should include a relevant history and physical exam along with laboratory studies: complete blood count, chest X-ray, urine culture, and blood cultures. Leukocytosis is usually present but may also be seen in the noninfected postpartum patient. Uterine cultures are often not done because of the difficulty in interpreting the results. Because the microorganisms recovered are usually part of the normal maternal flora, these may either represent contamination during specimen collection or be the cause of endometritis. Unless a blood culture is positive, there is no way to confirm that the isolates are significant. However, good aerobic and anaerobic cultures do show the range of potential pathogens and detect infections caused by unusual pathogens such as the rare group A β-hemolytic streptococci (GABHS) infection. Uterine cultures can be collected with a cotton swab *(33)*.

Surgical Site Infections

Episiotomy infections are uncommon and usually not serious, but severe complications such as necrotizing fasciitis can develop *(34,35)*. Episiotomy sites should be examined carefully to detect infection early and infections should be treated to prevent complications.

A more serious problem is SSI of a cesarean section. SSIs are reported to occur in about 3% to 4% of cesarean section patients, including both incisional and organ and space infections (2,*36*). Recently, this rate has declined, perhaps as a result of administering perioperative antibiotics just prior to incision (37). SSIs are usually caused by maternal flora in the endometrium but, as with any other SSI, can be caused by microorganisms from exogenous sources *(18,38)*. In the latter cases, *S. aureus* is the most frequent cause of infection. Although the pathogenicity of genital mycoplasma in SSIs has not been proved, a study reported these to be the most common bacteria isolated in infected postcesarean surgical sites *(38)*. SSIs should be cultured before antibiotic therapy is begun (see also Chapter 21).

Urinary Tract Infection

Urinary tract infections are a common problem in pregnancy and during the postpartum period *(39)*. Risk factors for postpartum infections include urinary retention from anesthesia, trauma during delivery, and the need for catheterization. Urine cultures of the febrile patient with urinary tract symptoms should always be collected, although midstream samples may be contaminated by vaginal discharge. In those cases, the results are interpreted in the context of the clinical findings and the response to empiric antibiotic therapy. The major preventable risk factor in the postpartum period is catheterization. Catheterization is indicated for urinary retention but should be done only as needed *(40)*, with the catheter removed as soon as possible. Another risk factor for postpartum urinary tract infection is bacteriuria during pregnancy. Pregnancy is one of the few conditions for which treatment of asymptomatic bacteriuria is indicated (41). Detection and treatment of bacteriuria in pregnant women may decrease postpartum urinary tract infections.

Chorioamnionitis (Intraamniotic Infection)

Intrauterine infection during pregnancy, such as postpartum endometritis, is usually caused by ascending infection from vaginal flora and is caused by similar bacteria *(16,42,43)*. Most infections are also polymicrobial, and the major risk factor is prolonged rupture of the membranes. Infection is rare in women with intact membranes. Other risk factors are similar to those for postpartum endometritis: duration of labor, number of vaginal examinations, internal monitoring, and possibly bacterial vaginosis. A variety of other obstetric procedures may introduce infection, including amniocentesis, chorionic villus sampling, and percutaneous umbilical blood sampling.

Because fever can be the only presenting sign, initial diagnosis may be difficult. Specific diagnosis requires examination of amniotic fluid by gram stain, culture, and amniotic fluid glucose level *(44)*. Healthcare-associated chorioamnionitis can be suspected in patients who become febrile after vaginal examinations, internal fetal monitoring, or other such procedures, but there is no standardized definition for healthcare-associated infection. Once the diagnosis is suspected, the patient should be started on broad spectrum antibiotic therapy, including anaerobic coverage, and delivered as soon as possible.

Mastitis

In a study of obstetric patients who were contacted after discharge from the hospital, mastitis was the most common infection reported (45). Very few breast infections were seen during hospitalization, because mastitis and breast abscess usually occur several weeks into the postpartum period. A slight fever can develop early with breast engorgement, but it is transient. Later in the postpartum period, infectious mastitis must be distinguished from milk stasis and noninfectious inflammation *(46)*. Infection is associated with higher fevers, erythema, and unilaterality.

The most common cause of breast infection is *S. aureus (47)*. Epidemics of staphylococcal mastitis occurred in the past but have not been reported in recent years. Therefore, the traditional classification of infectious mastitis into sporadic and epidemic forms is seldom useful. Both types are usually caused by *S. aureus*. Increasing numbers of cases due to community-acquired MRSA are also being reported *(48)*. Predisposing factors for mastitis include the lack of nipple care, poor feeding technique, and inadequate emptying of the breasts. Infection can be confirmed by gram stain and culture and responds to antistaphylococcal antibiotics and, if needed, surgical drainage. Continued breast drainage is important and can be accomplished by continued nursing, if appropriate, or pumping and discarding milk.

NONOBSTETRIC INFECTIONS IN THE OBSTETRIC PATIENT

There are many nonobstetric infections that must be considered in the evaluation and management of obstetric patients, not only for the sake of the patient but also for the safety of the fetus or neonate and the protection of others on the obstetric service. Selected infections of particular importance in the obstetric patient are described.

Listeria

Approximately one third of *Listeria monocytogenes* infections occur in pregnant women. *Listeria* can cause a febrile illness in obstetric patients and may rarely result in severe diseases such as meningitis *(49)*, miscarriage, or premature delivery. It can be transmitted to the neonate and cause severe disease. Contaminated food, particularly soft cheeses, cold meats, and hot dogs, can infect the obstetric patient. Transmission of *Listeria* to neonates in the delivery room has been reported on several occasions *(50,51)*. Routine blood cultures should be obtained from febrile patients, providing a diagnosis and allowing directed antibiotic therapy.

Streptococcus pyogenes (GABHS Infections)

Historically, GABHS has been a significant cause of postpartum endometritis but now is uncommon *(3)*. These infections occur in previously colonized mothers or can be acquired by cross-infection from healthcare workers, other patients, or colonized infants. GABHS endometritis may differ from endometritis caused by the usual maternal vaginal flora, with an abrupt onset of high spiking fevers and diffuse tenderness. Diagnosis can be made by gram stain and cultures of uterine discharge. The streptococcal toxic shock syndrome caused by GABHS has been reported in postpartum patients *(52)*.

As illustrated by an outbreak reported from a hospital in Washington state in the 1960s *(53,54)*, despite good infection control practices, GABHS epidemics can still occur if a member of the obstetric team is a streptococcal carrier. Eleven patients (nine obstetric and two gynecologic) developed GABHS infections, and one died. Although nasopharyngeal cultures were negative from all staff who had contact with the patients, epidemiologic investigation identified the only staff member who had contact with all infected patients. When he stopped practicing, the infections disappeared, and when he returned to practice, the infections reappeared. This pattern was seen on three separate occasions, despite empiric antibiotic treatment with penicillin. Finally, the physician was hospitalized for clinical and microbiologic studies and was found to be an anal carrier of GABHS. It was demonstrated that he disseminated streptococci when he was moving about. Antibiotic treatment of the physician and his family cleared the carrier state and ended the epidemic.

Such outbreaks of GABHS infections continue to occur rarely but must be recognized quickly because of the potential for severe disease *(3,55)*. Even a single case of postpartum GABHS infection should be investigated immediately (see also Chapter 32).

Group B Streptococcal Infection

Group B β-hemolytic streptococci (GBS), normal flora in the gastrointestinal and genitourinary tracts, occasionally cause obstetric infections: chorioamnionitis, endometritis, urinary tract infections, or SSIs *(56)*. More often, the colonized mother may transmit GBS to the neonate, sometimes causing neonatal sepsis and/or meningitis. The Centers for Disease Control and Prevention (CDC) recommends universal prenatal screening of pregnant women for GBS colonization of vagina and rectum (57). Antibiotic prophylaxis is recommended for colonized women delivering vaginally, for those with GBS bacteriuria during current pregnancy, or for those who have delivered an infant previously with early-onset GBS disease (57). Prophylaxis is also given to those women whose culture status is unknown and who have preterm labor, premature rupture of membranes, >18 hours of ruptured membranes, or maternal fever during labor (57) (see also Chapter 32).

Staphylococcus aureus

An outbreak of MRSA at a large regional maternity unit in England identified 37 patients who had MRSA *(58)*. Perineal colonization was common in postpartum women, but not in staff members. The wards in this hospital differed from most American hospitals in that common toilet facilities with baths were provided for each ward rather than private bathrooms. Contamination of baths and bidets with MRSA was documented. Mattress covers were also contaminated and remained contaminated even after cleaning with detergent. Most mattress covers were found to be porous, and the core of some mattresses contained MRSA. The relative contribution of environmental transmission cannot be determined from this study because, as in most MRSA outbreaks, transient carriage by staff members was demonstrated. MRSA was eradicated from the maternity wards with multiple infection control measures, including replacement of all mattresses.

Clusters of *S. aureus* should be investigated thoroughly. Screening for carriers can be considered. Because a limited number of MRSA clones circulate, DNA fingerprinting has limited utility *(59,60)* (see also Chapters 28 and 29).

HIV Infection

One of the most important infections to identify in the pregnant patient is HIV. An estimated 21% of those individuals infected with HIV in the United States are unknown *(61)*. HIV antibody testing should be done as a part of the initial evaluation, and the CDC recommends an opt-out approach (62). High-risk patients should be tested again in the third trimester (62). For those pregnant women identified as HIV-positive, antiretroviral therapy is recommended regardless of their CD4 count or viral load *(63)*. The objective of treatment is to suppress the viral load so as to prevent transmission to the fetus *(63)*. Pregnant women with HIV should be seen by an HIV specialist along with their regular obstetric care. Cesarean section may be needed in those women whose viral load is not adequately suppressed *(63)*. HIV-infected mothers should be counseled not to breast-feed their infant as HIV can be transmitted through breast milk *(63)*.

Hepatitis B Virus Infections

All pregnant women should be tested for hepatitis B virus (HBV) surface antigen to prevent transmission of HBV infection to neonates. If HBV infection is identified in the obstetric patient, the neonate should be treated with HBV immunoglobulin and hepatitis B vaccine within 12 hours (64).

Healthcare workers with HBV also pose a risk to uninfected obstetric patients during high-risk procedures. Obstetricians with HBV have been reported to infect their patients during cesarean section and forceps deliveries *(65)*. Every obstetrician should know his or her HBV status, including tests for HBV surface antigen, e antigen and antibody, and core antibody. If susceptible to HBV, obstetricians should be immunized (see also Chapters 46, 73, and 75).

Hepatitis C Virus Infection

No prophylaxis is currently available to prevent transmission of hepatitis C virus (HCV) from an infected mother to her infant. The transmission rate of HCV from mother to child is approximately 7% to 8% but is higher in patients coinfected with HIV (64). The risk of transmission to the fetus is related to the HCV viral load titer at the time of delivery (66). No cases of HCV transmission through breast milk have been identified *(67)*, but it may be prudent not to breast-feed.

HSV Infection

Genital HSV, both primary and recurrent infection, occurs in obstetric patients and on rare occasion may result in disseminated disease *(68)*. HSV can be transmitted from mother to neonate intrapartum. Cesarean section is indicated for women with active HSV lesions or with a typical prodrome at the time of delivery (69). Internal fetal monitoring should not be done if HSV is suspected (69).

Postpartum, the mother with HSV lesions should be advised of potential risks of transmission to her newborn and be educated about appropriate measures to limit contact transmission (69). If healthcare workers with active lesions are allowed to continue working with patients, similar measures should be taken (70) (see also Chapter 44).

Chickenpox (Varicella Zoster Virus Infection)

Chickenpox in the obstetric patient may result in severe pneumonia, requiring hospitalization and antiviral therapy *(71)*. Because airborne transmission can occur, the obstetric patient with chickenpox who is not in labor should be admitted to a nonobstetric unit and placed in a negative pressure room (72,*73*). A patient admitted to an obstetric unit and placed in a regular hospital room with the door closed still infected a susceptible nurse who walked past the closed door *(73)*. After a pregnant woman with chickenpox delivers, the mother and infant should be separated until all of the mother's lesions have crusted over. Pregnant women should not receive the varicella vaccine (74) (see also Chapters 43 and 52).

Influenza

During the influenza season, pregnant women, especially those in the third trimester, are at higher risk for being hospitalized with an acute cardiopulmonary condition *(75)*. The 2009 pandemic H1N1 influenza A resulted in more severe complications in pregnant women. Although only 1% of the population, pregnant women accounted for 9% of the hospitalizations *(76)* and 6% of reported deaths (77). Pregnant women who are hospitalized with either confirmed or suspected influenza should have the same infection control policies utilized as for nonpregnant patients: placement in a single room, use of a surgical mask by hospital staff within 6 ft, and masking of the patient outside of her room (78). Empiric therapy with oseltamivir or zanamivir should be started; although these drugs are Food and Drug Administration Category C, benefit outweighs risk in this setting. Following delivery, the infant should be separated from the ill mother until she has been on treatment for 48 hours, she is afebrile for 24 hours, and she can control cough and respiratory secretions (78). Women who are considering pregnancy during the flu season should be immunized (74). Inactivated influenza vaccine is safe and recommended for pregnant women; the live-attenuated (intranasal) form of the vaccine is not approved in pregnancy (74) (see also Chapter 42).

INFECTION CONTROL PROGRAM FOR OBSTETRICS

Surveillance

Surveillance data are available on healthcare-associated infections on obstetric units. The National Healthcare Safety Network (NHSN) (formerly the National Nosocomial Infections Surveillance (NNIS) system) and other organizations do provide some benchmarking data (37). As would be expected, these reports show that SSIs are the major healthcare-associated infection in obstetrics. However, the reported infection rates on obstetric services are lower than those on medical and surgical services. The infection rates vary by the size and type of hospital, and the SSIs vary by the number of risk factors. More recent NHSN reports are limited to data on SSIs from in-hospital surveillance of patients who have had cesarean sections (37). Hospitals can either benchmark against these published rates or their own historical rates *(79)*. The CDC provides standardized definitions for surveillance (Table 55-2) and risk stratification (80,81). As discussed previously, many risk factors have been identified for obstetric infections. A simplified approach is to relate infections to the type of delivery—vaginal or cesarean—and to distinguish between elective and nonelective cesarean sections.

The general value of surveillance and infection control programs in hospitals has been documented by the CDC Study on the Efficacy of Nosocomial Infection Control (82), and the effective use of surveillance data on an obstetrics and gynecology service has been demonstrated by a study at a Swedish hospital *(83)*. In the Swedish report, data collected on patients having cesarean sections showed that 15% of them were infected (urinary tract infections excluded). The infection rates decreased to 9% after the introduction of quarterly surveillance reports to obstetric personnel. These reports included surgeon-specific infection rates.

A traditional method of surveillance on obstetric services is to monitor fevers in all patients. Most infected patients will be detected by this approach, and a routine fever workup in the postpartum patient will identify many

TABLE 55-2

Definitions for Surveillance of Healthcare-Associated Infections on Obstetric Units: Centers for Disease Control and Prevention

Endometritis must meet either of the following criteria:
Microorganism isolated from culture of fluid or tissue from endometrium obtained during surgery, by needle aspiration, or by brush biopsy
Two of the following are present: purulent drainage from uterus, fever (>38°C), abdominal pain, or uterine tenderness
Episiotomy site infection must meet either of the following criteria:
Purulent drainage from episiotomy
Episiotomy abscess
Other infections (excluding surgical site infections) must meet either of the following criteria:
Microorganism isolated from culture of tissue or fluid from affected site
Abscess or other evidence of infection seen during surgery or by histopathologic examination
Two of the following: fever (>38°C), nausea, vomiting, pain, tenderness, dysuria, and either of the following:
Microorganism isolated from blood culture
Physician's diagnosis
Postcesarean surgical site infections must meet the definitions used for all surgical site infections and are classified into the following categories:
Superficial incisional involves only skin or subcutaneous tissue and excludes stitch abscess or an episiotomy infection
Deep incisional involves deep tissues, e.g., fascial or muscle layers
Organ/space involves any part of the anatomy, other than an incision, opened or manipulated during surgery and includes postoperative endometritis

(Data from Horan TC, Andrus M, Dudeck, MA. CDC definitions of nosocomial surgical site infection, 1992: a modification of CDC definitions of surgical wound infections. *Am J Infect Control* 1992;20:271–274.)

infectious causes. The limitation of fever surveillance is lack of specificity: half of the fevers are either noninfectious or of unknown cause *(84)*. Despite this limitation, fever surveillance on an obstetric unit is a good screening technique and can indicate the development of potential problems.

Mead et al. *(83)* reported the use of a "sentinel list" technique on an obstetric unit, where the bedside nurse is involved in collecting information including fever and antimicrobial therapy and the collected information is reviewed for continuous surveillance. This method may be implemented and maintained by the obstetric staff, who would report to infection control when problems develop.

Short hospital stays and outpatient management of most postdischarge infections limit hospital-based surveillance of obstetric patients. Supplemental postdischarge surveillance systems are needed to provide an accurate picture of obstetric infections.

Several different approaches to postdischarge surveillance have been tried, involving either the patients directly or their physicians. The gold standard of postdischarge surveillance is direct observation of patients after hospital discharge. Couto et al. *(86)* did this at a Brazilian hospital by having postcesarean patients return on the 10th to the 15th postoperative day *(86)*. While in the hospital, 1.6% of the patients had SSIs, and this increased to 9.6% with inclusion of postdischarge examination.

A more practical approach was used by Holbrook et al. (45) who mailed one-page questionnaires to 19,650 women who delivered at their hospital. They received responses from only 36% of them (45). Ten percent of the patients who responded reported infections after discharge, including mastitis (6%), urinary tract infections (3%), and endometritis (1%). Postdischarge surveillance detected twice as many infections as in-hospital surveillance. The additional infections that were identified were mostly mastitis and urinary tract infections. Most cases of endometritis were reported by in-hospital surveillance, but an additional 1% of women reported endometritis after discharge. A major limitation of this approach is the poor response rate by the patients.

Postdischarge surveillance using physician questionnaires to identify infections after cesarean section has been reported to be more successful *(87)*. In a study by Hulton et al. *(87)*, 90% of physicians completed questionnaires about their patients. These questionnaires indicated an infection rate of 6.3% compared with 1.6% observed by in-hospital surveillance. The increase occurred in incisional SSIs (0.3–3.9%) and endometritis (1.3–2.5%). A limitation of this method is variability among physicians in self-identifying infections *(88)*.

Data mining of computerized records can augment traditional surveillance. Yokoe et al. (2) have used this method to determine postpartum infection rates among women in a large managed care organization. Computers can link patients with cesarean section procedure codes to later infection codes *(89)*. Various computer algorithms have been developed and commercialized to aid in identification of infections. These aim to reduce both labor and subjectivity.

Facilities on an Obstetric Unit

Obstetric units vary greatly in design, ranging from birthing centers designed for low-risk deliveries to standard labor and delivery units including operating rooms for cesarean

sections. The design needs are similar to other patient care areas in the hospital, including conveniently placed alcohol hand rubs and sinks for hand disinfection by staff, easily cleaned surfaces, and, in the case of complicated deliveries, a fully equipped operating room. The American College of Obstetricians and Gynecologists outlined basic standards for obstetric facilities *(90)*. An isolation facility should be available for the rare delivery of an obstetric patient with airborne infectious diseases such as chickenpox or tuberculosis. A pregnant patient with such an infection who is not in labor can be isolated on other hospital units in a room with negative air pressure.

The use of hydrotherapy to assist in labor raises additional environmental infection control concerns *(91)*. Some obstetric units use baths, whirlpools, or Jacuzzi showers as an aid in delivery. This practice raises the same concerns about bacterial contamination as hydrotherapy in physical therapy. Very few studies have been reported that evaluate the potential infectious risks of obstetric hydrotherapy. In one nonrandomized study of 1,385 women with prelabor rupture of the membranes *(92)*, 538 chose to use a warm tub bath during labor and 847 did not. Of those who used the bath, 1.1% developed chorioamnionitis and 0.6% developed endometritis. Of those who did not, 0.2% developed chorioamnionitis and 0.4% developed endometritis, suggesting no infectious risk. However, in a small study of 32 women *(93)*, one infant developed a *Pseudomonas* infection; *Pseudomonas* was isolated from the prelabor bath water. Presumably, this resulted from a lapse in cleaning technique and indicates a potential infectious risk. Whirlpool baths present even more complex maintenance problems. In a randomized controlled trial of whirlpool baths, 785 patients were studied *(94)*. Benefits in regard to analgesics, instrumentation, and perineal conditions were reported, and no difference was observed in maternal and neonatal infections.

These studies provide limited guidance in making an infection control decision regarding maternal hydrotherapy. If a facility decides to use hydrotherapy, detailed policy and procedure must be followed for cleaning and maintenance. Women with complicated pregnancies should be excluded, and many facilities require that the patient sign a consent form. Cleaning and maintenance depends on the type of equipment used. To avoid these problems, some facilities use inflatable single-use tubs.

Prevention

Antepartum The goal of good medical care during pregnancy is to ensure that a healthy patient presents for delivery. Conditions that place the pregnant patient at risk for postpartum infection, including urinary tract infection and perhaps bacterial vaginosis, should be identified and treated during routine prenatal care *(39,95)*. Routine screening for infections, including sexually transmitted and blood-borne diseases such as HIV, HBV, syphilis, *Chlamydia*, and gonorrhea should identify other infections in the pregnant patient. Dietary restrictions, such as no unpasteurized soft cheese, cold deli meats, or undercooked hot dogs, are appropriate to avoid infection with *Listeria (96)*. All pregnant women should receive inactivated influenza vaccine.

Intrapartum Semmelweis' *(6,7)* original observations on the value of good hand washing with an antibacterial agent remain the cornerstone of good obstetric infection control. The number of vaginal examinations should be limited, and internal monitoring with pressure catheters and scalp electrodes should be used only when necessary and should be introduced with aseptic technique. Fetal electrodes should be avoided in women with HSV, HIV, or HBV.

Studies during obstetric procedures *(97–100)* have clearly shown the high risk of exposure during deliveries of the obstetric team to blood and body fluids. In one study, observers were placed in delivery rooms and directly recorded the frequency of blood or amniotic fluid exposures *(97)*. In 230 deliveries observed, blood or amniotic fluid exposure occurred in 39% of 202 vaginal deliveries and 50% of 28 cesarean sections. The highest rates of exposure occurred in obstetricians and midwives. Another study *(98)* comparing different surgical procedures showed that the frequency of blood exposures during cesarean sections was exceeded only by cardiothoracic and trauma surgery. Tichenor et al. *(99)* demonstrated the need for good eye protection. They collected eye shields attached to surgical masks worn during deliveries and counted the visible splashes. This study found that 54% of the eye shields from the primary obstetricians had been splashed, including 30 of 68 shields from vaginal deliveries and 30 of 44 from cesarean sections. Perforation of surgical gloves is also common during deliveries and often goes unrecognized. Serrano et al. *(100)* collected 754 surgical gloves used by obstetricians during vaginal and cesarean deliveries and postpartum ligations. The gloves were examined for perforations by an air inflation—water submersion technique, and 13% of the gloves had been perforated. They noted that 62% of the perforations were not recognized during the surgical procedure; thus, the obstetricians were unaware of the potential exposure to blood or body fluids.

Because all deliveries are associated with the splatter of blood and body fluids and exposures are common, the delivery team cannot predict exposures. Further, any patient may have a blood-borne disease. Therefore, personal protective equipment should always be worn: gloves, long-sleeved impervious gowns, shoe covers, masks, and eye protection. The obstetrician should always be aware of the possibility of glove perforation.

Prophylactic antibiotics are given for all cesarean sections and will prevent 50% or more of postpartum endometritis (*25*,27,*28*,*29*). Good surgical technique is critical as well to the prevention of surgical infections *(101)*.

Postpartum Good perineal, surgical site, and breast care is important in the postpartum period. Mother and newborn should be separated in the case of infections such as tuberculosis, chickenpox, or influenza. Masks should be worn during minor respiratory infections. The patient should be monitored for urinary retention, with urinary catheterization used only as needed.

CONCLUSIONS

Healthcare-associated infections in obstetric patients have a long and dramatic history, but modern obstetric practices have produced low infection rates and extremely

low maternal mortality. Nonetheless, it is important to appreciate that these infections still occur, produce significant maternal and neonatal morbidities, and require careful monitoring. Recent drops in infection rates (37) and improvements in perioperative antibiotics for cesarean section both demonstrate that further advances in infection prevention are possible.

CHAPTER 56

Healthcare-Associated Infections in Patients with Spinal Cord Injury

Rabih O. Darouiche

About 262,000 Americans suffer from spinal cord injury and its complications, with 12,000 new cases accruing each year (1). Although it remains unknown if the incidence of spinal cord injury has changed over the years, it is estimated that about 40 cases occur in the United States per million persons (1). However, the number of patients living with spinal cord injury is expected to continue to rise owing to the increase in their life expectancy that is almost similar to that in the able-bodied population. Most cases of spinal cord injury are traumatic, most notably due to motor vehicle accidents, gunshot wounds, falls, contact sports, diving injuries, earthquakes, and acupuncture *(2–4)*. Nontraumatic causes include spinal tumors, infection, transverse myelitis, and iatrogenic events, especially perioperative hypotension *(5)*. Although the vast majority of cases of spinal epidural abscess are bacterial and are caused mostly by *Staphylococcus aureus* (6), a variety of other microorganisms, including agents of tuberculosis *(7)*, brucellosis *(8)*, actinomycosis *(9)*, neurocisticercosis *(10)* and shistosomiasis *(11)* as well as fungi-like Candida *(12)* and Aspergillus *(13)* species, and HIV, may also be causes of spinal epidural abscess *(14)*.

Healthcare-associated infections in patients with spinal cord injury have unique attributes and commonly require multidisciplinary management. Healthcare-associated infections in spinal cord–injured persons are also a major cause of morbidity and often are lethal. Compared to those who do not become infected, patients with spinal cord injury who develop healthcare-associated infections have lower functional improvements, shorter survival, and a higher likelihood for prolonged future hospitalization *(15,16)*.

The three most prevalent infections in patients with spinal cord injury affect the urinary tract, respiratory tract, and the skin and soft tissues, in the form of decubiti, with or without involvement of the underlying bone. The main objectives of this chapter are to: (a) address the factors that predispose to healthcare-associated infections in relation to the time of injury; (b) delineate the interrelated pathogenesis and microbiology, unusual clinical manifestations, problematic diagnosis, and difficult prevention of infections involving the urinary tract, the respiratory tract, and the skin and soft tissues with or without involvement of the underlying bone; and (c) assess the spread, colonization, and infection by multiresistant microorganisms.

FACTORS THAT PREDISPOSE TO HEALTHCARE-ASSOCIATED INFECTIONS

Patients with spinal cord injury are predisposed to healthcare-associated infections both in the acute and the chronic settings after injury (Table 56-1). The administration of high doses of glucocorticosteroids immediately after traumatic injury is associated with a significant increase in respiratory and total infections *(17)*. Immediately after the spinal cord injury, patients are admitted to the hospital for management of injuries to the spinal cord and possibly other bodily organs. Not only do some injured patients initially require acute intensive care that poses its own risks for acquiring infection, but all subsequently undergo in-patient rehabilitation for up to few months (5). Critically ill patients and those residing in specialized spinal cord injury units have a particularly high risk of developing infections with resistant microorganisms, including extended-spectrum beta-lactamase (ESBL)-producing gram-negative bacilli, methicillin-resistant *S. aureus* (MRSA), and vancomycin-resistant enterococci (VRE).

TABLE 56-1

Factors that Predispose to Healthcare-Associated Infections

Soon after the spinal cord injury
Administration of glucocorticosteroids after the injury
Surgical management of injuries to the spinal cord and other bodily organs
Admission to the intensive care unit
Prolonged initial hospitalization
Bladder catheterization
Mechanical ventilation
Insertion of vascular catheters
Long after the injury
Bladder catheterization
Decubiti
Tracheostomy in patients with high cervical lesions
Surgical intervention for chronic complications emanating from the spinal cord injury
Immunologic changes

Furthermore, patients with spinal cord injury frequently have sustained concurrent wounds of the neck, chest, and abdomen that may require surgical intervention, thereby imposing additional risks for postoperative infections. The majority of patients during the period of spinal cord shock suffer from neurogenic bladder that necessitates catheter drainage, often leading to development of urinary tract infection. Likewise, the insertion of central vascular access for administration of fluids, blood and blood products, and medications or for hemodynamic monitoring may cause bloodstream infection. Patients with high cervical injury usually require mechanical ventilation and can develop ventilator-associated pneumonia.

Although the likelihood of developing infection appears to be the highest in the acute postinjury period, the vast majority of infections occur long after the spinal cord injury. This finding is attributed to the fact that many patients sustain spinal cord injury when still young and have an almost normal life expectancy. Since most patients with spinal cord injury chronically rely on bladder catheters for urinary drainage, urinary tract infection is the most common infection long after the injury. Second in frequency are infections associated with decubiti. Patients with high cervical lesions are especially predisposed to both tracheostomy- and endotracheal tube-related respiratory tract infections. Surgical management of the chronic sequelae of spinal cord injury can be complicated by surgical site infections. Injury to the spinal cord can result in immunosuppressive effects, particularly in patients with high-level injury that causes alteration to the sympathetic nervous system or the hypothalamic-pituitary-adrenal axis *(18)*. Possible immunologic deficits include impaired antibody synthesis *(18)*, reduced phagocytic activity (19), and aberrant accumulation of glucocorticoids and norepinephrine in the blood and spleen *(20)*.

URINARY TRACT INFECTIONS

Pathogenesis and Epidemiology

Accounting for 25% to 50% of all infections, urinary tract infections are the most common healthcare-associated infection in patients with spinal cord injury *(21)*. The two unique factors that predispose this population to urinary tract infection include bladder catheterization and urinary stasis. The incidence of urinary tract infection appears to be the same in patients with spinal cord injury who have either an indwelling transurethral or a suprapubic bladder catheter *(22)*. Since intermittent bladder catheterization predisposes to urinary tract infection less than indwelling bladder catheterization, the former approach is advised whenever feasible. Unfortunately, only one-fifth of patients continue to practice this method of bladder drainage *(23)*. Although the sterile technique of bladder catheterization can theoretically be safer, at least in hospitalized patients, than the clean technique, both catheterization techniques can introduce pathogens into the urinary tract. Urinary stasis impairs the naturally occurring mechanisms that protect the urinary tract from infection, including the washout effect of voiding and the phagocytic capacity of bladder epithelial cells. Multiplication of bacteria in the urine and invasion of host tissues are promoted in the presence of reduced bladder emptying, increased residual urine, and high bladder pressure.

Although more than 90% of episodes of urinary tract infection in this population seem to involve only the lower urinary tract, serious complications can still arise secondary to such infections. Ascending infection of the urinary tract may evolve in the presence of vesicoureteral reflux or as a consequence of manipulations aimed at emptying the bladder. Taking into consideration that renal failure was once the leading cause of death in this population, kidney infection with loss of renal function is particularly worrisome. Additionally, urinary tract infection can be associated with a number of anatomic changes, such as renal calculi (occupying the bladder, ureters, or kidneys), bladder diverticulae and fibrosis, penile and scrotal fistulas, epididymoorchitis, and abscesses. The frequency of these anatomic changes depends on the type and the duration of bladder drainage; for instance, these changes are most commonly detected in patients with indwelling bladder catheters.

The vast majority of episodes of urinary tract infection in patients with spinal cord injury are caused by commensal bowel flora, primarily gram-negative bacilli and enterococci. The microbiology of microorganisms residing in the bladder can be affected by patients' gender, the source of pathogens (i.e., healthcare-associated vs. community-associated), and the method of urinary drainage. For instance, *Klebsiella pneumoniae* is a very common cause of urinary tract infection in hospitalized patients, whereas *Escherichia coli* and the enterococci cause more than two-thirds of cases of urinary tract infection in female patients undergoing intermittent bladder catheterization. The presence of condom catheters increases the likelihood of colonizing the urethra and the perineal skin with *Pseudomonas*, *Klebsiella*, and other gram-negative bacilli. As in able-bodied subjects, the presence of renal calculi in patients with spinal cord injury suggests etiology by urease-producing bacteria. Spinal cord injury units are no different from other types of specialized care units as to the occurrence of outbreaks of urinary tract infection due to multiresistant gram-negative bacilli. Increasing antibacterial usage has been associated with occurrence of candiduria *(24)*. Polymicrobial growth is detected in almost half of positive urine cultures obtained from patients with spinal cord injury, particularly those with chronic indwelling urethral catheters *(25)*.

Clinical Manifestations

Urinary tract infection may manifest differently in patients with spinal cord injury than in the general population. For instance, infected patients with spinal cord injury may not complain of dysuria, frequency, and urgency—symptoms that usually exist in able-bodied patients with urinary tract infection. Furthermore, suprapubic and flank pain or tenderness are not felt in insensate patients. More common manifestations of urinary tract infection in patients with spinal cord injury include worsening spasm, increasing dysreflexia, and change in voiding habits. Fever is usually, but not always, present.

Diagnosis

Diagnosing urinary tract infection in patients with spinal cord injury can be problematic for several reasons. First, by masking urinary-specific symptoms, absent sensations

constitute the single most important obstacle in diagnosing this infection in this population. Second, the unusual manifestations of urinary tract infection in these patients are nonspecific and may be caused by a variety of other infectious or noninfectious conditions, including osteomyelitis beneath decubiti, ingrown toe nails, and heterotopic bone ossification. Third, bacteriuria, the cornerstone for diagnosing urinary tract infection, is nonspecifically prevalent in this population. Bacteriuria is most frequent in patients who have chronic indwelling bladder catheters, as cultures of randomly obtained urine samples yield bacterial growth in more than 90% of instances. Even patients who undergo intermittent bladder catheterization have a 70% likelihood of being bacteriuric. Most cases of bacteriuria in patients with spinal cord injury represent asymptomatic bladder colonization. Although asymptomatic bladder colonization can progress to symptomatic infection, often it does not. Fourth, the finding of pyuria, which can reflect inflammation of the uromucosal lining and signal the transition from bladder colonization to symptomatic urinary tract infection, is not specific for infection. Pyuria can be caused by a variety of noninfectious conditions, including catheter-induced trauma, renal stone, recent urologic procedure, and interstitial nephritis.

Because of these potential problems in establishing a diagnosis, particularly when based on patients' prediction *(26)*, there exists no universally accepted definition of symptomatic urinary tract infection in patients with spinal cord injury. A commonly used definition of symptomatic urinary tract infection in these patients requires the presence of significant bacteriuria ($\geq 10^5$ colony-forming units [CFU]/mL), pyuria (>10 WBC/high power field [hpf] for spun urine), and fever (>100°F) plus more than one of the following signs and symptoms—(a) suprapubic or flank discomfort, (b) bladder spasm, (c) change in voiding habits, (d) increased spasticity, and (e) worsening dysreflexia—provided that no other potential etiologies for these clinical manifestations can be identified (27,*28*). Most healthcare providers tend to distinguish upper from lower urinary tract infection based on clinical manifestations and laboratory rather than imaging findings. For example, the presence of high fever (>102°F), chills, systemic toxicity, high-grade leukocytosis (>20,000 per mm^3), and/or leukocyte casts in urinary sediment supports the presence of pyelonephritis.

Prevention

Mechanical Approaches Since the indwelling transurethral and suprapubic catheters pose a higher risk of infection than intermittent bladder catheterization, the latter method of bladder drainage should always be considered, barring any anatomic or functional constraints. Increasing the frequency of intermittent bladder catheterization can decrease the risk of urinary tract infection. Although the technique of clean nonsterile intermittent self-catheterization is considered rather safe for use by outpatients, sterile intermittent catheterization is implemented by most hospitals owing to the fear of healthcare-associated introduction of multiresistant and virulent microorganisms into the urinary tract. In patients with persistent or recurrent urinary tract infections, the urinary tract should be investigated for anatomic abnormalities (including abscess, stone, obstruction, and stricture) and functional alterations (such as vesicoureteral reflux, high residual volume of urine in bladder, and elevated bladder pressure). The use of drugs and surgical procedures to reduce bladder pressure and aid bladder emptying can help alleviate the risk of urinary tract infection. Recent evidence suggested that the use of a catheter-securing device has the potential for preventing symptomatic urinary tract infection in patients with spinal cord injury *(29)*.

Antimicrobial Approaches Treatment of asymptomatic bacteriuria with bladder instillation of antibiotic solutions may alleviate bacteriuria temporarily. However, this may result in the emergence of antibiotic resistance and there is no evidence that this practice prevents clinical urinary tract infection. Studies that examined the administration of systemic antimicrobial agents in patients with spinal cord injury *(30–32)* have yielded either conflicting or disappointing results in terms of efficacy and emergence of antibiotic resistance. In general, systemic antimicrobial use is discouraged for treatment of asymptomatic bacteriuria in patients with spinal cord injury (33,*34*,35). Exceptions may include patients with (a) enlarging struvite stones associated with urea-splitting microorganisms, such as *Proteus mirabilis* and *Providentia stuartii (36)*; (b) conditions that enhance the likelihood of developing significant complications from having asymptomatic bacteriuria, such as premature birth in pregnant women; and (c) recurrent episodes of upper urinary tract infection that are complicated by sepsis or other clinical complications, particularly if the recurrent infections are caused by the same microorganism. It is important to note that, in general, antimicrobial treatment of asymptomatic bacteriuria in women with diabetes mellitus is probably not warranted (37). Although Cochrane reviews suggested that the use of cranberry supplements (38) or methenamine hippurate (39) could be beneficial in some clinical scenarios, the applicability of these approaches in the population of patients with spinal cord injury is of unclear value *(40–42)*. The clinical efficacy of antimicrobial-impregnated bladder catheters has not been tested in the population of patients with spinal cord injury, or for that matter, in patients with chronic indwelling bladder catheters. Preprocedure systemic antibiotic prophylaxis is generally indicated before urologic procedures, including urodynamics, and the administered antibiotic regimen is best chosen based on results of urine cultures and antimicrobial susceptibility tests obtained before the procedure.

Bacterial Interference Approach The limited success of traditional antimicrobial prophylaxis prompted interest in exploring the novel approach of active bacterial interference *(43)*. This approach is based on the principle that nonpathogenic microorganisms may prevent colonization of the urinary tract by pathogenic microorganisms. A number of relatively small open-label or randomized, placebo-controlled double-blind clinical trials in patients with spinal cord injury who had suffered from frequent episodes of infection indicated that intentional colonization of the neurogenic bladder by a nonpathogenic strain of *E. coli* 83972 reduced the rate of symptomatic urinary tract infection and posed no safety issues (27,*28*,*44–46*).

The potential clinical benefit of artificially boosting the lactobacillus numbers through probiotic instillation into the genital tract to limit the inflammation due to urinary tract infection is too early to judge *(47)*.

RESPIRATORY TRACT INFECTIONS

Pathogenesis and Epidemiology

Respiratory complications are the most common cause of morbidity and mortality in patients with acute spinal cord injury *(48,49)*. Pneumonia, the most serious respiratory tract infection and the leading cause of death due to infection in this population, is the most common pulmonary complication in the immediate period after injury as almost one-third of patients developed pneumonia while undergoing initial rehabilitation in the hospital *(50)*. Pulmonary function at the time of completing the initial hospital course after sustaining spinal cord injury can predict subsequent respiratory infections *(51)*. Pneumonia is particularly likely to occur in the first few months after cervical or high thoracic injury and among quadriplegics and persons older than 55 years. Upper respiratory tract infections and acute bronchitis may be precipitating factors in the development of pneumonia or ventilatory failure *(52)*.

Factors that predispose patients with spinal cord injury to develop pneumonia or tracheitis include: (a) weakness of the diaphragmatic and intercostal muscles in patients with cervical or high thoracic spinal cord injury, which would impair the capacity to clear respiratory secretions; (b) aspiration that is promoted either by an abnormal state of consciousness due to illicit drug ingestion or associated head injury or by paralytic ileus that often occurs soon after spinal cord injury; and (c) indwelling respiratory devices, such as endotracheal or tracheostomy tubes.

The microbiology of healthcare-associated respiratory tract infections in this population is affected by the type of predisposing factor(s). For example, *S. aureus* (particularly MRSA) and *Pseudomonas aeruginosa* are the two most common causes of pneumonia and tracheitis in patients with respiratory devices, whereas aspiration pneumonia is mostly caused by gram-negative and anaerobic bacteria. Unfortunately, prescriptions for broad-spectrum antibiotics that are not indicated for specific clinical scenarios have recently increased *(53)*.

Clinical Manifestations

Patients with cervical or thoracic spinal cord injury can have absent or altered sensations of chest pain and dyspnea. Infected patients with weakness of the diaphragmatic and intercostal muscles may also have no or minimal cough, and are unlikely to spontaneously produce sputum. In such patients, the only clinical manifestations of pneumonia may consist of physical findings (distressed appearance, fever, tachypnea, and tachycardia) and abnormal test results (leukocytosis, hypoxemia, and infiltrates on chest radiographs).

Diagnosis

Because of ineffective cough, patients with cervical or high thoracic lesions may not be able to provide adequate sputum samples for Gram stain and cultures. If tracheal secretions cannot be adequately suctioned, bronchoscopy may be required for both diagnostic and therapeutic purposes. The most prominent impediment to diagnosing pneumonia in patients with spinal cord injury arises from the limited ability to clinically distinguish pneumonia from a number of noninfectious pulmonary complications, including atelectasis, chemical pneumonitis, pulmonary embolism, and fat embolism. For instance, atelectasis, like pneumonia, commonly occurs in patients with cervical or high thoracic spinal cord injury who retain pulmonary secretions and can also manifest with fever. Furthermore, the site of pulmonary involvement may not help differentiate atelectasis from pneumonia since both conditions predominantly affect the left lung. Chemical pneumonitis due to aspiration can also mimic bacterial pneumonia. When adequate samples of respiratory secretions are available, microbiologic examination may help distinguish between these two clinical entities by showing a plethora of microorganisms (along with WBCs) in samples obtained from patients with bacterial pneumonia. Pulmonary embolism can also be clinically confused with pneumonia. This is partially attributed to the fact that the majority of patients with spinal cord injury disclose no thrombotic source for pulmonary embolism *(54)*. Furthermore, since patients with spinal cord injury commonly display baseline roentgenographic changes in the lungs due to atelectasis or other causes that make it difficult to interpret ventilation-perfusion lung scans, a definitive diagnosis of pulmonary embolism often requires pulmonary angiography. Fat embolism, which can occur acutely after spinal cord injury in association with fracture of long bones, may be suspected if petechiae and cerebral dysfunction are present.

Prevention

Potential approaches for preventing pneumonia in patients with spinal cord injury include some that center around control of predisposing conditions and others that provide antimicrobial activity. The first group of approaches is intended to augment cough and lessen retention of secretions. Cough can be assisted by using abdominal binders or corsets. Adequate hydration, chest physical therapy, and postural drainage can enhance drainage of secretions, although it may be difficult to achieve certain optimal positions during the acute period following spinal cord injury.

Antimicrobial approaches include antibiotics and immunization. In general, the use of systemic antibiotics for prevention of pneumonia in high-risk patients with spinal cord injury is not advocated. Because pneumonia can either occur more frequently or result in more serious complications in patients with spinal cord injury than in the general population, eligible patients should be immunized against potentially preventable causes of pneumonia. Almost two-thirds of patients with spinal cord injury are eligible for vaccination against *Streptococcus pneumoniae* and influenza virus by virtue of old age, chronic respiratory disease, and/or residence in long-term care facilities (55). The antibody response to pneumococcal *(56)* and influenza vaccination *(57)* of patients with spinal cord injury appears adequate. Although there have been no prospective studies of the clinical efficacy of these vaccinations in patients with spinal cord injury, it is generally recommended that patients at risk receive influenza vaccine every year and

pneumococcal vaccine every 5 years. Mailing of reminders and educational materials to patients has been reported to increase rates of vaccination (58,*59*). Strategies to increase vaccination rates among healthcare workers should be effectively implemented by addressing the concerns about side effects, effectiveness, and protective value of the available vaccines *(60)*.

INFECTIONS OF DECUBITI AND UNDERLYING BONE

Pathogenesis and Epidemiology

Due to changes in the composition of the skin, alterations in local tissue pressure, infection by tinea pedis, and occurrence of onychomycosis, patients with spinal cord injury suffer from defects and infections of the skin and soft tissue more so than able-bodied persons *(61)*. In general, about one-third of patients develop clinically relevant decubiti at one time or another after the injury. However, the prevalence of decubiti varies among medical centers and is affected by the level and completeness of spinal cord injury. Decubiti delay rehabilitation, prolong hospital stay, and incur excessive costs, particularly when infected. Although decubiti may develop either at home or while residing at a medical institution, most patients get admitted for management of the infectious complications of the ulcers. Factors that contribute to skin and soft tissue infection in the vicinity of decubiti include break in skin integrity and bacterial contamination due to soiling of the ulcer by stools or urine. The former factor predisposes to infection by skin flora including staphylococci and streptococci, whereas the latter factor promotes infection by gram-negative bacilli and anaerobic bacteria. Infected decubiti involve mostly the ischial tuberosities, trochanters, and sacrum—areas that are anatomically exposed to high pressure and likely to be exposed to fecal or urinary microorganisms.

Decubiti often harbor multiple aerobes and anaerobes. The concentration and type of microbes colonizing the decubiti can be affected by the presence of devitalized tissue. For instance, deep necrotic tissues yield high concentrations of bacteria, both aerobes and anaerobes, but the bacterial density and the presence of anaerobes decrease after excising the necrotic tissue. *Bacteroides* species, *Peptostreptococcus* species, *E. coli*, *Proteus* species, and enterococci are more likely to be isolated from necrotic than relatively healthy tissues. Resilient microorganisms like *S. aureus* and *P. aeruginosa* are frequently cultured from necrotic and healing decubiti. There exists some variability in the culture results of deep tissue obtained from different parts of the decubitus, and the value of obtaining repeated cultures of decubiti remains in question. The polymicrobial spectrum of flora in decubiti in children is rather similar to that in adults, but, additionally, includes *Haemophilus influenzae (62). Candida* infection of decubiti in patients with spinal cord injury is quite unusual.

In patients with spinal cord injury, most cases of osteomyelitis occur beneath decubiti. Most such cases are caused by two or more bacterial species, including gram-positive cocci (particularly *S. aureus* and *Streptococcus* species), gram-negative bacilli (including the Enterobacteriaceae group and *P. aeruginosa*), and anaerobic bacteria (mainly *Bacteroides* species). Vertebral and cranial osteomyelitis may also occur in association with implanted spinal hardware and cervical halos, respectively.

Clinical Manifestations

Infection of decubiti can be associated with cellulitis, abscess formation, osteomyelitis of underlying bone, septic arthritis, infected bursa, and septicemia. Local signs of infection include erythema, drainage, and foul-smelling or purulent drainage. Systemic manifestations of fever and leukocytosis commonly, but not invariably, occur. Septicemia is much less frequent in the context of osteomyelitis beneath decubiti in patients with spinal cord injury than in able-bodied adult patients with spinal osteomyelitis or children with long bone osteomyelitis. Clinically relevant blood cultures in patients with infected decubiti suggest the presence of soft tissue abscess or, less commonly, an infected hematoma.

Diagnosis

A number of factors can impede making a proper diagnosis of infection of decubiti with or without underlying osteomyelitis in patients with spinal cord injury.

Inadequate History Patients with spinal cord injury usually have no or altered sensations in the area of the decubitus. Since most decubiti occur in the trochanteric, ischial, and sacral regions, immobile patients cannot directly visualize the ulcers. Furthermore, such patients often complain of neurogenic or referred pain that may have no relation to the infection. These factors frequently result in obtaining an incomplete or inaccurate history from patients and underscore the diagnostic importance of performing comprehensive physical examination by healthcare providers.

Microbiologic Uncertainties Since decubiti are universally colonized by bacteria, swab cultures of open ulcers should not be obtained unless infection is clinically evident. Sinus tract cultures are also usually unreliable. Cultures of material obtained by needle aspiration tend to overestimate the number of bacterial isolates *(63)*. Although cellulitis adjacent to a decubitus can theoretically be caused by a microorganism(s) present in the decubitus, there is no evidence that skin biopsy in patients with spinal cord injury yields clinically relevant results. Cultures of biopsied deep soft tissue remain the most accurate means for determining the microbiologic cause of soft tissue infection.

In patients with underlying osteomyelitis, swab cultures of decubiti do not accurately predict the microorganisms causing bone infection. Moreover, since fibrotic tissue adherent to bone is usually colonized with bacteria, bone cultures are positive in at least two-thirds of patients in whom histopathologic examination of bone tissue is incompatible with osteomyelitis. Therefore, osteomyelitis should not be diagnosed solely by positive cultures of biopsied bone.

Radiologic Limitations Another diagnostic problem in patients with spinal cord injury arises from the limited ability to delineate the extent and the depth of infection in association with decubiti. Deep soft tissue abscesses can

exist beneath apparently healed decubiti. Although highly sensitive for detecting soft tissue abscesses, radionuclide scans can yield false-positive results in patients with spinal cord injury who have an infected decubitus without an associated abscess. Computed tomography (CT) and magnetic resonance imaging (MRI) can detect abscesses in both soft tissue and muscle, as is the case with the infrequently diagnosed iliopsoas abscess *(64)*. Since the incomplete complaints by the insensate patient with spinal cord injury can limit the clinical ability to assess the depth and extension of the infection, it is important to radiologically assess these parameters, particularly in rapidly progressive infections such as Fournier's gangrene *(65)*.

Because pressure necrosis affects subcutaneous and muscular tissues more than skin, the visualized skin opening of a sinus tract may seem deceptively small. Although generally helpful, probing of the sinus tract may still not reveal the full depth of the sinus tract. Sinography can better delineate the full depth of the sinus tract and reveal potential communications with bone, joint, visceral organs, or deep-seated abscesses. In patients with nonhealing decubiti who have persistent or recurrent infection, injection of dye into the bladder or intestines may help establish the presence of fistulous communications.

Misinterpretation of the findings of imaging studies is particularly prominent when attempting to diagnose bone infection beneath decubiti. Bone scan is very sensitive (almost 100%) but poorly specific (<33%) for diagnosing osteomyelitis beneath decubiti (66). The low specificity of bone scan is attributed to the aggregation of technetium in areas of bone that are affected by pressure induced changes and in foci of heterotopic bone ossification. Therefore, bone scan should be used primarily for its high negative predictive value (i.e., in an attempt to rule out osteomyelitis and, therefore, obviate the need for bone biopsy) rather than its low positive predictive value (i.e., to diagnose osteomyelitis). Neither clinical evaluation (duration of ulcer, bone exposure, purulent drainage, fever, peripheral WBC count, and erythrocyte sedimentation rate) nor radiologic examination (plain roentgenogram and bone scan) correlates well with the likelihood of finding histopathologic evidence for bone infection (66). Although the finding of bone changes by CT scan or MRI can be very helpful in supporting the diagnosis of osteomyelitis, there are no studies in patients with spinal cord injury that correlate the abnormal findings of these imaging studies with bone biopsy results.

Multiple Decubiti Patients with spinal cord injury often have multiple decubiti. In such patients, infection of soft tissue and/or bone may exist at some sites but not others. Furthermore, different sites may be infected by different microorganisms.

Because of the above-described diagnostic limitations, definitive diagnosis of osteomyelitis beneath decubiti requires histopathologic examination of bone tissue (66). Percutaneous needle bone biopsy yields histopathologic evidence for infection of bone beneath nonhealing decubiti in only one-fifth to one-third of cases (66). These findings support the clinical observation that nonhealing of decubiti is much less likely to result from underlying osteomyelitis than from noninfectious conditions, such as pressure-related changes, malnutrition, anemia, heterotopic bone ossification, and spasticity.

Prevention

The process of preventing infection of decubiti and underlying bone starts with preventing the development of decubiti. This consists of quality nursing care, frequent turning of the patient for pressure relief, careful attention to bony prominences, avoidance of friction and shear forces, correction of anemia, adequate nutrition, and training patients and their attendants in skin care. The relationship between bacterial counts in wounds and delayed healing remains controversial, and there exists no evidence from prospective randomized studies that local or systemic antimicrobial agents enhance wound healing or prevent infection in patients with spinal cord injury. Systemic antibiotics, however, ought to be given perioperatively in patients undergoing myocutaneous flap surgery. Although perioperatively administered antibiotics are typically active against the gram-positive skin flora, a broader-spectrum regimen that provides additional coverage against gram-negative bacilli and anaerobes may be warranted if supported by the results of clinically relevant preoperative or intraoperative wound cultures. There exists no convincing evidence to support the prevailing practice of continuing perioperative antibiotics until wound drains are removed, usually 10 to 14 days after myocutaneous flap surgery.

SPREAD, COLONIZATION, AND INFECTION BY MULTIRESISTANT MICROORGANISMS

Like other closed hospital units, the spinal Cord Injury Unit is not immune from healthcare-associated transmission of highly resistant microorganisms. Patients in spinal cord injury units may acquire multiresistant microorganisms while residing at a referring institution (hospital or nursing home) or another unit (particularly the intensive care unit) within the same hospital. Alternatively, patients may acquire multiresistant microorganisms while hospitalized at the spinal cord injury unit either directly from already-colonized patients or indirectly via the hands of healthcare providers (who care for colonized persons) or contaminated inanimate surfaces (in patients' rooms, rehabilitation areas, and whirlpools). Fortunately, most cases of growth of multiresistant microorganisms in clinical specimens represent colonization rather than clinical infection.

MRSA

The most commonly studied multiresistant microorganism in spinal cord injury units is MRSA *(67)*, which accounts for almost two-thirds of all clinical isolates of *S. aureus*. The generally problematic diagnosis of infection in these insensate patients makes it sometimes difficult to distinguish between clinical infection and colonization. This microorganism most frequently infects the urinary tract, wounds, lungs, and blood. The sites that are most commonly colonized by MRSA include the anterior nares, wounds, urine, perineum, and stools. Patients may remain colonized with MRSA for months or years. Although topical mupirocin and some systemic

antibiotics may eradicate MRSA colonization, it is unwise to routinely attempt to eradicate MRSA colonization in this population of patients *(68)*. However, control of MRSA is feasible if infection control policies are vigorously applied (69). Unfortunately, transfer of hospitalized patients to nursing homes may be delayed until MRSA colonization is eradicated.

VRE

The prevalence of VRE in spinal cord injury units appears to have increased in recent years. For instance, unreported findings from our center indicated that the gastrointestinal tract of one-third to one-half of patients residing in the spinal cord injury unit is colonized with VRE. In the vast majority of instances, isolation of VRE from stools was not associated with clinical infection. Molecular typing demonstrated that the majority of VRE isolates had distinctly different patterns, even in the case of patients sharing bedrooms. These findings suggested that healthcare-associated transmission of VRE within the spinal cord injury unit was rather unusual.

Gram-negative Bacilli

Patients with spinal cord injury often harbor multiresistant gram-negative bacilli that produce ESBL. Such microorganisms are isolated mostly from the urine, wounds, and respiratory secretions *(70–71)*. Most urinary ESBL-producing isolates belong to the *Klebsiella–Enterobacter* group of microorganisms that are fully susceptible only to carbapenems, but some isolates are also susceptible to aminoglycosides.

Clostridium difficile

This toxin-producing microorganism is very likely to cause environmental contamination in nonisolation rooms, work areas for physicians and nurses, and portable equipment *(72)*. Equally important, patients with spinal cord injury who are admitted to rehabilitation units may have an elevated rate of intestinal colonization by *C. difficile* without having clinical symptoms *(73)*.

CHAPTER 57

Healthcare-Associated Infections in Patients with Neoplastic Diseases

Aditya H. Gaur and Patricia M. Flynn

A patient with a diagnosis of underlying cancer is at particular risk of infection related to a multitude of factors including immune suppression from the underlying disease and its treatment (e.g., chemotherapy, radiation, or stem cell transplantation) as well as breach in continuity of skin and mucosal barriers related to permanent central venous catheters (CVCs) and therapy-associated mucositis. The source of such infections can be endogenous (e.g., gastrointestinal tract flora) or exogenous (e.g., air, water, or fomites), and the setting of acquiring such infections can be at home, in the community, or a healthcare facility. Overall, advances in the field of oncology often test the fine balance between more aggressive therapy, leading to improved survival, and complications, predominantly infections. In this chapter, we review healthcare-associated infections (HAIs), that is, infections that patients acquire in a healthcare setting, in patients with an underlying malignancy. The more general term, "healthcare-associated," is now increasingly used in place of "nosocomial" (1,*2*). Especially for the oncology patient population that has repeated "encounters" with the healthcare system in the form of frequent hospitalizations, treatment in day-care facilities, and visits to outpatient clinics, the line that differentiates HAIs from community-acquired infections can become particularly blurry, with the actual source of infection often hard to discern. Early diagnosis, treatment, containment, and prevention of HAIs are of great importance to the management of neoplastic diseases.

PATHOGENESIS OF HEALTHCARE-ASSOCIATED INFECTIONS IN PATIENTS WITH NEOPLASTIC DISEASE

The Host

Influencing the pathogenesis of infections, including HAIs, in the cancer patient are a multitude of vulnerabilities in host defenses. First, in most patients, the defect is an iatrogenic impairment of the immune system such as suppression of B lymphocytes and antibody production, impairment of T lymphocytes impeding cell-mediated responses, or neutropenia due to intensive chemotherapy or irradiation. While the risk of bacterial infections in patients with neutropenia has long been recognized and drives the empiric management of febrile patients with low neutrophil counts, there is increasing recognition of the risk for viral infections and related morbidity in patients who are lymphopenic *(3)*.

Second is the role of compromised natural barriers to infection. A breach in the integrity of the skin and mucous membranes is a frequent portal of entry for microbes composing the resident flora of these sites. This is especially true in the neutropenic host. Factors that affect skin and mucosal integrity include chemotherapy-related gastrointestinal tract mucositis, skin graft-versus-host disease, urinary catheters, and insertion of temporary or permanent indwelling CVCs. In addition, a tumor mass may obstruct a vital organ, impair circulation, or invade adjacent tissue, resulting in an altered regional anatomy that provides a nidus for infection.

Third are differing levels of infection risk based on the nature of cancer treatment. Prednisone, although not a cause of neutropenia, is a potent inhibitor of both humoral and cell-mediated immune responses, especially T-lymphocyte activity. Cyclosporin adversely affects T lymphocytes by decreasing $CD4^+$ lymphocytes and interleukin-2 synthesis. Irradiation and malnutrition cause decreases in T-lymphocyte function. Mucositis in recipients of high-dose cytosine arabinoside is well recognized and is associated with increased infection risk from oral/gastrointestinal pathogens such as viridans streptococcal species. While most chemotherapeutic agents are associated with some degree of neutropenia, some chemotherapeutic agents may also influence infection risk via other mechanisms, including lung fibrosis related to busulfan, lymphopenia with rituximab, and cyclophosphamide-induced hemorrhagic cystitis.

The Pathogens Because of the extensive use of antibiotics and antifungal agents, the normal microbial flora is deranged, and selective antimicrobial pressure creates a microbial milieu that poses an infection risk to the compromised host. While methicillin-resistant *Staphylococcus aureus* (MRSA) infection was always considered a classic example of an HAI, the past decade has shown a marked increase in community-acquired MRSA *(4)*, making an assessment of every MRSA infection as a suspected HAI no longer accurate. Bacteria such as coagulase-negative staphylococci (CoNS), *Corynebacterium* species, and

Bacillus cereus (5), often regarded as contaminants in sterile site cultures collected from the immunocompetent host, pose a real infectious threat to the immunocompromised host. These infections are often associated with CVCs or prosthetic joint infections. Finally, with advances in the field of molecular microbiology, the ability to diagnose long-recognized viral pathogens such as respiratory syncytial virus (RSV) and influenza and the more recently identified viruses, such as human metapneumovirus *(6)*, has increased tremendously *(7)*.

DEFINING HEALTHCARE-ASSOCIATED INFECTIONS IN PATIENTS WITH NEOPLASTIC DISEASE

When reviewing the literature pertaining to surveillance of HAIs in patients with cancer, one should be cognizant of the criteria used to define such infections and the denominator used to quantify them, characteristics of patient populations primarily in terms of risk factors such as duration of neutropenia, existing infection control policies including antimicrobial prophylaxis, and types of resources available to diagnose infections. All of these influence the reported HAI rate. In two prospective surveillance studies in adult and pediatric hematology-oncology patients from Bonn, Germany, the researchers noted an overall HAI rate of 11 and 10.8 per 1,000 patient days, respectively, with roughly 75% of the infections occurring in patients who were neutropenic (11,61). To ensure comparability of surveillance data, these researchers recommend that all surveillance studies in the cancer population should include infection rates based on number of patient days at risk, where "at risk" may be defined as the period of neutropenia.

The National Healthcare Safety Network (NHSN) definitions for HAIs are widely used in the United States (1). While these Centers for Disease Control and Prevention (CDC) definitions are designed for surveillance purposes for use in all acute-care settings, including subpopulations such as patients with cancer, their interpretation in an oncology setting can sometimes be challenging. Consider adjudicating a bloodstream infection (BSI) in a patient with a CVC as a primary CVC-associated BSI versus a secondary BSI with oral or lower gastrointestinal tract mucositis as the source of infection. In a patient population with high baseline chemotherapy-related morbidity such as gastrointestinal tract mucositis, the adjudication of BSIs as secondary BSI by applying NHSN definitions of oral or intestinal tract infection can become particularly contentious.

The NHSN definitions recommend two or more blood cultures drawn on separate occasions to be positive to meet the criteria for a laboratory-confirmed BSI for common skin contaminants such as CoNS. With peripheral cultures becoming increasingly uncommon in cancer patients who have CVCs, most clinicians would consider two cultures drawn from two lumens of a double-lumen CVC as two separate cultures, which, if positive for CoNS, warrant considering that episode as a BSI. The latter is not clarified in the NHSN definitions, which leave room for variable interpretation.

The CDC NHSN criteria state that, for an infection to be called an HAI, "there must be no evidence that the infection was present or incubating at the time of admission to the acute-care setting" (1). Because infections have variable incubation periods, determining whether an infection was incubating at the time of admission may be difficult. For this reason, many define an HAI as occurring within 24 hours (8), 48 hours (9), or 72 hours after admission.

In conclusion, the above examples highlight the importance of having a standardized definition for HAIs for oncology patients that takes into account the nuances of this patient population. A consistent way of collecting and reporting the numerator and denominator information when it comes to describing HAI rates in this patient population is key to assessing the effectiveness of interventions to reduce HAIs and facilitate crosscenter comparisons. Of note, even with standardized definitions, there is variable interpretation, as shown by a survey of Australian infection-control professionals, who showed concordance of opinion only 62.5% of the time when adjudicating case scenarios as primary versus secondary BSI based on the NHSN definitions *(10)*.

EPIDEMIOLOGY

Cancer patients present the healthcare epidemiologist with several unique challenges. Foremost is the distinction between an HAI and a community-acquired infection. Cancer patients have a high frequency of interaction with the healthcare setting, with frequent outpatient visits and admissions related to chemotherapy and other noninfectious reasons. Under these circumstances, an HAI may be diagnosed when the patient is not in the hospital and vice versa. In addition, the endogenous microbial flora may change after hospitalization. Especially during prolonged hospital courses, microorganisms of the hospital environment may be acquired that will increase the patient's risk for an infectious episode. Furthermore, because of the multidisciplinary management, some cancer patients may move through many sites during one hospitalization, such as the operating room, intensive care unit, medical service, physical rehabilitation units, and diagnostic imaging and irradiation departments. Under such circumstances, tracking the source of infection sometimes requires exhaustive epidemiologic investigation.

The ability to diagnose viral infections with increased sensitivity using polymerase chain reaction (PCR)-based techniques may complicate distinguishing between reactivation of latent viral infections and new infections. Latent infections acquired early in life may become activated during immunosuppression and hospitalization. These must be differentiated from acute primary infections caused by the same microorganism that could have been acquired during hospitalization. Notable among these are the herpes virus infections, including herpes simplex and cytomegalovirus (CMV) disease. Also, recurrent *Varicella zoster* virus (VZV) infection in the form of disseminated zoster is sometimes difficult to differentiate from primary varicella. Evidence suggests that some cases of *Pneumocystis jiroveci* pneumonitis may be acutely acquired infections in the hospital rather than the more usual reactivation of a latent infection.

There are also challenges in establishing the etiology of an infectious episode in the immunocompromised cancer patient. Since most infections are due to commensal or opportunistic microorganisms of the normal microbial flora, the isolation of a microorganism by culture may not necessarily prove it to be the cause of the illness. For example, in the febrile neutropenic patient, a microorganism such as *Corynebacterium* species isolated from a blood culture may be the causative agent or may merely be a skin commensal or contaminant of the culture. Additionally, the recognition of an infected site can be challenging. In the severely neutropenic and anemic patient with cancer, the key signs of infection may be absent because of a lack of inflammatory response. *S. aureus* may be introduced in a healthcare setting at the time of a finger stick for a blood count. Without neutrophils, no infiltration occurs, so swelling of the affected finger may be absent; furthermore, the anemia does not allow the appearance of erythema, so the sole manifestation of the infected finger stick site may be local pain or fever. Meningeal infection in the neutropenic patient may lack the typical signs of meningeal inflammation such as a stiff neck and a paucity of neutrophils in the spinal fluid. Even with fairly extensive bacterial infection in the lung parenchyma, the neutropenic patient may not be able to mount a sufficient inflammatory response to create an infiltrate recognizable on a chest radiograph. Finally, as previously discussed, consideration should be given to creating oncology population–specific definitions of HAIs that allow for comparisons within and between institutions.

Thus, the healthcare epidemiologist must consider these and other nuances of the compromised host with cancer when tracking HAIs. Molecular techniques to characterize microbes by subcellular and genetic components are evolving as powerful tools for healthcare epidemiology. Analysis of chromosomal DNA by pulsed field gel electrophoresis, ribotyping, and random primer PCR methods permits more precise characterization than more conventional phenotyping techniques.

ETIOLOGIES OF INFECTION

HAIs in cancer patients can be caused by a variety of infectious microorganisms, but the most common pathogens that have been reported are bacterial, followed by fungal and then viral. This may change, as viral diagnostics have greatly improved and the routine use of molecular amplification techniques for diagnosis of respiratory infections is increasingly mainstream. These improved viral diagnostics are likely to influence diagnosis of polymicrobial infections (viral and bacterial coinfections) and lead to some reduction in the number of episodes categorized as healthcare-associated fever of unknown origin (FUO) (11). In previous reports from oncology centers, bacterial microorganisms were isolated in more than 75% of HAIs, fungal pathogens in approximately 3% to 10%, and viruses in only 2% (12,13). The distribution of 263 HAIs, prospectively assessed across 7 pediatric oncology centers in Switzerland and Germany between 2001 and 2005, is shown in Table 57-1 (8). Of all HAIs in this study, 58% were BSIs. The rate of fungal infections varies between institutions and even among units within an institution. In one oncology intensive care unit, fungal infections accounted for 22% of all their HAIs *(14)*. Another study of HAIs in neutropenic patients reported a rate of 19% (15). Polymicrobial infections are not uncommon in this patient population. Robinson et al. (12) noted multiple isolates

TABLE 57-1

Distribution and Incidence Densities of 263 Healthcare-Associated Infections

HAI	*N (Proportion)*	*ID*
All HAIs	263 (100%)	4.80
Bloodstream infections (BSI)	153 (58%)	2.79
Laboratory-confirmed (blood-culture–positive) BSI	138 (52%)	2.52
Blood-culture–negative BSI	15 (6%)	0.27
Radiologically confirmedpneumonia	20 (8%)	0.36
Invasive aspergillosis	26 (10%)	0.47
Respiratory syncytial virus infection	2 (1%)	0.04
Surgical site infection	15 (6%)	0.27
C. difficile–associated enterocolitis	24 (9%)	0.44
Rotavirus-associated enterocolitis	6 (2%)	0.11
Urinary tract infection	8 (3%)	0.15
Ventriculitis related to external CSF drainage	1 (0%)	0.02
Local infections at the central venous access device exit site	8 (3%)	0.15

HAI indicates healthcare-associated infection; N indicates the absolute number; ID indicates incidence density per 1,000 inpatient days.
(Adapted from Simon A, Ammann RA, Bode U, et al. Healthcare-associated infections in pediatric cancer patients: results of a prospective surveillance study from university hospitals in Germany and Switzerland. *BMC Infect Dis* 2008;8:70.)

in one-third of their infections. Both multiple bacterial isolates and mixed infections can occur. As mentioned earlier, when making comparisons between studies and centers, one has to keep in mind the differences in definitions, patient populations, and institute characteristics.

Bacterial Infections

The most important bacterial healthcare-associated pathogens are CoNS, *S. aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa* (12,13) (see Chapters 28, 30, 34, and 35). Together, these four microorganisms account for more than half of healthcare-associated bacterial infections in cancer patients.

Gram-Positive Microorganisms *S. aureus* was the most frequent bacterial isolate in two surveys of healthcare-associated pathogens in cancer patients, accounting for 14% to 18% of isolates (12,13). Surgical sites were most often involved. CoNS infections have increased dramatically over the past decade; these microorganisms are the most common microorganisms isolated from BSIs in some centers *(16,17)*. The rise of these fairly nonpathogenic bacteria has been linked to the use of tunneled CVCs, such as the Hickman catheter.

Viridans streptococci are normal inhabitants of the oropharynx that invade through damaged mucous membranes and cause bacteremia and pneumonia in cancer patients. A syndrome of severe shock and adult respiratory distress syndrome can result. There is a potential causal relationship with cytosine arabinoside administration *(18,19)*.

Clusters of *Corynebacterium jeikeium* bacteremia have been reported from several cancer centers *(20–22)*. Risk factors include immunosuppression and use of plastic devices such as intravenous catheters. Some evidence suggests that patient-to-patient transmission does not occur *(22)*. The microorganism is resistant to multiple antibiotics, and vancomycin is the suggested therapy.

Gram-Negative Microorganisms As a family, Enterobacteriaceae are common pathogens for HAIs in cancer patients. *E. coli* and *Klebsiella pneumoniae* predominate (12,*23*). These microorganisms, along with *Serratia* species *(24)*, *Enterobacter* species *(25)*, and *Citrobacter* species *(26)*, have been isolated in sporadic infections and in epidemics. They are common causes of bacteremia, pneumonia, and urinary tract infections (UTIs). Frequently, patients are already receiving antibiotic therapy when these infections develop *(23–26)*. *P. aeruginosa* is the most notorious pathogen in patients with malignancies. It is associated with healthcare-associated bacteremia, pneumonia, UTIs, and wound infections. Although a frequent healthcare-associated pathogen, it has a special predilection for granulocytopenic hosts. In a review of *P. aeruginosa* infections in cancer patients in the 1990s, Maschmeyer et al. *(27)* noted that the proportion of these infections among cases of gram-negative bacteremia over the past two decades has not generally declined, but there were marked local and regional differences in the incidence of infections. Infections with *P. aeruginosa* account for approximately 10% of all HAIs in cancer patients (12,13,*28*). In the hospital environment, *P. aeruginosa* is associated with respiratory equipment, sinks, and fresh fruit and vegetables. Colonization often precedes infection *(28,29)*. Historically, the case fatality rate for *P. aeruginosa* infections was reported to be as high as 65% to 70%, which was significantly higher than the rate for other gram-negative bacterial infections *(29,30)*. Newer antimicrobial agents with improved anti-*Pseudomonas* activity have lowered fatality rates *(31)*.

A variety of other gram-negative microorganisms have also been linked with HAIs in cancer patients. The *Legionella* species are fastidious gram-negative bacilli. Approximately 42% of cancer patients with Legionnaire's disease are infected in a hospital setting. The use of steroids and neutropenia appears to have causal roles *(32)*. *Stenotrophomonas maltophilia* (previously *Xanthomonas maltophilia*) has been reported as a cause of bacteremia, UTI, pneumonia, and wound infections in cancer patients. It is most often detected in patients who have received antibiotics and respiratory therapy. The microorganism has been isolated from hospital sinks and respirators. The association between the use of respiratory equipment and isolation of *S. maltophilia* from sputum suggests that the equipment may be a significant reservoir for the microorganism *(33)*.

Anaerobes Anaerobes are infrequent healthcare-associated pathogens in the oncology patient and are isolated in <5% of infections. Usually, obvious disruption of normal gastrointestinal barriers is apparent when infections do occur *(34)*.

Antibiotic-Resistant Bacteria Widespread use of antibiotics, both prophylactic and empiric, has resulted in HAIs caused by multiply resistant microorganisms. MRSA, vancomycin-resistant enterococci *(35)*, and fluoroquinolone-resistant enteric microorganisms have been reported to cause significant problems in an oncology population *(36–38)*. A single-center retrospective study in cancer patients shows recent receipt of carbapenem therapy as an independent risk factor for vancomycin-resistant *Enterococcus faecium* bacteremia, and recent receipt of aminoglycoside therapy as an independent risk factor for vancomycin-resistant *Enterococcus faecalis* bacteremia *(39)*. Prudent use of antibiotics and careful surveillance of this population are necessary to detect and control the spread of these pathogens.

Fungal Infections

Perhaps the most serious infectious threat to the cancer patient is that caused by the opportunistic fungi, especially candidiasis and aspergillosis. The secular trends in the epidemiology of healthcare-associated fungal infections in the United States from 1980 to 1990 have been described *(40)*. During this decade, the National Healthcare-associated Infections Surveillance system hospitals reported 30,477 healthcare-associated fungal infections. During this time, the fungal infection rate increased from 2.0 to 3.8 infections per 1,000 patients discharged. The medical specialty with a high infection rate was oncology, with rates that varied from 8.9 to 10.6 infections per 1,000 discharges. *Candida albicans* was the most frequently isolated fungal pathogen (59.7%), followed by other *Candida* species (18.6%).

While *C. albicans* is the most common fungal pathogen in cancer patients (see Chapter 40), studies have noted

increases in the frequency of other *Candida* species, including *Candida tropicalis*, *Candida parapsilosis*, and *Candida krusei (41)*. Within individual cancer centers, a significant species shift has been noted even within the non-*C. albicans* group, such as an increase in *C. parapsilosis* and a decrease in *C. tropicalis (42)*. Overall, these differences between institutions to some extent are influenced by institutional antifungal prophylaxis guidelines, the use of indwelling catheters, and the types of malignancies treated. A study of candidemia in cancer patients from November 1992 to October 1994 found that, of 249 episodes of candidemia, non-albicans candidemia accounted for 64% (101/159) of episodes in patients with hematologic malignancies and 30% (27/90) of the episodes in patients with solid tumors *(43)*.

Fungemia, pneumonia, UTI, or disseminated disease with involvement of the abdominal viscera may occur. Infections are usually preceded by colonization of the gastrointestinal tract with the offending microorganism, but common source outbreaks have also been reported. Risk factors include the use of antibiotics, colonization with the microorganism, neutropenia, and the presence of tunneled CVCs.

While it is clear that the incidence of invasive aspergillosis has been increasing in patients with cancer, especially those with hematologic malignancies and bone marrow transplant recipients *(44)*, controversy exists regarding the definition of healthcare-associated versus community-acquired infection. This is in part due to factors such as an unknown incubation period and size of "infectious" inoculum as well as lack of uniform, reliable methods for environmental sampling in studies that attempt to trace the source of infection *(45)*. The overall case fatality rate of this disease is very high, with the highest being in bone marrow transplant recipients *(46)*. Sites most often involved include the lungs and the paranasal sinuses. Inhalation of conidia (spores) is requisite to the development of this infection. Direct inoculation of *Aspergillus* species spores from occlusive materials, such as tape, has also been reported.

Although *Aspergillus* causes a much lower rate of infection than candidiasis, it is the mycosis that has been most convincingly associated with the hospital environment. Outbreaks of healthcare-associated aspergillosis have been reported to be due to hospital construction and renovation activities *(47–50)*. Bone marrow transplant patients are especially susceptible. The source of infection is airborne conidia of *Aspergillus* species often associated with contaminated air–handling systems. Evidence suggesting the hospital water distribution system as an additional indoor source for pathogenic airborne fungi has also been reported *(51)*.

Historically, while *C. albicans* accounts for the majority of infections in compromised patients, recent epidemiologic trends indicate a shift toward infections by *Aspergillus* species, non-albicans *Candida* species, and previously uncommon hyaline filamentous fungi (such as *Fusarium* species, *Acremonium* species, and *Pseudallescheria boydi*), dematiaceous filamentous fungi (such as *Bipolaris* species and *Alternaria* species), and yeastlike pathogens (such as *Trichosporon* species and Malassezia species) *(52)*. These emerging pathogens are increasingly encountered causing life-threatening invasive infections that are often refractory to conventional therapies. Increasing use of antifungal prophylaxis may be linked to the emergence of these microorganisms as well.

Viral Infections

Overall, viruses account for relatively few HAIs. This number is likely to increase as viral diagnostic technology improves. Known HAI pathogens include VZV virus *(53,54)*, RSV *(55)*, influenza, and rotavirus *(56)*. Hepatitis B and hepatitis C have also been reported from other countries as healthcare-associated pathogens in children with cancer *(57,58)*.

CLINICAL MANIFESTATIONS

Fever is the most frequent manifestation of an infection including an HAI in the cancer patient. When fever occurs, especially in the setting of neutropenia, a diagnostic workup, including careful history and physical examination and bacterial and fungal cultures of blood, and any obvious sites of infection such as wounds, should be done before beginning therapy. BSIs most often present with fever with or without evidence of shock. Catheter-related bacteremias or fungemias may present with chills or rigors after flushing the catheter. If a tunneled CVC is in place, all lumens and ports should be cultured. In addition, if symptoms are present, a chest radiograph, and possibly sinus radiographs, should also be obtained. If no source of infection is identified by the diagnostic workup, a diagnosis of FUO may be made.

As noted earlier because of lack of inflammatory response in the neutropenic patient, signs and symptoms may be subtle, and pain and fever may be the only clinical manifestations of a serious HAI. Differentiating an infection from side effects of chemotherapy or radiation can sometimes be very difficult, and, not uncommonly, empiric treatment for an infection is started while waiting for further information.

SITES OF HEALTHCARE-ASSOCIATED INFECTIONS

Bloodstream Infections

BSIs account for a major proportion of HAIs and are associated with an extended hospital stay, extra costs, and excess mortality (59). The mean central line–associated BSI rate between 2006 and 2008 based on data collected by the NHSN from various participating oncology units ranged from 1.7 to 3.9 per 1,000 catheter days for permanent central lines and 2.0 to 4.6 for temporary central lines *(60)* (Table 57-2). In three prospective surveillance studies of HAIs in adult and pediatric hematology/oncology patients, 43% and 58% of HAIs were BSIs (8,11,61). From March 1995 through February 2001, a total of 22,631 cases of BSI were reported by 49 US hospitals participating in the Surveillance and Control of Pathogens of Epidemiologic Importance (SCOPE) Project (9). Among these cases, 2,711 isolates from 2,340 clinically significant episodes of BSI that met the surveillance definition of HAI were identified in adult patients with malignancies. Of all the recorded

TABLE 57-2

Distribution of Laboratory-Confirmed Permanent and Temporary Central Line-associated Bloodstream Healthcare-Associated Infection Rates by Type of Location (NHSN Data 2006 through 2008)

Permanent Central Line–associated Bloodstream Infection (PCLABSI) rate[a]				
Type of Location	*No. of Locations*[b]	*No. of PCLABSI*	*Permanent Central Line Days*	*Pooled Mean*
Specialty care areas				
Bone marrow transplant	21	235	60,546	3.9
Hematology/oncology	41	158	95,535	1.7
Long-term acute care	43 (33)	38	23,278	1.6
Pediatric hematology/oncology	7	75	32,255	2.3
Solid organ transplant	9	11	3,953	2.8

Temporary Central Line–associated Bloodstream Infection (TCLABSI) rate[c]				
Type of Location	*No. of locations*[b]	*No. of TCLABSI*	*Temporary Central Line Days*	*Pooled Mean*
Specialty care areas				
Bone marrow transplant	18 (17)	96	27,290	3.5
Hematology/oncology	33 (31)	117	51,950	2.3
Long-term acute care	67 (64)	260	149,298	1.7
Pediatric hematology/oncology	5	47	10,287	4.6
Solid organ transplant	12	66	32,591	2.0

[c] $\frac{\text{Number of TCLABSI}}{\text{Number of temporary central line days}} \times 1000$

(Adapted from Edwards JR, Peterson KD, Mu Y, et al. National Healthcare Safety Network (NHSN) report: data summary for 2006 through 2008, issued December 2009. *Am J Infect Control* 2009;37(10):783–805.)

episodes, 61% were caused by gram-positive aerobic microorganisms, and 27% were caused by gram-negative aerobic microorganisms. The proportion of gram-positive microorganisms was 62% for BSIs in 1995 and 76% for those in 2000 ($p < .001$), indicating a shift from gram-negative to gram-positive infections that has been noted over the past two decades by other studies as well. The proportions of gram-negative pathogens during the same periods were 22% and 15%, respectively. The increasing use of tunneled CVCs and the concomitant increase in the number of CoNS infections are some of the factors believed to contribute to this shift toward gram-positive BSIs *(62)*. Another speculation to explain this shift is the widespread use of second- and third-generation cephalosporins for the empiric treatment of febrile neutropenia. Because these antibiotics have improved gram-negative coverage at the expense of gram-positive coverage, breakthrough healthcare-associated bacteremias are likely to be of gram-positive origin *(63)*.

Anaerobes were rarely isolated (3% of isolates), and the proportion remained stable throughout the study period. Fungi accounted for 10% of isolates, with a nadir of 6% in 1998 and a peak of 15% in 1995. Fungemia, most often with *Candida* species, is also increasing among oncology patients *(64)*.

Multiple reports note that patients with hematologic malignancies, such as leukemia and lymphoma, are at greater risk for healthcare-associated BSIs than patients with solid tumors are *(62,65,66)*. Mayo and Wenzel *(66)* noted that leukemia patients had an infection rate 15 times greater than that of patients with solid tumors. In their study, patients with solid tumors were at no greater risk for BSIs than patients without malignancies.

In the SCOPE project, among adult patients with malignancies, there were some differences in the etiology of healthcare-associated BSI among those who were neutropenic versus non-neutropenic (9) (Table 57-3). The microorganisms that were most frequently isolated from neutropenic patients were CoNS, *S. aureus*, *E. coli*, and enterococci. In non-neutropenic patients, the most common pathogens were CoNS, enterococci, and *S. aureus. Candida* species accounted for 9% and 8% of isolates recovered from neutropenic and non-neutropenic patients, respectively. Viridans group streptococci, which accounted for 3% of all isolates in neutropenic patients, were significantly more common in this group (odds ratio [OR], 1.9; 95% confidence interval [CI], 1.87–7.60; $p < .001$). *E. faecium* was more frequently isolated from patients without neutropenia than it was from patients with neutropenia (6% vs. 2%; OR, 3.0; 95% CI, 1.75–5.04; $p < .001$). A total of 329 (14%) of all episodes were polymicrobial.

The risk factors for developing healthcare-associated BSIs include hematologic malignancies, prolonged hospi-

ANC, absolute neutrophil count; CoNS, coagulase-negative staphylococci; VGS, viridans group streptococci.
[a]Patients with an ANC of ≤1,000 neutrophils/μL versus those with an ANC of ≥1,000 neutrophils/μL.
(Adapted from Wisplinghoff H, Seifert H, Wenzel RP, et al. Current trends in the epidemiology of healthcare-associated bloodstream infections in patients with hematological malignancies and solid neoplasms in hospitals in the United States. *Clin Infect Dis* 2003;36(9):1103–1110.)

talization, and bone marrow transplantation *(62)*. Patients with hematologic malignancies are at increased risk because of the intensive cytotoxic chemotherapy, which often renders them pancytopenic for long periods. Mayo and Wenzel *(66)* noted that more than 75% of healthcare-associated BSIs in leukemia patients occurred when the absolute neutrophil count was <100 cells/mm^3.

The prognosis of healthcare-associated BSI is related to many factors, including the microorganism causing the sepsis, the source of infection, the absolute neutrophil count, the bone marrow status, and the presence or absence of shock *(65)*. In general, the mortality rate of infections caused by gram-negative microorganisms is greater than that of infections caused by gram-positive microorganisms *(62)*. BSIs that are polymicrobial or that are associated with pulmonary or intra-abdominal infections also have a high mortality rate *(65)*. The overall mortality rate for the 2011 patients with a monomicrobial, healthcare-associated BSI followed in the SCOPE project was 32%, ranging from 16% in patients with BSI due to viridians group streptococci to 45% in patients with BSI due to *Candida* species (9). In general, the mortality rates were higher for neutropenic patients than they were for nonneutropenic patients. The mortality rate for patients with BSI due to *P. aeruginosa* was 36% (48% of neutropenic vs. 31% of non-neutropenic patients; $p = .2$); for *E. coli*, it was 35% (38% vs. 33%, respectively; $p = .6$); for vancomycin-resistant *E. faecium*, it was 34% (67% vs. 29%, respectively; $p = .05$); and for CoNS, it was 33% (34% vs. 32%, respectively; $p = .2$).

Respiratory Tract Infections

HAIs of the respiratory tract include pneumonia, sinusitis, pharyngitis, otitis, and rhinitis (see Chapters 22, 23, and 49). Of these, pneumonias are associated with a high morbidity and mortality. Of the 263 HAIs across seven pediatric oncology centers in Switzerland and Germany between 2001 and 2005, 20 (8%) and 21 (8%) were radiologically confirmed pneumonias and invasive pulmonary aspergillosis, respectively (8) (Table 57-1). In only 1 of the 20 cases of radiologically diagnosed pneumonia was a causal pathogen identified, a well-recognized limitation in the identification of pneumonias, especially in nonventilated patients.

A subset of healthcare-associated pneumonias (HAPs) is in mechanically ventilated patients and called "ventilator-associated pneumonia" (VAP). VAPs constitute a significant proportion of HAIs seen in intensive care units. Detailed evidence-based guidelines and recommendations regarding the prevention, diagnosis, and management of HAP and VAP are available from expert groups in the United States, Canada, and Britain *(67–69)*.

The top three identified pathogens in VAP identified by bronchoscopic techniques are *P. aeruginosa* (24.4%), *S. aureus* (20.4%), and the Enterobacteriaceae group (14.1%) *(70)*. These were identified in 24 studies (1989–2000) including 1,689 episodes and 2,490 pathogens, not limited to the oncology patient population.

Respiratory tract infections occur most commonly in patients with leukemia/lymphoma and those with solid tumors of the lung and head and neck regions (12,13). Postoperative pneumonias are more often diagnosed in solid tumor patients, because extensive surgical procedures are more often a part of their diagnosis or treatment (13).

Urinary Tract Infections

Overall, not specific to patients with malignancies, most hospital-acquired UTIs are associated with catheterization, and most occur in patients without signs or symptoms referable to the urinary tract. Catheter-associated bacteriuria is the most frequent HAI worldwide, accounting for up to 40% of HAIs in US hospitals each year.

UTIs have been reported to cause between 17% and 28% of HAIs in the oncology population (12,13) (see Chapter 20). Gram-negative microorganisms, particularly *E. coli, K. pneumoniae*, *P. aeruginosa*, and *Proteus mirabilis*, predominate. The most frequent gram-positive isolates are enterococci. Fungal microorganisms are unusual urinary tract pathogens (12,13).

Patients with cancer are at greater risk for healthcare-associated UTI than other hospitalized patients *(71)*. Those with underlying diagnoses of prostate, bladder, bone, joint, liver, ovarian, colorectal, or vulvar cancer are the most commonly afflicted (13). As with nononcology patients, urinary catheterization and manipulation of catheters are often instrumental in the development of healthcare-associated UTI *(71)*. International practice guidelines for the prevention, diagnosis, and treatment of catheter-associated UTI in adults from the Infectious Diseases Society of America (IDSA) were recently published *(72)*.

Surgical Site Infections

Surgical site infections accounted for approximately 20% of HAIs in cancer patients, according to reports from the 1980s (12,13), and 6% of all HAIs in the multicenter pediatric study published in 2008 (8) (see Chapter 21). Identification of infections of surgical sites is usually based on the presence of purulent drainage from the sites. However, special consideration must be given to the neutropenic patient who may manifest infection by serous drainage or erythema and induration alone (12). Patients with solid tumors are most likely to develop surgical site infections (12,13). This is due to the extensive surgical procedures involved in their diagnosis and treatment. Patients with carcinoma of the vulva or uterus, soft tissue sarcomas, or malignant melanoma are most susceptible. Other high-risk patients include those with gastrointestinal or head and neck malignancies (12,13).

S. aureus is the most common pathogen isolated from surgical site infections in the cancer patient (8,12,13). Others frequently noted include *E. coli*, CoNS, enterococci, and anaerobes (12,13).

We retrospectively investigated infections complicating limb-sparing surgery (104 procedures) in 103 children and young adults with bone malignancies and found a high incidence of infections (median, 4%; range, 0–13%), including local surgical site infections in 67% and secondary bacteremia in 21%. Patients who developed deep infections were more likely to undergo amputation (OR, 24.0; 95% CI, 5.1–114.0; $p < .001$) and were less likely to have good functional outcomes (OR, 0.02; 95% CI, 0.002–0.15; $p < .001$) *(73)*.

Gastrointestinal Infections

Little information is available about gastrointestinal HAIs in cancer patients (see Chapter 24). The diagnosis should be based on the development of clinical symptoms of diarrhea with or without the isolation of a known pathogen. It is often difficult to distinguish diarrhea associated with gastroenteritis from that caused by chemotherapy-related mucositis. Potential pathogens include *Salmonella* species, *Shigella* species, rotavirus, other viral agents, and *Clostridium difficile*. In general, surgical patients and those receiving antibiotics are at increased risk of developing *C. difficile*-associated diarrhea (see Chapter 37). These predisposing factors also apply to the oncology patient. *C. difficile*-associated enterocolitis constituted 9% of all HAIs in a prospective multicenter HAI surveillance study of pediatric oncology patients and 6% of all HAIs at a single transplant center *(74)*. Both groups observed that, unlike other site-specific infections such as BSI, the risk for *C. difficile*-associated enterocolitis was comparable between neutropenic and non-neutropenic patients, a finding likely explained by the overall high antibiotic exposure in both populations.

Fever of Unknown Origin

Although not officially recognized by the CDC as a reportable entity, healthcare-associated FUO is common in hospitalized adult (11) and pediatric (8) cancer patients. Despite intensive diagnostic workups and clinical symptoms suggestive of sepsis, pathogens are often not isolated. At St. Jude Children's Research Hospital, we have routinely included FUO in our surveillance, and it accounts for about one-third of HAIs in pediatric oncology patients. Including FUO as a separate, defined clinical entity, Engelhart et al. (11) described an overall rate of 8.2 per 1,000 days, with two-thirds of these episodes occurring during periods of neutropenia. These researchers recommended the inclusion of this entity routinely in studies of surveillance of HAIs in patients with cancer. A study comparing HAIs between pediatric and adult bone marrow or peripheral stem cell transplant recipients found the FUO rate higher among the pediatric patients (34 vs. 15 FUOs per 100 patients/transplants), a finding for which the investigators found no obvious explanation *(75)*.

DIAGNOSIS OF HEALTHCARE-ASSOCIATED INFECTIONS IN CANCER PATIENTS

Cultures for Bacteria, Fungi, and Viruses

The most meaningful cultures for bacteria and fungi are those of otherwise sterile body fluids, such as blood, spinal fluid, bone marrow, urine, and tissue biopsies. Cultures of specific surface lesions by swab (typically an inferior specimen in terms of sample yield), aspirate, or biopsy require correlation with clinical features, morphology, and type of microorganism isolated. Cultures of stool, oropharynx, and normal skin usually provide information only on microbial colonization rather than on the etiology of disease. In certain clinical settings, such as a patient with prolonged granulocytopenia with fever unresponsive to antibiotics, the isolation of *Aspergillus* species from the nares or *C. tropicalis* from the stool or the urine may raise the index of suspicion for invasive fungal disease.

Various techniques are used to diagnose catheter-related infections, including paired quantitative CVC and peripheral venous blood cultures and the difference in time to detection of blood cultures simultaneously drawn from these two sources *(76,77)* or from the two lumens of a double-lumen CVC *(78)*.

In terms of viral cultures, shell vial spin amplification cultures give a more rapid turnaround time than traditional viral cultures do for detection of CMV and the more common respiratory viruses including influenza A and B; parainfluenza 1, 2, and 3; RSV; and adenovirus. Respiratory viruses can be significant healthcare-associated pathogens, and molecular amplification techniques are increasingly replacing culture-based approaches for diagnosis of these infections. While the significance of herpes simplex and VZV isolates is easily discernible because of the typical lesions and illness associated with the overt infections, CMV isolates may be difficult to assess, because the disease patterns associated with this infection are varied, may be nonspecific, and range from asymptomatic latency to life-threatening disease. As mentioned earlier, differentiating a new-onset, viral HAI from reactivation of a latent infection can sometimes be difficult. Stool culture–based methods to diagnose viral gastrointestinal infections identify some adenoviruses, enteroviruses, and CMV. Because many enterovirus serotypes are noncultivable, and because enterovirus can be shed asymptomatically for several months, there is poor positive and negative predictive value for this agent in a stool specimen. All adenoviral serotypes that can be detected by culture are detected more sensitively by PCR. Culture-based yield for CMV is poor. All this points to the low yield of stool viral cultures and makes a case for pathogen-directed PCR-based approaches combined with clinical correlation.

Smears and Stains

Material obtained from infected sites may contain enough of the causative microorganism to permit recognition of the microbe with selective stains and microscopy. Bacterial stains include Gram stain for most bacteria and acid-fast stain for mycobacteria, *Nocardia* species, and *Cryptosporidium* species. While fungi are usually visualized directly by a Gram stain, a KOH (wet) mount, or a Calcofluor white stain, histopathologically or cytologically, stains such as methenamine silver, periodic acid-Schiff, or Papanicolaou stains are used. *Pneumocystis jiroveci* can be visualized by a Grocott-Gomori methenamine-silver nitrate, Calcofluor white, toluidine blue O, Giemsa, or monoclonal antibody stain. An India ink preparation can be made for *Cryptococcus neoformans* although this method has largely been supplanted by specific antigen detection methods. Rapid identification of viruses is based on tests that detect viral antigens, such as a direct fluorescent-antibody assay or enzyme immunoassay. These tests are currently used to detect respiratory viruses such as RSV, influenza, parainfluenza, and adenovirus; herpes simplex virus and VZV (lesional); and gastrointestinal pathogens such as rotavirus.

Tissue Biopsy

Biopsies or aspirates of various tissues may be obtained for histopathologic or cytopathologic examination, for microscopic examination of stained smears, and for culture, including skin biopsy (punch and excisional), lung biopsy (open biopsy and transbronchial), and liver and kidney biopsy (transcutaneous needle biopsy and open biopsy). In experienced hands, transthoracic needle biopsy of chest lesions is a generally safe and noninvasive tool for the diagnosis of pulmonary fungal disease *(79)*.

Antigen-Based Assays

There are several rapid antigen detection-based tests for RSV, influenza A and B, rotavirus, and adenovirus serotypes 40 and 41 based on enzyme immunoassays or direct fluorescent antigen assays. The rapid influenza antigen assay for diagnosis has a low sensitivity for the diagnosis of the 2009 H1N1 pandemic influenza strain. For fungi, the Platelia *Aspergillus galactomannan* antigenemia test (Bio-Rad Laboratories, Redmond, WA) is widely used and demonstrates an overall high sensitivity and specificity for the diagnosis of invasive aspergillosis in high-risk patient populations that are getting assayed serially.

Molecular Assays

Several molecular platforms that offer same-day detection of a panel of viruses, particularly respiratory viruses, are now commercially available and increasingly being used by centers that provide care for immunocompromised patients. PCR-based assays frequently identify respiratory virus infections not diagnosed by direct fluorescent- or culture-based tests *(7)* and have allowed characterization of viral infections such as those due to human metapneumovirus, rhinovirus, and coronavirus *(80,81)*. Molecular amplification techniques increasingly support outbreak investigations in establishing epidemiologic relatedness *(6,82,83)*.

Several new molecular assays offer faster pathogen identification than conventional culture-based bacterial and fungal assays. These include the GeneOhm StaphSR assay (BD Diagnostics) for identification of *S. aureus* and MRSA directly from blood cultures and the peptide nucleic acid fluorescence *in situ* hybridization (PNA FISH) assay (AdvanDx, Woburn, MA; bioMerieux, Durham, NC) for identification of *C. albicans* in smears made from positive blood cultures. The PNA FISH technology is also being applied

for the identification of other *Candida* species as well as gram-positive microorganisms such as enterococcus and *S. aureus*.

Radiography and Imaging

Radiography is most helpful in recognizing pneumonia. Serial chest radiographs are especially helpful in establishing healthcare-associated pneumonia. The absence of discernible infiltrates does not exclude significant infection of the pulmonary parenchyma in the neutropenic patient. A more sensitive diagnostic test for early diagnosis of chest disease, especially fungal disease, is computed axial tomography *(84,85)*. Even this test has limitations in the setting of a profoundly granulocytopenic host. Computed axial tomography of the liver, spleen, and kidneys is useful in identifying systemic fungal infections. The hypodense distinct lesions are highly suggestive of systemic candidiasis and aspergillosis *(86,87)*.

PREVENTION AND CONTROL

Prevention and control of HAIs in patients with neoplastic disease is one of the most important contributors to the overall success of treatment in this patient population. Not only do HAIs add to morbidity, mortality, and the overall cost of care, but they often necessitate modifications in dose and scheduling of antineoplastic therapies, potentially compromising the successful treatment of the patient's malignancy. The general principles of prevention of HAI and infection control that are applied to any hospitalized patient, including hand hygiene, remain the same for patients with neoplastic disease. Certain additional precautions are taken based on the immunosuppressed state of these patients and their ability to contract infections by opportunistic pathogens, such as environmental safeguards to minimize exposure to pathogens and antimicrobial prophylaxis during periods of risk. This is especially true in the very high-risk host, such as patients who have recently undergone bone marrow or peripheral stem cell transplantation or those with prolonged granulocytopenia. Special precautions to prevent such patients from acquiring infection by filamentous fungi, especially *Aspergillus* species, are extremely important. Although some preventive measures (e.g., sophisticated air-handling systems and total protected environment [TPE]) are labor intensive, consume a considerable amount of limited healthcare resources, and sometimes lack clear-cut supporting evidence, others (e.g., hand hygiene and appropriate aseptic techniques) are simple, inexpensive, and require very little of the busy healthcare worker's time, and their efficacy is firmly established. Another common principle to minimize HAI is regular review of the necessity of foreign bodies *in situ*, such as CVCs, urinary catheters, and endotracheal tubes, and minimizing their manipulations, such as by reducing CVC entries. Healthcare setups need to individualize their practices based on the availability of resources and a review of local problems.

Hand Hygiene

The importance of hand antisepsis in prevention of HAIs is well accepted *(88,89)*, and numerous professional societies and committees have published guidelines for appropriate hand hygiene practices. The biggest change in this field over the past decade has been the introduction of alcohol-based hand rubs. Guidelines on hand hygiene in healthcare settings are available both from the Healthcare Infection Control Practices Advisory Committee and the World Health Organization *(90,91)*.

WHO recommends alcohol hand rubs based on: (a) evidence-based, intrinsic advantages of fast-acting and broad-spectrum microbicidal activity with a minimal risk of generating resistance to antimicrobial agents; (b) suitability for use in resource-limited or remote areas with lack of accessibility to sinks or other facilities for hand hygiene (including clean water, towels, etc.); (c) capacity to promote improved compliance with hand hygiene by making the process faster and more convenient; (d) economic benefit by reducing annual costs for hand hygiene; and (e) minimization of risks from adverse events because of increased safety associated with better acceptability and tolerance than other products. Readers are encouraged to review the comprehensive WHO guidelines on hand hygiene in healthcare, which provide an excellent summary of the existing literature on this subject (92). Alternatively, the practice of hand washing with antimicrobial soap and water should be continued. Ready access at strategic locations of efficacious hand-hygiene products with low irritancy potential has been emphasized. Use of artificial fingernails or extenders by clinical care providers, especially those taking care of high-risk patients, is discouraged.

It seems clear that the simple act of hand hygiene greatly reduces the likelihood of transmitting pathogenic microorganisms to hospitalized patients on the hands of healthcare workers. What is also clear is that despite the presence of published guidelines and policies, adherence of healthcare workers to recommended hand-hygiene procedures has been poor, with mean baseline rates of 5% to 81% *(90)*. We encourage that institutions review these guidelines and, based on the resources available, select a hand-hygiene agent or agents and implement a hand hygiene policy. Periodic monitoring for compliance and focused interventions to improve it, based on the feedback generated, is critical to the success of this intervention.

Evidence-Based Guidelines and Recommendations for Prevention of Healthcare-Associated Infections

Comprehensive guidelines based on a review of current literature are available from professional societies and expert working groups on prevention, diagnosis, and management of various HAIs. These are applicable to the oncology patient population as well, and readers are encouraged to review the specific guidelines for details. To assist acute care hospitals in focusing and prioritizing efforts to implement evidence-based practices for the prevention of HAIs, the Society for Healthcare Epidemiology of America and the IDSA Standards and Practice Guidelines Committee appointed a task force to create a concise compendium of recommendations for the prevention of common HAIs *(93)*. This compendium is implementation-focused and differs from most previously published guidelines in that it highlights a set of basic HAI prevention strategies plus special approaches for use in locations and populations within the

hospital when infections are not controlled by the use of basic practices. In addition, it includes proposed performance measures for internal quality-improvement efforts. Summarized in this compendium are strategies to prevent central line–associated BSIs *(94)*, VAP *(67)*, catheter-associated UTIs *(95)*, surgical site infections *(96)*, MRSA *(97)*, and *C. difficile* infections *(98)*.

Specific to CVC, the big change in terms of prevention of central line–associated BSI in the past decade has been the concept of bundling a group of prevention practices rather than implementation of individual components that vary from site to site. Guidelines for the prevention of catheter-related BSIs recommended by a working group comprising numerous professional organizations have been published *(99)*. These include the use of antimicrobial- or antiseptic-impregnated CVCs in adults, recommendations for selection of catheter insertion sites, catheter care, and surveillance for catheter-related infections. Consideration should be given to establishing special intravenous therapy teams to ensure a high level of aseptic technique during catheter insertion and follow-up care. Policies and procedures for infusion therapy should be comprehensive, and those who perform manipulations of these devices should be thoroughly trained in appropriate infection-control techniques.

Updated guidelines for preventing infectious complications among hematopoietic cell transplantation recipients, cosponsored by various professional societies and organizations, are available and summarize the evidence basis for the current recommendations in this patient population (100). These include a summary of recommendations regarding room ventilation, construction, renovation and building cleaning, isolation and barrier precautions, and other environmental measures (see also Chapters 83 and 84).

Total Protected Environment Versus Care of the Allogenic Transplant Patient in the Outpatient Environment—A Wide Spectrum of Care

Because the causative agents of HAIs in patients with neoplastic diseases include endogenous and a wide variety of exogenous microorganisms, a comprehensive approach to preventing infection and colonization with hospital pathogens has been tried *(101,102)*. This comprehensive approach, TPE, has included the use of protective isolation (gowns, gloves, and masks for healthcare providers and visitors), selective decontamination of the digestive tract, rigorous antisepsis of the skin and perirectal area, and high-efficiency particulate air (HEPA)-filtered air supplied to the patient in a laminar or a turbulent fashion. TPE also includes provision of food and water low in microbial content, sterilization or high-level disinfection of objects before they are taken into the room, and frequent and thorough cleaning and disinfection of room surfaces.

A sterile patient environment cannot be achieved and maintained. Because the patient's endogenous flora and microorganisms in the room and in food and water can only be suppressed, not totally eliminated, a labor-intensive decontamination regimen must be continued throughout the isolation period. TPE is expensive and is beyond the capabilities of many hospitals providing care for patients with neoplastic diseases. Although a reduction in the incidence of infection has been associated with the use of TPE, it must be recognized that since the performance of these studies more than two decades ago, the treatment of infectious complications in neutropenic patients has improved considerably. Thus, a more relevant question is whether TPE would lessen infection-related mortality with the current availability of better treatment options. At this time, a comprehensive TPE approach is not a standard recommendation for patients with neoplastic disease. However, various components of this approach are followed by individual centers, especially those with a bone marrow transplant program.

On the other extreme, over the past two decades, some investigators have reported their experience managing highly immunosuppressed patients in an outpatient environment. The risk of HAI and financial costs of care are some of the factors that have prompted examining this approach. A review examined six published studies, including four comparative but nonrandomized analyses, describing the experience of home care for patients with cytopenia after high-dose therapy and stem cell transplantation *(103)*. The pooled statistics compiled in this review suggest that protective environments provided no benefit in decreasing mortality for the transplant patient.

In summary, there is significant variability between centers in terms of the infection control measures in place for patients with prolonged granulocytopenia, including stem cell transplant recipients. Few infection control and protective environment recommendations have been tested in randomized control trials. While such rigorous study designs to test the efficacy of all recommended infection control measures is not feasible, efforts should be made to re-examine those that are logistically intense and financially demanding.

Protective Isolation

Studies suggest that most bacterial infections in patients with granulocytopenia arise from the patient's own flora and that colonization by the causative microorganism in nearly half of the infections occurs only after admission to the hospital *(104)*. Contaminated hands of healthcare workers are thought to play a major role in the colonization of these patients. Protective isolation, using only gloves and gowns, has been shown to be effective in reducing infection rates in a pediatric intensive care unit, but patients with immunologic dysfunction were excluded from the study *(105)*. Protective isolation alone has been shown in one study *(106)* to be of no value in protecting patients with severe granulocytopenia. In a randomized clinical trial comparing the role of gown-and-glove isolation and strict hand washing in the reduction of HAI in children with solid organ transplantation admitted to a pediatric intensive care unit, Slota et al. *(107)* found that, while the rate of HAIs in both intervention groups was significantly reduced compared with the baseline rate, there was a trend toward a greater reduction in the gown-and-glove group than in the hand-washing group. While this study demonstrates the role of gown-and-glove isolation in certain specific clinical settings and indicates the possibility of some additional benefit of this intervention over simple hand washing, the latter intervention is undeniably relatively inexpensive and simple to implement. Until further studies demonstrating

the efficacy and cost-effectiveness of protective isolation in the routine care of patients with neoplastic diseases in various clinical settings are done, this intervention cannot be uniformly recommended. In the meantime, its use as a component of standard infection control procedures such as respiratory or enteric isolation in the setting of documented infections should be continued.

Air-Handling Systems

Guidelines for hospital room design and ventilation are available and should be followed *(108,109)*. While provision of clean air is important to any patient, additional measures to eliminate the risk of exposure to filamentous fungi such as *Aspergillus* species, are attempted, especially for high-risk hosts with prolonged granulocytopenia. Reported outbreaks of healthcare-associated invasive aspergillosis have been caused by concentration of conidia in hospital ventilation systems *(110)*, contaminated fireproofing materials *(111)*, and air contamination from construction *(47–50)*. One such measure is the use of HEPA filters. The modern HEPA filter, made of superfine spun-glass fibers less that 1 mm in diameter, was developed by the Army Chemical Corps and the Naval Research Laboratory in the years immediately after World War II. The maximum allowable penetration of a HEPA filter at any point in the media, frame, or gasket is 0.03% of the challenge concentration of monodispersed thermally generated dioctyl phthalate (DOP) having a count-median droplet diameter of $0.3 \pm 0.03\,\mu m$.

HEPA-filtered air has been used in many centers as a component of protective isolation to provide ultraclean air to patients during periods of granulocytopenia. In some studies, HEPA-filtered air was delivered to the patient in a unidirectional (formerly called "laminar flow") fashion, and in other studies, "life island" units that enclosed the patient's bed in a plastic canopy were used. Unidirectional airflow is not achieved in life island units. A concentration of about 2.12 microorganisms per cubic meter of air can be achieved in life island units and 0.21 microorganisms per cubic meter can be achieved in rooms with unidirectional flow, compared with approximately 106 microorganisms per cubic meter in conventional rooms. Although the efficacy of HEPA filters in preventing aspergillosis seems clear *(48,112,113)*, the effect on preventing other infections is less certain.

With proper installation, testing, and maintenance, ultraclean air can be maintained in the patient room. Patients with neoplastic diseases, however, must periodically leave this protected environment for a wide range of diagnostic and therapeutic procedures. Despite the lack of clear-cut data, for a subset of immunocompromised patients identified at high risk for aspergillosis, it is desirable to protect the respiratory tract from opportunistic pathogens during these periods. For this purpose, various masks or respirators are in use. High-efficiency masks have been successfully used for high-risk patients during periods when they are outside their hospital rooms *(114)*. A breakthrough in the manufacture of HEPA-filtered masks is the replacement of delicate fiberglass fibers with durable plastic fibers. This new technology has permitted the production of a durable, lightweight, comfortable mask that readily passes DOP leak tests and should provide the patient with air quality at least as good as that found in HEPA-filtered unidirectional-flow rooms. Another mask in clinical use is the N95 respirator. In the guidelines for Preventing Opportunistic Infections Among Hematopoietic Stem Cell Transplant Recipients published by the CDC, use of the N95 mask (particulate respirator) has been mentioned to prevent mold exposure during transportation near hospital construction or renovation areas because these respirators are regarded as effective against any aerosol *(115)*. For maximal efficacy of any face device, whether it be the HEPA mask or the N95, proper fit testing and training of the patient is very important. In this regard, unavailability of small masks poses a limitation for their use with infants and small children. In conclusion, while HEPA filters are important, especially in high-risk hosts, to prevent healthcare-associated aspergillosis, particularly if there is concurrent hospital renovation or construction, the correct and optimal installation and use of HEPA filters is relatively complex and expensive.

Other factors related to hospital air handling, including appropriate air exchanges and pressurization, are equally important in preventing healthcare-associated airborne infections, especially aspergillosis *(116)*. In a study assessing the ability of hospital air–handling systems to filter *Aspergillus*, other fungi, and particles after the implosion of an adjacent building, an encouraging observation was that even standard hospital air–handling systems with filtration exceeding minimum American Society of Heating, Refrigeration, and Air Conditioning Engineers standards have a significant safety buffer in filtering *Aspergillus* spores *(117)*. HEPA filters likely provide an additional level of safety. The design and maintenance of hospital ventilation systems is discussed in detail in Chapter 84.

Anaissie et al. *(51)* have submitted evidence to support the theory that hospital water distribution systems may be a potential indoor reservoir of *Aspergillus* species and other molds, leading to aerosolization of fungal spores and potential patient exposure. In a high-risk population such as bone marrow transplant patients, these researchers recommend the use of sterile (boiled) water for drinking and sterile sponges for bathing. In addition, they recommend cleaning of the floors of the patient shower facilities to reduce the air concentration of *Aspergillus* species and other pathogenic airborne molds *(118)*.

Antimicrobial Drugs

The concept of antimicrobial prophylaxis in patients with cancer to prevent infections in general, not necessarily HAIs, has been most widely studied in neutropenic patients. It is well accepted that infections in a healthcare setting can be of exogenous origin or of endogenous origin related to the patient's own residential microbial flora. The latter can be influenced by microorganisms acquired in the hospital environment as well as the antimicrobial pressure the patient is under. Initial trials of infection prophylaxis using combinations of nonabsorbable drugs such as aminoglycosides, polymyxins, and vancomycin were followed by studies of orally absorbable agents, primarily trimethoprim sulfamethoxazole (TMP-SMX) and quinolones. A review of studies of prophylaxis with TMP-SMX by the IDSA Fever and Neutropenia Panel found that, in most studies, there was some benefit in terms of lower infection rates in the TMP-SMX–treated group than in the placebo group *(119)*. Studies have shown the benefit of quinolone-based

prophylaxis in reducing the rates of febrile episodes and infections in neutropenic patients *(120–122)*. Fluoroquinolone prophylaxis reduces the risk of febrile episodes in neutropenic outpatients with solid tumors, including lymphomas, and is associated with a statistically insignificant, yet clinically important, decrease in mortality in all neutropenic patients. Prophylaxis with levofloxacin may reduce febrile episodes in neutropenic hematology patients and stem cell transplant recipients. As per the 2010 IDSA guidelines for the use of antimicrobial agents in neutropenic patients, fluoroquinolone prophylaxis should be considered for high-risk patients with expected durations of prolonged and profound neutropenia (ANC <100 cells/mm^3 for >7 days). With any prophylaxis strategy systematic surveillance to monitor for changes in patterns of antimicrobial resistance is critical and cannot be overstated (123).

Finally, with the increase in frequency of fungal infections in patients with neoplastic diseases, especially patients with hematologic malignancy, there has been considerable interest in the role of antifungal prophylaxis. A systematic meta-analytical review of the efficacy of antifungal prophylaxis in neutropenic chemotherapy recipients showed antifungal prophylaxis reduced overall morbidity, as evidenced by reductions in the use of parenteral antifungal therapy, superficial fungal infection, and invasive fungal infection, as well as reducing fungal infection-related mortality. These effects were most pronounced in patients with malignant disease who had prolonged neutropenia and HSCT recipients *(123a)*. There is no widely accepted standard for antifungal prophylaxis in patients with hematologic malignancies. In a randomized clinical trial in patients undergoing chemotherapy for acute myelogenous leukemia or myelodysplastic syndrome, posaconazole prevented invasive fungal infections more effectively than did either fluconazole or itraconazole and improved overall survival. There were more serious adverse events possibly or probably related to treatment in the posaconazole group *(124)*. In another randomized clinical trial in patients with graft-versus-host disease who were receiving immunosuppressive therapy, posaconazole was found superior to fluconazole in preventing invasive aspergillosis and reducing the rate of deaths related to fungal infections *(125)*. The Infectious Diseases Working Party of the German Society for Hematology and Oncology recommends posaconazole in patients with acute myelogenous leukemia/myelodysplastic syndrome and for patients undergoing allogeneic stem cell transplantation with graft-versus-host disease for the prevention of invasive fungal infections and attributable mortality *(126)*. The 2010 IDSA guidelines for the use of antimicrobial agents in neutropenic patients also list recommendations for prophylactic, empiric and preemptive use of antifungal agents based on risk stratification of the host (123). As more aggressive antifungal therapy and prophylaxis is used, there has been increasing concern about a shift in fungal pathogens isolated from oncology patients. Of particular concern have been breakthrough cases of zygomycosis in patients receiving voriconazole.

CHAPTER 58

Healthcare-Associated Infections in Solid Organ Transplant Recipients

Ryosuke Osawa and Nina Singh

Infections remain a significant complication and a leading cause of mortality, particularly within the first year after transplantation. Most infections in transplant recipients are healthcare-associated and represent either opportunistic infections resulting from iatrogenic immunosuppression or infections resulting from conventional healthcare-associated pathogens. The incidence of several opportunistic infections (e.g., cytomegalovirus [CMV] and *Pneumocystis jirovecii* pneumonia [PJP]) has declined dramatically, largely because of the advent of effective prophylaxis. On the other hand, healthcare-associated infections (primarily due to bacteria) transmitted from environmental reservoirs or harbored as a result of endogenous colonization in healthcare-associated settings have emerged as leading infections in organ transplant recipients. In liver transplant recipients, 82% of the episodes of fever documented in consecutive patients over a 2-year period were healthcare associated, of which 62% were bacterial in origin (1). Fifty-three percent of all infections in heart transplant recipients in another study were healthcare-associated, and of these, 63% were bacterial *(2)*.

Paralleling the trends in healthcare-associated infections, antimicrobial resistance is increasingly recognized as a problem in the transplant setting. It is noteworthy, however, that the emergence of several of the antibiotic-resistant pathogens was first documented in transplant recipients *(3)*. For example, vancomycin-resistant enterococci (VRE) were initially discovered in liver transplant recipients at several institutions where they eventually became a more widespread problem.

Transplant recipients are uniquely vulnerable to colonization and infection resulting from healthcare-associated pathogens. Within the same institution, transplant recipients have been shown to have a significantly higher incidence of healthcare-associated infections than nontransplant patients *(4)*. The predilection of immunocompromised patients to *Legionella* infection is well recognized. However, it is notable that within this subgroup, transplant recipients have the highest risk *(5)*. Among patients undergoing surgical procedures at one institution where legionellosis was documented, renal transplant recipients had an attack rate of 50%, whereas the general hospital population experienced an attack rate of only 0.4% *(6)*. Transplant recipients exposed to tuberculosis during an institutional outbreak were more likely to contract *Mycobacterium tuberculosis* as compared with nontransplant contacts of the source case *(7)*. During a healthcare-associated outbreak of extended-spectrum β-lactamase–producing *Escherichia coli*, 67% of patients on the liver transplant service, but no other surgical patients on the same floor, were shown to be colonized or infected with the outbreak isolate (8).

This chapter discusses the potential sources of infections, unique risk factors according to the type of organ transplanted, and the treatment and prevention of infections in solid organ transplant recipients that may be acquired during or after transplantation.

SOURCES OF INFECTIONS IN RECIPIENTS

Donor-Derived Infections

Latent Infections in the Donor Viral infections latent in the donor have by far the greatest potential for transmission by the transplanted organ and exert a more profound clinical impact in the allograft recipient compared with many other donor-transmitted infections. Thus, serologic screening of the donor for hepatitis B virus (HBV), hepatitis C virus (HCV), CMV, EBV, and human immunodeficiency virus (HIV) is routinely recommended (9). Nonviral infections (e.g., toxoplasmosis) are also discussed here.

Hepatitis B Virus The risk of transmission of HBV varies according to the HBV serologic profile of the donor and the recipient and the type of organ transplanted (liver vs. nonliver). Transplantation of allografts from hepatitis B surface antigen (HBsAg)-positive donors carries the highest risk of HBV transmission and is recommended only in life-threatening situations. IgM antibody to hepatitis B core antigen (anti-HBc IgM) positivity indicates either recent or current infection; it should be managed as in HBsAg-positive donors. Anti-HBc IgG positivity in the absence of HBsAg poses a low likelihood of transmission of HBV. The liver may continue to harbor the replicative form of HBV in such donors with the potential of HBV transmission even in the presence of anti-HBs *(10)*. Donors with isolated anti-HBc positivity should be considered infectious, especially for the hepatic allograft. Indeed, 78% (18/23) of the liver transplant recipients from donors with isolated

anti-HBc experienced HBV transmission *(11)*. Transplantation of an anti-HBc–positive liver into a nonimmune recipient should be performed only if deemed medically urgent and under a prophylactic regimen of lamivudine with or without hepatitis B immune globulin (HBIG) *(12,13)*. However, the risk of HBV transmission for recipients of nonhepatic organs is low. None of the seven heart transplant recipients and 2.3% (1/42) of the renal transplant recipients who received organs from isolated anti-HBc–positive donors became infected *(14)*. General consensus is that the organs from anti-HBc positive donors should be used for recipients who are HBsAg positive or who have evidence of HBV immunity. The risk of HBV transmission from anti-HBc–positive donors to nonhepatic organ recipients can be further stratified based on the presence of HBV DNA in the serum at the time of transplantation (15) as the risk is considered negligible if serum HBV DNA is negative. The use of anti-HBc–positive nonhepatic allografts has not been associated with poor outcomes *(16,17)*. Anti-HBs–positive liver donors who are negative for both HBsAg and anti-HBc are generally considered unlikely to transmit HBV. Anti-HBs positivity is usually explained by HBV vaccination or administration of hepatitis B immunoglobulin. However, the potential for HBV transmission can still exist for donors with isolated anti-HBs positivity since HBV DNA may be detectable in the hepatic allografts *(18)*.

The most important measure to prevent HBV transmission is the administration of HBV vaccine to nonimmune transplant candidates. However, HBV transmission may occur even if recipients are immune to HBV (positive anti-HBs status). Transplantation of any organs from HBsAg-positive donors should be ideally avoided. If a recipient emergently needs an organ from HBsAg-positive donors due to life-threatening situations, the recipient should receive HBIG and prophylactic antiviral therapy with lamivudine for a minimum of 1 year with close monitoring of liver enzymes, HBsAg, anti-HBs, and HBV DNA. Liver transplant from an IgG anti-HBc–positive donor should be managed in a similar manner. HBV-immune candidates can receive extrahepatic organs from an IgG anti-HBc–positive donor without any prophylaxis; however, posttransplant surveillance for liver enzymes, HBsAg, anti-HBs, and HBV DNA are recommended. If potential candidates are not immune to HBV, HBIG, and/or lamivudine are typically administered. The duration of prophylaxis depends on the presence of the donor HBV DNA. If the donor HBV DNA at the time of transplant is negative, prophylaxis may be discontinued. If the donor HBV DNA is positive or unknown, HBIG for >3 to 6 months or lamivudine for >12 months should be continued (*13*,15).

Hepatitis C Virus Approximately 5% of all cadaveric organ donors are positive for antibody to HCV (anti-HCV), and 50% of these have detectable HCV viremia by PCR *(19)*. Nearly all the recipients from anti-HCV-positive donors become infected with HCV (20). Donor-derived HCV infection is associated with rapid progression of fibrosis and high mortality *(21)*. Transplantation of livers from HCV-positive donors into HCV-positive recipients has not been associated with a decrease in graft or patient survival up to 8 years *(22–24)*. Most transplant centers use HCV-positive extrahepatic organs only for HCV-positive recipients, because there are data suggesting that donor HCV-positive status is independently associated with decreased survival regardless of recipient HCV status *(25,26)*. The use of anti-HCV–positive organs in anti-HCV–negative recipients should be avoided; however, it may be considered in life-threatening situations. Unlike HBV, no effective measures to prevent HCV transmission are currently available.

Herpesviruses The donor allograft is a significant and an efficient source of transmission of CMV *(27,28)*. The morbidity from infection is greatest in CMV-seronegative recipients of CMV-positive allografts. Superinfection (i.e., infection with an exogenous strain of CMV in patients with prior evidence of CMV infection) has also been documented. Symptomatic CMV disease occurred more frequently in patients infected with the new CMV strain compared with those with reactivation of the latent virus *(29)*. Donor transmission (documented by molecular typing) has also been demonstrated with other herpesviruses, including herpes simplex virus (HSV), varicella zoster virus (VZV), Epstein–Barr virus (EBV), and human herpesvirus-6 (HHV-6) *(30–34)*. EBV-seronegative recipients of EBV-positive allografts are at highest risk of developing EBV-associated posttransplant lymphoproliferative disorder, especially among intestinal transplant recipients *(35,36)*. Transmission of herpesviruses from donors to recipients is not preventable; however, identification of recipients is at high risk (i.e., seronegative recipients) followed by use of antiviral prophylaxis (CMV, HSV) with or without monitoring of viral replication and close clinical follow-up with symptoms is crucial. Management issues of herpesviruses infection are discussed later in this chapter.

Human Immunodeficiency Virus Donor positivity for HIV by enzyme-linked immunosorbent assay (ELISA) is considered an absolute contraindication to organ donation. There is a remote possibility that HIV can be transmitted from donors who test negative for HIV antibody if the time of transplantation is during the window period or if the test is false-negative due to resuscitation-associated hemodilution.

Recently, transmission of HIV was reported in three organ recipients from a donor who had sex with men who tested negative for HIV antibody (*37*,*38*,39). Scrutinizing the donor's behavioral and medical risks of HIV in a limited time frame followed by weighing these risks against the benefits of transplantation are critically important (40). Use of special consent forms for transplantation of organs from high-risk donors has been utilized in many transplant centers. Although more sensitive nucleic acid amplification assays are available, the cost and delayed turnover time may prohibit their routine use.

Human T-Cell Lymphotrophic Virus Type 1/2 Human T-cell Lymphotrophic Virus Type 1/2 (HTLV-1/2) is a retrovirus with marked geographically variant prevalence from 0.035% to 0.046% in the United States blood donors to 30% in Southern Japan *(41,42)*. UNOS data revealed that the prevalence of HTLV-1 and HTLV-2 among the US organ donors is 0.027% and 0.046%, respectively *(43)*. Although HTLV-1 is associated with the development of acute T-cell lymphoma and HTLV-1-associated myelopathy, the majority of these patients remain asymptomatic. Only a few cases of documented transmission and development of HTLV-1-associated disease in solid organ transplant

recipients have been reported *(44,45)*. HTLV-2 does not appear to be associated with the clinical syndrome. The OPTN/UNOS Ad Hoc Disease Transmission Advisory Committee recently recommended against routine screening for HTLV-1/2 given the lack of routine availability of some commercial assays, a high false-positive rate leading to the waste of organs, favorable short-term follow-up of recipients of HTLV-1/2 screen positive organs, and low prevalence of the disease in the United States *(46)*.

Mycobacterium tuberculosis Transmission of *M. tuberculosis* to recipients receiving allografts from donors with active tuberculosis has been documented. Transmission of *M. tuberculosis* to two renal transplant recipients from a donor with unrecognized tuberculous meningitis at the time of organ retrieval has been reported *(47)*. Tuberculin- positive donors without clinically overt tuberculosis may also transmit tuberculosis. Tuberculin-positive living donors should receive chemoprophylaxis after appropriate workup to rule out active tuberculosis if delay of transplant is acceptable. It is recommended that the recipients of allografts from donors with latent tuberculosis or a history of tuberculosis should receive chemoprophylaxis for tuberculosis after transplantation *(47)*.

Toxoplasma gondii *Toxoplasma gondii*, because of its predilection for latency in muscle tissue, poses a substantial risk for transmission of toxoplasmosis in heart transplant recipients. In the absence of prophylaxis, 50% to 70% of the seronegative recipients of *T. gondii* antibody-positive allografts have developed toxoplasmosis *(48)*. Heart transplant donors and recipients should be serotested to determine the risk for toxoplasmosis. Because of the paucity of *Toxoplasma* cysts in noncardiac tissue, toxoplasmosis is rarely transmitted by the nonheart organs and pretransplant screening is controversial in this population *(49)*. Prophylactic use of trimethoprim-sulfamethoxazole significantly decreases the risk of developing toxoplasmosis posttransplant in heart transplant recipients (*50*,51). Some experts administer a higher dose of trimethoprim-sulfamethoxazole or a combination of pyrimethamine and sulfadiazine to high-risk patients (seronegative recipients of a seropositive heart).

Trypanosoma cruzi *Trypanosoma cruzi* is an endemic parasitic disease in Latin America (American trypanosomiasis). It is transmitted by the triatomine insect, but blood transfusion, maternal–fetal transmission, and organ transplant are also the major routes of transmission in a nonendemic area *(52,53)*. Donor screening should be performed for those who lived or traveled in an endemic area. Organs from donors positive for *T. cruzi* should not be utilized especially for heart transplant given its fatal outcomes *(54)*. If nonheart organs are utilized in emergent situations, aggressive monitoring with direct parasitological tests and/or PCR-based assays (51).

Other Pathogens Transmission of endemic fungi including *Histoplasma capsulatum* and *Coccidioides immitus* via donor allograft has been reported *(55,56)*. Although active fungal infections should be excluded prior to procurement, no consensus exists with regard to donor screening for latent fungal infection. West Nile virus (WNV), rabies, and lymphocytic choriomeningitis virus (LCMV) are the examples of emerging pathogens that have been reported to be donor derived *(57–59)*.

Acquired Infections in the Donor Life-sustaining measures in critically ill donors may render them susceptible to healthcare-associated infections with the potential for transmission to allograft recipients. Two recent studies comprising a large number of patients have shown that donor bacteremia did not portend a higher risk of infectious complications or compromise graft or patient survival *(60,61)*. The most frequent cause of the donor bacteremias in these studies was gram-positive bacteria, of which *Staphylococcus aureus* was the predominant pathogen. Most recipients of organs retrieved from bacteremic donors in the aforementioned studies received antimicrobial therapy. In the study by Lumbreras et al. *(60)*, specific antibiotics were administered to the recipients for 7 to 10 days on receipt of donor blood culture results. In the report by Freeman et al. *(61)*, 91% of the recipients received antibiotics for a mean of 3.8 days. These data suggest that with appropriately administered antibiotic therapy, organs from bacteremic donors can be successfully transplanted without incurring an additional risk for infection or allograft dysfunction in the recipient.

A similar dilemma exists regarding the feasibility of using organs from donors with bacterial meningitis *(62)*. Lopez-Navidad et al. *(62)* described the outcome in 16 recipients who had received organs from five patients with bacterial meningitis. The pathogens included *Neisseria meningitidis, Streptococcus pneumoniae,* and *E. coli*. With antibiotic administration ranging from 5 to 10 days, infection caused by the aforementioned bacteria was not documented in any of the recipients. Thus, patients with brain death attributable to bacterial meningitis caused by these bacteria can also be suitable organ donors, if the donor and the recipient receive appropriate antibiotic therapy. An exception, however, is donors with a less commonly encountered bacterial infection, that is, *M. tuberculosis*. Unrecognized active *M. tuberculosis* infection in the donor can be efficiently transmitted to the recipient with deleterious sequelae. Moreover, caution must be exercised when transplantation from donors with a presumptive diagnosis of bacterial meningitis is considered.

Donor organs colonized with *Candida* or *Aspergillus* may transmit the fungi to lung and heart–lung transplant recipients. Karyotypic analysis of the *Candida albicans* isolates demonstrated identical strains from the donor lung and *C. albicans* isolates causing disseminated infection in a lung transplant recipient *(63)*. Donor organs have also been documented to transmit other fungal infections (e.g., *Cryptococcus neoformans* and *Histoplasma capsulatum*) *(64)*.

Contamination during Organ Procurement

Contamination during harvesting and preservation of the allograft has been reported to occur in 2% to 23% of the kidney allografts. Although some bacteria (e.g., *Staphylococcus epidermidis,* diphtheroid species, and *Propionibacterium acnes*) present little risk of infection to the allograft recipient, more virulent pathogens (e.g., gram-negative rods, particularly *Pseudomonas aeruginosa*; *S. aureus*; and

fungi) cultured from the donor or the preservation fluid can lead to serious infections (e.g., mycotic aneurysm and anastomotic rupture) in kidney transplant recipients *(64–66)*.

Blood Products

Although CMV infection has been shown to be transmitted by blood products in organ transplant recipients, the risk is small and has not been shown to correlate with the number of blood products transfused *(33)*. Over a 13-year period, only 2.6% (3/112) of CMV-seronegative recipients who received CMV negative renal, heart, lung, or liver allografts were documented to develop transfusion-associated CMV infection *(67)*. Furthermore, transfusion, compared with donor-transmitted CMV infection, has been associated with a lower frequency of symptomatic disease and, therefore, has a less profound clinical impact *(68)*. Nevertheless, the use of CMV seronegative blood products or leukoreduced blood product for recipients who are seronegative for CMV should be considered. Finally, the use of leukoreduced blood product further reduced the risk of CMV transmission.

Since 1990, all blood products in the United States have been routinely screened for HCV. Consequently, the risk of posttransfusion HCV has declined from 8% to 10% to <1% currently.

Environmental Reservoirs and Sources

Environmental sources are significant sites for acquisition of a number of infectious agents, particularly healthcare-associated pathogens in transplant recipients (Table 58-1). Most cases of *Legionella* in solid organ transplant recipients are healthcare-associated *(69)*. The source of posttransplant legionellosis in all studies where an environmental link was sought was the hospital's potable water distribution system *(5)*. Restriction fragment length polymorphism patterns documented that the hospital's central hot water supply was the source of legionellosis in a hospital where 14 cases were documented in transplant recipients over an 8-year period *(70)*. Healthcare-associated legionellosis in heart–lung transplant recipients at one institution was linked to a contaminated ice machine *(71)*.

Outbreaks of invasive aspergillosis in transplant recipients have been linked to construction or demolition activity within or near a hospital; contaminated or poorly maintained ventilation ducts, grids, or air filters; and other dust-generating activities that may aerosolize *Aspergillus* spores. Accommodation of marrow transplant recipients outside of rooms with laminar air flow and high-efficiency particulate air (HEPA) filters during periods of neutropenia have been shown to be a risk factor for invasive aspergillosis *(72)*. A seasonal variation in the incidence of invasive aspergillosis, coinciding with a high outdoor concentration of airborne spores in late summer or fall and a lower concentration in the winter months, has also been observed. The prevailing belief that *Aspergillus* is predominantly an airborne pathogen acquired via inhalation has recently been challenged. It has been proposed that *Fusarium* and *Aspergillus* can be detected in hospital water systems, and aspiration, as opposed to inhalation of *Aspergillus,* may be the mode of acquisition of healthcare-associated invasive aspergillosis in susceptible hosts *(73)*.

The prevailing assumption has been that *P. jirovecii* infection arises from reactivation of endogenous infections

TABLE 58-1

Mode of Acquisition of Major Pathogens in Transplant Recipients

Pathogen	*Mode of Acquisition*
Viruses	
Cytomegalovirus	
Seronegative recipient	Donor transmission, rarely transfusions
Seropositive recipient	Reactivation and donor transmission
Herpes simplex virus	Reactivation, rarely donor transmission
Varicella zoster virus	Reactivation, rarely donor transmission
Human herpesvirus-6	Reactivation and donor transmission
Hepatitis C virus	Reactivation, unless donor anti-HCV positive
Hepatitis B virus[a]	Rarely donor transmission
Adenovirus	Donor and healthcare-associated transmission
Respiratory viral infections	Healthcare-associated and community acquisition
Bacteria	
Staphylococcus aureus	Endogenous colonization, healthcare-associated transmission
Vancomycin resistant enterococci	Healthcare-associated transmission, endogenous gastrointestinal colonization
Pseudomonas aeruginosa	Healthcare-associated environmental acquisition
Enterobacteriaceae	Endogenous colonization, healthcare-associated transmission
Legionella	Environmental acquisition
Mycobacterium tuberculosis	Reactivation, donor transmission, healthcare-associated transmission
Fungi	
Candida	Endogenous infection (liver transplants), donor transmission (lung transplants)
Aspergillus	Environmental acquisition
Pneumocystis jirovecii	Reactivation, possibly healthcare-associated transmission
Cryptococcus neoformans	Primarily reactivation
Protozoa	
Toxoplasma gondii	Donor transmission, rarely reactivation

[a]HBsAg-positive donors can transmit hepatitis B virus (HBV) but are not considered acceptable organ donors. Rarely anti-HBs–positive donors (particularly of hepatic allografts) can transmit HBV.

acquired in childhood. However, healthcare-associated patient-to-patient transmission and environmental contamination of *P. jirovecii* has also been documented *(74,75)*. A cluster of renal transplant recipients who developed PJP shared the same strain confirmed by multilocus DNA sequence typing *(76,77)*. *P. jirovecii* DNA has been demonstrated in more than 50% of the air samples from the hospital rooms of *P. jirovecii*–infected patients *(78)*. It remains to be determined whether isolation of patients with PJP decreases the incidence of PJP, though such trials would be difficult in the current era of routine anti-PJP prophylaxis.

VRE and methicillin-resistant *S. aureus* (MRSA) have become established as endemic pathogens in many institutions and are increasingly recognized as significant microorganisms in transplant recipients. At many centers, VRE, MRSA, or *Clostridium difficile* are currently the most frequent etiologic agents of infections in transplant recipients. Although patient-specific variables (e.g., severity of illness, intensity of antimicrobial use, and length of hospital stay) are risk factors for acquisition, environmental contamination and, more importantly, person-to-person transmission are also considered significant factors in the healthcare-associated spread of these bacteria. Equipment and surfaces in the vicinity of patients colonized and infected with VRE have been shown to become contaminated with VRE; VRE could be recovered for at least 7 days from the surfaces of countertops and after 30 minutes from the stethoscopes *(79)*. Furthermore, epidemiologic studies have documented healthcare-associated VRE transmission by molecular typing techniques *(80)*. Likewise, pulse-field gel electrophoresis demonstrated that 43% of the MRSA isolates causing invasive infections at a transplant unit shared the same pattern, suggesting healthcare-associated transmission *(80)*.

C. difficile is currently the most common cause of infectious diarrhea in transplant recipients. Liver transplantation was identified as the most significant independent risk factor for *C. difficile* acquisition in one report *(81)*. Although the precise mode of transmission of *C. difficile* has not been determined, environmental contamination and healthcare-associated transmission are the likely mode of transmission of *C. difficile*; however, airborne dispersal of spores could be another important source *(82,83)*. *C. difficile* was recovered from 9% to 51% of the environmental cultures; objects contaminated with feces (e.g., bed pan, toilet seats, sinks, and scales were most likely to yield *C. difficile*) *(84)*. Positive hand cultures were documented in 59% of the hospital personnel caring for the patients with *C. difficile,* implicating hands of hospital personnel as a likely mode of transmission *(85)*. Prudent use of antimicrobial agents and measures to curtail healthcare-associated transmission are key toward effective prevention of infections caused by these pathogens.

RISK FACTORS FOR INFECTIONS

Surgical factors, intensity of immunosuppression, and variations in local and systemic host response are among the variables that determine not only the type but also the site and the severity of infections in different types of organ transplant recipients (Table 58-2).

TABLE 58-2

Risk Factors for Infection with Major Healthcare-Associated Pathogens in Transplant Recipients

Pathogen	*Risk factors*
Fungi	
Aspergillus	
Lung transplantation	Single-lung transplant, CMV infection, airway ischemia, hypogammaglobulinemia, pretransplant and posttransplant *Aspergillus* colonization, bronchial stent
Liver transplantation	Poor allograft function, renal failure (particularly a requirement for dialysis), retransplantation
Heart transplantation	Isolation of *Aspergillus* species in respiratory tract cultures, reoperation, CMV disease, posttransplant dialysis
Renal transplantation	Augmented immunosuppression, graft failure requiring hemodialysis
Candida	
Liver transplantation	Prolonged operation time, high transfusion requirement, renal failure, repeat operation, retransplantation, choledochojejunostomy
Pancreatic transplantation	Diabetes, exocrine enteric drainage
Pneumocystis jirovecii	Augmented immunosuppression, allograft rejection, CMV infection, low CD4 count
Viruses	
Cytomegalovirus	Donor CMV seropositivity, Augmented immunosuppression (particularly, antilymphocyte agents), allograft rejection, HHV-6 infection
Bacteria	
Vancomycin-resistant enterococcus	Rectal colonization prior to transplant, previous antibiotic use, biliary complications, prolonged hospitalization, surgical reexploration, allograft nonfunction
Methicillin-resistant *Staphylococcus aureus*	Nasal *S. aureus* carriage, prolonged hospitalization, ICU stay
Legionella	Contaminated hospital potable water system, humidifiers, and ice machines
Mycobacterium tuberculosis[a] (risk factors for early-onset tuberculosis)	Nonrenal transplantation, history of prior *M. tuberculosis* (positive tuberculin test or old active tuberculosis on chest radiographs), OKT3 use
Pseudomonas aeruginosa	Donor colonization (lung transplants), cystic fibrosis

[a]Early-onset tuberculosis implies infection occurring within 12 months of transplantation.
CMV, cytomegalovirus; HHV-6, human herpesvirus-6; ICU, intensive care unit.

Liver Transplantation

Liver transplant recipients, by virtue of having hepatic failure and malnutrition before transplantation, represent severely compromised hosts. Many of these patients have concomitant renal failure as a result of hepatorenal syndrome. Renal failure, particularly the requirement for dialysis, was an important predictor of early infections and adversely affected survival after liver transplantation (86,*87*).

Liver transplant recipients are uniquely susceptible to invasive candidiasis. Most cases originate from endogenous sources; deficient reticuloendothelial function and translocation across the gut mucosa are considered important pathogenetic factors predisposing to invasive candidiasis *(88)*. Vascular and anastomotic complications are also significant risk factors for infectious morbidity in liver transplant recipients. Duct-to-duct biliary anastomosis compared with Roux-en-Y choledochojejunostomy is associated with a lower incidence of infections, because the latter involves the breach of the bowel integrity and sacrificing the sphincter of Oddi, which may promote reflux of bowel contents into the biliary tree *(89)*. Hepatic artery thrombosis may lead to the development of hepatic infarcts with subsequent gangrene and abscess formation. The clinical presentation is usually acute or fulminant, although hepatic artery occlusion may occasionally be occult and present with a clinical picture of unexplained fever and relapsing subacute bacteremia. Hepatic artery thrombosis may also lead to liver abscesses by compromising the biliary vascular supply. Impaired arterial flow to the hepatic allograft preferentially affects the biliary tree because of the biliary tract's almost total reliance on the hepatic arterial blood supply. Hepatic artery thrombosis may thus lead to biliary tract ischemia and biliary leaks, eventually resulting in intrahepatic abscess formation.

The biliary tract may be a source of infection even with an intact vascular supply. Biliary composition is altered during liver transplantation, leading to supersaturation with cholesterol and sludge and stone formation that may predispose to infections (e.g., cholangitis). T tubes, commonly used to protect duct-to-duct biliary anastomoses, are prone to microbial colonization and form a nidus for the deposition of biliary sludge.

Portal vein thrombosis was shown to be the most significant independent predictor of early bacterial infections after liver transplantation *(90)*. Recurrent viral HCV hepatitis has been documented in nearly 50% of the patients undergoing liver transplantation for end-stage liver disease resulting from HCV. HCV is considered an immunosuppressive and an immunomodulatory virus. Patients with HCV recurrence were significantly more likely to develop late-occurring infections, particularly fungal infections after liver transplantation *(91)*.

Renal Transplantation

Urinary tract and postoperative surgical site infections are two of the most frequent and serious healthcare-associated infections in renal transplant recipients. Urinary tract infections occur in more than 50% of patients during the first 3 months after transplantation and are the most frequent source of bacteremia during this time. In the absence of antimicrobial prophylaxis, surgical site infections have been reported in up to 20% of patients. Organ/space surgical site infections after renal transplantation have been shown to adversely affect graft survival.

Surgical site infections in renal transplant recipients are usually due to staphylococci or gram-negative bacilli *(92,93)*. Staphylococcal infections were associated with incisional surgical site infections and occurred earlier, whereas those due to gram-negative bacilli occurred later; were organ/space surgical site infections; and often led to bacteremia, graft loss, or death. Prolonged urinary catheterization, a surgical site hematoma, a reopened surgical site, and a cadaveric donor graft are risk factors for healthcare-associated urinary or surgical site infections in renal transplant recipients *(94,95)*. Renal trauma with nephrectomy and graft contamination during transportation may likely account for a higher risk of infection in cadaveric compared with living allograft recipients. Bacteriuria occurring in the late posttransplant period is usually benign and rarely symptomatic; however, late-onset (>6 months) urinary tract infections were significantly associated with an increased risk of graft loss *(96–98)*. Antimicrobial prophylaxis has proven highly effective in reducing the rate of urinary tract and surgical site infections in renal transplant recipients. A single perioperative dose of antibiotics led to a reduction in the incidence of surgical site infections from 25% to 2% *(99)*. Prophylaxis with trimethoprim-sulfamethoxazole has been shown to significantly lower the incidence of urinary tract infections, bacteremias, and infections caused by gram-negative bacilli and *S. aureus* when compared with placebo *(100)*. Currently, no recommendations are made for screening and treatment of asymptomatic bacteriuria in renal transplant recipients *(101)*.

Heart and Lung Transplantation

Heart and lung transplant recipients are uniquely susceptible to healthcare-associated bacterial pulmonary infections, particularly in the first month after transplantation. Bacterial pneumonia has been reported in 35% to 48% of the lung and heart–lung transplant recipients *(102,103)*. Impaired mucociliary clearance, loss of cough reflex, postoperative pain with splinting, and donor tracheal colonization are some factors contributing to a high risk of postoperative pneumonia in lung transplant recipients.

Multiple drug-resistant strains of *P. aeruginosa* and *Burkholderia cepacia* complex are of particular concern in patients undergoing lung transplantation for cystic fibrosis. Although panresistant *P. aerguinosa* colonization was associated with worse survival (88.6% vs. 96.6% at 1 year) than sensitive *P. aeruginosa* colonization, their survival is comparable to CF patients in the UNOS registry (86% at 1 year) *(104)*. Thus, panresistant *P. aeruginosa* colonization should not be considered as a contraindication to lung transplant. Among *B. cepacia* complex, most transplant centers consider *B. cenocepacia* (*B. cepacia* complex genovar III) colonization or infection to be a contraindication for lung transplant given its worse outcomes compared with nongenovar III *B. cepacia* complex (*105*,*106*,107). In a retrospective study of 75 cystic fibrosis lung transplant recipients, 1-year survival rates are 92%, 89%, and 29% in noninfected patients, those with *B. cepacia* complex species other than *B. cenocepacia*, and those with *B. cenocepacia*, respectively (107). Although the infected lung is removed during transplantation, residual colonization of the airway, nasopharynx, and sinuses remains a potential

nidus for subsequent infection. Typically, a course of antimicrobial prophylaxis is given to prevent development of posttransplant lung infections based on the result of bacterial cultures from donor- and recipient-bronchus at the time of procurement.

Circulatory support devices (e.g., intraaortic balloon pump and left ventricular assist devices) are required in many potential heart transplant recipients, and their prolonged placement is a major risk factor for bacterial colonization and subsequent healthcare-associated infections after transplantation. Sternal surgical site infections occur in 5% to 20% of heart and heart–lung transplant recipients; staphylococci, *Enterobacteriaceae,* and *P. aeruginosa* are the most common causative microorganisms. Sternal surgical site infections may directly extend into the mediastinum and predispose to mediastinitis or mycotic aneurysms at the suture sites. Mediastinitis occurs in 2% to 9% of the heart and heart–lung transplant recipients; *S. aureus, P. aeruginosa,* and *C. albicans* have been the most commonly reported microorganisms *(108–111)*. An unusual cause of mediastinitis in transplant recipients is *Mycoplasma hominis (112)*.

Pancreatic Transplantation

Surgical site infections, abscesses, or urinary tract infections occur in 7% to 50% of the pancreatic transplant recipients *(113–116)*. Organ/space surgical site infections are a significant cause of graft loss and mortality in these patients. The postoperative infection rates and the causative pathogens depend primarily on the technique used for the drainage of exocrine secretions of the pancreas. Enteric drainage (diversion into the small bowel) and bladder drainage are the main approaches used for drainage of exocrine secretions. Infection rates are generally higher with enteric drainage (which facilitates contamination with gastrointestinal bacteria); however, in a recent retrospective review of pancreatic transplant recipients, bladder drainage was associated with higher risk of bacterial infections *(117)*.

Whereas aerobic and anaerobic enteric flora predominates in abscesses associated with enteric drainage, microorganisms in infections in which the viscus has not been opened are usually from the skin flora. *Candida,* however, is a common pathogen in all types of surgical site infections, including those using bladder drainage. A high incidence of *Candida* urinary colonization, because of diabetes in these patients, along with the nonacidic environment in the bladder created by the exocrine pancreatic secretions facilitate *Candida* colonization.

Small-Bowel Transplantation

Unique features predisposing to infections in small-bowel transplant recipients are the fact that the contents of the transplanted organ are nonsterile and that these patients require a higher intensity of immunosuppressive therapy to prevent graft rejection *(118–122)*. Virtually all small-bowel transplant recipients experience at least one episode of infection; the number of infectious episodes per patient may range from 1 to 11 (median, 5) *(119)*. Multivisceral transplant recipients and those undergoing colonic segment transplantation with small-bowel transplantation are more likely to develop infections *(119)*. It is noteworthy that small-bowel transplant recipients remain susceptible to infections, even in the late posttransplant period (i.e., more than 6 months after transplantation) *(119,123)*.

Small-bowel transplant recipients, particularly CMV-seronegative recipients of seropositive grafts, are uniquely vulnerable to CMV infection and to recurrent episodes of CMV disease *(118)*. CMV disease in recipient-negative donor-positive patients has been shown to adversely affect outcome in these patients. Consequently, some transplant centers do not use CMVseropositive small-bowel grafts for CMV-seronegative recipients *(122)*. Notably, a small-bowel graft is involved in 81% to 90% of the patients with CMV disease *(118,122)*.

Bacterial translocation in small-bowel transplant recipients predisposes these patients to intra-abdominal infections (peritonitis and abscesses). Selective decontamination of the gut after transplantation has been proposed to reduce early postoperative infections in small-bowel transplant recipients *(120)*.

TIME TO ONSET

The relative frequency, types of infection, and the specific pathogens encountered after transplantation generally have a predictable time of onset. Thus, infections in transplant recipients must be evaluated in the context of time elapsed since transplantation. These data also have implications relevant for the institution of prophylaxis and the duration of prophylaxis.

Infections During the First 30 Days

Most infections occurring within 30 days of transplantation are a consequence primarily of surgical or technical complications related to transplantation, healthcare-associated acquisition, and rarely reactivation of latent infections (e.g., herpesviruses) in the recipient. Bacterial infections are by far the most frequently occurring infections during this period; vascular catheter-related infections, healthcare-associated pneumonia, *C. difficile* infection, and surgical site infections are the most common types. Fungal infections likely to be encountered in the first month after transplantation include candidiasis and aspergillosis. Nearly 75% of the cases of invasive candidiasis and aspergillosis in liver transplant recipients occur within the first month and virtually all within 2 months of transplantation *(88,124)*. More recently, however, delayed occurrence of *Aspergillus* infections has been noted; 55% of the cases of invasive aspergillosis in liver transplant recipients occurred after 90 days of transplantation *(125)*. Liver transplant recipients are uniquely susceptible to invasive candidiasis; disruption of the integrity of the bowel and gastrointestinal translocation are the proposed mechanisms. The only significant viral infection occurring within the first 30 days of transplantation is that due to the HSV. However, there is accumulating evidence to suggest that HHV-6 may also be a pathogen in the early posttransplant period *(126)*. HHV-6 infection characteristically occurs earlier than CMV and may cause fever of unknown origin and idiopathic cytopenia during this period.

Infections Occurring between 30 and 180 Days

Although healthcare-associated infections may continue to pose a threat in patients requiring prolonged hospitalization, most infections occurring between 30 and 180 days after transplantation are opportunistic infections related to the effects of immunosuppression. The foremost pathogen in transplant recipients during this time period is CMV; however, infections resulting from *M. tuberculosis, P. jirovecii*, *T. gondii*, and *Nocardia* are also likely to be encountered during this interval. Clinically and histopathologically manifest recurrences of HCV hepatitis usually occur within 6 months of transplantation. In the absence of immunoprophylaxis for HBV, recurrence of HBV infections in the recipient occur a median of 3 months after transplantation.

Infections Occurring 6 Months or Later

Infectious diseases in the last posttransplant period are typically community-acquired infections similar to those occurring in the general population. However, patients requiring aggressive immunosuppression for recurrent or chronic rejection and those with poorly functioning allografts (e.g., liver transplant recipients with recurrent viral HBV or HCV) continue to be at risk for opportunistic infections. Posttransplant lymphoproliferative disorder, varicella-zoster virus (VZV) infections, cryptococcosis, and infections resulting from dematiaceous fungi typically occur 6 or more months after transplantation.

VIRAL INFECTIONS

Herpesviruses

Cytomegalovirus CMV has been recognized as one of the most significant pathogens in organ transplant recipients (*127*,*128*,129,*130*). Depending on the pretransplant CMV serostatus of the recipient, three distinct epidemiologic patterns of CMV infection exist. Primary infection occurs when a seronegative recipient acquires CMV, either from the transplanted allograft or less commonly from blood products. Reactivation infection results from endogenous reactivation of the latent virus. Superinfection implies acquisition of a new strain of CMV in a patient seropositive for CMV before transplantation. Because 50% to 70% of the general population is seropositive for CMV, most infections in transplant recipients represent reactivation infections. However, the clinical impact of CMV is by far greatest in the context of newly acquired or primary infection. Primary CMV acquisition is associated with a higher rate of CMV infection and symptomatic disease, earlier onset of CMV infection posttransplantation, higher incidence of recurrence, greater risk of dissemination, and higher mortality *(131,132)*. Symptomatic disease, CMV hepatitis, invasive fungal infections, and death in liver transplantation were more likely to occur when primary infection in the recipient was acquired from the donor organ compared with acquisition from transfusions *(68)*. The time to onset of CMV infection after transplantation is also shorter with donor versus transfusion-associated CMV infection *(68)*. Superinfection, as compared with reactivation infection, is also associated with a higher incidence and severity of symptomatic CMV disease *(133)*.

Risk Factors CMV serologic status of the recipient and donor is the most significant factor influencing the rate and severity of CMV infection. Eighty percent to 100% of the seronegative recipients of a seropositive donor allograft (D+/R–) acquire CMV infection after transplantation. The risk of CMV infection is lowest (<10%) in seronegative recipients of seronegative organ donors. CMV-seropositive recipients have an intermediate risk (40% to 60%) for developing CMV infection. The intensity and type of immunosuppression are also important determinants of the risk of CMV infection *(134)*. Antilymphocyte preparations (e.g., OKT3, thymoglobulin) are extremely potent reactivators of CMV. Primary immunosuppressive agents (e.g., cyclosporine and tacrolimus), on the other hand, are not efficient reactivators, but, when CMV reactivation occurs, they interfere with the host's ability to limit viral replication *(134)*.

Primary infection with HHV-6, which is considered an immunomodulatory virus, has been proposed to be a risk factor for subsequent CMV invasive disease *(135,136)*. Intraoperative hypothermia is a common complication of liver transplant surgery. In a study in liver transplant recipients, intraoperative hypothermia was an independently significant risk factor for early CMV infection and active warming using a convective heating device appeared to curtail this risk *(137)*. Human leukocyte antigen matching and retransplantation have also been shown to be risk factors for CMV infection *(131,138)*.

Pathogenesis CMV-specific major histocompatibility complex (MHC)-restricted cytotoxic T cells are pivotal in host defense against CMV; clinically significant CMV occurs predominantly among patients without an adequate T-lymphocyte response. Humoral immunity, on the other hand, is an ineffective host defense against CMV, although it may modify (or temper) the severity of infection. Tumor necrosis factor-alpha has been shown to be a powerful promoter of CMV *(134,139,140)*. Any physiologic stimulus for tumor necrosis factor-alpha release (e.g., OKT3, sepsis, and rejection), therefore, has the potential to activate CMV.

CMV is considered an immunosuppressive virus that may facilitate superinfection with opportunistic pathogens (e.g., fungi, gram-negative bacteria, and *P. jirovecii*) *(131,141)*. Other indirect sequelae of CMV infection include acute and chronic allograft rejection, bronchiolitis obliterans in lung transplant recipients, atherogenesis in heart transplant recipients, and glomerulopathy in renal transplant recipients.

Epidemiology and Clinical Features The overall incidence of CMV infection ranges between 40% and 90% in organ transplant recipients. Without prophylaxis, the highest incidence of CMV infection has been documented in lung or heart–lung transplant recipients (60–98%) and the lowest (40–50%) in renal transplant recipients. Liver and heart transplant recipients have an intermediate risk of CMV infection (50–67%). The frequency of symptomatic disease resulting from CMV ranges from 8% to 15% in renal, 20% to 35% in liver, 27% to 30% in heart, and 55% to 60% in lung transplant recipients. The incidence of CMV infection in small-bowel transplant recipients approaches that in lung transplant recipients *(118)*. Small-bowel transplant patients also appear to be uniquely susceptible to recurrent episodes of CMV infection *(118)*.

Traditionally, most CMV infections have occurred between 4 and 6 weeks. In patients receiving prolonged antiviral prophylaxis, onset of CMV infection has been noted to be delayed *(142–145)* as antiviral prophylaxis only inhibits viral replication and does not eradicate latent infection. A febrile mononucleosis syndrome characterized by fever, arthralgias, myalgias, leukopenia, and atypical lymphocytosis is the most common symptomatic disease caused by CMV, although localized or disseminated tissue invasive disease may also occur. Predilection to involve the transplanted allograft is a peculiar characteristic of CMV. CMV hepatitis occurs most commonly in liver transplant recipients, CMV pneumonitis occurs most commonly in lung transplant recipients, and CMV enteritis occurs most commonly in small-bowel transplant recipients. It is proposed that the transplanted allograft may provide a sequestered site for latently infected cells, because MHC mismatches at these sites may prevent the generation of virus-specific cytotoxic T-cell responses *(146)*.

Diagnosis The diagnosis of CMV infection has traditionally been made by viral isolation. These culture-based assays are considered obsolete because of their low sensitivity and time-consuming nature. Conventional cultures take up to 4 weeks. The shell vial assay uses a monoclonal antibody to detect a 72-kDa immediate early CMV antigen and allows detection of CMV within 16 to 24 hours *(147)*. The currently available tests not only allow rapid and reliable diagnosis of CMV infection but also may detect viral shedding at an earlier stage. The pp65 antigenemia assay detects CMV-infected leukocytes with monoclonal antibodies directed against the 65-kDa lower matrix phosphoprotein *(148,149)*. The CMV antigenemia assay is more sensitive and allows earlier detection of CMV than shell vial culture does. Furthermore, results of the antigenemia assay can be quantitated; the number of antigen-positive cells has been shown to correlate with the likelihood of CMV disease and can also be used to monitor response to antiviral therapy. The major drawback of the antigenemia assay is the need for immediate processing of blood samples. Detection of viral DNA by PCR in the plasma or whole blood is also very sensitive for the diagnosis of CMV, and it has been considered the gold standard given its high sensitivity and rapid turnover time. Although the PCR assays are not fully standardized, they have emerged as the preferred diagnostic tests for CMV.

Prevention

Matching Donors and Recipients by Serologic Status Attempts to decrease the morbidity associated with primary donor-acquired CMV infection have included the use of CMV-seropositive donor organs only for seropositive recipients. Although a decrease in graft loss and mortality attributable to CMV was noted in one report *(150)*, others have not shown a significant impact with such an approach. Widespread adoption of this approach, however, is not feasible given the limited organ donor pool.

Prophylaxis Two approaches exist for CMV prophylaxis: universal prophylaxis and preemptive therapy (129). Universal prophylaxis requires administration of antiviral prophylaxis to all organ transplant recipients except for seronegative recipients from seronegative donors for typically 3 to 6 months. The advantage of this strategy includes relatively easy implementation and favorable effects on "indirect effects" such as rejection and opportunistic infections; however, drug costs, their adverse effects, late-onset disease, and emergence of drug-resistant CMV may be potential issues *(3,142,151,152)*. Preemptive therapy requires periodic monitoring of CMV replication for early identification of CMV infection with prompt treatment to prevent asymptomatic infection from progressing to CMV disease. It decreases the cost and adverse effects; however, continuous CMV monitoring can be logistically difficult and viral load thresholds for initiating antiviral therapy have not been precisely defined. Preemptive therapy is typically administered until resolution of CMV viremia. Both strategies are efficacious to reduce the rate of CMV disease *(153,154)*, although superiority of one approach over the other has not been incontrovertibly documented. Although not approved for use in liver transplant recipients, valganciclovir is the most commonly used antiviral agents for prophylaxis of CMV.

Herpes Simplex Virus HSV infections in transplant recipients present as mucocutaneous lesions resulting from reactivation of the latent virus. However, visceral or disseminated HSV infection can be donor-transmitted and may have a fulminant presentation with a grave outcome without antiviral therapy. HSV hepatitis is the most frequently documented site of disseminated HSV infection; its incidence (cases per thousand) is reported to be 2.11 in renal, 2.23 in heart, and 4.81 in liver transplant recipients. In a report comprising 12 cases of HSV hepatitis in solid organ transplant recipients, 33% were due to primary HSV infection believed to be acquired from the donor *(155)*. The median time to onset of HSV hepatitis was 18 days, although it occurred as early as 5 days posttransplantation *(155)*. This characteristic time of onset is in contrast with CMV hepatitis, which usually occurs 30 to 40 days after transplantation. Clinical manifestations of HSV hepatitis include fever, leukocytosis, thrombocytopenia, and marked elevation of hepatocellular enzymes. Mortality from primary visceral HSV infection in seronegative recipients was 75%; hypotension, disseminated intravascular coagulation, metabolic acidosis, low platelet count, and high creatinine were significant predictors of mortality *(155)*.

HSV accounted for 41% of all non-CMV isolates from the respiratory tract in lung transplant recipients; 80% of the isolates were deemed clinically significant and were associated with pneumonitis *(156)*. Another clinical presentation of HSV, predominantly reported in intubated lung and cardiac transplant recipients, is HSV tracheobronchitis that manifested as fever, bronchospasm, leukocytosis, and difficulty weaning. Paradoxically, HSV tracheobronchitis had a more severe presentation and worse outcome in immunocompetent compared with immunosuppressed patients *(157)*. It was proposed that this may be due to a more exuberant local immune response in the immunocompetent patients *(157)*.

Low-dose acyclovir (200–400 mg orally three times daily) generally used for a month posttransplant is highly effective as prophylaxis for HSV in transplant recipients *(158)*. At one institution, HSV hepatitis was documented

in 12 of 3,536 solid organ transplant recipients before the routine use of acyclovir prophylaxis and in none of the 1,144 patients since the use of acyclovir prophylaxis *(155)*. Longer duration of acyclovir can be considered for organ recipients who develop frequent recurrences of HSV lesions.

Varicella-Zoster Virus Up to 70% of the pediatric and 5% of the adult transplant recipients have been reported to be seronegative for VZV *(159,160)*. Exposure to VZV infection may result in primary varicella in these susceptible patients. Donor-derived primary varicella infection was also reported in a cardiac transplant recipient whose donor suffered from varicella 2 weeks prior to transplant *(34)*. Median time to onset of varicella was 2 years after transplantation in one report *(160)* and 2.4 years in another *(161)*. Visceral dissemination, frequently documented in transplant recipients, is the primary cause of mortality in patients with VZV. Hepatitis, pneumonitis, pancreatitis, gastroenteritis, or meningoencephalitis are the most commonly documented sites of visceral dissemination. Varicella may initially present with acute abdominal pain, and in the absence of skin lesions can defy early recognition. It is notable that up to 16% to 18% of the pediatric transplant recipients may have recurrent varicella infections *(161,162)*.

All transplant candidates susceptible to VZV should receive varicella vaccination prior to transplantation. Varicella-zoster immunoglobulin (VZIG) is recommended for susceptible transplant recipients exposed to varicella within 96 hours. VZIG, however, is not entirely protective; in up to one third of the patients with varicella, lesions have occurred despite VZIG prophylaxis. Since the production of VZIG was discontinued, VariZIG is the only immunoglobulin currently available in the United States under an investigational new drug application. Exposed susceptible organ recipients should be isolated in Airborne and Contact Precautions from day 10 to day 21 (day 28 if receiving VZIG or VariZIG) to decrease the risk of transmission to other susceptible patients. Some centers use high-dose oral acyclovir or valacyclovir for the duration of the incubation period of varicella (i.e., 2–3 weeks after exposure of susceptible patients to varicella). Use of varicella vaccine is not recommended in transplant recipients *(163)* (see also Chapter 43).

Human Herpesvirus-6 HHV-6 is a large double-stranded DNA virus that is antigenically distinct from other human herpesviruses. Its closest phylogenetic relative is CMV; nucleotide sequencing has revealed 66% DNA homology between CMV and HHV-6. On the basis of genomic DNA sequences, cell tropism, and protein expression, two distinct variants of HHV-6, designated as variant A and variant B, have been described *(164,165)*. The two variants differ in virulence; the HHV-6A variant is intrinsically more virulent and neurotropic than the HHV-6B variant *(126)*. Most infections in transplant recipients are due to the HHV-6B variant *(126)*.

Most HHV-6 infections are believed to result from endogenous reactivation of the recipient's latent virus; however, donor transmission has also been documented. Although the precise incidence and clinical sequelae of HHV-6 infection after transplantation remain to be fully elucidated, HHV-6 infection has been reported in 31% to 55% of solid transplant recipients *(126)*. The usual timing of onset is between 2 and 4 weeks posttransplantation. Bone marrow suppression, interstitial pneumonia, encephalopathy, and fever of unknown origin are the most commonly reported clinical manifestations of HHV-6 *(126,166–168)*. Diagnosis for acute or reactivation infection is based on the detection of viral nucleic acids by polymerase chain reaction (PCR) in noncellular samples such as serum or plasma. It is worth noting that PCR can detect latent HHV-6 in peripheral blood mononuclear cells or chromosomally integrated HHV-6. The antiviral susceptibilities of HHV-6 resemble those of CMV *(169–171)*. HHV-6 is sensitive to both ganciclovir and foscarnet and resistant to acyclovir at achievable serum concentrations. The role of prophylaxis for HHV-6 has not yet been fully discerned. Active HHV-6 infection does not require antiviral treatment except for patients with encephalitis and other tissue-invasive diseases.

Hepatotropic Viruses

Hepatitis C Virus End-stage liver disease resulting from HCV has been documented in up to 50% of the patients undergoing liver transplantation in recent years. Up to 95% of the patients with pretransplant HCV infection remain viremic after transplantation, as demonstrated by the presence of HCV RNA in the blood. Clinically and histologically manifest recurrence occurs in 30% to 70% of patients with pretransplant HCV, generally within 1 to 12 months after transplantation *(172–174)*. Progression to cirrhosis has been observed in 15% to 20% of patients 1 to 3 years after initial transplantation. Despite significant morbidity associated with HCV, survival rates in patients with and without HCV recurrence have not been different *(173)*.

The prevalence of HCV positivity in hemodialysis patients ranges between 5% and 54% *(175)*. The number of blood units transfused, the duration of hemodialysis, and the type of dialysis (hemodialysis as opposed to peritoneal dialysis) correlated with a higher incidence of HCV infection in renal transplant candidates *(175–177)*. After transplantation, chronic liver disease has been reported in 10% to 60% of renal transplant recipients and occurred significantly more frequently in patients with HCV compared with those without HCV *(176–178)*. Earlier studies showed pretransplant HCV infection did not adversely affect the graft or patient survival after renal transplantation *(178,179)*; however, a more recent study suggested that pretransplant HCV infection was independently associated with patient and graft survivals *(180)*.

Although most posttransplant HCV infections are due to recurrence of pretransplant HCV, *de novo* infections resulting from acquisition from the donor organ or transfused blood products have been reported. A 35% rate of acquired HCV-RNA infection was reported in 89 liver transplant recipients, most of whom were transplanted before the routine screening of blood products for anti-HCV *(172)*. Routine screening of blood products has led to a significantly lower acquisition rate of HCV (i.e., 2.5–4%). HCV has also been transmitted by organs from anti-HCV–positive donors (see the section "Sources

of Infections in Recipients"). HCV infection is also considered a significant risk to the personnel involved in the care of HCV-infected transplant patients. The seroprevalence of HCV (7%) in healthcare workers directly involved in the care of liver transplant patients was significantly higher when compared with those not associated with liver transplantation (0.5%) or in volunteer blood donors (0.3%) *(181)*. None of the transplant personnel had hepatitis or a history of transfusion *(181)*. The risk of acquiring HCV after needle stick injuries may be as high as 10%. Serum immunoglobulin is not protective against HCV and is not recommended (also see Chapter 73).

A number of variables are believed to influence the rate and severity of recurrent HCV hepatitis after transplantation, including the level of pretransplant viremia, genotype of the virus, and the intensity of posttransplant immunosuppression *(173,182,183)*. HCV genotype 1b has been associated with more severe recurrent HCV infection after liver transplantation *(173)*.

Corticosteroids have been shown to result in a several fold increase in the HCV-RNA level. Finally, allograft rejection and steroid-resistant rejection requiring lymphocyte-depleting agents can lead to a higher incidence and earlier onset of recurrent HCV hepatitis after liver transplantation *(183,184)*.

Effective prophylaxis against HCV in transplant recipients is not available. It has been shown that polyclonal immunoglobulin preparations against HBsAg administered to liver transplant patients for HBV were also protective against HCV *(185)*. Among the patients who had HCV infection before transplantation, the incidence of HCV viremia after transplantation in the patients receiving HBIG was significantly lower than in those who did not receive HBIG (54% vs. 94%, $p = .001$). This protective effect may have been due to the presence of anti-HCV in HBIG *(185)*. Prophylaxis with interferon-alpha, administered for 6 months posttransplantation in liver transplant recipients, delayed the occurrence of HCV but decreased neither the incidence nor the severity of recurrent HCV hepatitis *(186)*. The majority of liver transplant recipients receiving posttransplant antiviral therapy with pegylated interferon alfa-2b and ribavirin developed adverse effects *(187)*, and this approach was not practical. Nonhepatic organ transplant candidates with chronic hepatitis C infection should undergo evaluation (i.e., liver biopsy) for therapy prior to transplant *(13)*.

Hepatitis B Virus

The clinical impact of HBV is of greatest importance in the context of liver and renal transplantation. In studies in which long-term immunoprophylaxis was not used, the reinfection rate of the hepatic allograft with HBV was virtually 100% with progression to liver failure and death in as little as 2 to 2.5 years. Anti-HBs immunoprophylaxis has significantly altered the natural history of HBV after liver transplantation. In a large study assessing the outcome in HBsAg-positive patients undergoing liver transplantation for HBV-related cirrhosis, the overall risk of HBV recurrence after 3 years was 67% (188). HBV recurrence was documented a mean of 3 months posttransplant in 78% to 90% of patients who did not receive long-term immunoprophylaxis; recurrence was significantly less (56%) and delayed, occurring a mean of 8 months posttransplant, in patients receiving long-term anti-HBs immunoprophylaxis (188). HBV adversely affects graft and patient survival; survival at 3 years was 54% in patients with HBV recurrence and 83% in those who remained HBsAg negative after transplantation (188).

Several factors influence the recurrence of HBV after transplantation. The risk of recurrence is greater for patients with markers for active replication of HBV before transplantation (e.g., those seropositive for HBeAg or HBV DNA) (188,*189*). The risk of HBV recurrence was 83%± 6% in liver transplant recipients seropositive for HBV DNA compared with 58% ± 7% in those with neither HBV DNA nor HBeAg detectable at the time of transplantation (188). Fulminant HBV (as opposed to chronic HBV infection) is associated with a lower rate of recurrence. Recurrence was observed in 17% of patients with fulminant HBV compared with 67% in those with chronic HBV cirrhosis (188). Patients with fulminant HBV tend to have lower levels of HBV DNA or replicative HBV. Coinfection with hepatitis delta virus decreases the risk of recurrence in HBV infection after transplantation (188). Delta virus is a naturally occurring inhibitor of HBV replication, and hence, HBV DNA levels in delta virus coinfected patients are lower.

Strains of HBV that fail to produce HBeAg because of mutations in the precore region of the HBV genome (also known as precore mutants or HBeAg-deficient mutants) have been identified *(190)*. Such patients have high levels of viral DNA in the absence of HBeAg. Patients infected with the precore mutants pretransplant, as opposed to the wild-type virus, have a greater risk of hepatic graft loss resulting from early recurrence *(190)*.

A unique and particularly aggressive syndrome of recurrent HBV infection observed in 12% to 20% of patients with HBV recurrence is fibrosing cholestatic hepatitis, characterized by marked cholestasis and hypoprothrombinemia but only modest increases in serum transaminases *(191)*. Fibrosing cholestatic hepatitis is more likely to occur in patients with pretransplant HBV replication and results in rapid death in almost all cases. A paucity of inflammatory response in this syndrome suggests that the virus may be directly cytopathic.

HBV infection also follows an aggressive clinical course after renal transplantation. Progression of liver disease to cirrhosis and death, however, occurs considerably later than in liver transplantation (i.e., 6–8 years after transplantation). Chronic active or persistent hepatitis occurred in 76% of HBsAg-positive patients undergoing renal transplantation compared with 31% in HBsAg-negative patients.

The most effective approach to prevent recurrent HBV in high-risk patients is the use of combination therapy with antiviral agents and HBIG in addition to pretransplant antiviral therapy. Prophylaxis with the use of lamivudine monotherapy is not recommended because of the reappearance of HBsAg after liver transplantation in 32% to 50% of the patients. Combination therapy with HBIG and lamivudine prevents HBV recurrence in more than 90% of the patients undergoing liver transplantation for HBV (192,*193*). Newer antiviral agents including adefovir dipivoxil, tenofovir, and entecavir have also been available for lamivudine-resistant HBV. Discontinuation or tapering of HBIG may be considered in low-risk patients (i.e., undetectable HBV DNA at the time of transplant). Periodic monitoring of HBsAg and HBV DNA is also critical for early detection of recurrent graft infection.

Other Viruses

BK Virus BK virus (BKV) has emerged as a significant pathogen in renal transplant recipients. BKV is a polyomavirus that is acquired during childhood. Renal and uroepithelial cells are the main sites of latency. Seroprevalence rates in the general population range from 70% to 90%. BKV-induced nephropathy has been reported in 1% to 10% of the renal transplant recipients with allograft loss occurring in nearly half of those patients *(194,195)*. This entity was encountered only rarely before the mid-1990s. Although precise reasons for the emergence of BKV as a significant pathogen are unclear, use of novel, more potent immunosuppressive agents (e.g., tacrolimus, mycophenolate mofetil, and sirolimus) is considered to play a role. Donor transmission has been reported; however, most cases of BKV nephropathy occur as a result of reactivation of the latent virus.

The usual time to onset of BKV nephropathy is 28 to 40 weeks posttransplantation. Its typical manifestations resemble those of acute rejection and include a modest rise in creatinine that fails to respond to antirejection therapy. The hallmark of BKV replication is decoy cells, which are urinary epithelial cells bearing ground-glass intranuclear inclusions. Decoy cells, however, lack sensitivity and specificity for the diagnosis. Screening for BKV replication in urine should be performed at least quarterly (ideally monthly) during the first 2 years and whenever renal dysfunction occurs *(194,196)*, followed by quantitative plasma PCR for BKV if viuria is detected. Some centers use plasma PCR for screening. Patients with sustained high-degree BKV viremia should undergo allograft renal biopsy to guide further therapy. The mainstay of therapy is judicious reduction of immunosuppression, but may not always be successful. Specific antiviral therapy for BKV is not available; however, cidofovir, fluoroquinolones, IVIG, and leflunomide have been used anecdotally. Given the high seroprevalence in the general population, specific infection control measures are not deemed necessary.

Adenovirus Adenovirus infections have been documented in up to 10% of the pediatric and 1% to 15% of adult transplant recipients *(197–200)*. Symptomatic disease is more common and generally more severe in pediatric compared with adult patients after transplantation; 60% of the children and 27% of the adult transplant recipients with adenoviral shedding have been shown to have disease resulting from adenovirus *(197–199)*. The precise mode of transmission of adenovirus infections has not been determined, although both donor transmission and healthcare-associated transmission have been proposed to occur *(197–199)*. In pediatric liver transplant recipients, most severe disease occurred in seronegative children *(198)*, and donor serology was positive in five of six patients evaluated, suggesting that donor transmission is a likely source of infection. Healthcare-associated acquisition is also a consideration, because several patients with the similar adenovirus strains were found temporally clustered in one report *(197)*. Accordingly, Contact and Droplet Precautions as well as disinfection of environment are strongly advised.

Adenovirus infection typically occurs in the donor allograft. Hepatitis in liver transplant recipients, pneumonitis in lung transplant recipients, and hemorrhagic cystitis in renal transplant recipients are the most common invasive forms of adenovirus disease. Serotypes 5 and 11 were the most frequent serotypes causing hepatitis and hemorrhagic cystitis, respectively, in transplant recipients. Diagnosis is suggested by the detection of microabscesses with smudgy intranuclear targeted inclusions in histopathologic specimens *(201)*. Immunohistochemistry and culture can be used to confirm adenovirus infection. Reduction of immunosuppression and supportive care are the critical parts of treatment. No antiviral agents have been studied in controlled trials; however, cidofovir has been used for severe adenovirus infections in solid organ transplant recipients *(202,203)*.

Respiratory Viruses The impact of respiratory viral infections (e.g., respiratory syncytial virus [RSV], influenza, parainfluenza virus, human metapneumovirus [hMPV]) has been recognized in solid organ transplant recipients (204). Although clinical manifestations are similar to those in immunocompetent patients, progression from upper tract infection to lower tract infection is relatively rapid, and respiratory viral infections are associated with allograft rejection in lung transplant recipients *(205,206)*. In a case–control study of 100 lung transplant recipients, 8 of 50 (16%) patients with respiratory tract infections developed acute rejection, whereas none of 50 patients without respiratory tract infections developed acute rejection *(206)*. Early diagnosis and prompt initiation of treatment (if available) are the key to prevent allograft damage. Organ transplant recipients with respiratory symptoms especially in the early posttransplant period should have a nasal swab and/or bronchoscopic aspirate sent for viral culture, rapid antigen testing (RSV, influenza), and PCR-based assays *(207)*. Treatment consists of general supportive care and prompt initiation of antiviral agents if available. In a multicenter study of influenza A H1N1 infection in solid organ transplant recipients, early administration (within 48 hours of symptom onset) of antiviral agents was associated with a decrease in admission to hospital and ICU, need for mechanical ventilation, and death (*207a*). Although the duration of treatment with antiviral agents for influenza is typically 5 days in general population, some experts recommend continuation of antiviral agents until patients stop shedding virus from their respiratory secretion *(207,208)*. Aerosolized ribavirin with antibody-based therapy such as IVIG and palivizumab are recommended for treatment of severe RSV infection based on experience in hematopoietic cell transplant recipients *(209,210)*. Vaccination is the most effective method for prophylaxis; however, it is only available against influenza in the form of trivalent inactivated vaccine or live attenuated influenza vaccine. Organ transplant recipients should not receive live attenuated influenza vaccine given the potential safety concern *(211)*. Antiviral chemoprophylaxis may also be considered as alternative.

BACTERIAL INFECTIONS

Staphylococci

Staphylococci, particularly *S. aureus*, are increasingly recognized as pathogens in transplant recipients and have emerged as the leading cause of bacterial infections in liver, heart, kidney, and pancreatic transplant recipients at many centers *(212–216)*. This increase largely parallels

the more widespread rise in gram-positive infections in the healthcare-associated setting in recent years. Forty-nine percent of the bacteremias in liver transplant recipients in one report were due to *S. aureus (215)*. Although intravascular catheters, accounting for 54% of all MRSA bacteremias, were the predominant source, wound infections, healthcare-associated pneumonia, intraabdominal abscess, and peritonitis were also documented as sources of MRSA bacteremia *(215)*. Over one-half of the *S. aureus* infections occur in the intensive care unit setting *(215)*. Requirement of invasive procedures, mechanical ventilation, continuous need for intravenous access, and overall debilitated condition of the patients in the intensive care unit provide conditions conducive to the development of healthcare-associated *S. aureus* infections. *S. aureus* infections generally occur very early after transplantation. In a study in liver transplant recipients, nearly one third of such infections occurred within the first week of transplantation; the median time to onset was 16 days (39). *S. aureus* is also the most frequent cause of endocarditis in organ transplant recipients *(216)*. Notably, 74% of the cases of endocarditis were associated with previous hospital-acquired infection, especially venous access device and wound infections *(216)*.

S. aureus colonization of the anterior nares has been shown to be a significant predictor of infections resulting from *S. aureus* in liver transplant patients *(80)*. Overall, nasal carriage was documented in 67% of the patients; infected patients were significantly more likely to be nasal carriers of *S. aureus* compared with the noninfected patients. Pulsefield gel electrophoresis documented that the isolates causing infections matched the isolates from the anterior nares in all cases *(80)*. Furthermore, 43% of infected patients shared the isolates with the same restriction pattern, indicating cross-transmission in the healthcare-associated setting *(80)*. Eradication of nasal carriage by mupirocin, however, has not been shown to prevent *S. aureus* infections in liver transplant recipients *(217)*. Although 87% of the colonized patients were successfully decolonized, recolonization occurred in 37% *(217)*. Healthcare-associated transmission leading to exogenous colonization and colonization at nonnasal sites unaffected by nasal administration of mupirocin likely accounted for the failure of mupirocin to decrease *S. aureus* infections *(217)*. Recently, an active surveillance program using nasal and rectal swabs for cultures in the peritransplant period followed by targeted infection control interventions including isolation precautions and cohorting of patients colonized with *S. aureus* were shown to be effective in reducing new acquisition of *S. aureus* and infection in liver transplant recipients (218).

Enterococci

Enterococci, which are normal inhabitants of the gastrointestinal tract, are of greatest relevance in liver transplant recipients. Most enterococcal bacteremias in these patients result from complications related to the biliary tree. Roux-en-Y choledochojejunostomy (which facilitates reflux of enteric bacteria into the biliary tree) and biliary strictures have been shown to be independent risk factors for enterococcal bacteremia after liver transplantation *(219)*.

VRE have emerged as healthcare-associated pathogens of grave concern, particularly after liver transplantation. VRE infections were documented in 11% to 16% of the liver transplant recipients *(220–222)*. Notably, VRE was the most frequently isolated pathogen in infected liver transplant recipients in one study *(221)*. Infections were documented a median of 10 to 42 days after transplantation *(220,221)*. Intra-abdominal infections and catheter-related infections were the frequent sites of VRE infection. VRE fecal carriage before transplantation; previous antibiotic use (vancomycin); biliary complications; prolonged hospitalization and intensive care unit stay; surgical reexploration; surgical complications during transplantation, including hypotension; and primary nonfunction of the allograft have been identified as significant risk factors for VRE infections *(220,221,223,224)*. Mortality in the infected patients ranges between 16% and 50%. Intensive care unit stay before transplantation, hemodialysis, liver failure, and shock have been shown to be independent predictors of mortality in patients with VRE infections *(221,224)*. Treatment consists of removal or debridement of infected sources and antibiotics (i.e., daptomycin, linezolid, quinupristin-dalfopristin, tigecycline) effective against VRE.

VRE colonization once established is often a persistent event; spontaneous conversion to VRE-negative carriage is uncommon. In liver transplant recipients, 18% of recipients who were not colonized with VRE acquired VRE within a mean of 12 days posttransplant (225). These patients, therefore, remain at risk for invasive infections and a threat for healthcare-associated transmission (225). A variety of gut decontamination regimens have been tried; however, none have been shown to be consistently effective. Consequently, infection control practices to prevent healthcare-associated acquisition and cross-transmission and judicious use of antimicrobial agents, particularly vancomycin, are critically important in curtailing VRE infections (see also Chapter 33).

Mycobacterium tuberculosis

The incidence of tuberculosis in solid organ transplant patients ranges from 0.35% to 5% in the United States and Europe *(226–228)*. However, in highly endemic areas (e.g., India and Pakistan), tuberculosis may develop in 5% to 15% of the transplant patients. The median time to onset after transplantation is 9 months and ranges from 0.5 to 144 months *(226,228)*. Tuberculosis occurs significantly later after transplantation in renal compared with nonrenal transplant recipients. Disseminated disease occurs in nearly one-third of the transplant recipients with tuberculosis *(226)*. The gastrointestinal tract is the most frequent extrapulmonary site of tuberculosis in transplant recipients. Other reported extrapulmonary sites of involvement include the skin and osteoarticular tissue, central nervous system, kidneys, and urogenital tract.

Tuberculin reactivity has been documented in 20% of the transplant recipients with tuberculosis, and chest radiographs with evidence of old active tuberculosis were documented in 12% of the patients *(226)*. These patients are more likely to develop tuberculosis earlier after transplantation than those without a history of tuberculin reactivity or abnormal chest radiograph before transplantation. Most tuberculosis infections in transplant recipients represent reactivation of old dormant disease. However, healthcare-associated acquisition and donor transmission are also well-documented modes of transmission. Tuberculosis has

been shown to be transmitted both by living and cadaveric organ donors. Tuberculosis, involving the renal allograft, was documented 35 and 39 days after renal transplantation in two recipients of the same donor who died of hypoglycorrhachic lymphocytic meningitis of unknown etiology; the donor's cerebrospinal fluid culture was positive for *M. tuberculosis* 3 weeks after death *(47)*. One renal allograft recipient of this donor died of disseminated tuberculosis, whereas the second recovered, although rejection secondary to antituberculosis therapy necessitated allograft nephrectomy *(47)*. Two recipients of a single-lung transplant from a common donor had the same *M. tuberculosis* isolate as demonstrated by restriction fragment length polymorphism *(229)*. Tuberculosis involving a hepatic allograft was documented in a pediatric transplant recipient who received a living related lateral segment hepatic allograft from the mother *(230)*. Pulmonary tuberculosis was detected concomitantly in the mother who was apparently asymptomatic at the time of donation of the hepatic segmental graft.

A healthcare-associated outbreak involving 10 renal transplant patients was documented from one institution; eight of these cases were clustered within a 5-month period *(7)*. The source case was a renal transplant recipient who was exposed to tuberculosis at another hospital. Tuberculosis was not suspected in the source case on admission, thus delaying the isolation precautions. Restriction fragment length polymorphism documented transmission of *M. tuberculosis* from the index case to five renal transplant recipients. The median incubation period for tuberculosis in this outbreak was only 7.5 weeks, and death occurred in 5 of 10 patients a median of 8 weeks after diagnosis *(7)*. It is noteworthy that the exposed transplant recipients were more likely to contract tuberculosis compared with the nontransplant contacts of the source case *(7)*. Overall mortality in organ transplant recipients with tuberculosis is approximately 30% *(226)*. Disseminated compared with localized tuberculosis, prior rejection, and OKT3 receipt were significant predictors of mortality in transplant recipients with tuberculosis.

All transplant recipients should have a tuberculin skin test administered before transplantation unless they had a history of tuberculosis or previous positive test (231,*232*). Isoniazid prophylaxis should be considered for the transplant recipients with the characteristics outlined in Table 58-3 regardless of the tuberculin skin test reactivity. Isoniazid chemoprophylaxis initiated during liver transplant candidacy was safe and effective in one study *(233)*. Rifampin is alternative to isoniazid; however, its interaction with calcineurin inhibitors usually precludes its use posttransplant *(234)*. Other reports recommend that chemoprophylaxis for latent tuberculosis be deferred until after transplantation. Tuberculin skin test reactivity *per se* is a controversial indication for prophylaxis in transplant recipients. The rate of tuberculosis among skin-test positive liver transplant candidates and recipients who receive no chemoprophylaxis has been estimated to be 1,585.3 cases per 1,000,000 person-years *(235)*. Tuberculosis has been documented in up to 2% of the tuberculin skin-test–negative liver transplant recipients *(236)*. It has been proposed that clinical or radiographic evidence of previous tuberculosis may more reliably identify high-risk patients as compared with the tuberculin skin test result. Although the interferon-gamma release assay has been used as an alternative in immunocompetent patients *(237)*, its utility in solid organ transplant recipients has not been tested extensively.

TABLE 58-3

Indications for Chemoprophylaxis with Isoniazid in Organ Transplant Recipients

I. Tuberculin skin reactivity ≥5 mm before transplantation
II. Patients with the following characteristics, regardless of tuberculin skin test reactivity:
    1. Radiographic evidence of old active tuberculosis and no prior prophylaxis
    2. Prior history of inadequately treated tuberculosis
    3. Close contact with an infectious case
    4. Receipt of an allograft from a donor with a history of tuberculosis or tuberculin reactivity
III. Newly infected persons (recent tuberculin skin test converters)

Legionella

Legionellosis has been reported in 2% to 9% of solid organ transplant recipients with pneumonia; however, at certain institutions, 25% to 38% of the bacterial pneumonias have been due to *Legionella (5). Legionella pneumophila* and *Legionella micdadei* are the most common species implicated; however, *Legionella bozemanii*, *Legionella birminghamensis*, *Legionella dumoffii*, and *Legionella cincinnatiensis* have also caused infections in transplant recipients.

Inhalation of aerosols containing *Legionella* has been proposed as the mode of transmission for this microorganism. However, aspiration of water contaminated with *Legionella* is considered the most likely and underrecognized mode of transmission *(238,239)* and *Legionella*-contaminated potable water distribution systems as the predominant source of legionellosis *(5)*. Molecular fingerprinting methods have linked *L. pneumophila* infection in transplant recipients to hospital drinking water *(240)*. Ice machines *(71)* and ultrasonic humidifiers *(241)* have also been shown to be the sources of *Legionella* infection after transplantation. Pneumonia is the predominant clinical manifestation of legionellosis, although pericarditis, necrotizing cellulitis, peritonitis, hepatic allograft infection, and hemodialysis fistula infections have been reported after transplantation *(5)*. Nodular pulmonary densities and cavitation (reported in 50–70% of the pulmonary infections in some reports) are characteristic radiographic features but may not be invariably present. *Legionella* are fastidious microorganisms that do not grow on standard bacteriologic media. Selective media containing dyes and antimicrobial agents are needed for optimal growth. Urinary antigen is both sensitive and specific for the detection of *Legionella* and may also be diagnostically useful for detecting *Legionella* in body fluids (e.g., pleural fluids).

It is recommended that hospitals performing large numbers of transplants should routinely culture the hospital water supply for *Legionella,* perhaps once a year (*242*,243). If such cultures are positive, specialized *Legionella* laboratory tests, especially culture on selective media and urinary antigen tests, should be made routinely available

in the clinical microbiology laboratory. Two disinfection methods for the water supply have emerged as cost effective: superheating the water to 70°C and flushing the distal outlets or the installation of copper–silver ionization units *(244)*. Hyperchlorination is no longer recommended because of the expense, erratic efficacy, corrosive damage to the piping, and the carcinogenic potential of ingested chlorine (see also Chapter 36).

Nocardia

Infections resulting from *Nocardia* species may occur in 0.6% to 4% of organ transplant recipients; the median time to the onset of nocardiosis after transplantation ranges between 2 and 8 months. Nocardiosis most commonly occurs in lung transplant recipients; the incidence was up to 3.5% in a recent large single-center study *(245)*. Pulmonary disease is the most common manifestation and central nervous system involvement occurs in 17% to 38% of these patients. Brain abscesses are usually multiple; meningitis is rare and usually associated with an abscess. An important clue to central nervous system nocardiosis is concomitant skin or subcutaneous lesions from which *Nocardia* species can be readily isolated.

Nocardia is a soil microorganism whose primary portal of entry is the lung. There is evidence to suggest that healthcare-associated transmission of nocardiosis may occur *(246–252)*. Cases of *Nocardia* infection clustered in time have been reported in renal transplant units. An epidemic strain of *Nocardia* common to the infected patients and environmental dust samples from the unit housing the patients but distinct from environmental isolates elsewhere in the hospital was documented to cause seven infections in a renal transplant and dialysis unit *(252)*. Respiratory isolation of the cases of nocardiosis during outbreaks has been recommended by some *(249,252)*. There was an outbreak of *N. farcinica* surgical site infection that was traced to a colonized anesthesiologist *(247)*. Trimethoprim-sulfamethoxazole used as prophylaxis for PJP is also effective against nocardiosis; however, breakthrough infections particularly among solid organ recipients receiving low-dose trimethoprim-sulfamethoxazole have been reported *(245)*.

FUNGAL INFECTIONS

Aspergillus

Invasive aspergillosis remains a devastating fungal infection in all types of transplant recipients (253,*254*). It has, however, unique clinical characteristics and risk factors in different types of solid organ transplant recipients.

Epidemiology

Lung Transplantation Lung transplant recipients are more likely than other solid organ recipients to develop infection with *Aspergillus*. Up to 23% of lung transplant recipients develop invasive aspergillosis *(255)*. Risk factors for *Aspergillus* infection after lung transplantation include CMV infection, single-lung transplantation *(256)*, relative ischemia at the anastomosis *(257)*, hypogammaglobulinemia *(258)*, colonization of the airways with *Aspergillus (259,260)*, and placement of a bronchial stent *(261)*. Most cases of invasive aspergillosis in lung transplant recipients occur within the first 9 months posttransplantation. A unique form of invasive aspergillosis occurring in lung transplant recipients is ulcerative tracheobronchitis, which usually occurs in the first 2 to 3 months.

Liver Transplantation The incidence of invasive aspergillosis in liver transplant recipients ranges from 1% to 8% *(254,262–265)*. The infection was most often diagnosed between 2 and 4 weeks after transplantation; however, it has recently been shown that the infection occurs in the late posttransplant period *(125)*. Indeed, 55% of the infections now occur after 90 days of transplantation. Advance in surgical technique, antifungal prophylaxis practice, and delayed onset of CMV infection are proposed as possible explanations. A poorly functioning hepatic allograft and renal insufficiency, particularly the requirement for hemodialysis, are considered important risk factors for invasive aspergillosis in liver transplant recipients. Approximately 25% of the cases of invasive aspergillosis in liver transplant recipients occur after retransplantation *(263)*. Rarely, the *Aspergillus* infection is confined to the surgical site (producing necrotizing fasciitis) or intra-abdominal sites in liver transplant recipients.

Heart Transplantation Invasive aspergillosis occurs in 1% to 14% of heart transplant recipients *(266)*. The median time to development of invasive aspergillosis in these patients is 1 to 2 months. Most infections originate in the lungs, and 20% to 35% disseminate to other organs.

Renal Transplantation Invasive aspergillosis has been reported in 0.7% to 4% of the patients undergoing renal transplantation *(266–268)*. Cases of invasive aspergillosis in renal transplant recipients have usually been pulmonary infections and occasionally disseminated disease. Augmented immunosuppression and graft failure requiring hemodialysis are risk factors for invasive aspergillosis in renal transplant recipients.

Diagnosis Early diagnosis is critically important in reducing the mortality from invasive aspergillosis. *Aspergillus* can be cultured from sputum in only 8% to 34% and from bronchoalveolar lavage fluid in 45% to 62% of patients with invasive pulmonary aspergillosis *(269)*. Respiratory cultures, therefore, may not detect aspergillosis before significant vascular invasion has occurred. Furthermore, a positive culture with *Aspergillus* may indicate colonization. Serum galactomannan assay, however, may potentially be more useful. It has been shown to have a sensitivity of 50% to 90% and specificity of 81% to 93% for the diagnosis of invasive aspergillosis *(269–271)*. Furthermore, the galactomannan assay may be positive as long as 28 days before clinical and radiographic signs of invasive aspergillosis become apparent *(270)*. The efficacy of the galactomannan assay may be improved significantly by using a bronchoalveolar lavage specimen *(272,273)* with sensitivity of 67% to 100% and specificity of 91% to 98%. High-resolution thoracic computed tomography (CT) may be able to raise the index of suspicion for invasive pulmonary aspergillosis soon after the development of symptoms and before culture results are available. Such imaging in neutropenic patients

whose fever persisted for more than 2 days despite empiric antibiotic treatment showed findings highly suggestive of invasive pulmonary aspergillosis 5 days earlier than the use of chest roentgenograms *(274)*.

Prevention and Prophylaxis Outbreaks of aspergillosis have been linked to construction activity within or near a transplant unit and to contaminated or poorly maintained ventilating ducts, grids, and air filters. Outbreaks associated with construction activity in bone marrow transplant recipients have been curtailed by use of laminar air flow units with HEPA filtration. Not all solid organ transplant recipients require antifungal prophylaxis. Current recommendation is to administer antifungal agents to high-risk patients only such as lung transplant recipients and high-risk liver transplant recipients (253). Targeted prophylaxis with a lipid formulation of amphotericin B and echinocandins has proven effective for high-risk liver transplant recipients *(275–277)*, and itraconazole or voriconazole are commonly used for antifungal prophylaxis following lung transplantation. Some centers employ aerosolized lipid polyenes in lung transplant recipients, which limit systemic exposure to the drug, and therefore, fewer adverse effects; however, unequal distribution to the native lung in case of single-lung transplantation and lack of efficacy for systemic fungal infections are concerning *(278)*.

Candida

Invasive candidiasis is the most frequent fungal infection in solid organ transplant recipients *(88,279)*. The incidence of *Candida* infections is highest in liver transplant recipients. Virtually all *Candida* infections are healthcare-associated although the source may vary depending on the type of organ transplant recipients. Whereas in liver transplant recipients candidiasis results from endogenous (generally gut) colonization, donor organs are the potential source in heart–lung and lung transplant recipients. Karyotypic analysis has demonstrated *Candida* infection originating in the donor lung as a cause of disseminated disease in a lung transplant recipient *(63)*.

In the earlier studies in liver transplant recipients, 15% to 20% of the patients were documented to have invasive candidiasis *(264,280)*. Intra-abdominal infections, with or without subsequent dissemination, are the usual clinical manifestations. Prolonged operation time, retransplantation, greater transfusion requirements, high serum creatinine, and CMV infection were the proposed risk factors for *Candida* infections (Table 58-2). More recently, however, many transplant centers have documented a decline in the incidence of invasive candidiasis, even in the absence of specific antifungal prophylaxis *(73,124,164,211,213,281)*. More conservative immunosuppression but, more importantly, improvement in surgical technique likely accounts for this decline. After pancreatic transplantation, *Candida* infections occur in 15% to 30% of the patients and manifest predominantly as surgical site or bloodstream infections. The incidence of infections was almost twofold higher for enteric-drained than for bladder-drained pancreatic transplantations *(282)*. In heart–lung or lung transplant recipients, the clinical pattern of *Candida* infections may range from tracheobronchitis to systemic invasive disease. Invasive candidiasis in these patients may also result in anastomotic dehiscence, mediastinitis, and mycotic aneurysm. The anastomotic site is particularly vulnerable because of poor blood supply and the presence of suture material. Invasive bronchial infection can then result in breakdown of the anastomosis. In kidney transplant recipients, candiduria occurs in 11% of these recipients *(283)*. Although asymptomatic candiduria is typically treated with antifungal agents, little evidence exists to support this practice. Persistent symptomatic candiduria warrants imaging studies to exclude the possibility of fungus ball and abscess.

The precise patient population to be targeted, optimal regimen, and duration of antifungal prophylaxis for *Candida* remains controversial. Currently, fluconazole is commonly used for prophylaxis at many liver, pancreatic, and small-bowel transplant centers *(284)*. In liver transplant recipients, it is common practice to administer antifungal prophylaxis using fluconazole in patients at risk for developing invasive candidiasis. High-risk recipients are defined those with ≥2 of the following factors: choledochojejunostomy anastomosis, preoperative renal insufficiency, retransplantation, administration of at least 40 units of cellular blood products, early abdominal reexploration for bleeding or graft dysfunction, and perioperative colonization with *Candida* species *(264)*. Low-risk recipients do not require antifungal prophylaxis. Only 2% of these patients developed invasive candidiasis that could be preventable by fluconazole in a prospective observational study *(285)*. In lung transplant recipients, given the relatively high incidence of invasive pulmonary aspergillosis and rarity of invasive pulmonary candidasis, antifungal prophylaxis should be targeted toward the prevention of aspergillosis. The risk of invasive candidiasis is considered too low to warrant prophylaxis in kidney or heart transplant recipients. A major concern with routine azole antifungal prophylaxis is the emergence of azole-resistant *Candida* species *(286)*. Azole-resistant invasive *Candida glabrata* infection occurred in 4% (4/101) of the liver transplant recipients receiving fluconazole prophylaxis and was the direct cause of death in one patient *(286)*. The routine use of fluconazole is expected to have the potential of selecting fungi innately resistant to fluconazole (e.g., *Aspergillus*).

Pneumocystis jirovecii

P. jirovecii has long been classified as a protozoan microorganism on the basis of morphologic features and lack of growth on fungal media. However, gene sequencing of *P. jirovecii* suggests that the microorganism is indeed a fungus.

Lung transplant recipients are at greatest risk of developing pulmonary infection with *P. jirovecii*; in the absence of prophylaxis, PJP may develop in up to 80% of the patients *(287)*. Not all of these patients, however, are symptomatic. Up to 40% of the lung transplant recipients have been shown to have normal chest radiographs, be asymptomatic, and have the microorganism detected on routine posttransplant bronchoscopy. Several factors may account for the high incidence of *P. jirovecii* infection in lung transplant recipients. First, local defense mechanisms are impaired as a result of lung denervation. Second, it has been hypothesized that an incompatibility exists between the immune effector cells and parenchymal cells in the

allograft lung. Infiltrating lymphocytes and mononuclear phagocytes recruited to the infected allograft are derived from the recipient and, therefore, express different MHC antigens than do the donor-derived parenchymal cells *(102)*. Finally, surveillance bronchoscopy may increase the chance of early detection of occult infection. *P. jirovecii* infection in lung transplant recipients usually occurs in the fourth month after transplantation. Up to 25% of the cases may occur more than a year after transplant; these patients had usually received more intense immunosuppressive therapy.

The incidence of infection with *P. jirovecii* in patients not receiving PJP prophylaxis is 2% in renal transplant recipients, 5% in heart, and 9% in liver transplant recipients. Most infections occur between 3 and 6 months after transplantation. Between 10% and 20% of the cases occur >6 months posttransplantation, usually in those receiving augmented immunosuppression for rejection *(219)*. Other risk factors for PJP include use of corticosteroids and antilymphocyte therapy (e.g., alemtuzumab) *(288,289)*, CMV infection *(29)*, allograft rejection *(290)*, and low CD4 count (291). Mycophenolate mofetil has been shown to have *in vitro* activity against *P. jirovecii*; however, this has not been confirmed in human studies *(292)*.

Unlike HIV-infected patients, PJP in transplant recipients is rarely diagnosed by examination of an induced sputum sample. Virtually all cases require bronchoalveolar lavage for diagnosis. Coinfection with CMV or bacteria (especially in lung transplant recipients) is common.

Prophylaxis with oral trimethoprim-sulfamethoxazole has proven highly efficacious and is recommended for all transplant recipients *(293,294)*. The recommended dose is either 160/800 mg (double-strength) daily or every other day, or 80/400 mg (single-strength) daily.

A more controversial issue in prophylaxis of *P. jirovecii* infection in transplant recipients is the duration of prophylaxis. The duration of prophylaxis should be based on the type of allograft, immunosuppressive regimen (e.g., corticosteroid, antilymphocyte agents), and other risk factors (e.g., CMV infection, rejection) for *P. jirovecii* infection. The risk of *P. jirovecii* infection is the highest in the first 6 months posttransplant regardless of the type of allograft, and it declines substantially after this period. Prolonged or lifelong prophylaxis may be indicated in lung or small-bowel transplant recipients and any organ recipients with those risk factors *(294)*. An additional advantage of trimethoprim-sulfamethoxazole prophylaxis is that it is also effective against other microorganisms such as *Nocardia, Listeria, Toxoplasma,* and *Legionella* in transplant recipients, and the majority of transplant centers offer life-long prophylaxis unless an adverse effect is concerning.

Nebulized pentamidine, dapsone, and atovaquone are alternative prophylactic agents in patients intolerant of trimethoprim-sulfamethoxazole. Breakthrough infections, however, have been reported in such patients. Neither drug has significant interactions with cyclosporine or tacrolimus.

Cryptococcus neoformans

The incidence of cryptococcosis in organ transplant recipients ranges from 0.3% to 5.0% *(295)*. The infection usually develops in the late period after transplantation: the median time to onset was 21 months and some cases are detected 4 or more years after transplantation *(296)*. Cryptococcosis is considered to be a reactivation of latent disease; however, primary infection or transmission from donor organs may occur *(297–299)*. Given the low incidence of cryptococcosis in transplant recipients and the delayed and often unpredictable time of onset after transplantation, primary antifungal prophylaxis is not usually considered necessary in transplant recipients.

Endemic Mycosis (Histoplasmosis, Coccidioidomycosis, and Blastomycosis)

Histoplasmosis has been infrequently reported in transplant recipients. In endemic regions, 0% to 0.4% of transplant recipients developed histoplasmosis *(300,301)*. The prevalence of disseminated histoplasmosis rose to 2.1% during an outbreak associated with construction activity near a hospital in Indianapolis (302). The median time to onset is 17 months after transplantation *(300)*. The modes of infection include primary acquisition from inhalation, reactivation of latent disease, and infected allografts *(55,303)*. Disseminated disease occurs in more than 75% of the transplant recipients developing histoplasmosis. Culture of *H. capsulatum* remains the gold standard of diagnosis but is often delayed. The antigen detection using serum and/or urine has proven useful in providing a more rapid diagnosis of histoplasmosis in transplant recipients *(300)*, despite lower sensitivity compared with AIDS patients *(304)*. Given the low incidence of posttransplant histoplasmosis, pretransplant screening for prior histoplasmosis and secondary prophylaxis is not currently recommended *(305)*.

Coccidioidomycosis in transplant recipients has been described predominantly from the centers in Arizona and southern California. The risk of overt infection in solid organ transplant recipients in Arizona is about 3% per year, with an overall prevalence of 4.5% for heart transplant recipients *(306)* and 6.9% for renal transplant recipients *(307)*. In liver transplant recipients in Los Angeles, 0.6% of patients developed overt coccidioidomycosis *(308)*. The usual time to onset is 2 to 6 months posttransplant *(306–308)*. However, cases have also been reported in the first 4 weeks posttransplantation. Sometimes, this early infection may manifest as fever, a sepsis-like syndrome, or an aggressive pneumonia *(308)*. A subacute presentation occurring several to many months after transplantation, however, is a more common finding. Some patients have disseminated disease with arthritis, meningitis, or skin lesions *(309)*.

Transplant candidates who reside in or travel to endemic areas should be screened for coccidioidomycosis before transplantation. Patients at high risk of developing coccidioidomycosis posttransplant include those with detectable titers of coccidioidal antibodies on complement fixation tests, those with radiographic evidence of prior pulmonary infection, and those with a history of active coccidioidomycosis. Prophylactic fluconazole (400 mg/day) should be considered for these patients posttransplant *(305,310)*.

Blastomycosis is rarely reported in transplant recipients and its incidence was 0.14% in one study *(311)*. Given its low incidence and the lack of a sensitive screening test, pretransplant screening is currently not recommended *(305)*.

Mucormycosis

The incidence of mucormycosis complicating organ transplantation ranges between 0.3% and 5% *(312)*. The usual time to onset is 5 months after transplantation (interquartile range, 6 weeks to 12 months) *(313)*. Most cases are due to *Rhizophus* and *Mucor* species. Pulmonary disease has been observed in 48% of the cases and is the most common clinical presentation. Mucormycosis can be healthcare-associated; the usual portal of entry is believed to be pulmonary. Adhesive bandages have been incriminated as a source of surgical site infections in transplant recipients.

PROTOZOAL INFECTIONS

Toxoplasma gondii

Heart transplantation poses the highest risk for transmission of *T. gondii* because of the parasite's predilection to invade muscular tissue. Fifty percent to 75% of seronegative recipients of seropositive cardiac allografts may develop primary *T. gondii* infection *(48). T. gondii* infections are distinctly unusual in noncardiac transplant recipients *(314)*.

Most symptomatic infections occur within 3 months of transplantation. Meningoencephalitis, brain abscess, myocarditis, and pneumonitis are the usual clinical manifestations. Demonstration of tachyzoites in tissue sections establishes the diagnosis of acute infection. An immuno-peroxidase stain is both sensitive and specific. Significant changes in antibody titer may not occur in transplant recipients with acute toxoplasmosis. Conversely, a rise in IgM and IgG titers is frequent after heart transplantation without evidence of clinical disease. Modalities for posttransplant prophylaxis in heart transplant recipients were discussed earlier in this chapter.

APPROACH TO MAJOR HEALTHCARE-ASSOCIATED INFECTIONS IN TRANSPLANT RECIPIENTS

Pulmonary Infiltrates

Pulmonary infiltrates, including those resulting from pneumonitis, remain a serious and frequently encountered complication in transplant recipients. In heart transplant recipients, pulmonary infections have been documented in 28% to 40% of patients (*2,212*). Fifty-one percent (36/71) of all pulmonary infections in heart transplant recipients in one report were healthcare-associated in origin; 32% (23/71) were opportunistic, and only 17% (12/71) were community acquired. The latter usually occur in the late posttransplant period (>1 year) (2). Nearly one half of all pneumonias in these patients are bacterial in origin. Prolonged intubation, reintubation, and high-dose corticosteroids were significant risk factors for pneumonia in heart transplant recipients.

The differential diagnosis of pulmonary infiltrates in lung and heart–lung transplant recipients, among other entities, includes acute rejection. Acute rejection may develop in up to 60% of these patients, and most of these episodes occur within the first 3 months. Bronchiolitis obliterans is a significant late-occurring complication in lung transplant recipients. Rejection and/or infection, particularly resulting from CMV, are proposed to be the leading risk factors.

After liver transplantation, pneumonia occurs in 13% to 34% of patients. Forty-four percent of the liver transplant recipients requiring intensive care unit admission developed pulmonary infiltrates in one study; pulmonary edema (40%), pneumonia (38%), atelectasis (10%), and acute respiratory distress syndrome (8%) were the documented causes *(315)*. Acute respiratory distress syndrome has been reported in 5% to 17% of liver transplant recipients. Large-volume transfusions, liver failure, retransplantation, and sepsis are considered factors predisposing to acute respiratory distress syndrome in these patients *(315)*. Bacteria account for 40% to 67% of all pneumonias in liver transplant recipients. In the earlier reports, viral pneumonitis (CMV or HSV) was documented in 15% to 20% of the pulmonary infections. This incidence, however, has declined to <5% in the more recent reports *(234)*. Pneumonias are less common after renal transplantation (occurring in 8% to 16% of the patients) but are nevertheless a significant complication in these patients.

Healthcare-associated bacterial pneumonitis is the predominant cause of pneumonia in all types of solid organ transplantation, particularly in the first month after transplantation; *P. aeruginosa,* Enterobacteriaceae, and *S. aureus* are the bacteria usually implicated. Legionellosis has been reported in 2% to 9% of solid organ transplant recipients with pneumonia *(5)*. After the first month, opportunistic pathogens emerge as the etiology of pneumonia. Fungal pneumonias in transplant recipients are predominantly due to invasive aspergillosis. Although isolation of *Candida* species from respiratory cultures is common, *Candida* pneumonitis is a rare entity *(63)*. It may present as tracheobronchitis in lung transplant recipients. Other less frequent causes of pulmonary infection include cryptococcosis, mucormycosis, coccidioidomycosis, histoplasmosis, nocardiosis, and infections due to dematiaceous fungi. CMV and to a lesser degree HSV account for most cases of viral pneumonitis. Whereas 5% to 20% of renal, liver, and heart transplant patients develop CMV pneumonitis, the incidence in heart–lung and lung transplant recipients is higher and ranges from 10% to 50%. It is believed that the host immune response is more important for the development of CMV pneumonitis than viral replication is *(29)*. Pneumonia resulting from RSV generally occurs in pediatric patients and may occur 3 weeks to 2 years after transplantation. Up to 20% to 50% of the cases of RSV are healthcare associated. Early identification and isolation of cases, however, is crucial to prevent healthcare-associated spread.

Given the diversity of likely causes and the immunosuppressive state in transplant recipients, early and aggressive pursuit of the etiology of pulmonary infection with initiation of broad-spectrum antibiotics are warranted. Although the radiographic appearance of the lesion is never diagnostic, a number of entities may have distinctive or suggestive radiographic characteristics. Nodular pulmonary infiltrates of infectious etiology in liver transplant recipients were most frequently due to *Aspergillus* or *Cryptococcus* in one study *(316)*. However, *S. aureus, Nocardia,* tuberculosis, PJP, CMV, mucormycosis, *Bartonella henselae,* and coccidioidomycosis may present similarly in

transplant recipients. Noninfectious causes of pulmonary nodules include metastatic carcinoma, pulmonary calcification, and lymphoproliferative disorders. Pulmonary infarcts, rounded atelectasis, and pulmonary varix in cardiac transplant recipients and acute or chronic rejection in lung transplant patients may have a nodular appearance. Cavitary pneumonia in transplant recipients may be due to *Aspergillus, Cryptococcus, Nocardia, Legionella, M. tuberculosis, Rhodococcus equi,* or other fungi.

CT offers a number of advantages over conventional radiographs, including detection of additional lesions, precise morphology of the lesion, and delineation of mediastinal lymphadenopathy. Bacterial pneumonia presents more focal features compared with viral or pneumocystis pneumonia *(317)*. CT in patients suspected of having aspergillosis has often revealed lesions that appeared nonspecific or were not visualized on routine x-ray examination.

Isolation or detection of *Legionella, Nocardia, Cryptococcus, M. tuberculosis,* or *P. jirovecii* in the sputum or respiratory secretions is diagnostic of pulmonary infection resulting from these pathogens. However, smears and cultures of sputum or respiratory secretions may be diagnostic in fewer than 50% of patients. In a patient with focal air space disease and nondiagnostic noninvasive tests, the choice lies between empiric antibacterial therapy or a diagnostic procedure; we recommend early bronchoscopy with bronchoalveolar lavage. In patients with focal nodular infiltrates, percutaneous needle aspiration is superior to bronchoalveolar lavage with a diagnostic accuracy of 70% to 90%. In patients with diffuse pulmonary infiltrates, bronchoalveolar lavage with or without transbronchial biopsy is the preferred approach. Transbronchial biopsy is particularly valuable for the diagnosis of rejection in lung transplant recipients and for the differentiation of allograft rejection and CMV pneumonitis in these patients. Open lung biopsy should be reserved only for patients with progressive disease refractory to antimicrobial agents in whom bronchoalveolar lavage or percutaneous needle aspiration is nondiagnostic.

Healthcare-Associated Bacteremias

Although the incidence of bacteremia may vary, identifiable portals of entry and defined pathogens exist for most solid organ transplant recipients with bacteremia. The frequency of bacteremia varies from 5% to 10% in kidney, 8% to 11% in heart, 8% to 25% in lung, 5% to 20% in pancreatic, and 10% to 25% in liver transplant recipients *(318,214,319–322*). Ninety-four percent (75/80) of all bacteremias in liver transplant recipients, 56% (15/27) in renal transplant recipients, and 78% (13/18) in heart transplant recipients were healthcare-associated in one study *(318)*. Besides catheter-related infections, pneumonia in heart and heart–lung transplant recipients, urinary tract infections in renal transplant recipients, abdominal and biliary infections in liver transplant recipients, and surgical site and urinary tract infections in pancreatic transplant recipients have been shown to be the most common identifiable sources of bacteremia *(214,318)*. Aerobic gram-negative bacilli constituted 48% to 62% of the bacteremic isolates in renal transplant recipients, 44% to 49% in liver transplant recipients, 39% to 41% in heart transplant recipients, and 17% to 52% of lung transplant recipients *(318,320,322)*. *E. coli, Acinetobacter baumanii, P. aeruginosa*, *Klebsiella species,* and other Enterobacteriaceae were the predominant gram-negative bacteria *(320)*.

The sources and pathogens causing bacteremias in transplant recipients appear, however, to have undergone a striking evolution in the recent years. Many transplant centers documented the emergence of gram-positive cocci (enterococci and staphylococci) as foremost pathogens in transplant recipients in the mid-1990s *(215)*. However, the proportion of gram-negative bacteremias doubled from 25% in 1989 to 1993 to 52% in 1998 to 2003 in one center *(323)*. Within the hospital, intensive care units are the most common site of acquisition of healthcare-associated bacteremias. Ninety-three percent of the bacteremias in one report were healthcare-associated, and 52% occurred in the intensive care unit setting *(215)*. Indeed, intensive care unit stay has been shown to be an independent predictor of bacteremic compared with nonbacteremic infections in liver transplant recipients *(87)*. Patients developing bacteremia in the intensive care unit were also more likely to die than those not in the intensive care unit *(87)*; this likely reflected the greater severity of illness of the patients hospitalized in the intensive care unit. A recent study also confirms that septic shock and the need for mechanical ventilation, common factors for ICU stay, were independently associated with mortality *(320)*.

In small-bowel transplant recipients, 72% of patients had at least one episode of bloodstream infection *(119)*. Intravascular catheters accounted for 43% of these infections and were the most frequently identifiable portal of entry. Sixty-two percent of all bloodstream infections were due to gram-positive bacteria *(119)*. In another report, 45% of all bacterial infections and 72% of all bacteremias after small-bowel transplantation were due to staphylococci *(121)*.

Most VRE infections originate from an abdominal or biliary source; 38% to 68% of these infections have been associated with bacteremia *(221,224)*. Vancomycin resistance was an independent predictor of mortality in liver transplant recipients with enterococcal bacteremia *(221)*. A noteworthy observation is the predilection of VRE to cause endovascular complications, including mycotic aneurysms and endocarditis *(221)*. Delayed metastatic complications, including endocarditis and osteomyelitis, have also been documented in transplant recipients with MRSA bacteremia. Prophylaxis and infection control measures pertinent to these infections are discussed in the sections on staphylococci and enterococci.

Intra-Abdominal Infections

Intra-abdominal abscesses, peritonitis, and biliary infections are a significant complication after liver transplantation. Intrahepatic abscesses usually occur within 30 days of transplantation; technical problems involving the implanted allograft (e.g., hepatic artery thrombosis, biliary leak, and, rarely, tear of the donor liver) are the primary risk factors. Nearly one half of patients with intrahepatic abscesses may be bacteremic *(89)*. Peritonitis after liver transplantation is typically related to biliary anastomotic leaks or, less frequently, bowel perforation *(89)*. Aerobic enteric gram-negative bacteria, enterococci, anaerobes, and, *Candida* species are the causal pathogens in most

intra-abdominal abscesses and peritonitis. An unusual cause of abdominal abscesses in liver transplant recipients is *M. hominis*.

Cholangitis has been documented in 4% to 15% of patients after liver transplantation, with most episodes occurring within 30 days of transplantation. Biliary strictures and biliary leaks are significant predisposing risk factors. Enterococci are characteristically the most common pathogen, whereas anaerobes are encountered rarely. Biliary strictures (e.g., in patients with primary biliary cirrhosis and in those with previous bile duct surgeries) often necessitate Roux-en-Y anastomosis, which is associated with a high rate of intrahepatic and biliary complications. Sterile intra-abdominal fluid collections are common after liver transplant surgery. Diagnosis of peritonitis or abscess, thus, requires percutaneous or open drainage and culture. Cultures from abdominal drains often reflect colonization and are not reliable in diagnosing the infection or its etiology.

Central Nervous System Mass Lesions

Although mild neurologic complications may occur in 10% to 47% of organ transplant recipients, 1% to 8% of such patients have major neurologic sequelae or central nervous system lesions. Brain abscesses are among the most serious central nervous system lesions in these patients *(324)*. The frequency of brain abscesses was 0.36% in kidney, 0.63% in liver, and 1.17% in heart and heart–lung transplant recipients *(325)*. Most brain abscesses in solid organ transplant recipients are fungal and represent a healthcare-associated complication *(324,325)*. Although *Aspergillus* is the most common cause of brain abscesses in organ transplant recipients, less frequently encountered fungal pathogens include *Mucorales, Candida* species, and dematiaceous fungi. Central nervous system lesions resulting from *T. gondii* have been reported mainly in heart transplant recipients.

Selby et al. *(325)* showed that two distinct groups of solid organ transplant recipients existed with regard to timing and susceptibility to brain abscesses. One group, comprising predominantly liver and renal transplant recipients, developed brain abscesses a median of 24 days post-transplant. Ninety-five percent of these patients were in the intensive care unit and were ventilator dependent; brain abscesses in this setting were exclusively fungal. In the second group, abscesses developed a median of 264 days after transplantation, occurred almost exclusively in heart transplant recipients, and were due to *T. gondii* and *Nocardia*.

Most patients (up to 75%) with fungal brain abscesses have been shown to concurrently have pulmonary lesions resulting from the same fungus *(324)*. A brain biopsy may not be required in such cases.

In the absence of an extraneural focus, brain biopsy should be considered, given the diversity of causal fungal pathogens in such lesions *(324)*.

CONCLUSIONS

Improvement in surgical techniques, the advent of modern immunosuppressive drugs, the availability of rapid and reliable diagnostic modalities, and effective prophylaxis against a number of pathogens have undoubtedly led to a decrease in infectious morbidity and improved outcome in transplant recipients in recent years. Increasing documentation of the emergence of antimicrobial resistance in several key pathogens in transplant recipients, however, is worrisome. Strategies for antimicrobial prophylaxis must comprise approaches that are not only efficacious but minimize the emergence of resistance. Finally, for therapy and prevention to be effective, classic opportunistic infections typically encountered in these patients must be considered, and the emerging trends in new infectious agents and the changing epidemiology of these complicating infections must be understood.

CHAPTER 59

Infection Prevention and Control in Hematopoietic Stem Cell Transplant Patients

Leilani Paitoonpong, Dionissios Neofytos, Sara E. Cosgrove, and Trish M. Perl

BASIC CONCEPTS OF HEMATOPOIETIC STEM CELL TRANSPLANTATIONS

Bone marrow or hematopoietic stem cell transplantation (HSCT) is a lifesaving therapy for many malignancies and genetic or acquired hematologic syndromes. Worldwide, over 25,000 allogeneic and 30,000 autologous HSCTs were performed in 2009 (1). HSCTs are the transfer of hematopoietic stem cells from one individual to another (allogeneic HSCT) or the return of the previously harvested cells to the same individual (autologous HSCT) (1). HSCT is used in the treatment of numerous conditions, including hematologic and other malignancies and nonmalignant disorders (i.e., bone marrow failure syndromes, congenital immunodeficiencies, enzyme deficiencies, and hemoglobinopathies) (1,*2*). Prior to transplantation, the recipient's own marrow is fully or partially ablated to allow the engraftment of new bone marrow (1,*2*). Recipients receive a conditioning regimen that usually includes high-dose chemotherapy with or without total body radiation. After the conditioning regimen is completed, the graft is infused. At this point, the host is usually granulocytopenic and the peripheral neutrophil count has reached its nadir. The patient remains granulocytopenic and profoundly immunosuppressed until the donated or reinfused stem cells engraft. The time to engraftment depends on a number of factors and usually takes 2 to 4 weeks. Recovery of marrow function is accompanied by a prolonged, progressive restoration of the recipient's immunologic competence *(*1,*2)*.

The most serious complication of allogeneic transplantation is graft versus host disease (GVHD), which occurs when immunologically competent cells target antigens on the recipient's cells *(3,4)*. The potential immunologic phenomena that accompany foreign cell transplantation are minimized by closely matching the human leukocyte antigen (HLA) of the donor and recipient *(5,6)*. In patients undergoing allogeneic HSCT, additional immunosuppression, such as cyclosporine, corticosteroids, and antithymocyte globulin, or other therapies, may be required to minimize the immunologically mediated complications, such as GVHD *(3–5,7–9)*. Some degree of GVHD is desirable, because it produces a graft versus tumor effect, which results in lower relapse rates *(10)*. GVHD occurs in acute or chronic forms and primarily affects the skin, liver, and gastrointestinal tract *(3,4)*.

High-risk HSCT for GVHD includes stem cell source (unmatched or unrelated donor–recipients), types of manipulation to the stem cells, and conditioning regimens. For instance, nonmyeloablative conditioning regimens, also known as reduced-intensity conditioning (RIC) regimens, have been increasingly used *(2,11)*. In these procedures, patients undergo less aggressive chemotherapy or immune-suppressive therapy prior to allogeneic transplant, so there is not complete ablation of the bone marrow *(11)*. This strategy decreases chemotherapy-related toxicities such as mucositis and end-organ toxicity and the ability to treat older or sicker patients. However, as the recipient's bone marrow is not fully ablated, the risk for GVHD has become a significant problem *(9,12–14)*.

The recipient serves as his own donor in autologous HSCT transplants. Bone marrow stem cells are collected prior to treatment for the underlying disease. The most serious complication of this type of HSCT is relapse of the underlying disease. Purging is a technique that eliminates malignant cells from the recovered marrow and is used to prevent this complication.

In the past, bone marrow stem cells were obtained directly from the marrow space by repeated aspiration from the iliac crest. More recently, stem cells circulating in the peripheral blood are collected as there may be more rapid engraftment and, in some studies, higher recipient disease-free survival *(15–18)*. The major limitation of allogeneic peripheral blood stem cell transplantation is the high risk of developing GVHD, since approximately a 10-fold greater number of T cells can be found in peripheral blood grafts than in the bone marrow *(19)*. Umbilical cord blood grafts, collected from the umbilical vessels in the placenta at the time of delivery, may also be used for HSCT. Umbilical cord blood graft cells are considered naïve hence associated with lower GVHD risk *(20)*. The major disadvantages of blood as the HSCT source are the limited cell dose and delayed engraftment (1,*21*).

RISK FACTORS FOR INFECTION

Risk factors for infection among HSCT recipients can be classified as endogenous, including those related to the host and recipient, and exogenous, including those related

to administered conditioning regimens and high-dose steroids for GVHD and the environment of care.

Host and Pretransplant Factors

The patients' overall state of health is often compromised at the time of transplant with a predisposition to infection from either their underlying illness or any previous treatments received *(22)*. Age considerably increases the risk of GVHD in allogeneic transplantation, and therefore the risk of infection *(23)*. The recipient's underlying disease may be associated with immune function impairment; for instance, chronic lymphocytic leukemia and multiple myeloma are associated with deficient humoral immunity *(24,25)*. The more advanced the patient's underlying disease at the time of transplant, the higher the risk of infection may be (1). The intensity of previously administered regimens may also influence the host's immunity (1).

Transplant-Related Factors

Types of conditioning regimens, transplant source, and donor–recipient matching are the major transplant-related variables that dictate the risk for infectious complications. Conditioning-related mucositis and degree or/and duration of cytopenias represent the major risk factors for infection during the pre-engraftment period. Nonmyeloablative conditioning regimens have been associated with lower infection risk compared to fully ablative regimens, in part because of shorter duration of neutropenia and less mucosal damage (26). The above observations appear most likely in the early period after HSCT. However, during the late posttransplant period, mostly correlating with GVHD, the risks for late (after engraftment) viral and fungal infections persist (26,*27*). In addition, stem cell source may impact the risk for infectious complications: lower in peripheral blood graft and higher in cord blood transplants, in part, due to slower engraftment in the latter *(28)*. The type of transplant may also affect the risk of infection: higher risk with unmatched or unrelated allogeneic (in part due to higher risk for GVHD and associated treatments) and lower risk with autologous or matched related allogeneic HSCT (1). Stem cell manipulation, such as T-cell depletion, may lead to higher rates of infections (1,*29–31*).

Environmental Factors

During the preparative and early posttransplant periods, HSCT recipients are usually hospitalized; hence, the hospital environment represents a major potential source for infections. The source can be related to the facility and the physical environment, the care provided including treatments and equipment, and personnel, visitors, and other human interactions.

Based on serial surveillance cultures and cultures from normally sterile body sites obtained over a 2-year period among patients with acute myeloid leukemia, most infections developed from the patients' endogenous flora; however, 47% of patients became colonized with healthcare-associated microorganisms *(32)*. Ultimately, 39/43 (91%) patients who developed bacteremia were colonized with the implicated microorganism prior to developing a bloodstream infection *(32)*.

Healthcare workers' hands are another potential source of microorganisms. Schimpff et al. *(32)* found that the hands of 43 out of 126 (34%) healthcare workers caring for leukemic patients were colonized with gram-negative microorganisms or *Staphylococcus aureus*. Hands can become contaminated by lotions or contaminated soaps *(33)*. For example, 12 of 25 (48%) HSCT recipients became colonized or infected (9 of 25; 36%) with *Paecilomyces lilacinus* after exposure to a contaminated, pharmaceutically prepared skin lotion *(34)*. Healthcare workers and other patient contacts transmit microorganisms in other ways. Contact with such infected or colonized visitors and staff, many of whom may be asymptomatic, increases the risk of respiratory viral infections. Clearly, the season of the year the patient receives their HSCT and transplant-related care would dictate the risk of developing these infections *(35–38)*.

Treatments and the environment can also lead to infections in this population. For instance, institutional water is a potential source of microorganisms such as gram-negative rods, *Pseudomonas* species, *Legionella* species, and *Mycobacterium* species and fungi *(39–45)*.

At another institution, seven of eight immunocompromised patients developed *Pseudomonas aeruginosa* septicemia *(46)*. The microorganism was also isolated from mouthwash used by the patients, the water, and two sinks *(46)*.

One outbreak of *Stenotrophomonas maltophilia* infections among allogeneic HSCTs was linked to a single room on the unit, although no source was found *(47)*.

Heating and air conditioning systems can aerosolize and facilitate the spread of *Aspergillus conidia.* Arnow et al. *(48)* demonstrated that the mean concentration of *A. fumigatus* and *A. flavus* spores in the air correlated with the incidence of invasive aspergillosis (IA). When the *Aspergillus* concentration was 0.02 colony-forming units (CFU)/m^3 of air, the incidence of invasive *Aspergillus* infections among high-risk patients was 0.3% *(48)*. However, when the *Aspergillus* concentration rose to 1.1 to 2.2 CFU/m^3 of air, the incidence of *Aspergillus* infections among high-risk patients rose to 1.2% *(48)*. Notably, it is not entirely clear what the minimum concentration of *Aspergillus* spores in the air is to cause disease. Rhame et al. *(49)* reported that 5.4% of HSCT recipients developed IA when the mean concentration of *A. fumigatus* was 0.9 CFU/m^3. Sherertz et al. *(50)* did not identify any cases of IA when 0.0009 CFU/m^3 of *Aspergillus* was measured in air samples. Thio et al. (51) noted that air samples obtained on units that house high-risk patients must be obtained using appropriate high-volume samples. Multiple outbreaks of *Aspergillus* infection reported in the literature have illustrated the risks associated with construction and/or renovation and suboptimal maintenance, cleaning, and protection of the environment. Patients housed outside of a high-efficiency particulate air (HEPA)-filtered laminar airflow environment are at a 10-fold higher risk for developing healthcare-associated *Aspergillus* infection *(50)*.

By the time HSCT recipients return home, their immune systems have been partially reconstituted, although environmental sources remain an ongoing potential source of infection. Clearly, the variety of exposures and variables makes it very difficult to study the effect of environmental factors for an infection after discharge. Prospective, well-designed studies are required to be able to make any further conclusions.

Risk Periods of Infectious Complications

The risk periods for infectious complications are traditionally divided into pre- and postengraftment. The former includes the time from initiation of the conditioning regimen to the infusion of the transplant and extends through engraftment. The latter starts from engraftment and is commonly divided into the early (up to 100 days after HSCT) and late phases (>100 days after HSCT).

Pre-Engraftment Host Risks

The major risk factors during the pre-engraftment period include mucositis and neutropenia associated with the administered chemotherapy and skin breakdowns from central venous catheters (1). Infections appear at a median of 6 days after the transplant, with 10% of the infections occurring in the pretransplant period *(52)*. During this early period after HSCT, most patients develop neutropenic fever and 35% to 71% of patients may develop an infection, with an estimated overall infection rate during this period of 18 infections per 1,000 patient days *(52–54)*. Engels et al. *(54)* reported that 30% and 55% of autologous and allogeneic HSCT recipients, respectively, developed infections during the early phase of HSCT ($p < .01$), and the risk of infection correlated with the severity of neutropenia. Among 35 autologous HSCT recipients with early infectious complications, the following factors were found to be independent mortality predictors: male gender, total body irradiation, low pretransplant albumin, and mucositis or diarrhea *(53)*.

Neutropenia Innate immunity is disrupted early in HSCT manifested primarily by the conditioning-associated neutropenia that occurs in the immediate posttransplant period and that coincides with the period when the patient's natural barriers to infection are most likely to be breached *(22)*. In addition to being decreased in numbers, the neutrophils are functionally impaired and display decreased chemotaxis *(22)*. The risk of infections is related to both the duration and degree of neutropenia, with the risk of infection increasing sharply when the absolute neutrophil count (ANC) falls below 500 mm^3 *(55)*. In one study, the risk of serious infections was 5 and 43 infections per 100 admissions when the ANC was above and below 500 cells/mm^3, respectively *(55)*. Granulocytopenia allows for otherwise minor localized infections to disseminate. Prolonged neutropenia may predispose to infections due to pathogens resistant to multiple antimicrobial agents (e.g., *S. maltophilia*, *Acinetobacter* species), which may in part be due to the selective pressure of antibiotic therapy administered earlier in the course of the neutropenia.

Mucositis Conditioning-related oral and gastrointestinal mucositis occur in the vast majority of patients undergoing HSCT *(56–58)*. Additionally, it can be induced by regimens used to prevent GVHD *(59)*. Breaches are created in the normal mucosal barrier of the oropharynx and gut that results in translocation of bacteria or fungi (mainly *Candida* species) *(60,61)*. Mucositis-associated candidemia and viridans *Streptococcus* bacteremia post-HSCT are well described *(61–69)*. In a prospective study involving severe oral mucositis among autologous HSCT recipients, severe mucositis was associated with higher rates of fever and microbiologically confirmed infection, duration of antibiotic administration, and use of total parenteral nutrition (TPN) *(70)*.

Postengraftment Host Risks

Several factors influence the degree of immunosuppression experienced after HSCT following recovery of neutrophil function. In allogeneic HSCT, the presence of GVHD greatly increases the risk of infection by prolonging the impairment in cellular immunity, by virtue of GVHD itself and the associated treatments *(71)*. After the resolution of neutropenia, defects in acquired immunity become apparent as the spectrum of infections switches to include those ordinarily prevented by intact humoral and cellular immunity. Both allogeneic and autologous HSCTs are associated with quantitative decreases in lymphocyte counts *(72)*. Furthermore, $CD8^+$ suppressor cell populations recover sooner than the $CD4^+$ helper cells *(22)*. Thus, although the absolute lymphocyte count recovers to normal by the second month posttransplant, cellular immunity remains impaired by an abnormal $CD8^+/CD4^+$ ratio for at least a year after transplantation *(72)*. In certain cases, the immune deficiency state can be prolonged for several years after transplantation (1). In addition, B-cell recovery may take up to 6 months posttransplant (1). In fact, an association between chronic GVHD and pneumococcal infections has been reported *(73,74)*. Notably, Witherspoon et al. demonstrated that HSCT recipients 180 days posttransplant without chronic GVHD, had antibody responses indistinguishable from those of normal donors compared to patients with chronic GVHD *(75)*. Other infections can occur during this period primarily due to impaired cell-mediated immunity, including infections caused by *Aspergillus* species, CMV, VZV, and *Pneumocystis jiroveci* (1)

INCIDENCE AND PREVALENCE OF HEALTHCARE-ASSOCIATED INFECTIONS

The incidence and prevalence of healthcare-associated infections among patients undergoing HSCT have not been well studied. In an early study, 12% of patients hospitalized in an oncology center developed a healthcare-associated infection *(76)*. The highest incidence of healthcare-associated infections occurred among patients with acute myelogenous leukemia, 30.5 per 1,000 patient days *(76)*. Among patients with acute lymphocytic leukemia, non-Hodgkin's lymphoma, Hodgkin's disease, and breast cancer, the reported rates were lower, 16.7, 13.4, 5.4, and 3.3 per 1,000 patient days, respectively. Carlisle et al. performed a prospective observational study over a 42-month period among neutropenic patients with leukemia and solid organ malignancies, of whom 8% had undergone an HSCT *(77)*. Four hundred and forty-four infections were identified among 920 patients during 9,582 days of neutropenia. Overall, 48.3 infections occurred per 100 neutropenic patients (46.3 infections per 1,000 days of risk). The rates of site-specific healthcare-associated infections per 100 neutropenic patients were 13.5 for bloodstream infections, 5.7 for urinary tract infections, 5.5 for respiratory tract infections, and 3.4 each for skin and gastrointestinal infections. In 88% of infections, pathogens were identified; 35% of pathogens were classified as gram-positive cocci,

27% as gram-negative bacilli, 18% as *Candida* species, 9% as gram-positive bacilli, 6% as viruses, and 4% as *Aspergillus*. Dettenkofer et al. *(78)* reported 48% of 351 German HSCT recipients developed healthcare-associated infections. The most common cause of infections were catheter-related bloodstream infection, pneumonia, and gastroenteritis *(78)*. The main pathogens were coagulase-negative staphylococci (36.3%), *Clostridium difficile* (20.4%), and enterococci *(78)*.

Infections that occur more than 3 months after HSCT have not been well studied, as the vast majority of those patients have been discharged by that time. Hoyle and Goldman canvassed 18 of 22 centers performing HSCT in the United Kingdom to determine the prevalence of infections that developed at least 3 months after transplant *(79)*. Six percent of HSCT recipients were readmitted for a serious infection. The most common microorganisms causing serious infections included cytomegalovirus (CMV), *Pneumocystis jirovecii*, *Streptococcus pneumoniae*, *Pseudomonas* species, and *Aspergillus* species *(79)*. Other groups have shown that 6 months or more after HSCT, recipients remain at increased risk for *S. pneumoniae* infections and *Pseudomonas* pneumonia *(80,81)*. More prospective studies are needed to determine the risk of healthcare-associated infection among recipients of HSCTs and bridge the inpatient/outpatient care model that is being adopted by many HSCT centers.

SITE-SPECIFIC INFECTIONS

Bacteremia and Catheter-Related Infections

Bacteremia or bloodstream infection (BSI) is reported to be the most common infections in HSCT recipients. The incidence is estimated to be 38.6% per 100 patients based on a 249 episodes of bacteremia occurring over 4 years among 172 patients followed longitudinally *(82)*. In this series, 82% of these infections occurred within 30 days of HSCT, whereas 18% occurred after this time period. The most common microorganisms included coagulase-negative staphylococci and viridans streptococci *(82)*. Similarly, Almyroudis et al. *(83)* demonstrated that 170 BSI occurred among 298 HSCTs. Twenty-two percent of all HSCT recipients developed a BSI during the pre-engraftment period, while 19.5% developed a BSI after engraftment *(83)*. The most common pathogens during pre-engraftment and postengraftment were viridans streptococci, *Enterococcus faecium*, and coagulase-negative staphylococci *(83)*. All except one patient in this study had an indewelling intravascular catheter *(83)*.

In a study from Spain, intravascular catheters were the source of BSI in 44% of HSCT recipients *(84)*. Vascular access catheters are used in HSCT patients for an extended period of time. Most HSCT recipients have central venous access especially in the pretransplant phase and the pre-engraftment phase for delivery of conditioning regimens, stem cells, and other supportive treatments *(85,86)*. However, it is difficult to determine the risk of infection because of variations in the definitions of infection employed, host and treatment factors as mentioned above, and the types of catheters used. In a study of 123 patients who underwent HSCT, 139 double- or triple-lumen catheters were placed and a catheter-related infection occurred in 22 (15.8%); 127 of the 139 catheters were placed and remained in place for a mean of 65 ± 55 days *(87)*. The most common microorganisms causing BSI in most series were gram-positive bacteria, especially coagulase-negative staphylococci *(78,85,88–90)*. HSCT recipients with tunneled catheters are also at risk for catheter-related bloodstream infection, most commonly due to coagulase-negative staphylococci *(91–93)*. Among 242 HSCT recipients with indwelling, tunneled catheters who had daily blood cultures drawn, 5.28 patients per 1,000 catheter days developed a catheter-related bloodstream infection and 2.59 per 1,000 catheter days developed an exit site infection. Sixty-five percent of these infections occurred during neutropenia *(94)*. Although subcutaneous ports are believed to be associated with lower infection rates, studies are needed to document this finding in HSCT patients *(95)*.

Risk factors for healthcare-associated BSIs among HSCT recipients include an allograft from a matched unrelated or partially matched family donor, GVHD prophylaxis without methotrexate (MTX), presence of a tunneled catheter, and duration of TPN. A Dutch multicenter study on high-dose chemotherapy followed by peripheral stem cell transplantation in high-risk breast cancer patients demonstrated that factors predictive of BSI were duration of neutropenia >10 days, use of catheter for both stem-cell apheresis and high-dose chemotherapy, and use of TPN *(85)*. An outbreak of catheter-related polymicrobial bloodstream infections among 13 HSCT outpatients was reported in one study *(96)*. Risk factors included use of predrawn saline flush solution in which multiple doses were obtained from single-dose preservative-free vials *(96)*.

The Centers for Disease Control and Prevention (CDC) has developed guidelines for the prevention of catheter-related BSI, and these should be followed for all HSCT patients with intravascular catheters *(97)*. Recommendations in these guidelines should be followed when catheters are inserted and maintained. Given that many patients are discharged home with indwelling catheters, education regarding prevention of catheter-associated infection should be provided to patients and caregivers, including the recommendation that contact with tap water at the catheter site should be avoided *(97)* (see also Chapter 17).

Pneumonia

Pulmonary complications occur during the early and late periods after HSCT and are associated with significant morbidity and mortality. They can be either noninfectious or infectious in origin. For infectious processes, the source may be from endogenous reactivation, acquired from the environment or from person-to-person contact. The most common early-onset complication is interstitial pneumonitis, occurring in 10% to 40% of patients and usually associated with CMV coinfection *(98,99)*. During the first 100 days after HSCT, only 20% of pneumonias are caused by bacteria, and these are usually due to gram-negative bacilli *(91)*. Sinopulmonary infections caused by other microorganisms and obstructive airway disease associated with chronic GVHD are among the late-onset problems.

HSCT patients are at a higher risk than general hospital patients for developing healthcare-associated pneumonia, and 40% to 60% develop adverse pulmonary sequelae *(100,101)*. Pulmonary fungal infections, primarily *Aspergillus* species, develop in up to 16% of allogeneic HSCT patients *(102,103)*. Healthcare-associated pneumonia in immunocompromised hosts can be caused by inhalation of aerosols carrying *Legionella* species or *Aspergillus* species, or exposure to individuals with RSV, influenza, or parainfluenza virus. These microorganisms are important pathogens in HSCT recipients, and outbreaks of healthcare-associated pneumonia have been documented *(104–110)*. Among nonbacterial causes of pneumonia in recipients of allogeneic HSCTs, CMV pneumonia has the highest mortality rate, 91% *(111)*. Diffuse interstitial pneumonia caused by CMV during the postengraftment period occurs in 30% to 40% of the cases *(22)*.

Gastrointestinal Infections

Gastrointestinal illness in HSCT patients can be both an infectious and noninfectious process. HSCT patients can develop gastrointestinal symptoms from the conditioning regimen, radiation, acute GVHD, or medications *(112–114)*. A number of microorganisms including viruses, bacteria, protozoa, and helminthes can cause gastrointestinal infection *(112,115–118)*. Diarrhea may be caused by endogenous reactivation such as with CMV or acquired by various mechanisms such as respiratory transmission (e.g., adenovirus, influenza H1N1), ingestion (e.g., *Salmonella*), or contact transmission (e.g., *C. difficile*). The likely etiology of diarrhea following HSCT depends on the timing after transplantation *(119)*. Early after transplantation, intestinal damage due to chemotherapy is a common cause. Later onset, 20 to 100 days after HSCT the differential diagnosis includes acute GVHD *(120)*. In a cohort of 296 HSCT patients with diarrhea, Cox et al. *(121)* found that infectious pathogens accounted for only 13% of cases, whereas acute GVHD accounted for 48%. No etiology was identified in 39% of diarrheal episodes. Among patients with infections, the most common infecting microorganisms identified were viruses (12/126 patients; 9.5%) and *C. difficile* (6/126 patients; 4.8%). Another study reported identification of an infectious cause of diarrhea in up to 40% of episodes *(122)*. Of the 31 patients where a pathogen was identified, 12 (39%) had adenovirus, 12 (39%) had *C. difficile*, and 9 (29%) had rotavirus. More importantly, the mortality rate was 55% among patients with a pathogen isolated and only 13% among those patients who did not develop infectious diarrhea ($p < .0001$). Likewise, Blakey et al. *(116)* identified the cause of diarrhea in children undergoing HSCT. Enteric pathogens caused diarrhea 52% of the time; 14% of cases of diarrhea were caused by *C. difficile*. Interestingly, other *Clostridial species* including cytotoxin-negative *C. difficile* and *C. innocuum* were excreted in 90% of diarrheal episodes when no enteric pathogen was identified.

Typhlitis or neutropenic enterocolitis is a complication following chemotherapy that is commonly found in patients with hematologic cancer and patients undergoing autologous HSCT *(123,124)*. One study demonstrated that 75% of patients with typhlitis had at least cultured blood growing at least one microorganism at some time during their illness *(125)*.

If infectious diarrhea is suspected in HSCT patients, Contact Precautions should be applied, because many of these pathogens such as adenovirus, rotavirus, and *C. difficile* can be healthcare-associated (126,127).

Details about specific microorganisms can be found below.

Sinusitis

Approximately 1.7% of HSCT patients, most commonly allogeneic grafts, develop sinusitis *(128,129)*. Among 41 cultures of the paranasal sinuses obtained from 18 HSCT patients with sinusitis, the most common microorganisms identified were gram-negative bacteria (56.7%), gram-positive bacteria (26.7%), and fungi (16.6%) *(130)*. With the increasing use of high-risk HSCT and new cytotoxic chemotherapy, more cases of sinusitis due to less frequently identified pathogens have been reported including invasive fungi such as *Aspergillus* species, the Zygomycetes, and other filamentous microorganisms, which is a potentially lethal complication of HSCT-induced neutropenia. A mortality rate of 62% is reported despite appropriate antifungal therapy and surgical debridement *(128)*.

MICROORGANISMS

We review those microorganisms that require infection prevention and control interventions or have implications for healthcare workers or the environment. Certain infections characteristically occur at different time periods following HSCT. This pattern, however, has evolved as the management of HSCT patients had changed, including the use of prophylactic antibiotics and antiviral agents. The risk of developing a blood-borne infection (HIV; hepatitis A, B, C, D, E, G, and H; malaria; Chagas' disease; etc.) also exists in this population.

Infections in the early posttransplant period are usually due to the host's own flora colonizing the skin and mucous membranes and the urogenital or alimentary tracts. Medical therapies and the hospital environment, however, may alter the profile of microorganisms that colonize individual patients. Owing to the liberal use of broad-spectrum antibiotics in HSCT units, acquisition of highly resistant microorganisms, such as vancomycin-resistant *Enterococcus* (VRE), multidrug-resistant gram-negative rods, and *S. maltophilia*, is common. The profound immunosuppression allows these patients to acquire potentially pathogenic microorganisms from sources that are of little concern in other hosts, such as uncooked foods and water. Free-living microorganisms, such as *Pseudomonas* species, normally colonize fresh fruits and vegetables and plants; institutional water sources are potential sources of microorganisms such as *Pseudomonas* species, *Legionella* species, fungi, and *Mycobacterium* species *(39)*. Similarly, construction and renovation in and around healthcare institutions have been associated with infection due to *Aspergillus* spp. and other molds (51). During the neutropenic phase immediately following transplantation, pathogens whose removal is dependent on phagocytic function predominate. It is estimated that 60% of febrile episodes in neutropenic patients are accompanied by bacteremia, but there have been important shifts in the microorganisms responsible

for these infections *(131)*. In the 1970s, gram-negative septicemia often caused by *P. aeruginosa*, *Escherichia coli*, *Enterobacter cloacae*, and *Klebsiella* species resulted in high mortality of febrile neutropenic patients *(132,133)*. More recent prophylactic regimens have led to the emergence of fluoroquinolone resistant gram-negative rods and fungi. Driven by the extensive use of prophylactic and empiric antibiotic regimens active against gram-negative microorganisms, gram-positive microorganisms have now emerged as the most common pathogens *(134)*. Gram-positive microorganisms now account for 60% of bacteremias in HSCT centers *(134,135)*. Most of these infections are caused by *Staphylococcus epidermidis* and other coagulase-negative staphylococci. Wade et al. *(134)* found that the incidence of *S. epidermidis* infections increased from 2.0 per 1,000 patient days in 1972 to 14.6 per 1,000 patient days in 1979. Increased use of long-term indwelling venous catheters has also been implicated in the increase in gram-positive infections *(134,135)*. Streptococci, in particular alpha-hemolytic strains, commonly found in the oral flora have been recovered with increasing frequency owing to the poorer activity of fluoroquinolones against these microorganisms *(54)*. Furthermore, many gram-positive bacteremias, especially those due to *S. epidermidis*, now occur after engraftment *(136)*. The proportion of gram-positive and gram-negative bacterial infections varies from study to study due to the variation of timing of study period, antibiotic prophylaxis use, and type of center performing transplantation. Between 2004 and 2007, Cattaneo et al. *(137)* performed a prospective surveillance study in Italy analyzing microbiological isolates of all infectious episodes at a hematology unit that also included autologous HSCT recipients. Gram-negative bacteria caused 49.3% of infections, gram-positive bacteria caused 40.9% of infections, and fungi caused 8.9% of infections in this series *(137)*. These authors used levofloxacin for antibacterial prophylaxis in patients with expected neutropenia more than 7 days.

Viral Infections

Respiratory Virus Infections

Respiratory viruses cause infections in approximately 19% of HSCT patients each season (generally considered to be from November to May in the Northern Hemisphere). Respiratory syncytial virus (RSV), influenza A and B viruses, parainfluenza virus, adenovirus, picornaviruses, coronavirus, human metapneumovirus, and rhinovirus have been described as agents that affect HSCT patients *(138,139)*. These viruses commonly cause upper respiratory tract infections and can lead to serious lower respiratory tract infections associated with significant morbidity and mortality in this population. Adenovirus can lead to disseminated visceral syndromes *(140)*. Suspicion for respiratory virus infection should be maintained throughout the year, because parainfluenza and adenovirus occur year-round. While respiratory viruses are frequently acquired in the community, hospital transmission is well described. One group reported that 48% of these types of infections were acquired within the hospital *(138)*. A study of HSCT patients with respiratory symptoms who had cultures and direct fluorescent antibody examination of nasopharyngeal wash/throat specimens demonstrated that the most common community-acquired respiratory agent was RSV (35%), followed by parainfluenza virus (30%), rhinovirus (25%), and influenza (11%) *(141)*. Adenovirus was not included in the study because of the difficulty in differentiating new infection from reactivation of latent disease. Patients with radiographic evidence of pneumonia underwent bronchoalveolar lavage; 49% of patients with RSV had pneumonia and 22% of patients with parainfluenza had pneumonia, but pneumonia due to influenza and rhinovirus was uncommon (<10% of patients). In contrast, a more recent study reported the results of direct immunofluorescence assays performed on respiratory specimens from 179 HSCT patients who had 392 episodes of upper respiratory illness *(142)*. Of the 68 (38%) in whom virus was detected, respiratory syncytial virus was detected in 18 patients (26.4%), influenza A or B in 28 (41.2%), and parainfluenza in 7 (10.3%). Fourteen patients (20.6%) had multiple viruses isolated. RSV pneumonia developed in 55.5% of the patients with RSV upper respiratory infections. One of the 15 patients (6.7%) with RSV pneumonia died. Influenza pneumonia was diagnosed in three patients (7.3%). These investigators report a lower mortality than previously reported.

HSCT recipients or candidates who have symptoms of respiratory tract infection should be placed on Droplet Precautions and sometimes on both Droplet and Contact Precautions to avoid transmitting to other patients (127,143). Optimal isolation precautions should be modified after the causative agent is identified and the epidemiology understood (143). In some cases, prolonged shedding of virus is described requiring prolonged use of barrier precautions *(144–148)*. Diagnosis and the cause of upper respiratory infections should be established in HSCT patients, because they can progress to serious complications, some can be treated with antiviral agents, and others require precautions and rarely prophylaxis of exposed healthcare workers (143). HSCT candidates with upper respiratory tract symptoms, if possible, should postpone conditioning therapy until symptoms resolve (143) (see Table 59-1).

Adenovirus Adenoviruses are nonenveloped, double-stranded DNA viruses 70 to 90 nm in diameter *(149)*. At least 7 human adenovirus subgroups, including 52 serotypes, have been documented *(150)*. The incidence of disease in HSCT patients ranges from 5% to 27% in different studies *(151–157)*. Among HSCT recipients, especially children, the common serotypes that cause disease are 31 in subgroup A; 7, 11, 34, and 35 in subgroup B; 1, 2, 5, and 6 in subgroup C; and 4 in subgroup E *(158)*. One group found that subgroup B serotype 35 was the most prevalent adenovirus strain in their institution, and half of the adult patients infected with this strain had the same serotype recovered from cultures prior to HSCT *(152)*. Most of reported cases were diagnosed during the first 100 days posttransplant; however, the onset of adenoviral disease after 100 days has also been reported *(152,154,159)*. HSCT patients who develop adenovirus infections can present with upper and lower respiratory tract illness, acute hepatitis, gastrointestinal disease, acute hemorrhagic cystitis, nephritis, conjunctivitis, and central nervous system disease *(140,149,159–164)*. Patients who have recently undergone transplantation have an increased risk of severe disease (OR = 2.7) *(165)*.

TABLE 59-1

Prevention and Control Strategies for Respiratory Virus Infections

	Measurements
Transmission-based precautions	HSCT recipients with respiratory symptoms due to suspected respiratory virus infections should empirically be placed on Contact plus Droplet Precautions. After identification, precautions should be adjusted. - Droplet Precautions for influenza, parainfluenza and adenovirus - Droplet plus Contact Precautions for RSV - Prolonged shedding of virus is described in HSCT patients requiring prolonged use of barrier precautions Obtain nasopharyngeal swabs, throat swabs, or aspirates for culture, PCR, or rapid antigen testing to help determine whether patients have stopped shedding virus.
Hand hygiene	Healthcare personnel and visitors should disinfect hands with an alcohol-based gel, or if hands are visibly soiled, with soap and water.
Laboratory diagnosis	Hospitalized HSCT recipients with signs or symptoms of a respiratory virus infection should be promptly tested to identify respiratory viruses. - Appropriate samples include nasopharyngeal washes, swabs, aspirates, and bronchoalveolar lavage fluid. - In outbreak setting, prioritize and reduce turnaround time for diagnostic tests.
Visitor screening	Consider a daily screening of all persons who enter the unit for URI symptoms during hospital or community outbreaks of respiratory virus infections. - Visitors with URI symptoms should be asked to defer their visit to the unit until their symptoms resolve. - Visitors with infectious conjunctivitis should be restricted from direct patient contact until drainage resolves.
Personnel	- Personnel with URI symptoms should be restricted from patient contact and reassigned to nonpatient care duties until symptoms resolve.
Active surveillance	- Active surveillance of HSCT recipients may occur during respiratory virus season.
Outpatient setting	During hospital or community outbreak - Triage screening at the entrance of outpatient center. - HSCT recipients or family members with symptoms compatible with respiratory virus infections should be separated from other patients and don a mask. - HSCT recipients should be educated to use respiratory hygiene/cough etiquette.
Specific measurements	Influenza - HSCT recipients who are more than 4–6 mo after transplantation should receive a yearly inactivated influenza vaccine. - Personnel and close contacts of HSCT recipients should receive a yearly influenza vaccine at the start of the influenza season, preferably with trivalent inactivated influenza vaccine rather than with live attenuated influenza vaccine. - HSCT recipients less than 4–6 mo after transplantation should receive chemoprophylaxis with neuraminidase inhibitors during community influenza outbreaks that lead to healthcare-associated outbreaks. - Influenza postexposure prophylaxis is recommended for all influenza-exposed HSCT recipients who are less than 24 mo after transplantation or who are more than 24 mo after HSCT and substantially immunocompromised regardless of vaccination history, because of their likely suboptimal immunological response to influenza vaccine. RSV - During an outbreak of healthcare associated RSV infection, restrict healthcare personnel who care for RSV-infected patients from giving care for uninfected patients. Adenovirus - Recommendations for isolation Precautions depend on type of syndrome ◦ Gastroenteritis patients should be placed on Contact Precautions for at least the duration of illness. ◦ Cases with respiratory illness, conjunctivitis, or disseminated infection should be placed on Contact and Droplet Precautions. - Environmental disinfection with hospital-approved disinfectants

(Data from references 126 and 127.)

Disseminated adenovirus infection, in which two or more organ systems are involved, is associated with a 60% mortality rate *(140,163,166)*. The mortality rate may be as high as 70% in patients with pneumonia and disseminated disease *(154,167,168)*. Lymphopenia (<300 per μL) is one of the significant risk factors for severe disease, because lymphocytes play an important role in clearance of adenovirus viremia *(154,169,170)*. Receipt of an allogeneic transplant, presence of GVHD, and receipt of concurrent immunosuppressive therapy are risk factors for disseminated infection *(163,171)*. In addition, others have reported that the incidence of adenovirus is higher in children than adults *(172)*.

The diagnosis of adenovirus infection has traditionally been made by isolation of the virus in culture or by documentation of adenovirus in tissue. PCR is emerging as a promising diagnostic modality that provides a more rapid diagnosis and can be a monitoring tool for the virus *(156,173–176)*.

Because they are nonenveloped viruses, adenovirus are highly resistant to chemical and physical agents and can remain infectious at room temperature for prolonged periods of time, up to 49 days on plastic and up to 35 days on metal *(150,177)*. They are stable at low pH and resistant to gastric and biliary secretions allowing them to replicate and achieve high viral loads in the gastrointestinal tract *(150)*.

Transmission can occur by inhalation of aerosolized droplets, direct and indirect contact, fecal–oral spread, or exposure to infected tissue or blood (126,*159*). In general, type-specific immunity develops after a self-limited, 2-week illness, although latent infection may be established in lymphoid tissue *(149)*. Outbreaks have been reported primarily in pediatric HSCT patients *(167,178–180)*. The clinical presentation described in these outbreaks is diarrhea *(178–180)*.

Because the microorganism can be transmitted from person to person, attention to infection control practices is important. Recommendations for isolation precautions in a hospital setting depend on the type of clinical syndrome (126). Patients with diarrhea should be placed on Contact Precautions for at least the duration of illness (127). Since immunocompromised hosts may have asymptomatic shedding of adenovirus for months after infection, precautions should be continued for the duration of hospitalization or viral shedding to prevent transmission (126). For respiratory disease, conjunctivitis, or disseminated infection, Droplet and Contact Precautions should be maintained for at least the duration of illness (126,127).

Environmental cleaning with approved disinfectants such as a chlorine-based product, ethyl alcohol, or ethanol mixed with quaternary ammonium compounds is important to prevent spread of the microorganism (126). High-level disinfectants maybe used for instruments when applicable *(181)*.

Influenza Influenza is a segmented RNA virus with three subtypes, A, B, and C. The former two most commonly cause infection in humans. The virus is characterized by its hemaglutinin (H) and neuraminisase (N) moieties. Beyond the hemaglutinin and neuraminidase, minor genetic variations occur annually so that hosts can be susceptible to any strain that emerges each year *(182)*. Influenza causes a febrile syndrome characterized by the sudden onset of fever, myalgias, cough, and sometimes gastrointestinal complaints *(182–184)*. It can lead to viral pneumonia, encephalitis, myocarditis, rhabdomyolysis, and other disseminated processes *(185–190)*. Secondary bacterial infections with *S. pneumoniae*, *S. aureus,* and methicillin-resistant *S. aureus* (MRSA) are well described *(191–194)*. Immunocompromised patients receiving HSCT are considered to be at high risk for healthcare-associated influenza. Hospital outbreaks of influenza often occur during community epidemics and can be explosive among hospitalized high-risk patients and have been documented with the same frequency among neutropenic and nonneutropenic and autologous and allogeneic HSCT recipients *(195)*. Whimbey et al. *(195)* found that almost one-third (29%) of the hospitalized adult HSCT recipients had influenza type A cultured after developing respiratory symptoms. Hospital transmission was responsible for 60% of these 68 infections. Seventy-five percent of the cases were complicated by pneumonia and 17% (1/6) of these patients died *(195)*.

Pandemic H1N1 influenza, which emerged in 2009, has also been associated with morbidity and mortality in HSCT patients *(145,196–198)*. Five of thirteen HSCT recipients infected with H1N1 influenza had lower respiratory tract involvement that occurred when they were profoundly neutropenic *(196)*. Only one patient with lower respiratory tract infection survived, whereas all with upper respiratory tract infections were alive at follow up through 100 days *(196)*.

Infection prevention and control of influenza in the HSCT population can be challenging, because many of these patients have prolonged infection and viral shedding. Gooskens et al. *(144*) evaluated eight immunosuppressed patients with prolonged influenza virus infection. Virus was shed for more than 2 weeks and it was found that shedding was associated with lymphocytopenia, lower respiratory tract infection, and development of drug resistance during oseltamivir treatment *(144)*. Although patients who received antiviral treatment had clinical improvement, lymphocyte reconstitution was required for complete viral clearance *(144)*. A similar finding has been noted in patients with pandemic H1N1 influenza infection *(145)*. Tramontana et al. reported on 17 HSCT patients and 15 oncologic patients with laboratory-confirmed pandemic H1N1 influenza. All HSCT patients <100 days posttransplant or with severe GVHD required ICU admission, and the in-hospital mortality rate was 21.9% *(145)*. Virus was shed up to 28 days during oseltamivir therapy. An H275Y mutation developed in four of seven patients who were PCR positive after 4 days of oseltamivir therapy *(145)*. These studies suggest that HSCT patients should not be removed from Droplet Precautions until it is documented that they are no longer shedding influenza virus *(145)*.

Outbreaks of influenza among hospitalized patients including HSCT patients are commonly reported *(108, 199–203)*. Healthcare workers are often implicated as potential sources of transmission demonstrating the importance that all healthcare personnel who work in HSCT units receive annual influenza vaccination *(201–203)*. Additional interventions in the setting of an outbreak include strict infection prevention and control precautions. These include enforcing barrier precautions, masking universally, minimizing the number of staff entering the unit and patients' rooms, screening of visitors and other personnel, delaying nonessential admissions to the unit, surveying

actively for respiratory virus infection in all patients and unit staff, and using antiviral chemoprophylaxis for HSCT patients regardless of earlier vaccine status for the duration of the outbreak (*108*,143).

Influenza vaccine should be administered to patients prior to transplantation, because response to influenza vaccine is extremely limited for at least 6 months after transplantation *(204)*. Influenza vaccine does not fully protect patients until 2 years following HSCT. All family members and close or household contacts of HSCT recipients should continue to be vaccinated annually as long as the HSCT recipient remains immunosuppressed (143) (see also Chapter 42).

Parainfluenza Parainfluenza viruses are divided into four serotypes (205). Of the four types, parainfluenza 3 is the most common, followed by serotypes 1 and 2 (205). Parainfluenza virus can cause serious lower respiratory tract disease in both adults and children who undergo HSCT *(206)*. Significant risk factors for progression from upper to lower respiratory tract infection have included corticosteroids use and lymphopenia (205,*207,208*). Parainfluenza outbreaks in HSCT recipients have been reported *(109,110,209,210)*. These outbreaks were caused by introduction of parainfluenza 3 virus strains from a community reservoir into the HSCT population with subsequent person-to-person transmission within the unit *(110,211)*. Some studies revealed that, most likely, transmission occurred initially in the outpatient setting *(209–211)*. The mortality rate in HSCT patients infected with parainfluenza has been reported to be 33% to 38.5% *(110,208,210)*. Infection prevention and control measures much like those described for influenza are the most important strategy for preventing parainfluenza infection and transmission among HSCT recipients. Many outbreaks report the need for prolonged enforcement of surveillance, isolation, cohorting, and other infection prevention issues *(210,211)*. The outpatient setting should also be included in these prevention strategies.

Respiratory Syncytial Virus RSV accounts for one-third to one half of community-acquired respiratory viral infections among HSCT recipients *(138,141)*. Healthcare-associated transmission has been well documented among HSCT recipients, and the risk of healthcare-associated infection increases during community outbreaks *(106,107,212)*. Almost 60% (19/33) of the RSV infections in HSCT recipients are complicated by pneumonia, with an associated mortality between 51% and 80%. This infection may be complicated by pneumonia, and the risk of progression to pneumonia is greater in patients who are pre-engraftment, who underwent HSCT <1 month prior to infection, who are lymphopenic, and who have preexisting obstructive airway disease (*103*,143). RSV spreads via large droplets from respiratory secretions or by contamination of hands or surfaces and subsequent contact with the mucous membranes of the eyes and nose. Prevention of this viral infection is the best strategy given the limited therapeutic options and the tremendous morbidity associated with these infections. Comprehensive programs that include surveillance and isolation have been shown to prevent transmission among children *(213)*. A multifaceted infection control strategy is essential in the event of a healthcare-associated RSV outbreak; prompt identification of cases with active screening, cohorting, isolation of infected patients, screening of staff and visitors for upper respiratory tract symptoms, cleaning of equipment, and educating staff have been demonstrated as effective measures in controlling outbreaks on HSCT units *(214)*.

Coronavirus Coronaviruses are a family of single-stranded RNA viruses that cause respiratory disease among humans. Until the 2002 to 2003 respiratory virus season, two coronavirus strains, OC43 and 229E, were known to cause respiratory disease *(215)*. Patients generally present with mild upper respiratory symptoms, although pneumonia has been described *(215,216)*. Limited data are available about the clinical syndromes among HSCT patients. In a case series of two patients who had received autologous transplants, both developed pneumonia characterized by a dry, nonproductive cough and interstitial infiltrates on radiographs *(139)*. Milano et al. *(146)* conducted a prospective surveillance study in allogeneic HSCT recipients and reported that the incidence of coronavirus infection among these patients was 11.1%. Nine of twenty-two patients were asymptomatic and 3/22 patients had prolonged viral shedding *(146)*.

In 2003, severe acute respiratory syndrome was described, which has rejuvenated interest in this virus and the clinical syndromes it causes. Published reports from several cohorts of patients noted a febrile syndrome characterized by cough, myalgias, dyspnea, and occasionally diarrhea with some patients going on to develop respiratory failure *(217–219)*. The spectrum of disease in HSCT patients is not well described.

Human Herpes Viruses Infections

Cytomegalovirus Cytomegalovirus (CMV), a double-stranded DNA herpes virus, is a major cause of morbidity and mortality among HSCT patients. Asymptomatic infection or symptomatic disease can result from either newly acquired infection from CMV-infected bone marrow or blood products or reactivation of previous infection. Risk factors for symptomatic CMV disease in HSCT patients include CMV seropositivity in the HSCT recipient, receipt of CMV seropositive hematopoietic stem cells or blood products by a CMV-seronegative recipient, allogeneic HSCT, use of T-cell–depleted graft, use of a mismatched or unrelated donor, the development of GVHD, prolonged immunosuppression, lymphopenia following transplantation, use of high-dose corticosteroids, alemtuzumab, fludarabine, or 2-chlorodeoxyadenosine, and failure of development of a CMV-specific cellular immune response *(22,91,220–225)*.

Serious CMV disease most frequently results in interstitial pneumonitis (143). Other manifestations include gastroenteritis, hepatitis, and encephalitis; retinitis has also been reported in HSCT recipients *(226,227)*.

Quantitative polymerase chain reaction (PCR) for CMV DNA or RNA is the most sensitive method for detecting CMV and has been used to determine the need for preemptive therapy (143,*225*,*228*). CMV pp65 Ag in leukocytes (antigenemia) can also be used, but the test may be falsely negative in patients with neutropenia (143,*229*,*230*).

Despite treatment with ganciclovir and IVIG, mortality from CMV pneumonia remains as high as 20% to 75% *(231–234)*. Among autologous HCST patients who developed

CMV pneumonia, all were previously CMV seropositive and all except two had underlying hematologic malignancies *(235)*. Most cases (n = 11) occurred <30 days posttransplant, although five cases occurred >100 days posttransplant. Thirty-one percent of patients died. New infection with CMV among CMV-seronegative HSCT patients has dramatically decreased since the use of CMV seronegative or leukocyte-reduced blood products have been implemented. In one study, the rate of exogenous infection was 23% compared to 0% in seronegative patients receiving CMV-seronegative red blood cell and leukocyte-depleted platelets *(236)*. CMV-seronegative blood products are felt to be comparable to filtered leukocyte-reduced blood products with regard to risk of CMV transmission *(236)*.

The overall incidence of developing CMV pneumonia in the first 100 days after transplantation is 7% *(91)*. CMV infection is much less likely to cause serious disease following autologous HSCT *(237)*. The incidence of CMV infection is 38.8% to 61%; however, only 0.8% to 6.9% of patients develop end-organ disease *(230,237,238)*. A review of CMV pneumonia in autologous HSCT recipients at one institution reported that 2% (16/795) of autologous HSCT patients developed CMV pneumonitis *(235)*. However, historically, 45% to 87% of allogeneic HSCT patients develop CMV infection and 21% to 43% develop disease *(237,239)*. The current standard of care in patients who are seropositive or have received seropositive transplants is to receive prophylactic antiviral therapy or preemptive antiviral therapy after detection of CMV reactivation with diagnostic testing. The rates of CMV disease in HSCT patients are now 5% to 18% (143,*222,240*).

Historically, the majority of CMV infections occur between 30 and 100 days following transplantation, with a median day of onset between the 40th and 50th day *(22,237)*. However, the risk of developing CMV disease later after transplantation appears to be increasing as prophylaxis and preemptive strategies are employed early after HSCT. The trend where CMV infection develops in HSCT cases at longer intervals after the transplant may be related to delayed reconstitution of CMV-specific T-cell immunity in the face of ganciclovir prophylaxis. Strategies for preventing late CMV disease in HSCT patients with high risk include use of continued surveillance and preemptive antiviral therapy. No precautions beyond Standard Precautions are recommended.

Herpes Simplex Virus Herpes simplex virus (HSV) infection is an important cause of morbidity in HSCT patients due to the severe mucocutaneous lesions produced by reactivation of latent virus *(136)*. Prior to the routine implementation of prophylaxis, HSV was the most common viral infection seen after HSCT, occurring in up to 80% of seropositive individuals in the first 50 days after HSCT *(136,241)*. Shedding of the virus is most frequent from days 14 through 28 after HSCT *(136)*. In contrast, only 1% of previously seronegative patients excrete the virus. The disease most often involves the oropharynx, but can manifest itself by limited or disseminated cutaneous disease. Less frequently, HSV may produce keratitis, pneumonitis, hepatitis, or encephalitis *(136)*. Importantly, healthcare-associated transmission of HSV from infected patients to healthcare workers and family members is reported *(242,243)*. Several outbreaks suggest that immunocompromised patients with herpes simplex pneumonia are most likely to transmit the virus *(242,243)*. In one of these studies, molecular typing of strains confirmed that the patients', healthcare workers', and family members' strains were genetically identical *(242)*. An emerging concern is the increasing frequency of HSV strains that are resistant to acyclovir *(244–249)*. One study demonstrated that 7% (14/196) of patients undergoing allogeneic HSCT were infected with acyclovir resistant HSV-1; seven cases were also resistant to foscarnet. Standard Precautions are recommended for all patients. In addition, patients with lesions should be placed on Contact Precautions (127). In instances with HSV pneumonia, Droplet Precautions should be considered.

Varicella-Zoster Virus Varicella-zoster virus (VZV) is caused by a DNA virus in the herpes family. It is the cause of varicella (chicken pox), which represents primary infection, and herpes zoster (shingles), which represents reactivation of latent VZV infection *(250)*. Although varicella is generally a mild disease in children, serious morbidity and mortality are common if infection occurs in immunocompromised patients *(251)*. Among patients developing varicella while receiving chemotherapy for malignancy or immunosuppressive therapy following transplantation, severe disease has been reported in 36% and death in 13% *(252,253)*. Encephalitis has also been reported in allogeneic HSCT patients *(254,255)*. In children, 28% not treated with antivirals develop pneumonia *(251)*. The skin lesions may form for up to 2 weeks and crusting may require 3 to 4 weeks *(251)*.

The majority of VZV infections in adults are due to reactivation of latent virus. In contrast to HSV infections that usually develop in the first month after HSCT, VZV-seropositive HSCT recipients develop VZV reactivation during the 3 to 12 months after HSCT (median = 5 months) *(252,256–264)*.

Risk factors for reactivation of VZV include chronic GVHD, a diagnosis of leukemia and other lymphoproliferative disorder, CD4 lymphocyte count of <800 cells/L, HLA mismatch, a myeloablative regimen with total body irradiation, CD34+ cell-selected allogeneic and autologous peripheral blood HSCT, and age >50 years *(252,258,260,265–268)*. Although most patients present with a dermatomal rash, cutaneous dissemination occurs in 6% to 23% of patients, encephalitis occurs in 5% of patients, and visceral involvement is noted in up to 14% of patients *(261,264,268–270)*. Visceral involvement most commonly involves the lungs and liver, and abdominal symptoms such as pain, nausea, and vomiting can precede the development of vesicular rash by several days *(271)*. Although antiviral suppression is standard of care for HSV disease, the role of antiviral suppression for the prevention of VZV has not been established in HSCT patients. While oral acyclovir for 6 months after transplant suppressed VZV reactivation, patients have developed rapid onset of VZV infections after the cessation of therapy *(256,268,272)*. The concerns about development of resistant strains of herpes viruses may outweigh the utility of prophylaxis. Regardless of VZV serologic status, HSCT candidates and recipients should avoid exposure to persons with active VZV infections and to persons who develop a rash after VZV vaccine (143). In hospital such patients should be placed on Airborne and Contact Precautions as immunocompromised hosts with VZV shed virus from the respiratory tract and lesions and transmission

to other patients is documented *(273)*. VZV-seronegative HSCT patients who are exposed to VZV or a vaccinee with a rash and are not immunocompetent should receive VZIG within 96 hours of exposure (143,*274*). A recent study by Hata et al. (*275*) demonstrated that inactivated varicella vaccine given before autologous HSCT and during the first 90 days after significantly reduced the risk of herpes zoster; 33% of unvaccinated patients compared to 13% of vaccinated patients developed zoster.

Varicella is extremely contagious, with secondary attack rates of >90% *(276,277)*. The incubation period of varicella ranges from 8 to 21 days, but most patients develop disease between 14 and 16 days after exposure. Patients with varicella become infectious 24 to 48 hours prior to the onset of rash, and viral shedding is prolonged by 2 days in the immunocompromised host *(251)*. Transmission is thought to be due to direct contact with infectious persons. However, based on several outbreaks where patients and/or healthcare workers with no exposure developed varicella, airborne transmission is presumed *(273,278–280)*. Sawyer et al. *(281)* used PCR technology to determine whether VZV could be transmitted by aerosol spray. VZV DNA was detected in 64 of 78 (82%) air samples from hospital rooms housing patients with varicella infections and 9 of 13 (69%) rooms of patients with herpes zoster *(281)*. VZV was detected from infected patients' beds for 1 to 6 days following the onset of rash, and on some occasions could be detected outside of the patients' rooms. Interestingly, this study contradicts investigators who suggest fomites are not important in the transmission of VZV *(276)*.

Airborne transmission is suspected to be a primary mechanism of transmission of disease among patients with hematologic malignancy and patients undergoing HSCT *(273,278–280)*. Leclair et al. *(279)* described an outbreak of varicella that occurred in a pediatric hospital. Twenty-four of thirty-two patients hospitalized on an infant ward were exposed and susceptible to varicella. Ultimately 15 (62.5%) patients developed chickenpox after an index case requiring mechanical ventilation was hospitalized. Studies of distribution of air documented increased airflow to those rooms where a higher number of cases occurred. These investigators suggest that increased concentrations of virus and droplets were expelled from the exhaust loop of the ventilator. In a similar instance, Gustafson et al. *(280)* demonstrated that the risk of children developing varicella was related to how near they came to the index case's room. Eight (11%) exposed children developed varicella. The attack rate was higher for children exposed to the patient early in his disease (8/28; 28.6%) *(280)*. Based on airflow studies, the pressure in all rooms was positive relative to that of the outside corridor. Moreover, 10% of a tracer gas released in the patient's room was measured in corridor air *(280)*. Furthermore, airborne transmission may occur with herpes zoster that involves more than one dermatome. For instance, an adult patient developed herpes zoster after receiving high-dose steroids, and three nurses developed varicella *(273)*. Two of the three nurses had no contact with the patient. HSCT recipients with primary varicella infection or disseminated herpes zoster should be placed on Airborne and Contact Precautions (127). Patients with localized herpes zoster should also be placed on Airborne Precautions until disseminated infection is ruled out, because most HSCT recipients are in an immunocompromised state (127). The precautions should be maintained until lesions are dry and crusted (127). In HSCT recipients with varicella pneumonia, precautions should be maintained for the duration of the illness (127). Susceptible healthcare personnel should not enter the room if immune caregivers are available (127). For susceptible nonimmunized healthcare personnel who are exposed to a varicella patient, postexposure prophylaxis with vaccine is recommended as soon as possible but within 120 hours; for susceptible exposed personnel for whom vaccine is contraindicated, Varicella Zoster Immunoglobulin (VZIG) should be provided within 96 hours. Use Airborne Precautions for exposed susceptible persons and furlough exposed susceptible healthcare personnel beginning 8 days after the first exposure until 21 days after the last exposure or for 28 days if VZIG was given (127).

Hospital transmission of varicella is well recognized. Healthcare personnel should have evidence of immunity to varicella *(274)*. Institutions should establish protocols and recommendations for screening and vaccinating personnel and for management personnel after exposures in the work place *(274)* (see also Chapter 43).

Epstein–Barr Virus Epstein–Barr virus (EBV) has been associated with various clinical syndromes. It can cause primary infection, reactivation, and chronic active infection in HSCT patients *(264,282)*. Most EBV reactivations are asymptomatic; however, the complications such as encephalitis/myelitis, pneumonia, and hepatitis can occur *(264)*. The role of EBV as a cause of posttransplant lymphoproliferative disorder (PTLD) is well described *(264,282)*. This disorder occurs predominantly in recipients with profound T-cell cytopenia such as a T-cell–depleted graft (143,*283*). Other risk factors include unrelated donor HLA mismatch, use of antithymocyte globulin, and use of anti-CD3 monocloncal antibodies for GVHD prophylaxis *(282–284)*.

HSCT donors and candidates should be tested for the presence of anti-EBV IgG antibody before transplantation to determine the risk for primary EBV after HSCT (143). Standard Precautions are used for this microorganism (127). No additional isolation is needed.

Human Herpes Virus Types 6 and 7 The scope of disease caused by human herpes virus type 6 or 7 (HHV-6 or HHV-7) in HSCT patients has yet to be fully elucidated. Both viruses are frequent causes of febrile infection in children and the etiologic agents of exanthem subitum. Primary infection usually occurs in the first year of life and seroprevalence in adults exceeds 90% *(285)*. Following primary infection, the virus establishes latency in peripheral blood mononuclear cells as well as salivary glands and neural cells *(286)*. Reactivation of latent virus is felt to be the source of infection in the majority of HSCT patients. Although HHV-6 cannot be cultured from the blood of healthy adults, roughly 40% to 50% of HSCT patients develop HHV-6 viremia 2 to 4 weeks after transplantation *(287,288)*. Patients receiving allogeneic HSCT have been reported to be at higher risk for reactivation of HHV-6 *(287)*. Although most HSCT patients with HHV-6 reactivation are asymptomatic, several studies have demonstrated a correlation between reactivation of HHV-6 and both maculopapular rash and fever following HSCT transplantation *(287,289–291)*. Other studies have

shown an association between central nervous system symptoms including encephalitis and detection of HHV-6 in cerebrospinal fluid (CSF) *(288)*. Wang et al. *(292)* examined CSF from 22 allogeneic HSCT patients with central nervous system symptoms and found that 23% (5/22) had detectable HHV-6 DNA and no other potential pathogen identified. In addition, 11 of the 22 patients without detectable HHV-6 had other causes identified that explained central nervous system symptoms *(292)*. Hospital transmission has not been reported to date. Standard Precautions are recommended for these patients.

Limited studies have examined HHV-7 infection in these patients. HHV-7 associated CNS involvement among HSCT recipients has been reported *(293–296)*.

Viral Gastroenteritis

Rotavirus Rotavirus is a common cause of nonbacterial gastroenteritis in children. It has also been a significant cause of diarrhea in HSCT recipients *(297,298)*. The symptoms of rotavirus infection in HSCT patients included diarrhea, vomiting, abdominal pain, and loss of appetite *(298)*.

Several healthcare-associated outbreaks of rotavirus infection have been reported *(299–302)*. One outbreak was reported to be related to shared toys in a playroom on a pediatric oncology floor *(303)*.

Environmental contamination is common despite cleaning since rotavirus is a nonenveloped virus and can survive on nonporous surfaces for a long period of time *(300,301,304–306)*. Disinfectants that can be used for rotavirus include sodium hypochlorite, phenol-based products, and *ortho*-phenylphenol with alcohol *(307)*.

Rotavirus was reported to have asymptomatic shedding, and prolonged shedding may occur in immunocompromised patients (126,*303,308*) (see also Chapter 50).

Norovirus Norovirus is the leading cause of outbreaks of nonbacterial gastroenteritis in the community and can be explosive in healthcare settings (126,*309*). Roddie et al. *(310)* retrospectively reviewed 12 HSCT recipients with norovirus infection. The median time after transplantation to the development of symptoms was 10.5 months (range 0.25–96 months). Patients present with fever, transient nausea, and vomiting. Diarrhea can be prolonged, lasting a median of 3 months (range = 0.5–14 months). Norovirus is highly transmissible by the fecal–oral route and by environmental and fomite contamination *(309)*. Moreover, it can survive in chlorine and varying temperatures (freezing and heating to 60°C). Quaternary ammonium compounds and alcohols are ineffective as disinfectants *(309,311)*. Hand washing with soap and water should be implemented. Routine alcohol-based hand rubs may be ineffective for preventing norovirus transmission (126,*309*). Newer alcohol-based products have been introduced and are effective in inactivating the virus *(312)*.

Patients should be placed on Contact Precautions. The environment should be aggressively cleaned. A hypochlorite-based cleaning agent is recommended for use on hard, nonporous environmental surfaces at a concentration of 1,000 ppm depending on the level of contamination and types of surfaces (126,*313*). Cohorting and symptom screening may be instituted if ongoing transmission occurs. Rapid and aggressive responses are important when this microorganism is suspected because of how explosive it can be in hospitals *(309,314)*.

Other Viruses

Parvovirus B19 Parvovirus B19 is an uncommon pathogen in the HSCT population, occurring in 1.4% of transplant patients at one institution *(315)*. Transmission via transplantation may occur *(316)*. It has been associated with prolonged anemia and viral shedding in the peritransplant period as well as in patients with chronic GVHD *(317–320)*. Parvovirus B19 has also been associated with rash, arthralgia, hepatitis, pneumonitis, and myocarditis *(321)*. Multiorgan failure has also been reported *(322)*. IVIG has been used for treatment in the absence of evidence from a randomized trial *(321)*.

Polyoma Virus Two viruses warrant mention. First, Polyoma BK virus was first reported in renal transplant patients in 1971 *(323)*. The isolation of BK virus in HSCT recipients most often correlates with secondary viral replication due to impaired polyomavirus-specific cellular immunity (143). Hence, viruria occurs in about 60% to 80% of patients after HSCT, usually within 2 months *(324–330)*. Approximately 20% of patients with viruria will develop hemorrhagic cystitis *(324,331,332)*. Factors that may contribute to hemorrhagic cystitis include presence of pretransplant BK virus IgG antibody, type of conditioning regimen, allogeneic HSCT, type of donor, GVHD, and a high peak BK urine viral load *(324,331,333)*. Hemorrhagic cystitis from BK virus typically occurs after engraftment and must be distinguished from hemorrhagic cystitis caused by other pathogens including adenovirus and CMV (143,*324*).

Second, Polyoma JC virus infection has also been reported to cause progressive multifocal leukoencephalopathy (PML) in HSCT recipients *(334,335)*. Standard Precautions are used for patients with either polyoma virus infection.

West Nile Virus West Nile virus (WNV) is a mosquito-borne flavivirus that is indigenous to Africa, Asia, Australia, and southern Europe *(336)*. It was first noted in North America in 1999, and the number of yearly cases in the United States has continued to increase since that time. It is of concern to caregivers of HSCT patients because of convincing evidence that it can be transmitted by blood transfusion and organ transplantation *(337,338)*. Tests to detect viral nucleic acid within blood products are now available and are being used to assess the blood supply for WNV.

In the general population, approximately 20% of persons infected with the virus develop a mild febrile illness and only 1 in 150 develops meningitis or encephalitis *(339)*. However, all of the patients who received organs from a donor who had received blood containing WNV developed clinical WNV; three of the four developed encephalitis and one died, suggesting that the disease is more virulent in immunocompromised hosts *(338)*. The diverse clinical presentations of WNV neurologic disease include meningoencephalitis, meningitis, flaccid paralysis, ataxia, cranial nerve abnormalities, extrapyramidal signs, myelitis, polyradiculitis, optic neuritis, and seizures. The incubation period is 3 to 14 days, and most patients

demonstrate a CSF pleocytosis *(339)*. At least two cases of WNV infection have been reported in patients who underwent HSCT *(340)*. In both cases, the infection was fatal.

This population is considered to be at increased risk of infection if they come from areas where WNV is endemic or because they receive blood products. WNV should be suspected in all HSCT patients who have received blood products or have exposure to mosquitoes and present with fevers and neurologic symptoms *(337,341–343)*.

Prevention strategies include avoiding exposure to mosquitoes and may include screening of the blood supply. Standard Precautions are used in these patients.

Bacterial Infections

Viridans streptococci Bacteremia caused by viridans streptococci is associated with a sepsis-like syndrome among HSCT and neutropenic patients *(62,65)*. One investigator reported that streptococci cause 71% of bloodstream infections in children undergoing HSCT *(344)*. Likewise, Heimdahl et al. *(60)* showed that oral microorganisms, particularly α-hemolytic streptococci, caused 24 of 59 infections that occurred in neutropenic patients early after HSCT. The important predisposing factors for viridans streptococcal bacteremia are severe neutropenia and oral mucositis. Besides mucositis, dental health also has impact on viridans streptococcal bacteremia in HSCT recipients. Graber et al. *(345)* demonstrated that HSCT recipients with streptococcal bacteremia were more likely to have severe intraoral pathology while neutropenic compared to patients without an identified focus of infection (26% vs. 0%) and slightly shorter interval between the last dental procedure and the onset of neutropenia (11 vs. 14 days). Risk factors for viridans streptococcal bacteremia include prophylactic administration of trimethoprim-sulfamethoxazole, beta-lactams, or a fluoroquinolone and chemotherapy-induced gastrointestinal toxicity treated with H2 antagonists or antacids *(67,346)*. Penicillin-, cephalosporin-, and quinolone-resistant strains of viridans streptococci have been reported *(346–350)*. Attributable mortality rate for pre-engraftment viridans streptococcal bacteremia is 6% to 30% *(67)*. Empiric vancomycin therapy is recommended in HSCT patients with viridians streptococcal infection if penicillin resistance is suspected either because of local microbiologic data or host risk factors *(351)*. Vancomycin should be narrowed based on final susceptibilities. The prudent use of vancomycin is needed to minimize vancomycin-resistant microorganisms in this patient group.

Vancomycin-Resistant Enterococcus Enterococci are commensal flora of the human gastrointestinal tract. In normal hosts, they may have limited pathogenicity, but in HSCT recipients VRE are associated with significant morbidity and mortality *(352,353)*. Reported rates of colonization are variable (4.7–40.2%), although rates are increasing in some studies *(352,354–356)*. Kamboj et al. *(357)* noted that 27.5% of allogeneic HSCT had VRE colonization at pretransplant screening between 2008 and 2009. VRE were the most common cause of primary bacteremia (53.5% of all positive blood cultures) in the early posttransplant period (days 4–10 after HSCT), and only 53% of patients with VRE bacteremia had positive surveillance cultures growing at pretransplant screening. The independent risk factors for VRE bacteremia were VRE colonization and allograft with T-cell depletion. The mortality in this study was 4.4% compared to 15% in patients with non-VRE bacteremia *(357)*. The increased incidence of VRE occurred after implementing vancomycin prophylaxis in the peritransplant period to prevent viridans streptococci infection in myeloablative HSCT *(357)*.

Several studies have evaluated risk factors for VRE infection *(132,133,358–360)*. Independent risk factors for developing VRE infection include neutropenia for more than 1 week, the use of oral vancomycin, and mucositis severity *(133,358)*. Zaas et al. *(132)* reported that the risk factors for infection in colonized patients included diabetes mellitus, gastrointestinal procedures, acute renal failure, and use of vancomycin for 7 days in the 60 days before admission. *C. difficile*–associated diarrhea has also been noted as a risk factor for VRE colonization and bacteremia *(132,358)*.

Hospital factors that predict colonization and infection with VRE include location in a high-risk area such as the ICU or oncology unit, length of hospitalization, number of individual contacts with VRE carriers, and overall proportion of patients colonized with VRE on a unit *(361–364)*. VRE can be transmitted by person-to-person spread or from the contaminated environment. Most hospital transmission occurs via the contaminated hands of healthcare workers. VRE survives on hands for at least 60 minutes after inoculation and are recovered on the hands in 10% to 43% of workers caring for VRE-colonized patients *(241,365)*. In addition, case–control studies have shown that exposure to a healthcare worker caring for a VRE-infected or a VRE-colonized patient increases the risk of acquiring VRE *(366)*. VRE can survive for long periods (up to 7 days) on dry surfaces and is recovered in 7% to 30% of environmental surfaces cultured during outbreaks of VRE *(365,367,368)*. Environmental contamination increases twofold when patients have diarrhea or are colonized in multiple body sites *(368,369)*. Not surprisingly, VRE outbreaks have been linked to many fomites including contaminated electronic thermometers and ear oximeters *(370,371)*.

The relationship between antibiotic exposure and colonization and infection with VRE has been extensively studied. The most consistently recognized antimicrobials associated with VRE acquisition are vancomycin, extended-spectrum cephalosporins, and antianaerobic agents *(363,372–375)*. Both the total amount of antimicrobials and the therapy are risk factors for VRE *(364)*. There is a consistent epidemiologic association between previous use of oral vancomycin and subsequent development of VRE colonization, which is likely related to selection pressure in the gastrointestinal tract, leading to the recommendation that oral vancomycin not be used routinely in the therapy of *C. difficile* colitis *(364)*. The relationship between intravenous vancomycin therapy and VRE colonization and infection is more controversial. Although several studies have noted an association between vancomycin and VRE, others have not found an effect *(369,372–374,376–382)*. Although vancomycin therapy likely does not cause VRE to develop or increase the chance that a patient will acquire VRE, it likely exerts selective pressure in the gastrointestinal tract and increases the burden of preexisting VRE to a detectable level *(364)*. Consequently, the prudent use of vancomycin

in patients at high risk for VRE, particularly HSCT patients, is highly recommended.

Extended-spectrum cephalosporins and antianaerobic drugs have also been strongly associated with VRE *(376,381,383)*. Among HSCT patients, Edmond et al. *(363)* reported that patients who received metronidazole or imipenem were 2.5 times more likely to develop a VRE bloodstream infection. One group was able to reduce the VRE acquisition rate on a leukemia unit by substituting piperacillin-tazobactam for ceftazidime as therapy for febrile neutropenia with no change in vancomycin use *(384)*. The theoretical mechanism of this observation is that extended-spectrum penicillins have some activity against enterococci whereas cephalosporins do not, allowing for some reduction of VRE overgrowth in the gastrointestinal tract *(364)*. Some oncology centers have moved toward the use of extended-spectrum penicillins rather than cephalosporins as a means to reduce rates of VRE colonization and infection, but studies to date have not confirmed the benefit of this approach *(385–387)*.

VRE colonization may persist for up to 1 year *(388)*. Among 253 immunocompromised patients, Lai et al. found 70% of patients were persistent fecal carriers for up to 303 days (median = 41) *(389)*. Of the 49 patients whose later stool cultures no longer grew VRE, four patients became recolonized. Beezhold et al. *(390)* found that all patients with VRE bloodstream infections were colonized either in the gastrointestinal tract (100%) or on the skin (86%).

The impact of these infections cannot be underestimated in this population. VRE bacteremia is associated with increased mortality in HSCT patients. In a well-designed historical cohort study of 27 leukemic patients with VRE bacteremia, Edmond et al. *(363)* reported a mortality of 67%, compared to a 30% mortality in closely matched controls without VRE bacteremia. Several studies suggest that VRE infections not only increase hospital length of stay, but also consequently inflate the cost of care to both the hospital and the patient *(363,391)*.

A number of outbreaks of VRE among HSCT units or hematological wards have been reported *(376,392,393)*. Most implicate infection control breaches and antibiotic overuse *(376,392,393)*. Approaches to outbreak control included staff education, weekly surveillance, isolation of colonized patients, hand hygiene, environmental cleaning, and changing antibiotic policies *(376,392,393)* (see also Chapter 33).

Methicillin-Resistant Staphylococcus aureus Resistance to methicillin among *S. aureus* was first noted in 1961, the first year that methicillin was available. Since the late 1980s, rates of MRSA in the hospital setting have continued to increase. Among HSCT patients, *S. aureus* is a significant pathogen, particularly as a cause of catheter-related bloodstream infection *(94)*. Risk factors for the acquisition of MRSA include previous or prolonged hospitalization, advanced age, recent surgery, enteral feedings, and open skin lesions *(394–396)*. The overall frequency of MRSA in a study of HSCT recipients was 5%, and was most commonly seen in unrelated-donor (9%), sibling allogeneic (6%), and autologous (3%) recipients. More than half (21/41) of the events occur 1 month to 6 years after transplantation, 15/41 occurred pretransplant and 5/41 were detected early posttransplant. The mortality rate was highest in the early posttransplant group with most patients presenting with bacteremia *(397,398)*. Mihu et al. *(397)* reported a case fatality rate of 15% with an attributable mortality rate of 8%. Risk factors for late *S. aureus* bacteremia in allogeneic HSCT recipients included skin GVHD and prolonged hospital length of stay *(397)*. MRSA is transmitted primarily on the hands of healthcare workers; thus, hand hygiene coupled with Contact Precautions form the backbone of the prevention of transmission of MRSA. One study suggested that the environment and common items in the environment may play a more important role than previously recognized *(399)*. Many centers perform surveillance cultures of the anterior nares at the time of admission and weekly to facilitate the early identification of patients with MRSA. This strategy facilitates the identification and rapid isolation of patients who could be colonized with the microorganism. Given that many of these patients have been previously hospitalized and exposed to antibiotics, such a strategy may be cost effective in this population. For patients with recurrent MRSA infection, current guidelines suggest that eradication of the carrier state can be attempted by applying a 2% mupirocin calcium ointment to the nares, and by the use of topical antiseptics such as chlorhexidine for bathing (126) (see also Chapter 29).

S. aureus with reduced susceptibility to glycopeptides has been reported in HSCT patients *(400)*. Current guidelines recommend that institutions should conduct routine surveillance for the emergence of *Staphylococcus* species strains with reduced susceptibility to vancomycin (126).

Antibiotic-Resistant Gram-Negative Microorganisms Gram-negative pathogens are described in detail in Chapters 34 and 35 "Enterobacteriaceae" and "Nonfermentative Gram-Negative Bacilli," respectively. These microorganisms are significant causes of bloodstream infection in HSCT patients. Mikulska et al. *(401)* found a significant decrease in the gram-positive bacteria/gram-negative rods ratio from 2.4 to 1 between 2004 and 2007. Fluoroquinolone resistance was common (74%) among gram-negative microorganisms in this study, likely because all patients received fluoroquinolones for prophylaxis. In a prospective multicenter study from Brazil, it was found that bacteremia was caused by gram-negative bacteria in 37% of patients and by gram-positive bacteria in 47% of patients *(402)*. Mixed infections were noted in 16% of patients *(402)*. *P. aeruginosa* (22%), *Klebsiella pneumoniae* (19%), and *E. coli* (17%) accounted for the majority of gram-negative isolates and 37% were resistant to multiple antimicrobials *(402)*.

A number of outbreaks of gram-negative microorganisms have been reported among HSCT patients and on hematologic units (*47*,*403*,404,*405–413*). Most *P. aeruginosa* outbreaks are related to water sources such as shower heads, basins, sinks, bathtubs, faucets, bidets, water closets, and bath toys *(403,405,407–412)*. Some studies have demonstrated microorganisms on healthcare personnel's hands suggesting that poor hand hygiene plays a role in transmitting these microorganisms *(414–416)*. Infected healthcare personnel can also play a role in healthcare-associated *P. aeruginosa* infection. Healthcare personnel with intermittent otitis externa and onychomycosis have

been implicated in outbreaks *(415–418)*. Artificial fingernails have also been associated with a *P. aeruginosa* outbreak *(419)*.

S. maltophilia has been well described in HSCT recipients *(47,420–425)*. This microorganism is typically resistant to extended-spectrum beta-lactam agents and carbapenems *(426)*. Patients commonly present with breakthrough infections while receiving broad-spectrum antibacterial treatment *(427)*. Risk factors for *S. maltophilia* infection included broad-spectrum antibacterial therapy, mechanical ventilation, intravenous catheterization, neutropenia, mucositis, and diarrhea *(47,425,426,428–431)*.

Outbreaks of *S. maltophilia* have been associated with contaminated water faucets, bottled water, and hand moisturizers *(47,422–424)*.

Other gram-negative pathogens are causes of infections and outbreaks in this patient population. An outbreak of multidrug-resistant *Serratia marcescens* infections in an oncology unit involving HSCT patients resulted from inadequate infection control practices and poor hand hygiene *(432)*. No environmental culture was positive for *S. marcescens* except for the control buttons of an intravenous pump, which yielded *S. marcescens (432)*. A few studies also demonstrated the role of healthcare personnels' hands in transmitting *S. marcescens (433–435)*.

In Israel, an outbreak of carbapenem-resistant *K. pneumoniae* among HSCT patients was reported *(436)*. Eight patients had bacteremia, and all were neutropenic or had GVHD *(436)*. Three patients died *(436)*.

Overall, outbreaks of these resistant microorganisms can occur from inadequate infection control measurements including hand hygiene and environmental cleaning and use of broad-spectrum antibacterial agents.

HSCT patients with colonization/infection with multidrug-resistant microorganisms should be placed on Contact Precautions. Institutions should have a written policy to minimize the impact of these resistant microorganisms on quality of patient care.

Clostridium difficile *C. difficile* was first identified as a cause of antibiotic-associated colitis in 1978; it has now become the most common cause of healthcare-associated diarrhea and inflammatory colitis. *C. difficile* disease and diagnosis is discussed in Chapter 37.

Patients who develop *C. difficile*-associated disease (CDAD) have altered intestinal flora related to the use of antibiotics, enemas, and intestinal stimulants *(437–439)*. Up to 30% of patients treated with antibiotics develop diarrhea, and in 20% to 25% of cases of antibiotic-associated diarrhea *C. difficile* is detected in stool *(438,439)*. The risk of acquisition increases as the patients' length of hospital stay increases, and more than 20% of adults are colonized after a week of hospitalization *(437,440)*. Clabots et al. *(441)* found the rate of acquisition proportionate to the length of hospital stay; 13% of patients hospitalized for 1 to 2 weeks were colonized and 50% of those hospitalized for more than 4 weeks were colonized. Patients who have been recently exposed to a healthcare institution are at increased risk of *C. difficile* colonization and diarrhea *(442)*. Importantly, broad-spectrum antibiotics commonly used for empiric therapy for neutropenic fevers and prophylaxis against opportunistic infections are associated with *C. difficile* colonization and infections *(114,437,443,444)*. In addition, antineoplastic chemotherapeutic agents, especially methotrexate, increase the risk of CDAD *(445)*. Gerard et al. recovered *C. difficile* and/or its toxin in 13 of 37 (35%) hospitalized cancer patients on oral antibiotics and in 15/119 (13%) of other patients ($p < .005$) *(443)*.

C. difficile colonization may be a marker for VRE colonization in patients with hematologic malignancies and HSCT *(446)*. Recipients of HSCT are at high risk of developing CDAD. One study suggests that CDAD may be more common among HSCT recipients than previous studies suggest *(443)*. Yuen et al. *(447)* prospectively studied HSCT recipients and found that *C. difficile* was the most common microorganism recovered from diarrheal stools. Among these patients, mortality was no different among patients with and without *C. difficile* isolated from stools. Chopra et al. *(448)* demonstrated that the CDAD rate /10,000 patients days among HSCT recipients was 24 compared to 2.6 in general patients and 16.8 in oncology patients. Most cases of CDAD occurred in the peritransplant period, within 30 days before or after HSCT. The authors addressed that conventional risk factors such as exposure to antibiotics and conditioning regimens likely play a significant role in the pathogenesis of CDAD in this population *(448)*.

Healthcare-associated outbreaks of *C. difficile* have been well documented, including outbreaks in HSCT units *(439,449–458)*. Contaminated environmental surfaces are an important and underrecognized reservoir of *C. difficile* spores, and serve as a source of the microorganism from which it can be transmitted to other patients *(450,459–461)*. These spores can remain viable on surfaces of inanimate objects for months. *C. difficile* is transmitted directly from patient to patient via the hands of healthcare workers or indirectly through contaminated equipment such as bedpans, urinals, call bells, and contaminated environmental surfaces such as bed rails, floors, and toilet seats *(437,449,450,459–461)*.

Prevention and control for endemic and epidemic disease is similar. Patients should be placed on Contact Precautions. Single rooms are preferred. Aggressive cleaning of the environment with bleach or other agents with activity against spores is an important control measure. Finally, antibiotic use should be minimized and tailored to agents that are less likely to aggravate disease (see also Chapter 37). The use of lyophilized *Saccharomyces boulardii* to reduce diarrhea is not recommended because of the risk for development of fungemia with the microorganism (126,*462*).

Legionella species Since the first documented legionellosis outbreak in Philadelphia involving American Legion convention delegates in 1976, numerous epidemic and sporadic cases including those associated with hospitals have been reported in the literature *(463–465)*. Initially, healthcare-associated *Legionella* infections were reported in centers that housed immunocompromised patients *(463)*. Outbreaks pointed to HSCT patients as high-risk patients with significant morbidity and mortality of 40% to 50% *(45,158,463,466)*. Marston et al. *(467)* found that patients with hematologic malignancies and *Legionella* infections were 22.4 times (95% confidence interval [CI], 19.0, 25.9) more likely to die than nonimmunocompromised hosts. These patients are at particular risk of developing

a *Legionella* infection, because they are neutropenic for long periods of time and have defects in cell-mediated immunity *(468)*. The incidence of healthcare-associated Legionella pneumonia among HSCT recipients varies. Several factors contribute to the incidence: (a) the concentration of *Legionella* spp. in the hospital's water supply; (b) the type of exposure to water; (c) the weather and rainfall; (d) the monitoring and treatment strategy for the water supply; and (e) the availability of adequate diagnostic tests (culture, direct fluorescent antigen, and urinary antigen) *(466,469–475)*. Among the 40 *Legionella* species, *Legionella pneumophila* is the most pathogenic, accounting for about 90% of the cases. Furthermore, of more than 14 identified serogroups of *L.pneumophila,* serogroup 1 accounts for more than 80% of the reported cases *(467)*. Other species that have been reported in HSCT patients include *L. micdadei* and *L. feelleii (469,476). L. pneumophila,* its concentration and density in the hospital water distribution system and the number of distal sites in the water distribution system that are culture positive for *Legionella* have been epidemiologically linked to healthcare-associated Legionnaires' disease *(44,463,471,477–481)*.

Legionnaire's disease is acquired by inhalation of water aerosols or aspiration of water contaminated by *Legionella (482–484)*. Aerosols have been generated from cooling towers, air conditioners, humidifiers, evaporative condensers, respiratory therapy equipment, and whirlpool baths *(472,477,485–496)*. Other investigators suggest that nasogastric tubes increase the risk of legionellosis presumably by facilitating microaspiration *(497,498). Legionella* infection should be considered in any HSCT patient with pneumonia, and appropriate testing for the agent should occur in all cases. Methods for detection of *Legionella* include culture, direct fluorescent antibody testing of bronchoalveolar lavage washings, and urine testing for *L. pneumophila* serogroup 1 antigen. Outbreaks of *L. pneumophila* serogroup 3 and nonpneumophila species in HSCT transplant units emphasize the importance of not relying only on urine testing for diagnosis *(499,500)*. Furthermore, isolates from clinical samples are needed to compare to water isolates to establish an epidemiologic link.

Surveillance for cases of healthcare-associated *Legionella* should be performed routinely in HSCT patients (126,501). Cases that occur in patients who have been continuously hospitalized for 10 days before the onset of illness are considered definite healthcare-associated cases, and cases that occur 2 to 9 days after admission are considered possible healthcare-associated cases (126). Appropriate reporting to the healthcare epidemiologist or infection preventionist (IP) and the health department should occur in response to a suspected healthcare-associated case; patients do not need to be isolated. However, healthcare epidemiology will initiate an investigation to determine the potential sources and implement prevention and control measures (as discussed below and in Chapter 36).

Mycobacterium tuberculosis The frequency of occurrence of *M. tuberculosis* infection in HSCT patients ranges from 0.001% to 16% in published studies *(502–504)*. The incidence of tuberculosis in HSCT patients is proportional to the incidence of tuberculosis in the general population and varies in different geographic areas *(505)*. One study showed that the incidence in allogeneic HSCT was higher than in the general population but equally frequent in autologous HSCT patients *(506)*. Patients can present with pulmonary, extrapulmonary, or disseminated disease. Pulmonary tuberculosis is the most common site of infection, but the classical manifestations of tuberculosis such as apical infiltration and cavitation are rare, and nonspecific pulmonary infiltrates are more common *(502,503,505,507)*. The diagnosis of tuberculosis can be challenging, with only a few patients having sputum showing acid-fast bacilli on smear. Nucleic acid amplification techniques have high specificity (98–99%) but low sensitivity (at least 80% in a smear-positive specimen and lower in a smear-negative specimen). Given the diagnostic challenges, therapy should be initiated in suspected cases after an aggressive diagnostic workup to obtain the relevant tissues for culture *(508)*. Clinical disease may be caused by reactivation of latent infection or may be newly acquired infection *(503,507)*. A number of biomarkers are being investigated for predicting reactivation disease *(509)*. The Interferon (IFN)-gamma release assay (IGRA) facilitates the diagnosis of latent tuberculosis with good specificity (99%) but low sensitivity (70–90%) *(510,511)*. Signs and symptoms usually occur late (median 324 days posttransplant in one study), but one quarter of reported cases occur before day 100 *(506,507,512)*. Risk factors for developing tuberculosis included allogeneic transplant, total body irradiation, corticosteroid use, and chronic GVHD *(504,506,512)*. Mortality varies from 0% to 50% in various studies and is higher in allogeneic HSCT and in disseminated disease *(507)*. Guidelines recommend evaluation for latent or active tuberculosis in patients who are candidates for HSCT *(513)*. Assessment should include a history of previous active tuberculosis, previous exposure, and results of previous tuberculin skin tests (TSTs) or IGRAs *(513)*. Concurrent, TST may not be helpful because patients are often already immunosuppressed prior to transplant *(513)*. Results from a meta-analysis demonstrated that IGRAs were more sensitive than TSTs among immunocompromised patients suspected of having tuberculosis *(511)*.

There have been no reports of outbreaks of tuberculosis in HSCT patients, but they have been well described in other settings; some of them involved transmission of multidrug-resistant tuberculosis (MDR-TB) *(514–521)*. Outbreaks are likely not reported, because these patients are cared for in a protective environment, some patients have latent infection, a long incubation period, or there are problems in diagnosis. There is a lack of good molecular techniques for epidemiologic investigations, especially in the countries where tuberculosis is endemic *(514,522)*. Institutions should follow CDC guidelines for preventing the transmission of *Mycobacterium tuberculosis* that are detailed in Chapter 38 "*Mycobacterium tuberculosis*."

Nontuberculous Mycobacteria Unlike tuberculosis, the healthcare-associated environment plays an important role in nontuberculous mycobacterial infections *(523)*. Municipal water supplies and potable water systems are major reservoirs for these microorganisms *(523,524)*. Nontuberculous Mycobacteria (NTM) are relatively resistant to disinfection, elevated temperature, and ultraviolet light compared with other pathogenic bacteria that may colonize potable water systems *(524)*.

A number of outbreaks and pseudo-outbreaks due to NTM have been reported in healthcare facilities *(524)*.

They have also been described in HSCT patients, with the majority being catheter-related, pulmonary, cutaneous, and disseminated infections *(525–529)*. The incidence ranges from 0.4% to 4.9% *(512,526,528, 530–532)*. The median time between HSCT and appearance of infection was 4.6 months *(525)*. The most commonly isolated *Mycobacterium* species are those that grow rapidly, such as *M. avium intracellulare* and *M. haemophilum*. Risk factors for NTM infections include having a matched-unrelated donor or a mismatched HSCT, and bronchiolitis obliterans *(532)*.

An outbreak of bacteremia associated with *M. mucogenicum* in six HSCT patients has been reported *(43)*. The microorganisms were isolated from several water sources in the hospital and DNA analysis demonstrated that one patient's blood isolate and an isolate from shower water were identical. The authors hypothesized that water contaminated the central venous catheters during bathing and concluded that guidelines on prevention of catheter-related infection should be strictly followed *(43)* (see also Chapter 39).

Nocardia species Nocardia species are aerobic actinomycetes that are found in organic matter and soil *(533)*. Commonly, this microorganism produces a focal lung lesion that may cavitate; it frequently disseminates to involve the brain and skin. Disease in this population is commonly associated with a normal white blood cell count *(534)*. Approximately 0.2% (1 of 554) of autologous HSCT patients and 1.6% (5 of 320) of allogeneic HSCT recipients have developed nocardiosis *(534)*. The risk of a patient developing nocardial infection was 9.3 times higher among allogeneic HSCT recipients especially in the setting of acute or chronic GVHD *(534)*. Some patients have had extensive exposure to soil or to organic matter before the nocardial infection developed. Nocardial infection can develop despite receiving trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis. The mortality among these patient populations is high *(535–538)*. Standard Precautions are recommended for patients with this infection.

Fungal Infections

Invasive fungal infections (IFIs) are important causes of morbidity and mortality after HSCT. Infections due to *Candida* and *Aspergillus* species represent the vast majority of IFIs post-HSCT. *Candida* species were the most frequent cause of IFIs in the 1980s, predominately occurring before engraftment associated with conditioning-induced mucositis and central lines *(539,540)*. Prospective randomized placebo-control clinical trials demonstrated that primary antifungal prophylaxis with fluconazole post-HSCT decreases rates of infection due to *Candida* species significantly (541,*542*). One study showed a significant survival benefit as well (541,*542*). The above led to the almost routine use of fluconazole prophylaxis in most transplant centers in the 1990s, which resulted in marked reductions in the rates of candidiasis (541,*543*). With the rates of *Candida* infections post-HSCT decreasing, there were increasing reports of emergence of fluconazole-resistant *Candida* species and invasive mold infections, caused predominately by *Aspergillus* species (*544,545,*546). In addition, IFIs due to other than A*spergillus* molds, including the Zygomycetes, *Fusarium,* and *Scedosporium* species, are emerging *(547,548)*. In a prospective study from the Prospective Antifungal Therapy (PATH) Alliance registry, invasive aspergillosis (IA) was the most common IFI in HSCT patients, followed by candidiasis and zygomycosis (549). Another prospective surveillance study from the transplant-associated infection surveillance network (TRANSNET), which identified 983 IFIs among 875 HSCT recipients, also showed that IA was the most frequently identified infection followed by invasive candidiasis and zygomycosis (546).

Aspergillus species *Aspergillus* species produce conidia that are inhaled and can potentially colonize human airways and—under the right circumstances—cause invasive disease *(550)*. The most common species causing infection in HSCT patients is *A. fumigatus*, although an increase in non-*fumigatus* species of *Aspergillus* (e.g., *A. flavus* and *A. terreus*) has been described over the past several decades (546,*551,552*). Invasive aspergillosis most commonly involves the sinuses and the lungs, but can occasionally disseminate to other organs including the skin and the brain *(553–560)*. The incidence of IA among allogeneic HSCT recipients increased from 5% in the late 1980s to approximately 11% in the early 1990s and has remained high since then (*401*,*551*,*561–566*,567,*568*). Higher rates of IA may, in part, be attributed to higher risk HSCTs practices leading to more immunocompromised hosts, prolonged patient survival, longer periods of susceptibility to *Aspergillus* infections, and the widespread use of fluconazole leading to a lower incidence of infections due to *Candida* species *(561,569)*.

Notably, all HSCT recipients are not equally affected by *Aspergillus* species., as the incidence of IA differs based on the severity and the duration of neutropenia and GVHD, the type of transplant (lower among autologous [0–5.3%] compared to allogeneic HSCT [10%]), HLA match (higher in HLA mismatched and unrelated donors 10.5% vs. matched related 7.3%), and graft manipulation (higher in T-cell–depleted [4–16%] versus unmanipulated grafts [2.2–7%]) *(401,561,565,566,568,570,571)*. Infections due to *Aspergillus* species occur following a bimodal distribution with an early (before) and late (after engraftment) peak that correlate with neutropenia and GVHD and associated therapies, respectively *(572)*.

Mortality rates in HSCT recipients have decreased from older estimates of 75% to 90% (*401*,546,549,*562,572–576*). The risk of death increases when pulmonary function before HSCT is impaired, HLA-mismatched stem cells are received, neutropenia, malnutrition, elevated bilirubin, and creatinine levels are present, corticosteroids at ≥2 mg/kg per day are administered, or disseminated and proven invasive aspergillosis occurring >40days after HSCT is diagnosed (567). Notably, receipt of nonmyeloablative conditioning and peripheral blood stem cells were associated with a decreased risk of all-cause mortality (567). Standard Precautions are used to care for these patients.

The environment clearly has an impact on whether patients develop disease. Construction and/or renovation and suboptimal maintenance, cleaning, and protection of the environment have been the most important causes of *Aspergillus* infection. Multiple outbreaks reported in the literature have illustrated the risks associated with these activities (Table 59-2) (*50,*51,*553,577–600*). Patients housed outside of a HEPA-filtered or laminar airflow environment

are at a 10-fold higher risk to develop healthcare-associated *Aspergillus* infection *(50)*. The use of HEPA filtration with laminar airflow for HSCT recipients can reduce the magnitude of risk for acquiring healthcare-associated *Aspergillus* infections and is discussed below (see "Prevention and Control Strategies"). Several experts argue that potable water is a source of fungi in this population *(601–603)*.

Candida species The incidence of *Candida* infections ranges from 22% to 25% among HSCT recipients *(604–607)*. *Candida* infections generally occur in the early posttransplant period with a mean time to onset of 2 weeks, coinciding with postconditioning periods of mucositis and neutropenia. *Candida* species may translocate via breaks in the mucosal surfaces associated with mucositis or by colonizing long-term intravascular catheters. Healthcare-associated transmission of *Candida* species may occur via indirect contact between patients by the contaminated hands of healthcare workers *(608–610)*.

The spectrum of candidal disease has changed with the widespread use of fluconazole for prophylaxis, with a shift from *C. albicans* responsible for more than 50% of cases, to non-*Candida albicans Candida* species (*543*,546,*611*). For instance, in a prospective surveillance study of invasive fungal infection in HSCT recipients, Kontoyiannis et al. reported that *C. glabata* is the most common *Candida* sp. followed by *C. albicans* and *C. parapsilosis* (546). Similarly, in a recent study on prospectively collected data from a multicenter registry on HSCT recipients with IFIs between 2004 and 2007, non-*C. albicans Candida* species collectively were the most common cause of invasive candidiasis with *C. glabrata* being the most frequently isolated species (549).

Clinically, *Candida* species cause infections ranging from superficial skin and mucosal involvement to fungemia and dissemination to internal organs, predominately the liver and spleen *(611)*. Hepatosplenic candidiasis is a distinct syndrome in neutropenic patients most commonly observed upon resolution of neutropenia and manifesting with right upper quadrant pain, elevated transaminases, and liver and spleen lesions on imaging tests *(612)*. Risk factors for candidal infection have included advanced age, prolonged neutropenia, delayed engraftment, cytotoxic chemotherapy, the use of broad-spectrum antibiotics or steroids, longer duration of hospitalization, presence of GVHD, concomitant CMV disease, and transplantation for acute leukemia *(608,611,613)*. One study demonstrated that prior use of a tunneled catheter and being colonized at other sites increased the odds of developing candidemia 7- and 10-fold, respectively *(614)*. Prospective studies among patients admitted to a medical intensive care unit and an HSCT unit found that risk factors for *C. glabrata* acquisition increased with prolonged hospitalization and prior antimicrobial use *(615)*. Patients with leukemia and those who had received antifungal prophylaxis were more likely to develop non-*C. albicans* fungemia and the rates of *C. krusei* and *C. glabrata* infections and colonization among HSCT patients receiving fluconazole are increasing *(616)*. In another study, fluconazole prophylaxis was the single most important risk factor accounting for the increase in *C. krusei* (OR = 27.07) and *C. glabrata* (OR = 5.08) *(617)*. Standard Precautions are used for patients with fungal infections. In some settings, infection control personnel may add Contact Precautions if the resistance pattern causes them concern.

Other Fungal Infections Less frequently encountered molds, such as the Zygomycetes, *Fusarium*, and *Scedosporium* species, have emerged as significant pathogens causing IFIs among HSCT recipients *(539,618,619)*. These microorganisms produce spectra of human disease similar to *Aspergillus* species. Zygomycosis can present as rhinocerebral, pulmonary, or disseminated disease and is associated with high mortality rates *(620)*. Recent studies suggest potential breakthrough zycomycosis infections in HSCT patients while on voriconazole *(621–623)*. Outbreaks of zygomycosis associated with construction, renovation, and disruption of the hospital environment have also been reported *(624)*. For example, cases in a pediatric oncology unit were deemed secondary to water damage in a linen storeroom and a patient's shower room *(625)*.

Fusarium infections in the immunocompromised host may disseminate rapidly and occasionally present with characteristic skin lesions with central necrosis and an erythematous base *(626,627)*. A recent epidemiologic study showed that *Fusarium* species isolated from the water and from aerosolized water within a hospital were genetically related to isolates from patients infected with *Fusarium (628). Scedosporium* species have also been increasingly reported as pathogens in the HSCT setting *(552)*. Common clinical manifestations may vary from localized cutaneous infection to disseminated disease with CNS, pulmonary, and skin involvement *(629,630)*. They can also present as fungemia *(630,631). Trichosporon capitatum* may cause bloodstream infections in HSCT patients; in one report, it was isolated from the stool of three leukemic patients, and all three patients were treated with an azole antifungal compound *(632)*. Mortality can be as high as 64% *(633)*. Standard Precautions are used for these patients.

Pneumocystis jiroveci *Pneumocystis jiroveci* is a fungus that remains an important pathogen among HSCT recipients. Prior to the routine use of antimicrobial prophylaxis, *P. jiroveci* pneumonia (PCP) complicated 6.8% to 16% of HSCT and occurred between 40 and 80 days after transplantation *(136,634)*. Since the implementation of prophylaxis, PCP occurs in approximately 2% to 13% of HSCT patients with most cases occurring more than 6 months post-HSCT when prophylaxis is stopped or terminated due to toxicity *(635–637)*. Risk factors for PCP include corticosteroid and other immunosuppressant use, relapse, and chronic GVHD, and patients with these risk factors should have prophylaxis continued beyond the standard 6 months. Mortality varies among studies, with rates up to 89% in some reports *(638)*.

Person-to-person transmission of *P. jiroveci* has been proposed based on studies in animal models, geographically and temporally linked clusters of PCP among immunocompromised patients, and increases in *of P. jiroveci* antibody titers among persons in contact with patients who have PCP. Outbreaks of *P. jiroveci* infections have been reported including patients with hematologic malignancy and renal transplant patients *(639–649)*. Some studies had evidence from molecular typing to confirm person-to-person transmission *(644–646,648,649). P. jiroveci* was found on environmental

surveys, but environmental cleaning did not terminate the outbreak *(648)*. No outbreaks have been reported in HSCT units. This may be due to the efficacy of prophylactic regimens and possibly due to the protective environment. Standard Precautions are recommended for patients with PCP; however, if evidence of person-to-person spread is suspected or confirmed within HSCT units, it seems prudent to implement Contact and Airborne Precautions for the patients (127).

Toxoplasma gondii *Toxoplasma gondii* is a protozoan that commonly causes asymptomatic infection in immunocompetent individuals. However, the microorganism can cause life-threatening infection in immunocompromised patients including those undergoing HSCT *(650)*. In these hosts, infection can occur as a new primary infection, but 95% of cases represents reactivation of old disease *(513)*. Toxoplasmosis most commonly involves the central nervous system, presenting as focal lesions, encephalitis, or rarely, chorioretinitis *(651,652)*. In areas of low endemicity, toxoplasmosis occurs in approximately 0.3% of transplants, with higher rates of 6% seen in Europe *(650,651,653,654)*. Disease most often occurs within the first 6 months after transplant, with a median time to symptom onset of 50 to 64 days *(651,652)*. Risk factors for toxoplasmosis included seropositive allogeneic HSCT who have received cord blood, an unrelated donor, T-cell–depleted transplants, previous alemtuzumab, acute and chronic GVHD, and inability to take trimethoprim/sulfamethaxoazole *(653)*.

Guidelines recommend that candidates for allogeneic HSCT be tested for toxoplasmosis IgG antibody to determine whether they are at risk for disease reactivation after HSCT *(513)*. To facilitate the early diagnosis of reactivated infection, PCR screening of peripheral blood specimen and preemptive therapy can be considered in patients at high risk *(513,653)*.

PREVENTION AND CONTROL STRATEGIES

The source of infections in HSCT recipients may come from an exogenous source, such as person-to-person contact or the environment, or from an endogenous source by reactivation of previous infections. Standard infection prevention and control approaches and vaccination are used to prevent infections form exogenous sources and antimicrobial prophylaxis and preemptive therapy are used to prevent some endogenous infections.

Additional prevention and control strategies are based on summary evidence in some cases, expert opinion based on epidemiology, or results of an outbreak investigation. In this patient population and with movements of patients from the inpatient to the outpatient settings, careful attention must be paid to the role played by the environment, foods, pets, and daily activities in the pathogenesis of opportunistic infections. Given that the immunosuppression from HSCT lasts much longer than the patient's stay in hospital and as HSCTs are increasingly being performed in the outpatient setting, many practices should be incorporated into the outpatient setting, the home environment, and the hospital setting. Because of the high mortality associated with infections in these patients, diagnostic challenges, and limited therapeutic agents, attention to control and prevention of infections is critical in this high-risk population.

Guidelines for preventing opportunistic infections among HCST recipients have been published as have guidelines regarding environmental infection control (501,*655*). These documents and additional scientific evidence that can be extrapolated from studies in other patient populations can be used to develop a plan for infection control in HSCT patients. In addition, the CDC's Healthcare Infection Control Practices Advisory Committee (HICPAC), the Society for Healthcare Epidemiology of America (SHEA), and the Infectious Diseases Society of America (IDSA) have developed several other relevant sets of compendiums and guidelines, including ones regarding:

1. Prevention of transmission of infectious disease in healthcare settings (127)
2. Hand hygiene methods *(656)*
3. Prevention of central line–associated BSI, and urinary tract infections *(97,657,658)*
4. Prevention of *C. difficile* infection, and MRSA *(659–661)*
5. Prevention and control of multidrug-resistant microorganisms in healthcare setting *(662)*
6. Prevention of healthcare-associated pneumonia and ventilator-associated pneumonia including policies and procedures on HSCT units or on their patients *(663,664)*

Beyond the guidelines, several caveats should be further considered in these patients. First, prevention and control of infection in these patients can involve their caregivers and family members, and their environment. Healthcare-associated infection may be acquired from infected patients, staff, visitors, or contaminated items in the patients' environment. Although this tenet is true with many patient groups, it particularly applies to HSCT recipients and the units where they are housed. Second, for many diseases, the infection control procedures are multifaceted. For example, healthcare-associated outbreaks or transmission of RSV, influenza, *C. difficile*, and VRE require integrated programs with strict attention to isolation procedures, hand hygiene, and environmental cleaning procedures to control and prevent transmission. Third, because data are not always available for this setting, common sense is critical in developing prevention and control plans. Recent studies have shown that these measures may be cost-effective; by decreasing the number of infections in a hospital with a high prevalence of VRE, authors in two studies projected over $100,000 in annual savings *(665,666)*. Karanfil et al. *(213)* also projected a savings of $88,000 annually with a comprehensive program to control RSV. Garcia et al. *(214)* reduced the incidence of RSV infections from 4.4 per 1,000 patient days before the interventions were applied to 1.0 per 1,000 patient days after introducing such a program in an HCST unit.

We discuss the specific elements of programs that can be developed to prevent transmission of epidemiologically important diseases below. Healthcare workers should be educated; feedback should be provided to physicians, providers, and nurses about infection rates and compliance with policies and procedures (process measures); infection control practices (isolation precautions) must be complied with; the environment must be carefully cleaned; and antibiotics must be used judiciously. Furthermore, management always includes strict hand hygiene, limiting exposure to infected persons during the respiratory virus season, screening of patients and healthcare workers, restricting visitors who could be incubating communicable diseases,

using appropriate barrier precautions, and furloughing ill healthcare workers. This section reviews infection data so that programs can be tailored to the epidemiologic issues in a given hospital and applied to HSCT units.

Hand Hygiene

General guidelines from HICPAC and WHO on hand hygiene and antisepsis should be followed and have recently been revised *(656,667)*. Because microorganisms are transmitted by contaminated hands, appropriate hand hygiene is the cornerstone for controlling the spread of many infectious agents (see also Chapter 91).

Isolation and Barrier Precautions

Isolation and the use of barrier precautions are implemented to prevent patients or healthcare workers from acquiring or transmitting communicable diseases or pathogenic microorganisms.

CDC/HICPAC isolation guidelines for hospitalized patients should be similarly applied to HSCT patients (127). The guidelines are formulated using two levels of protection: one is standard and applied to all patients, and the other is based on the potential of disease or microorganism transmission. Contact, Droplet, and Airborne Precautions are the most common forms of isolation that are implemented in addition to Standard Precautions. Personal protective equipment such as gowns, gloves, or masks should be donned before entering a patient's room and discarded before leaving the patient's environment (127,*668*).

HSCT units should implement Airborne Precautions for HSCT recipients with airborne infections such as pulmonary or laryngeal tuberculosis, varicella-zoster, and measles. Optimally, this would include placing patients in a protective environment with anteroom and providing N95 or higher-level respirators or masks for healthcare personnel (127). An anteroom is used to further support the appropriate air-balance relative to the corridor and the protective environment (127). Alternatively, place the patient in an Airborne Infection Isolation Room (AIIR) and use portable, industrial-grade HEPA filters in the room to enhance filtration of spores (127). A patient with varicella infection also needs Contact Precautions (see also Chapter 84).

Examples of infectious diseases that require Contact Precautions include VRE, multidrug-resistant gram-negative bacilli, MRSA, *C. difficile*, rotavirus, norovirus, RSV, parainfluenza, and adenovirus (126,127). Adenovirus, influenza, parvovirus, and pertussis require Droplet Precautions for prevention (See the HICPAC "2007 Guideline for isolation precautions" for other infectious diseases [127]). Precautions should be maintained for at least the duration of illness and longer if there is evidence of persistent shedding of the microorganism *(147,669–672)*.

In centers in which many patients are transferred from other institutions, consideration can be given to preemptive isolation while awaiting results of surveillance cultures. Colonization with VRE, MRSA, or MDR gram-negative microorganisms may remain for long periods extending beyond the hospitalization. The duration of Contact Precautions remains an unresolved issue for many infections in this population. Some microorganisms may demonstrate clearance after decolonization therapy but subsequently return *(662)*. One recommended approach is to discontinue Contact Precautions when three or more surveillance cultures are repeatedly negative over the course of a week or two in a patient who has not received antimicrobial therapy for several weeks, especially in the absence of a draining wound, profuse respiratory secretions, or evidence implicating the specific patient in ongoing transmission within the facility *(662)*. In patients with known colonization, Contact Precautions should be continued during hospital readmissions (126). The institutions should have policies about isolation in patients with multidrug-resistant microorganisms.

Blood Product Screening and Prevention of Infection from Extraneous Contamination

As blood products are an important source of several viruses and parasites, screening for agents that cause hepatitis, HIV, and other agents is standard practice in North America. Still, CMV transmission via residual buffy coat cells remains a significant issue in these patients. Among 97 HSCT recipients who were CMV seronegative before transplantation, one of 32 patients who received seronegative products and eight of 25 who received standard blood products developed CMV infection ($p < .007$) *(673)*. In the absence of seronegative products, blood should be depleted of cellular elements. This can be accomplished by several techniques including irradiation or use of specialized filters. Hematopoietic cells for either allogeneic or autologous transplantation are collected from a donor and stored. Infections can occur among recipients of contaminated marrow or blood products *(674)*. Rarely, an infected donor can transmit microorganisms to a patient. More commonly, the patient receives contaminated blood products or marrow that was contaminated during processing and storage. Transfusion-associated infection caused by several microorganisms have been reported: HIV, HTLV I and II, human herpesviruses including CMV, EBV, HHV-6, and HHV-8; Hepatitis viruses that are hepatitis A, B, C, D, E, G, SEN virus and transfusion transmitted virus (TTV); WNV; Parvovirus, dengue virus, bacteria, *Rickettsia*, protozoa (*Toxoplasma gondii*, *Leishmania* species,*Trypanosoma cruzi*, *Babesia* species, *Plasmodium* species) and prion disease (vCJD) *(338,340,341,650,675–724)*. To prevent transmission to HSCT recipients, programs now obtain a history and perform a physical examination on the donor *(725,726)*. Donors are asked about high-risk behaviors, previous travel, and signs and symptoms of infection prior to harvesting the marrow, and serum is screened for serologic evidence of disease *(674,725,727)*. Some infections, such as HBV, can be prevented by vaccination. HBV-naïve HSCT candidates should not receive transplants from hepatitis B-infected donors, if another equally suitable donor is available but it is not absolutely contraindicated (143). Antiviral treatment plays an important role in this situation (143).

Bone marrow can be contaminated during harvesting and during the *ex vivo* processing. The amount of contamination that occurs during *in vitro* processing of bone marrow varies between 2.6% and 17% *(728–732)*. In one study, cultured bone marrow from both allogeneic and autologous donors did not grow microorganisms at the time of harvest; however, 12/153 (8%) samples grew microorganisms when the marrow was thawed prior to infusion (729). Gram-negative microorganisms were most commonly isolated

including *Pseudomonas* species in 5/12 samples. One patient developed *R. picketti* sepsis following infusion of bone marrow cells. Rowley et al. showed that the risk of contamination of marrow increased as it was manipulated *(728)*. Schepers et al. demonstrated a significant decrease in contamination from 5% to 2.6% when appropriate procedures were introduced *(730)*. Contamination has been traced to heparin and contaminated ficoll separation medium *(730,733)*. Finally, Kassis et al. describe an outbreak due to a *Mycobacterium mucogenicum*-related pathogen that contaminated peripheral hematopoietic stem cell products *(734)*. The source of the outbreak was traced to ice cubes used in processing the peripheral blood stem cell products *(734)*.

Environmental Management

Room Ventilation and Protective Environment Ventilation systems are a critical infrastructure in hospitals and must have certain capacities to protect high-risk patients (501). HSCT patients should be placed in protective environment (PE) rooms with positive airflow relative to the corridor and have >12 air exchanges per hour (126). Airflow should be directed and enter one side of the room and be exhausted from the opposite side (501). Air pressure in patient rooms should be maintained at 2.5 Pa higher than any adjoining corridors, anterooms, or bathrooms. Minimal leakage of air is required; therefore, rooms should be well sealed around windows, electrical outlets, and other sources of air (126). Based on a large amount of data showing that filtered air decreases the risk of invasive fungal disease, the evidence-based guidelines for preventing opportunistic infections among HSCT recipients recommend several air filtration strategies, such as air filtration with point-of-use HEPA filtration that removes 99.97% of particles >0.3 μm in size (126). Some institutions have built laminar airflow (LAF) rooms, which are more efficient than HEPA filtration alone but are more expensive and produce more noise. Studies have found that laminar air flow, HEPA filtration, and portable HEPA filters improve ventilation overall and in the setting of hospital renovation and construction *(584,735)*. Many investigators have found a significant decrease in particles and in *Aspergillus* spores in air samples. For example, one of these investigators reported 32% (6/19) of the children undergoing HSCT died of invasive pulmonary aspergillosis during an *Aspergillus* outbreak associated with construction *(736)*. With use of LAF rooms, no more cases of invasive pulmonary aspergillosis occurred *(736)* (Table 59-3). More importantly, a group of allogeneic HSCT patients placed in conventional protective isolation (single patient room and any combination of hand washing, gloves, mask, and gown) were compared to a group placed in HEPA-filtered LAF rooms *(737)*. The 1-year overall risk of transplant-related mortality in the first 100 days post-transplantation was significantly lower in the group treated in HEPA-filtered LAF units compared to those treated by conventional protective isolation. Other investigators have examined the importance of other interventions in the setting of HEPA filtration or LAF rooms. At least two studies have shown that LAF rooms and gastrointestinal decontamination decrease infection rates and decrease adverse outcomes *(738,739)*. Buckner et al. *(738)* found that patients in LAF rooms with gastrointestinal tract decontamination had less illness severity and required fewer granulocyte transfusions (5/46 vs. 22/44; $p < .0001$). Several other investigators advocate use of LAF rooms and sterile diet, gastrointestinal decontamination, and skin cleansing to prevent infections in granulocytopenic patients *(737,740,741)*. To reiterate, HSCT patients, especially allogeneic transplants, should be placed in private rooms with HEPA filtration of air (point of use) with at least 12 air exchanges per hour (126). These rooms should be under positive pressure with respect to the corridors. Although this technology is expensive, the data support improved patient outcomes.

The efficacy of portable machines with HEPA filters has been evaluated and showed benefit in some studies *(593,742)*. Guidelines recommended their use only for lower-risk neutropenic patients in the setting of a shortage of protective environment rooms, because they have never been compared with central HEPA filters in preventing infection.

To reiterate, HSCT patients, especially allogeneic transplants, should be placed in private rooms with HEPA filtration of air (point of use) with at least 12 air exchanges per hour (126). These rooms should be under positive pressure with respect to the corridors. Although this technology is expensive, the data support improved patient outcomes.

Anterooms are helpful in case of HSCT recipients requiring Airborne Precautions, but they are optional according to guidelines (126,501). Anterooms should be used to ensure appropriate air balance relative to the protective environment and the hallway; an independent exhaust of contaminated air to the outside should be provided, or a HEPA filter should be placed in the exhaust duct if return air is to be recirculated (126,501). If a protective environment room with an anteroom is not available, the patient should be placed in a standard airborne infection isolation room and a portable, industrial-grade HEPA filter should be used to enhance the removal of spores in the room (126).

The pressure in the room should be continuously monitored using a system that alarms when the pressure differential between any patients' room and hallway or anteroom falls to below 2.5 Pa *(743)*.

If an outbreak of healthcare-associated pneumonia caused by *Aspergillus* is identified, air should be sampled while a source is investigated *(663)*. Air samples should be taken using a high-volume air sampler. Sample volumes of at least 1,000 L is recommended (51). Low-volume air samplers are not effective for detection of the low numbers of microorganisms that can be of concern among these patients (51) (see also Chapter 84).

Room Decoration and Furnishings Floor surfaces should be smooth and nonporous that makes them easy to clean to diminish dust in the rooms (126). Carpeting should not be placed in any part of a unit since it is associated with healthcare-associated aspergillosis *(589)*. Furniture should be scrubable, nonporous, and easily disinfected (126). Gerson et al. *(589)* reported an outbreak related to carpet tile that was contaminated after a fire. Hence, when damage occurs in a unit due to fire or water, infection control personnel need to inspect the area and consider air and environmental sampling as described below.

Construction and Renovation Construction and renovation projects are common in many hospitals as they strive

TABLE 59-3

General Recommendations for Prevention and Outbreak Management of Healthcare-Associated Aspergillosis and Other Invasive Fungal Infections among HSCT Recipients

Category	*Specific Element*
Education	- HSCT recipients and their caregivers should be educated regarding strategies to avoid environmental exposure to *Aspergillus* and other fungal infections
Ventilation	- Protective environment that consists of ◦ HEPA filtration with 99.97% efficiency ◦ Maintain ≥12 air changes per hour ◦ Well-sealed rooms - Direct airflow - Continuous pressure monitoring with alarm system
Environment	- Eliminate carpet and other sources of dust - Clean rooms (all surfaces) at least daily for dust control - Avoid dust generating activities (use wet mopping, HEPA vacuuming) - Eliminate flowers, potted ornamental plants - Eliminate areas where water or condensation can collect - Clean area after any renovation or construction
Personal hygiene	- Have patients wear masks (N-95) when out of protected environment - Avoid unprocessed food; certain beans and raw fruits - Consider other protective environment (mobile tents)
Construction	- Develop policy for construction and renovation with risk levels - Seal off construction areas and place under negative pressure; use rigid dust proof barriers; seal door, etc. - During outdoor construction seal intake air - Clean area daily if within the hospital or buildings - Treat fireproofing with fungicide (copper-8-quinolinolate) - Assure filters properly sealed in new buildings - Minimize patient exposure to high-risk activities - Minimize the traffic through construction area - Exhaust construction dust
Cleaning rooms	- Use thorough cleaning procedures to ensure daily decontamination and cleanliness of the room - Using approved solution, remove fingerprints and smudges from light switches, door flames, walls, window sills, and glass; spray the solution on the cleaning cloth or carefully on the wall surface to prevent exposure - Terminally clean room on patient discharge or every 3 week
Cleaning bathrooms	- Using an approved solution, wipe down surfaces, lower ledges, and pipes of sink; for more aggressive sink cleaning, use a scouring cleanser to remove soil or stain buildup; clean the mirror with glass cleaner and wipe dry with paper towels; thoroughly clean all ceiling vents, shelves, cabinets, and waste baskets, with germicide - Pay special attention to corners, soap and dish, and drain in showers and sinks; sanitize the shower with germicide and a cleaning cloth; wipe the ceramic tile to prevent a soap buildup; check the shower curtain for possible replacement; clean inside toilet bowl with an approved cleanser and clean the outside bowl with approved germicidal solution, sanitize the inside of the toilet and urinal using a bowl mop saturated with germicide solution; the bowl mop should be worked around, making sure to get into the upper and the lower ledges; accidental spills can be cleaned up by flushing with water and wiping
Waste removal	- Put on gloves, grasp the liner twist, and tie closed - Remove the liner from the basket and replace with a new liner - Place the waste in a trash cart approved by infection control; wash hands thoroughly again and put on new gloves
Restock supplies and inspect room	- Wash hands thoroughly again and put on new gloves; replace soap and paper products in restroom and at the sink; if a discharge, make the patient bed according to discharge procedures; area cleaner inspects room to see that all steps have been covered and the room meets approval - Notify nursing manager or responsible administrator and maintenance of leaks, wet dry wall, or water damage.

(*Continued*)

TABLE 59-3

General Recommendations for Prevention and Outbreak Management of Healthcare-Associated Aspergillosis and Other Invasive Fungal Infections among HSCT Recipients (*Continued*)

Category	*Specific Element*
Surveillance	- Define disease and find cases of healthcare-associated infection - Use large-volume (>1,000 L) air samplers to detect *Aspergillus* or fungal spores
Intervention if healthcare-associated case occurs (501)	- Review pressure-differential monitoring documentation to verify the pressure differentials in the PE rooms and outside - Conduct a prospective search for additional cases and intensify retrospective epidemiologic review of the hospital's medical and laboratory records - Conduct an environmental assessment to find and eliminate the source - Collect environmental samples from potential sources - If either an environmental source of airborne fungi or an engineering problem with filtration or pressure differentials is identified, promptly perform corrective measures to eliminate the source and route of entry - Use an EPA-registered antifungal biocide (e.g., copper-8-quinolinolate) for decontaminating structural materials - If an environmental source of airborne fungi is not identified, review infection-control measures, including engineering controls, to identify potential areas for correction or improvement - If possible, perform molecular subtyping of *Aspergillus* spp. isolated from patients and the environment to compare their strain identities - If they receive antifungal prophylaxis without activity against *Aspergillus* (e.g., fluconazole), consideration could be given to using voriconazole or posaconazole

to update facilities. Construction, renovation, and maintenance, whether minor or major, pose special problems for patients undergoing HSCT. Because of their immunosuppression, patients are at risk for developing infections from microorganisms (e.g., *Aspergillus* or *Legionella* spp.) released from construction sites, or from destruction of existing structures and renovation, or from the water supply. This association with construction has been based on outbreak investigations and endemic assessment of cases with geographic proximity, temporal relationships, the finding of *Aspergillus* in the environment and supporting molecular typing data, and the control of these infections with appropriate interventions. Despite the lack of direct proof, few dispute the relationship. Hence, any construction or renovation project requires a multidisciplinary team to review the plans for demolition and construction, placement of barriers, and egress and entry to areas (126). All institutions should have a policy for construction and renovation that allows hospital staff to assess the risks any project could pose to patients. Such construction policies should be part of contracts if outside contractors are used for institutionally based projects. Contractors should have back up equipment available and onsite. The numbers of *Aspergillus* spores in unfiltered ambient air have been measured in several locales and vary from 0.1 to 15 CFU/m^3. The numbers vary with wind, weather conditions, and season *(744)*. Streifel et al. *(745)* showed that the numbers and concentrations of thermotolerant fungi, especially *A. fumigatus*, increase significantly after demolition of a hospital building. The concentration of thermotolerant fungi and *A. fumigatus* increased by 1.8 log 10—10^2 to 10^5 and 3.3 log10—10 to 10^4, respectively, after the building's demolition *(745)*. Because of these data, construction standards are required for any unit housing HSCT patients. These include many elements such as placing appropriate barriers, sealing the barriers, moving high-risk patients away from construction, using negative pressure and HEPA filtration, and assuring that the air-handling system is functioning properly, and exhausting construction dust appropriately. Because of the risk of transmission of *Aspergillus* or other microorganisms in the air-handling systems, construction personnel must work with the institution's engineers to isolate heating and ventilation systems. In addition, airtight barriers have been found to significantly reduce the number of *Aspergillus* spores from 4.2 ± 0.4 spores/m^3 inside the barrier to 1.0 ± 0.3 spores/m^3 outside the barrier *(581)*. Spore counts were also obtained from adjacent hospital units and found to be highest on the floor directly below construction (2.3 ± 1.3 spores/m^3 below the construction site and 1.1 ± 0.6 spores/m^3 in adjacent wards). Implosions require concurrent monitoring to determine whether the air-handling system will require manipulation *(746)*. Srinivasan et al. *(746)* did serial measurements in adjacent buildings and city blocks when a building was imploded near a cancer center. They found that engineers could adjust hospital air-handling systems to the movement of the debris cloud produced by the implosion *(746)*. These systems could accommodate the modest increase in *Aspergillus*, other fungi, and particles generated by the implosion. In addition, air samples containing *Aspergillus* species were paralleled by particle counts, suggesting these can be used to guide any interventions.

Fireproofing can harbor microorganisms including *Aspergillus*. Copper-8-quinolinolate, a fungicide, can be used to decontaminate environmental surfaces. This compound

is highly active against clinically important fungi including *Aspergillus* species and has been used to abort several outbreaks *(578)*. It also has the advantage of having persistent antifungal activity and will theoretically prevent fungi or molds from growing if subsequent water damage occurs *(578)*. Opal et al. *(581)* cultured a mean of 4.9 ± 1.5 *Aspergillus* spores/m^3 from environmental surfaces in a hospital unit before they were treated with copper-8-quinolinolate. After treating surfaces with this fungicide, a mean of 0.1 ± 0.1 *Aspergillus* spores/m^3 were cultured *(581)*. Construction traffic patterns should be directed to allow for efficient waste disposal through garbage chutes. If not feasible, construction waste should be removed in covered bins. Floors should be cleaned (wet mopped) following the removal of construction waste. Construction personnel should avoid traversing areas where high-risk patients are located. Protective clothing may be appropriate to prevent dissemination of microorganisms into the air. Traffic should be directed away from construction. Cooper et al. *(747)* demonstrated that the construction measures described above were effective in controlling the amount of ambient *Aspergillus* and *Aspergillus* disease. The amounts of viable pathogenic fungi were similar between areas under construction and those that were not. There was no difference in the incidence of invasive aspergillosis between 2000 and 2001 (incidence density ratio = 1.2; 95% CI = 0.3–4.1).

HSCT recipients should avoid construction areas. Wearing N95 respirators is recommended while traveling outside protective environment rooms (51). Raad et al. *(748)* demonstrated the effectiveness of wearing high-efficiency masks when the high-risk neutropenic patients left their rooms in construction periods. The rate of healthcare-associated aspergillosis decreased from 0.73 cases per 1,000 hospital patient days to 0.24 per 1,000 hospital patient days during the two study periods *(748)*.

During construction periods, environmental surveillance should be considered; however, monitoring for cases of aspergillosis should also be performed (126). If an outbreak is suspected, microbiological air sampling may be performed (126).

After construction, one must ensure new filters are properly seated. We recommend visual inspections to determine whether or not water damage has occurred. Based on the experience of Rhame we further recommend obtaining air samples prior to opening such areas to patients *(749)* (see Chapter 83).

Water and Water Management Water treatment beyond that provided by municipal water systems is primarily aimed at preventing healthcare-associated *Legionella* infections. Prevention strategies vary by institution and depend on the immunologic status of the patients, the design and construction of the facility, the available resources, and state and local health department regulations *(483)*. Strategies for prevention and control of healthcare-associated legionellosis may include decontamination followed by a maintenance phase. Several caveats must be considered in any plan to treat water and to prevent *Legionella* infections. First, in the initial phase, the effectiveness of a water treatment plan in a hospital water distribution system should be assessed long-term, over 3 to 5 years. Second, most strategies to treat hospital water distribution systems have not been compared to each other. Hence, one is forced to look at the characteristics of the water system in the institution and choose the best engineering and most cost-effective option.

Surveillance for healthcare-associated *Legionella* in the water is the ultimate test of the efficacy of any water treatment plan. If this approach is taken, a comprehensive plan will provide the most useful information (501). Appropriate diagnostic tests must be used to evaluate patients with healthcare-associated pneumonia and to diagnose *Legionella* infections (126). Targeting high-risk patients such as those who have undergone transplantation has been proposed and has the advantage of being cost efficient *(483,750)*. Goetz and Yu *(750)* suggest that culturing the water supply and targeting high-risk patients for specialized *Legionella* laboratory tests may help clinicians discover *Legionella* cases in the absence of an outbreak. One strategy requires periodic culturing of the potable water system if more than 30% of cultures of distal outlets (faucets) yield *Legionella* species, or if the system has been decontaminated *(751)*. Current guidelines recommend performing periodic culture surveillance for *Legionella* species in potable water for HSCT units (126,501). Documentation of environmental sources of *Legionella* or a case of healthcare-associated infection should prompt active surveillance, looking for clinical cases and a source of *Legionella*. The approach is based on the theory that in the absence of *Legionella* in water cultures, no cases of healthcare-associated legionellosis can occur *(483)*. In this case, the potable water system, potable water outlets in the patient's room, and cooling towers should be cultured by a laboratory with expertise in processing environmental samples. In addition, other potential sources including humidifiers, portable airconditioners, nebulizers, fountains, irrigation equipment, whirlpools, and ice machines should be investigated. If such environmental surveillance cultures yield *Legionella*, the water supply should be decontaminated; HSCT patients should be restricted from bathing or showering in *Legionella*-contaminated water; water from faucets should not be used in the HSCT area, and bottled water should be used by patients for drinking, brushing teeth, or flushing nasogastric tubes (126).

A decorative fountain was reported to be the source of a healthcare-associated *Legionella* outbreak in one study *(105)*. Hence, fountains should not be installed in HSCT units or in other areas where these patients spend time (126).

For additional information, see Chapter 36.

Besides *Legionella*, the hospital water system can be a source of an outbreak or pseudo-outbreak involving other microorganisms such as NTM, fungi, and nonfermenter gram-negative microorganisms (*Pseudomonas* spp., *Burkholderia* spp., *Stenotrophomonas* spp., *Acinetobacter* spp., *Ralstonia* spp., *Sphingomonas* spp., *Afipia felis*) *(523,524,752)*. Whenever outbreaks of these microorganisms occur, the link to a water reservoir should be on the priority list to investigate.

Equipment Supplies and equipment should be monitored for dust or potential mold contamination, particularly materials that are used on patients' skin. An outbreak of mucormycosis has been linked to contaminated elastic bandages;

therefore, dressing supplies should be examined regularly. Materials that are out of date, damaged, or contaminated should be discarded (126,*753*). An outbreak of primary cutaneous aspergillosis has been associated with the use of an intravenous arm board *(754)*. For this reason, when arm boards are used, they should be changed frequently (126).

Plants and Fresh Flowers Plants, fresh flowers, and vases have been shown to harbor bacteria and other microorganisms that are pathogenic for immunocompromised patients. Within 3 days of fresh flowers being placed in water, the water contains up to 1×10^{13} CFU of bacteria per milliliter of water *(39)*. When cultured, *P. aeruginosa*, *Burkholderia cepacia*, *P. alcaligenes*, *A. hydrophila*, *Acinetobacter* spp., *Flavobacterium* spp., *E. coli*, *Klebsiella* spp., and *Proteus mirabilis* may be recovered *(39)*. Other authors have found that water cultured from flower vases in hospitals may contain pathogenic fungi as well *(40)*. The microorganism counts increased logarithmically and significantly ($p < .0005$) over time and were not different if distilled or sterile water was substituted for tap water *(39)*. Several investigators found that water obtained from flower vases contains microorganisms that are highly resistant to antimicrobial agents *(39,40)*. Because of these data, most HSCT units do not allow fresh flowers or live plants to be brought in to patients. Although there is no strong evidence that fresh flowers and plants cause invasive mold infections among HSCT recipients, current guidelines suggest that they not be allowed in HSCT recipients' rooms and that exposure to soil-based materials should be avoided (126).

Toys Toys have been associated with outbreaks on pediatric oncology units *(303,409)*. For example, outbreaks of rotavirus in pediatric oncology units related to communal toys in the playroom and an outbreak of multidrug-resistant *P. aeruginosa* related to water-retaining bath toys in a pediatric oncology ward have been reported *(303,409)*. If toys are used in HSCT units, they should be cleaned and disinfected appropriately. Toys that cannot be washed or disinfected should not be used (126).

Environmental Cleaning The overall cleanliness of the unit is important and recent data highlight the role of the environment in contribution to healthcare-associated infections and outbreaks *(755–761)*: Bootsma et al. (*761*) used mathematical modeling and estimated that the prevalence of gram-negatives on environmental surfaces in ICUs was between 15% and 26%. They then estimated that between 21% and 28% of gram-negative colonizations were acquired from exogenous sources *(761)*. Carling et al. *(762)* showed that only 47% of targeted objects and surfaces had been cleaned. With education, sustained cleaning of over 85% of objects was achieved *(762)*. Thorough cleaning has been integrated into protocols to decrease environmental contamination and infection and hence is required after patients are discharged from a hospital room, or after a patient is seen in the outpatient clinic (501,*757*,*763–766*). If a dedicated clinic room is provided, cleaning at the end of the day may suffice. Many microorganisms can contaminate the environment through contaminated secretions or through transmission on contaminated hands. Environmental cleaning is an important method to reduce transmission of multidrug-resistant microorganisms *(767)*. Because these microorganisms survive in harsh conditions, thorough cleaning is indicated with the appropriate disinfectant. Isopropyl alcohol and most disinfectants (sodium hypochlorite, phenolic, and quaternary ammonium compounds) are effective against VRE *(768)*. To prevent transmission of *C. difficile*, chlorine-containing cleaning products with at least 1,000 ppm available chlorine are recommended for decontamination of inanimate objects and environmental surfaces *(661)*. Chlorine bleach solution (1,000–5,000 ppm) is also recommended to prevent norovirus transmission *(755)*. However, novel methods that evaluate the effectiveness of cleaning illustrate that attention to compliance with standard cleaning techniques and the use of appropriate products is important *(762)*.

Accumulation of dust should be prevented. Furthermore, cleaning activities should not generate dust (Table 59-3) (126). Thus, surfaces should be wiped with wet cloths and mops. Special HEPA vacuums should be used in HSCT units (126). Thio et al. (*51*) demonstrated that wet mopping could disperse 30,000 particles/m^3 into the air as compared to 800,000 particles/m^3 after dry mopping. Anderson et al. *(590)* noted that airborne *A. fumigatus* rose from 24 CFU/m^3 before vacuuming to 62 CFU/m^3 while the vacuum was being used.

Personal Hygiene

Damage to the oral cavity caused by cytotoxic, infectious, and hemorrhagic complications of GVHD is reflected by the severity of the mucositis. The oral cavity is a reservoir for microorganisms. The microorganisms accounting for most oral infections are HSV and *C. albicans (57)*. By reducing the number of oral microorganisms through optimal care, the risk of developing a life-threatening systemic infection from an oral source may be reduced. Aggressive dental and oral hygiene interventions can ameliorate oral complications prior to transplantation, as elimination of oral infection is paramount for the success of HSCT (126). Preferably, all HSCT candidates should undergo a dental evaluation and complete invasive oral procedures 10–14 days before starting conditioning therapy (126,*769*). Daily showers and good perineal care are recommended to optimize skin care (126). Mucositis should be managed following established guidelines *(770)*.

Food Preparation and Handling

Careful food preparation is required in all patients but particularly important in patients undergoing transplantation. Guidelines recommend a low-microbial diet for HSCT recipients, although the evidence to support this practice is limited (126,*771*,*772*). Gardner et al. *(773)* investigated the value of a neutropenic diet in 153 patients with newly diagnosed acute myeloid leukemia or high-risk myelodysplastic syndrome. The patients were randomized to receive only a cooked diet or a diet containing fresh fruit and fresh vegetables (raw diet). All patients were in a protective environment and received antimicrobial prophylaxis. The outcome revealed 29% of patients in the cooked group and 35% of patients in the raw group developed a major infection, which was not statistically different *(773)*. Fever of unknown origin in the group receiving cooked food was higher than in the group eating raw food (51% vs. 36%), but the probability of death was not different *(773)*. However, attention to the types

of foods and appropriate storage and handling is needed for all HSCT recipients to prevent food-borne diseases (774). Non-neutropenic HSCT recipients still have immunosuppression for a period of time after transplantation; therefore, food safety is an important issue for these patients. Formal recommendations have been published that include recommendations for adequately cooking certain foods, although restricting exposure to certain fruits and vegetables and dairy products is advised *(775)*. HSCT recipients should not consume raw or undercooked eggs or foods that might have them in the ingredients (774). Several microorganisms that cause foodborne illnesses could also infect these hosts and cause severe illness. One example is nontyphoidal salmonellosis (NTS), which is an emerging problem that can lead to bacteremia in HSCT recipients *(118,776)*. Hence, food should be appropriately stored and well cooked. HSCT recipients and their caregivers should be educated regarding diet; they should be advised about which foods to avoid including those which may contain yeast or molds (774).

Visitors

Visitors and family members, although critical to the care of the HSCT patients, can be a source of infectious diseases that can lead to infection in patients. Visitors must clean their hands and follow isolation and barrier precautions. They should be vaccinated including vaccination for influenza to prevent transmission of diseases to HSCT patients. Visitors who are ill with potentially infectious diseases should not be allowed into the institution and should be screened for diarrhea, vomiting, fever, conjunctivitis, undiagnosed rash, upper respiratory symptoms, recent exposure to people with symptoms consistent with an acute infectious illness, or recently vaccinated with live vaccine (e.g., polio, MMR, or varicella vaccines). In addition, visitors should be screened for respiratory illness and not allowed to visit an HSCT unit while symptomatic or infectious. Allowing children to visit is very controversial, as they are exposed to many infectious and communicable diseases in school, at play, or in day-care settings. The risks and benefits should be weighed, but additional precautions may be necessary if children are allowed on units. Certainly, more restrictive policies are needed if community or unit-based outbreaks of a communicable disease are in progress. Such strategies have been effectively used to prevent further transmission of influenza, pertussis, SARS, and RSV.

Healthcare Personnel

All healthcare workers should have immunizations required by the institution including measles, mumps, rubella, and evidence of immunity to varicella or of receipt of the varicella vaccine (see Chapters 43, 51, and 75). Varicella vaccine can be administered to susceptible healthcare workers working on HSCT units *(274)*. If a local, vesicular reaction after the vaccine occurs, the healthcare worker should avoid contact with HSCT recipients until all lesions resolve or no new lesions appear within a 24-hour period *(274)*. Vaccine-associated infections can be spread among household contacts, but no data are available on spread among healthcare workers *(777)*.

All healthcare workers should be vaccinated against influenza annually. Early detection of influenza in healthcare institutions is crucial for preventing healthcare-associated transmission. Influenza vaccine in healthy, young healthcare workers is 88% efficacious for influenza A and 89% for influenza B *(778)*. In addition, Potter et al. demonstrated that vaccinating healthcare workers for influenza reduced influenza-like illness and decreased mortality 47% *(779)*. Current guidelines strongly recommend influenza vaccine in healthcare workers *(182)*.

Healthcare workers with transmissible infectious diseases should follow the recommendations regarding work restrictions *(780)*. Institutions should provide a written policy about immunizations and work restrictions for healthcare workers who work in HSCT units.

ANTIMICROBIAL PROPHYLAXIS

Antiviral Chemoprophylaxis

Cytomegalovirus CMV disease causes significant morbidity and mortality among patients undergoing HSCT, even in the face of antiviral therapy. As such, much effort has been directed toward prevention of CMV disease. Two basic strategies for CMV prevention have been employed: use of antiviral agents in all patients (prophylactic therapy), and screening of at-risk populations for evidence of CMV shedding with early treatment of those patients (preemptive therapy). All patients undergoing HSCT should undergo serum testing for anti-CMV antibodies before transplantation (143). In addition, the guidelines strongly recommend that all at-risk allogenic HSCT recipients (CMV-seropositive HSCT recipients and CMV-seronegative recipients with a CMV-seropositive donor) should receive either prophylactic or preemptive treatment with ganciclovir, with preemptive therapy being preferred (143). Further discussion of this subject is beyond the scope of this chapter. The high incidence of granulocytopenia associated with these therapies potentially exposes a large number of patients who do not have CMV disease to the risk of neutropenic bacterial infections. Furthermore, prophylaxis does not prevent reactivation of CMV later in the patient's course after ganciclovir has been discontinued.

Newer antiviral agents have also been tested and have been shown to be effective in preventing CMV infection including valacyclovir.

The preemptive treatment strategy relies on active surveillance for CMV shedding and initiation of treatment prior to the development of clinical CMV disease. A number of techniques have been employed to detect CMV shedding including shell-vial cultures, detection of pp65 antigen, and detection of CMV-DNA PCR. Shell-vial cultures can take up to 2 days to give a positive result and are therefore less useful in prompt detection of shedding. Detection of CMV pp65 antigen from peripheral white blood cells is currently the most common technique to detect viremia; however, false-negative tests can occur if the patient is neutropenic. The highest levels of serum antigen are seen among patients with pneumonitis, gastroenteritis, and viremia. Overall, the positive predictive value for CMV disease in HSCT patients is 53% and the negative predictive value 91%, and the antigen test was positive a median of 10 days before cultures were positive in all pneumonitis patients *(229)*.

Valganciclovir, an oral prodrug of ganciclovir, has been used in preemptive therapy (143). The results from uncontrolled studies suggest that the efficacy and safety of

valganciclovir, when used as preemptive therapy, are comparable with intravenous ganciclovir *(225,781–788)*.

Foscarnet has been studied for preemptive therapy in allogeneic HSCT patients with CMV antigenemia and the result was comparable to ganciclovir *(789)*. The guideline places it as alternative therapy, because it requires prehydration and electrolyte monitoring (143). However, patients who cannot tolerate ganciclovir should be treated with foscarnet (143).

Cidofovir has also been evaluated in a number of nonrandomized studies with acceptable results *(790–792)*. Because of nephrotoxicity, its use in HSCT may be limited *(225)*. The current guideline recommends cidofovir as second-line preemptive therapy (143). Cross-resistance between ganciclovir and cidofovir can occur *(793)*.

Currently, there is no benefit to routinely administering ganciclovir to HSCT patients who are greater than 100 days posttransplant (143). However, antiviral therapy should be continued after 100 days in HSCT patients in whom virus can be detected.

Prophylaxis for HSV and VZV Acyclovir should be offered prophylactically to all HSCT patients who are HSV seropositive (143). This strategy prevents reactivation of disease. Prophylaxis should be initiated with the conditioning regimen and continued until engraftment occurs or mucositis resolves. Several studies have shown that oral acyclovir prevents the reactivation of oral HSV infections *(794–797)*. Eighty percent of seropositive patients excrete HSV during the first 50 days after transplantation *(136)*. In contrast, fewer than 1% of seronegative patients excrete virus. Wade et al. *(796)* gave acyclovir or placebo to 49 HSCT patients for 5 weeks beginning 1 week before transplantation. Five of twenty-four patients receiving acyclovir developed HSV infection during prophylaxis, compared to 17 of 25 patients receiving placebo ($p < .01$) *(796)*. Among patients taking a minimum of 40% of their prescribed drug, acyclovir was 96% virologically effective and 100% clinically effective during the period of administration.

Valaciclovir, famciclovir, and ganciclovir are active against HSV (143,*264*,*798*). Although less studied, valaciclovir and famciclovir can be used for HSV prevention (143,*264*,*799,800*). Use of ganciclovir prophylaxis for CMV is adequate for HSV prevention (143).

Two prospective studies suggest that acyclovir prevents varicella infection in HSCT recipients *(801,802)*. In these studies, acyclovir was continued for 1 year, and was demonstrated to be highly effective in reducing the risk of VZV disease during the year while receiving the medication *(801,802)*. Post study, VZV occurred in patients who needed to continue immunosuppressive therapy *(801,802)*. Continued use of acyclovir may be recommended in HSCT recipients with chronic GVHD or patients with immunosuppressive therapy *(279)*.

Valacyclovir may be used for VZV prophylaxis based on a nonrandomized study in allogeneic HSCT recipients *(803)*.

Ganciclovir also has activity against VZV. One nonrandomized study demonstrated that it is effective for VZV prophylaxis in HSCT *(268)*.

Optimal duration of VZV prophylaxis in HSCT recipients with chronic GVHD or patients with immunosuppressive therapy is unknown. The current guideline suggests that acyclovir may continue until 6 months after discontinuing all systemic immunosuppressive agents (143).

Antibacterial Prophylaxis

Because of the high mortality associated with bacterial infections, particularly during the pre-engraftment phase, research has been directed toward the prevention of these infections using antimicrobial agents. Importantly, guidelines for the use of antimicrobial agents in neutropenic patients have been developed that include a risk assessment, a systematic evaluation of the patient, and a stepwise approach to use of these agents *(351)*. These guidelines provide a measured and thoughtful approach to the use of vancomycin that will help limit resistance *(253)*. The rationale for prophylactic administration of antibiotics is based on data that show that the majority of bacterial infections arise during the neutropenic phase from the patient's endogenous flora. Prophylactic antibiotics, therefore, have been used to selectively decontaminate certain body sites. As the gut is the primary reservoir of potentially pathogenic bacteria, attempts at decontamination have focused on this site. The downside of eliminating the resident flora is the potential for selection of other, potentially more resistant, microorganisms. In addition, the benefits of these agents must be balanced against the deleterious effects including toxicity, resistance, fungal overgrowth, and superinfections *(804–807)*. Although many regimens have been used in the past, this discussion focuses on agents currently in use and on studies focusing on HSCT patients *(351,808–810)*.

Two meta-analyses in the 1990s performed by Cruciani et al. *(810)* and Engels et al. *(809)* revealed that fluoroquinolone prophylaxis compared to placebo or trimethoprim-sulfamethoxazole in neutropenic patients could reduce the rate of infectious complications, but it had no effect on infection-related mortality. Gafter-Gvili et al *(811)*. performed another meta-analysis and showed that fluoroquinolone prophylaxis reduced the risk for all-cause mortality when compared to placebo (relative risk = 0.52). However, fluoroquinolone prophylaxis increased the risk for harboring bacilli resistant to this class of agents *(811)*.

Bucaneve et al. *(808)* performed a prospective, multicenter, double-blinded, randomized study to investigate the effect of prophylactic use of 500 mg of levofloxacin in patients with cancer and neutropenia. Patients were assigned to receive 500 mg of levofloxacin orally or placebo everyday until neutropenia had resolved. Patients who received levofloxacin had a lower rate of microbiologically confirmed infections than the placebo group, but the mortality rates were similar *(808)*. Current guidelines recommend levofloxacin for prevention of bacterial infections in adult HSCT recipients with predicted neutropenia for 7 days or more (812). No data are available in children, although some experts also use levofloxacin for pediatric HSCT (812). Prophylaxis should start at the time of stem cell infusion and should be continued until recovery from neutropenia or the start of empiric treatment for febrile neutropenia (812). Local epidemiological data should be determined before utilizing fluoroquinolone in prophylactic regimens for HSCT patients because of increasing rates of fluoroquinolone resistance worldwide (812,*813*). For example, a study from Taiwan reported by Chen et al. *(814)*

demonstrates that only 50% of *E. coli* and 44% of *P. aeruginosa* isolated from patients admitted to hemato-oncology wards were susceptible to ciprofloxacin. Gram-negative microorganisms caused 60% of the cases of bacteremia in neutropenic patients in this institution *(814)*.

The expected consequences of antibacterial prophylaxis that impact infection control groups are the emergence of resistant microorganisms and infections and superinfections caused by fungi *(805,806)*.

TMP-SMX has been used to prevent PCP for years, and retrospective data provide information about its utility in preventing bacterial infections *(815)*. In most studies, patients receiving TMP-SMX have lower infection rates than patients receiving placebo *(351,815)*. In one large study of adult and pediatric patients who were randomized to placebo or 160/800 mg of TMP-SMX until the neutropenia resolved, those who received TMP-SMX developed fewer infections (26% vs. 39%; $p < .02$) *(816)*. There have been no studies examining the use of TMP-SMX specifically in HSCT recipients, but its use is attractive, as these patients require TMP-SMX for PCP prophylaxis. TMP-SMX also provides some protection against toxoplasma, nocardia, and some enteric pathogens *(513)*. Unfortunately, drug side effects associated with higher doses, primarily skin manifestations, occur in approximately 20% of patients *(817)*.

The spectrum of infecting microorganisms in HSCT patients has shifted with the use of both TMP-SMX and quinolones; gram-positive infections have increased *(818)*. A particularly marked increase in alpha-hemolytic streptococcal infections has been noted in patients receiving ciprofloxacin, which has poor activity against streptococci *(54,60,344)*. The mortality associated with gram-positive infections is lower than that seen with gram-negative sepsis, and the overall burden of bacterial infections is decreased with prophylaxis *(136)*. Prophylactic strategies to decrease the morbidity associated with these infections have yet to be defined in randomized trials. Some centers currently include penicillin V, a first-generation cephalosporin, or vancomycin in their regimen, at least while the patient has mucositis *(344,819–821)*. Of note, there is no good evidence to confirm the benefit of adding an anti–gram-positive agent to the prophylaxis regimen. One meta-analysis demonstrated no difference between patients who received a fluoroquinolone alone and patients who received a fluoroquinolone in combination with gram-positive prophylaxis in terms of occurrence of clinically documented infections, unexplained fever, or infections-related mortality *(822)*.

Current guidelines only recommend that prolonged antibiotic prophylaxis for preventing infection with *S. pneumoniae* among allogeneic recipients with chronic GVHD for as long as active chronic GVHD treatment is administered. Antibiotic selection should be guided by local antibiotic resistance patterns (812).

Vancomycin flushes, injections, and dwells and insertion prophylaxis have been used to prevent catheter-related bloodstream infections *(823–828)*. Prophylaxis to prevent infections related to insertion has not been shown efficacious, and centers should follow the recommendations for skin preparation and catheter care described in the national guidelines *(97,826,828)*. Studies examining the impact of vancomycin prophylaxis to prevent line-associated infections report mixed results *(823–828)*. Controversy arises as other components tested including heparin may have impacted the results, and antimicrobial resistance likely develops in this setting.

In summary, prophylaxis is recommended for bacterial infection prevention in patients with neutropenia and for prevention of PCP (812). The routine use of vancomycin (or other antimicrobial agents) to prevent central-line infections is not recommended (*351*,812,*829*).

Antifungal Prophylaxis

Invasive fungal infections cause significant morbidity and mortality among HSCT recipients (549,*830*,*831*). As their presentation may be insidious, diagnosis and treatment challenging, and clinical outcomes dismal, primary antifungal prophylaxis has become an attractive strategy. The advent of potent and well-tolerated antifungal agents, namely the azoles, has made primary antifungal prophylaxis achievable. Two large randomized, placebo-controlled trials validated the use of fluconazole for primary antifungal prophylaxis among HSCT recipients (541,*832*). Goodman et al. conducted a double-blinded randomized clinical trial in which patients were randomized to receive 400 mg of fluconazole or placebo (541). Autologous and allogeneic HSCT recipients received fluconazole or placebo upon initiation of the conditioning regimen, which was discontinued when the ANC was over 1,000/mm^3 for 7 consecutive days. (541). Fluconazole was associated with significantly fewer IFIs (2.8% for fluconazole vs. 15.8% for placebo; $p < .001$), predominately *Candida* infections, and lower mortality attributable to IFIs compared to placebo (1 of 179 for patients taking fluconazole vs. 10 of 177 for patients taking placebo; $p < .001$) (541). Another study involving 300 allogeneic HSCT recipients showed that fluconazole again lowered rates of IFIs (no *C. albicans* infections in fluconazole group compared with 18 in the placebo group, $p < .001$) *(832)*. A significant survival benefit was also found in this study, with 20% mortality in the fluconazole arm versus 35% in the placebo; *p*-value .004 *(832)*. In a subsequent analysis of this study, administration of fluconazole was associated with persistent survival benefit in terms of candidiasis-related death, even after discontinuation of fluconazole at day 75 post-HSCT *(542)*. There were 17.5% more patients in the fluconazole arm surviving compared to the placebo group by 8 years after HSCT *(542)*. In addition, fluconazole administration appeared to be associated with a decreased incidence of severe gut GVHD *(542)*. Moreover, the patients who were treated with fluconazole for 75 days had significantly fewer systemic candidal infections "late" (more than 110 days) after HSCT, and more patients who received placebo died with candidiasis during this late period *(542)*.

The higher rates of IA prompted investigators to study antifungal agents with activity against *Aspergillus* species as primary antifungal prophylaxis in the HSCT setting. Itraconazole is a broad-spectrum triazole with activity against—among others—*Aspergillus* and *Candida* species. A randomized, placebo-controlled, double-blind, multicenter trial among 405 neutropenic patients with hematologic malignancies showed that proven or suspected deep fungal infection occurred in 24% (48/201) and 33% (67/204) of patients in the itraconazole and placebo arms,

respectively ($p = .035$) *(833)*. Candidemia was significantly lower among patients receiving itraconazole as compared to placebo ($p = .01$), and a marginal survival benefit ($p = .06$) was found in the itraconazole arm. In another randomized, placebo-controlled trial involving over 200 HSCT patients, those patients receiving placebo developed fungal infections (superficial or systemic) more frequently than those receiving itraconazole (15% vs. 6%; $p = .03$) *(834)*. Among patients with profound and prolonged neutropenia, those receiving placebo used more empirical amphotericin B (61% vs. 22%; $p = .0001$) and developed more systemic fungal infections (19% vs. 6%; $p = .04$). Additional prospective randomized studies examined the impact of fluconazole or itraconazole for 180 days posttransplant or until 4 weeks after discontinuation of GVHD) therapy *(835)*. Significantly fewer patients developed an IFI in the itraconazole (7%) compared to the fluconazole arm (15%; $p = .03$) *(835)*. Rates of invasive candidiasis were similar in both arms ($p = .67$), while invasive mold infections were significantly lower in the itraconazole group (5%) compared to the fluconazole arm (12%; $p = .03$) *(835)*. More patients in the itraconazole arm had to discontinue their prophylaxis, because of toxicities or gastrointestinal intolerance (36% vs. 16%, $p < .001$) *(835)*. Due to poor tolerability, absorption issues, drug–drug interactions, and toxicities, the utility of itraconazole as a primary universal antifungal prophylaxis agent is limited (*833*,*836*,*837*,838).

Low-dose amphotericin B prophylaxis to avoid the toxicity of conventional doses has been considered for antifungal prophylaxis. A number of studies have examined the use of different low-dose protocols in different populations at potential risk with varying results. Rousey et al. *(839)* demonstrated that low-dose amphotericin B starting during the conditioning regimen significantly decreased the overall and *Aspergillus*-specific mortality *(839)*. In fact, when used among patients receiving corticosteroids for acute GVHD, low-dose amphotericin B reduced the risk for fungal infection from 30% to 9%; *p*-value .01 *(840)*. Other formulations of amphotericin B have also been studied and similar results found, including an aerosolized form and a liposomal preparation *(841–844)*. However, at least one investigator did not replicate these findings among autologous HSCT patients *(845)*. Aerosolized liposomal amphotericin B (L-AmB) was evaluated as prophylaxis during neutropenia in a randomized, placebo-controlled trial among 271 patients. The patients were randomized to receive 2.5 mL of L-AmB. Nebulization was performed for 30 minute per day on 2 consecutive days per week. The weekly regimen was repeated until neutrophil recovery, with a maximum of 12 inhalations per neutropenic episodes. The outcomes showed that 4% of 139 patients treated with liposomal amphotericin B had developed invasive pulmonary aspergillosis (IPA), while 14% of 132 patients receiving placebo developed IPA with significantly more adverse effect (most frequently coughing but not renal toxicity) in the L-AmB group; *p* .002 *(846)*.

More recently voriconazole, a newer agent, has been studied. Fluconazole 400 mg per day was compared to voriconazole 400 mg per day in 600 allogeneic HSCT recipients *(847)*. Antifungal agents were given for 100 days after transplant and up to 180 days in case of higher-risk patients. The primary end point was fungal-free survival at 180 days. There were trends to fewer IFIs, A*spergillus* infections, and less frequent empiric antifungal therapy in the voriconazole arm. There was no survival benefit, and safety was similar in both arms.

Posaconazole, a newer broad-spectrum oral triazole with activity against the Zygomycetes, was compared with oral fluconazole for prophylaxis against IFIs in allogeneic HSCT recipients with GVHD who were receiving immunosuppressive therapy *(848)*. Posaconazole was found to be as effective as fluconazole in preventing all IFIs (5.3% and 9.0%, respectively; odds ratio, 0.56; 95 percent confidence interval [CI], 0.30 to 1.07; $p = 0.07$) and was superior to fluconazole in preventing proven or probable IA (1% in posaconazole group vs. 7% in fluconazole group; $p < .001$); however, overall mortality was similar in the two groups *(848)*. Based on the above, the Infectious Diseases Society of America's clinical practice guidelines for the treatment of aspergillosis recommends the use of posaconazole in HSCT recipients with GVHD who are at high risk for IA *(849)*.

Micafungin, an echinocandin antifungal agent, was evaluated for prophylaxis against IFIs during neutropenia in patients undergoing HSCT *(850)*. A prospective, randomized, double-blind study in adult and pediatric patients compared micafungin and fluconazole *(851)*. Micafungin treatment decreased proven, probable, or suspected systemic fungal infections more often than among patients in the fluconazole group (80% in the micafungin group vs. 73.5% in the fluconazole group were free of IFIs; $p = .03$) *(851)*. However, use of micafungin as a prophylactic agent is limited due to cost and lack of an oral formulation (838).

Ultimately, the selection of an appropriate prophylaxis protocol depends on the epidemiology at a given institution. Daily fluconazole prophylaxis is still recommended (838,*852*). However, institutions with high-risk HSCT patients, high rates of fluconazole-resistant *Candida* infections or *Aspergillus* infections may consider using other alternatives, including voriconazole or posaconazole. Moreover, ongoing surveillance efforts are necessary to adjust prophylaxis strategies to an evolving microbiologic flora.

Prophylaxis for *Pneumocystis jiroveci* Pneumonia

Prophylaxis with TMP-SMX has been shown to prevent PCP in immunocompromised patients *(351,638,853)*. (TMP-SMX has already been mentioned in antibacterial prophylaxis.)

Oral dapsone is recommended as alternative regimens for PCP prophylaxis *(655)*. For HIV-positive patients, it has been considered to be the best alternative regimen after TMP-SMX, but there are limited data for HSCT patients *(854)*. Souza et al. *(855)* performed a study that compared the effectiveness between dapsone and TMP-SMZ in preventing PCP among allogeneic HSCT recipients and demonstrated that the incidence of PCP among patients receiving dapsone was 7.2%, whereas the incidence of PCP among patients receiving TMP-SMX was 0.37% and 6.8% in historical controls who received no prophylaxis *(855)*. However, the dose regimen used in this study was lower than the current recommendation in the guideline, and this study was not a randomized study. Dapsone was recommended

only for patients who had TMP-SMZ allergy and failed to have desensitization *(855)*. Adverse effects of dapsone include hypersensitivity, methemoglobinemia, hepatitis, and hemolysis *(655)*.

Atovaquone and aerosolized pentamidine have limited data in HSCT recipients.

Prophylaxis should be administered from engraftment until at least 6 months after HSCT in all allogeneic HSCT recipients and autologous HSCT recipients with underlying hematologic malignancies, those receiving intense conditioning regimens or graft manipulation, or those who have recently received purine analogs *(638,655)*. Some experts recommend an additional 1- to 2-week course of PCP prophylaxis before transplantation *(655)* (see Table 59-4).

Postexposure Prophylaxis for Communicable Diseases

Infection control personnel should evaluate HSCT patients who are exposed to communicable diseases based on hospital policy. Personnel need to assess the type of exposure, the duration of exposure, how infectious the microorganism is, how it is transmitted, and in some instances consider how immunocompromised the patient is. In several situations, additional interventions may be needed. For example, HSCT patients who are not immunocompetent and who are susceptible to varicella and exposed should receive varicella-zoster immunoglobulin (VZIG), if available within 72 to 96 hours of exposure, ideally within 48 hours (143,*274*). Exposure is defined as sharing a room with an infected patient or prolonged face-to-face contact with an infectious person *(276)*. Adults should receive 125 U/10 kg or a maximum of 625 U (143). The prophylaxis should be given to HSCT recipients <24 months after HSCT or >24 months and on immunosuppressive therapy or with chronic GVHD. Since VZIG efficacy was not impressive, 25% to 45% of patients receiving VZIG developed clinical varicella infection (856,*857*,*858*). For this reason, many centers offer acyclovir or valciclovir in addition to VZIG as a postexposure regimen, although data to support this practice are limited, and it has not been studied in HSCT recipients (859). The medications should continue until 22 days after exposure or 28 days in patients receiving VZIG (143,859). The other issue that remains controversial is postexposure prophylaxis among VZV-seropositive HSCT recipients (859). At least 57 possible reinfections in immunocompromised patients have been described (856). Moreover, false-positive VZV antibody results can occur in patients who received immunoglobulin or blood products (859). Experts recommend consideration of postexposure prophylaxis for VZV in seropositive-HSCT recipients as an optional therapy (*264*,859). Weinstock et al. *(859)* suggest that postexposure prophylaxis for VZV in seropositive-HSCT recipients should be offered routinely in autologous HSCT recipients <6 months, allogeneic HSCT recipients <12 months, patients receiving immunosuppressive therapy, and patients with active GVHD or other immunosuppressive states. The single exception is seropositive patients who have previously experienced and episode of VZV disease after HSCT who appear to be at no risk (859). The varicella vaccine is contraindicated in HSCT patients until 24 months after HSCT (860).

Antiviral agents with activity against influenza, such as amantadine, rimantadine, or the newer neuraminidase inhibitors (oseltamivir, zanamivir), are indicated for preemptive therapy (or prophylaxis) during outbreaks and may be administered during influenza season, while influenza-like illness is present in the community. These agents have been used in the setting of influenza in HSCT patients, although little information is available about the efficacy in these patients. Drug resistance patterns of the virus should be used for guiding the choice of antiviral agents (143).

Prophylaxis should be administered to patients exposed to *Neisseria meningitidis* infections. Pneumonia may present a special case and guidelines for prophylaxis of patients exposed to *N. meningitidis* pneumonia should be individualized. One outbreak in the literature describes five oncology patients hospitalized on the same hospital unit, but not in adjacent rooms, who developed *N. meningitidis* colonization or infection *(861)*. The index patient had *N. meningitidis* pneumonia. Based on the extensive transmission associated with this cluster, we believe more liberal standards for prophylaxis are indicated in HSCT patients exposed to patients with *N. meningitidis* pneumonia.

Immunization of HSCT Recipients

Vaccines for influenza and hepatitis B, pneumococcal conjugate vaccine (PCV), *Haemophilus influenzae* conjugate vaccine, inactivated polio, MMR, and TDaP should be administered to patients optimally prior to undergoing HSCT (860). These vaccinations are important in preventing infections that occur late after HSCT. HSCT recipients should be routinely revaccinated after transplantation because antibody titers decline during the 1 to 10 years after HSCT (860). The American College of Physicians recommends annual influenza vaccination of immunocompromised individuals and their family members before the winter season. HSCT patients who do not receive pretransplant vaccination may demonstrate an immune response with PCV and inactivated influenza vaccine as soon as 4 to 6 months after HSCT (860). Vaccination with TDaP, *H. influenzae* conjugate vaccine, inactivated polio, and recombinant hepatitis B can be given 6 to 12 months after HSCT (860). Vaccination with MMR should occur 24 months after HSCT (860). These vaccines have been shown to be efficacious in healthy individuals but may not stimulate an adequate antibody response in individuals receiving chemotherapy.

Antimicrobial Stewardship

Because of prolonged hospitalization, an immunosuppressed state, and often extensive exposure to antimicrobials, the HSCT population is uniquely at risk for developing infections with resistant microorganisms. Antimicrobial stewardship is important in this population to lower the risk of such infections and to ensure that antimicrobials are given at the correct dose and for only as long as they are needed to maximize patient safety. Although the topic of Antimicrobial Stewardship is covered in Chapter 87, specific areas that may be of use to address in the HSCT population include indications for initial and prolonged vancomycin use and tailoring antimicrobial use based on microbiology data.

TABLE 59-4

Common Antimicrobial Prophylaxis Use in HSCT Patients

Infection	*Host*	*Pre-engraftment*	*Postengraftment*
Bacteria (all)	Neutropenic patients	Fluoroquinolone with antipseudomonal activity First line: Levofloxacin 500 mg once daily or ciprofloxacin 500 mg twice daily [a]Depend on local susceptibility data	
S. pneumoniae	cGVHD		Late phase: Penicillin, in areas in which the incidence of penicillin-resistant *Streptococcus pneumoniae* is not high 250–500 mg orally twice daily or 500–1,000 mg once daily Alternatives: macrolides or fluoroquinolones or second-generation cephalosporins
PCP	All allogeneic HSCT recipients; or autologous HSCT recipients with underlying hematological malignancies, those receiving intense conditioning regimens or graft manipulation, or those who have recently received purine analogs (BIII)		First choice: Trimethoprim-sulfamethoxazole 1 double-strength (160/800 mg) tablet orally daily or 1 double-strength tablet orally thrice per week administered per BMT unit protocol, preferably postengraftment Alternatives: Dapsone, Atovaquone, Nebulized pentamidine Until at least 6 mo
CMV	All CMV-sero-positive and CMV-sero-negative with a CMV-sero-positive donor		Preemptive or prophylactic treatment First line: ganciclovir 5 mg/kg/dose iv Induction: twice daily for 7–14 d Maintenance: daily Alternatives: Foscarnet, valganciclovir, cidofovir
HSV	HSV-seropositive allogeneic recipients	Acyclovir Adult: 400–800 mg orally twice daily Pediatrics: (<40 kg) 250 mg/m^2/dose iv every 8 h; Maximum dose: 80 mg/kg/d (or until mucositis resolved) Alternatives: Valacyclovir	
VZV	VZV- sero-positive		Acyclovir 800 mg orally twice daily for 1 y Alternative: Valacyclovir May continue beyond 1 y in GVHD
Fungus:	Allogeneic HSCT recipients; or autologous HSCT recipients who have or will have prolonged neutropenia and mucosal damage from intense conditioning regimens, graft manipulation or who have recently received purine analogs	First choice: Fluconazole 400 mg daily	
Candida spp.		Alternative: Itraconazole, micafungin Fluconazole resistant *Candida* spp.: Micafungin Posaconazole	
Fungus: *Aspergillus* spp.	Allogeneic HSCT recipients with GVHD		Posaconazole or voriconazole

[a]Depend on local susceptibility. In some parts of the world, the incidence of quinolone resistance organisms is high *(350,402,813)*.

Surveillance Activities

Surveillance activities should target disease processes and microorganisms that are most problematic in the HSCT population at an individual institution. Helpful guidelines for appropriate surveillance activities are emerging for institutions that maintain HSCT services (126). They advocate strongly for the development of three types of surveillance: an environmentally, a microbiologically, and a clinically based program to support surveillance functions for epidemiologically important microorganisms and communicable diseases. A fourth type, syndromic has been used in the settings of pandemic influenza and may be used in specific settings. However, discussion of this later strategy is beyond the scope of this chapter

For environmental surveillance, periodic routine culturing for *Legionella* species in water samples from the potable water supply should be included (126). Infection control programs must have the expertise and resources to respond quickly to outbreaks, clusters, or a case of healthcare-associated *Legionella* infection (501,*862*). We have noted many of these recommendations throughout this chapter.

In the setting of construction, monitoring for clinical cases of aspergillosis and other invasive mold infections should be performed (126). Microbiological air sampling may be performed in patient care areas when an outbreak is suspected (126).

In the era of multidrug-resistant microorganisms, laboratories must have the capability of identifying resistant enterococci, methicillin- and vancomycin-resistant *S. aureus,* and microorganisms that produce extended-spectrum beta-lactamases (ESBL), and other important resistant mechanisms in gram-negative pathogens (126). Institutions should conduct routine surveillance for the emergence of *Staphylococcus* species strains with reduced susceptibility to vancomycin (126). Patients not known to be colonized with VRE or MRSA should have weekly perirectal and nares swabs, respectively. Guidelines for management of multidrug-resistant microorganisms in healthcare settings should be followed (126,*662*). Data on antibiotic susceptibility of viridans streptococci should be collected in these patients to guide antibiotic selection in neutropenic patients.

Because bloodstream infections cause significant morbidity and mortality in these patients, we recommend that, at a minimum, surveillance for healthcare-associated bloodstream infections be done with a focus on those related to catheters *(88,89,863–865)*. However, there are some challenging issues about definitions for surveillance especially for catheter-related bloodstream infection. Because almost all of these patients had indwelling catheters during treatment, including while they had bacteremia, which might occur primarily from mucositis or infection somewhere else that cannot be detected because of the absence of a leukocyte response line-associated bacteremia may be difficult to identify with confidence *(866)*. CDC definitions may not be appropriate in these settings and may produce data that does not reflect just those microorganisms related to catheters. Hence, some studies use modified CDC definitions among neutropenic patients *(77,867,868)* (Table 59-5).

TABLE 59-5

Recommendation for Infection Control Surveillance in HSCT Recipients

Surveillance	*Descriptions*
Environmental	*Legionella*: Periodic routine culturing of potable water supply Aspergillus/Other molds:consider in the setting of construction/renovation
Microbiological	Bacteria: - Active surveillance for vancomycin-resistance enterococci Surveillance for clinical cultures for - Viridans-*Streptococci* and their susceptibility to penicillin and cephalosporin - *S. aureus* species with reduced susceptibility to vancomycin - Multidrug-resistance gram-negative bacilli - Fluoroquinolone resistance (to consider antimicrobial prophylaxis during neutropenia) - *C. difficile* infection Virus: Consider monitoring for respiratory viruses Monitoring influenza activity and oseltamivir resistance in influenza viruses
Clinical	Consider surveillance for - Bacteremia/catheter-related bloodstream infection and their susceptibility pattern

SECTION VIII

Epidemiology and Prevention of Healthcare-Associated Infections Related to Diagnostic and Therapeutic Procedures

CHAPTER 60

Healthcare-Associated Infections in Anesthesia

Loreen A. Herwaldt, Matthew D. Koff, Randy W. Loftus, and Jean M. Pottinger

INTRODUCTION

Modern anesthesiology originated in the 1800s *(1)*. William Clark was reportedly the first person to use ether as an anesthetic, administering it initially during a tooth extraction *(1,2)*. Soon thereafter, other healthcare providers followed suit, including William T. G. Morton, a dentist, and John Collins Warren, a professor of surgery at Harvard, who both utilized ether for anesthetic purposes *(1)*. From the very beginning, anesthesiology attracted physicians with a broad range of clinical interests and skill sets. It is, therefore, not surprising that Dr. John Snow, an early British anesthesiologist who calculated dosages for chloroform and ether, conducted epidemiologic studies that elucidated the source of the cholera epidemic in Soho, London, in 1854. His data convinced the local council to remove the handle of the Broad Street pump *(3–5)*. Thus, both modern anesthesiology and epidemiology have similar roots.

Snow further developed his epidemiological expertise over time, but he did not address the potential relationship between the practice of general anesthesia and healthcare-associated infections (HAIs). This question was first raised in 1873 by Skinner, a physician interested in the infection control and prevention practices of anesthesiologists *(6)*. Since then, numerous anesthesia personnel have investigated whether anesthesia equipment and medications transmit infections to patients, and numerous groups have published infection prevention and control guidelines and practice advisories specifically for anesthesia practice (*7*,*8*,9,*10–13*,14–17,*18–27*). In addition, the Centers for Disease Control and Prevention (CDC) has published guidelines that are relevant to anesthesia practice (28,*29–33*).

However, despite these guidelines and despite advances in anesthetic practices, surgical techniques, sterilization, and disinfection, HAIs continue to complicate healthcare, including procedures done by anesthesia providers. Some of the anesthetic and surgical advancements have increased the complexity of patient care, thereby providing more reservoirs for pathogens and more opportunities for these pathogens to cause infections. Moreover, multidrug-resistant bacteria cause many HAIs, further complicating care *(30)*. Given the human and monetary costs of these infections, numerous governments have created programs that encourage healthcare providers to adopt best practices and implement other preventive measures. In the United States, for example, the Centers for Medicaid and Medicare Services (CMS) will no longer reimburse healthcare facilities for the excess costs associated with some HAIs *(34)*. Thus, healthcare facilities and healthcare providers have additional incentives to study transmission of pathogenic microorganisms, risk factors for HAIs, and preventive measures in *all healthcare settings*, including those in which anesthesia providers work (e.g., operating rooms, preanesthesia and postanesthesia rooms, and pain clinics).

This chapter summarizes the available literature pertaining to the potential role of anesthetic practice and

equipment in intraoperative transmission of pathogens and subsequent HAIs. We review the pathogenesis and epidemiology of infections potentially related to the administration of anesthesia (general, neuraxial, and intravenous), describe and critique reports of outbreaks in which anesthesia personnel may have been the reservoirs of infection, and discuss various anesthetic practices that put either anesthesia providers or patients at risk for exposure to potential pathogens. In addition, we summarize recent studies that have assessed measures for preventing intraoperative bacterial transmission, subsequent HAIs, and occupationally acquired infections.

The Pathogenesis of HAIs Hospital-Wide

Many HAIs are acquired because pathogenic microorganisms are transmitted within the healthcare setting by healthcare workers who do not follow basic precautions that prevent spread, such as those described by the CDC *(30,31)*. For example, healthcare workers may be more likely to follow Standard Precautions and practice good hand hygiene if the patient has an obvious infection than they are if the patient does not have an apparent infection. Consequently, healthcare workers may not do hand hygiene or may not use other precautions that could prevent spread of pathogenic microorganisms from a patient's normal flora (e.g., *Escherichia coli* in the gastrointestinal tract) or from an occult infection. In fact, contaminated hands are the major vector for transmission in the healthcare setting *(31,35–39)*. Hayden et al. *(35)* demonstrated how easy it is for healthcare workers to contaminate their hands. Of 103 healthcare workers (HCWs) whose hand cultures were negative when they entered the room of a patient colonized with vancomycin-resistant enterococci (VRE), 52% contaminated their hands or gloves after touching the environment and 70% contaminated their hands or gloves after touching the patient and the environment. HCWs who wore gloves were significantly less likely to contaminate their hands (5%) despite touching more sites than HCWs who did not wear gloves (37%). Thus, noncompliance with simple preventative measures, such as hand hygiene and Contact Precautions, increases the likelihood that HCWs will transmit pathogenic microorganisms to the next patients they care for or to the environment, which can then serve as a reservoir, particularly for microorganisms such as VRE that survive on environmental surfaces for prolonged periods *(35)*. We must, therefore, study work patterns and practices in various hospital settings, including the operating room and other places where anesthesia providers work, to identify those patterns and practices that enhance transmission of pathogens from patient to patient or from patients to the environment. We must also identify interventions that prevent transmission within specific work environments, such as operating rooms.

Epidemiology of Postoperative HAIs Occurring after General Anesthesia

General Comments General anesthesia, itself, may increase the risk of HAIs. Drugs used routinely during general anesthesia can impair the function of the ciliated epithelium. Opiates directly depress ciliary activity *(40)*, atropine impairs mucociliary clearance by decreasing bronchial secretions and drying the mucous membranes *(41,42)*, and dry anesthetic gases damage the ciliated cells and slow mucus flow *(43–45)*. In addition, high concentrations of oxygen cause an inflammatory response in the ciliated epithelium that leads to tissue sloughing *(46)*.

The patients' intrinsic risk of HAIs and the risk associated with surgical procedures may be increasing. For example, patients undergoing operations at this time are often older and have more underlying diseases than patients undergoing the same procedures a decade ago and, thus, may be at high risk of HAIs *(47)*. In addition, new, more complex procedures have been introduced that may increase patients' risk of infections more than older, less complex procedures. Moreover, surgical procedures and general anesthesia compromise the patient's immune system by (a) breaching the skin and mucus membranes, the first lines of defense against infection; (b) impairing the patients' immune response by exposure to general anesthetics; and (c) inducing a postsurgical inflammatory state *(48)*. Furthermore, the anesthesia environment can become contaminated and some anesthesia equipment can create aerosols of infectious particles that contaminate equipment in the anesthesia work area, which subsequently can be a source of infectious agents for these vulnerable patients *(49–53)*.

Data Suggesting that the Practice of General Anesthesiology and Anesthesia Equipment Are not Source of Infection

Some investigators maintain that anesthesia machines, even when contaminated, do not transmit significant numbers of bacteria because (a) microorganisms are unlikely to survive in the hostile environment of the anesthesia machine due to desiccation by the flow of cold, dry anesthetic gases *(54)* and (b) the rubber and metal parts of the machine and the highly alkaline condensate at the bottom of the CO_2 absorber inhibit growth of bacteria *(55,56)*. The literature discussed below provides evidence in support of these hypotheses.

Colonized or Infected Patients Are not Likely to Contaminate the Anesthesia Machine Several studies suggest that patients colonized or infected with bacterial pathogens rarely contaminate the anesthesia machine *(55,57,58)*. For example, Du Moulin and Saubermann *(55)* studied 15 patients anesthetized with sterile machines. Two throat and sputum cultures were obtained from each patient before general anesthesia was administered; 40% of the patients had cultures yielding more than 10 colony-forming units (CFU) of gram-negative bacteria and 60% had cultures that did not yield gram-negative bacteria. The investigators isolated 1 to 9 CFU per segment of the breathing circuit. However, all cultures from machines used on colonized patients were negative and only three cultures from machines used on patients without gram-negative colonization were positive. Similarly, Stemmermann and Stern *(57)* asked 14 patients with cavitary tuberculosis to breathe into a basal metabolic rate machine (which is similar to an anesthesia breathing circuit) for 10 minutes and then cough. The investigators did not identify *Mycobacterium tuberculosis* in smears or cultures of the saline used to wash the masks and tubing and, thus, concluded that the anesthesia circuit was unlikely to contribute significantly to bacterial

crosscontamination. These data suggest that colonized or infected patients rarely transmit bacterial pathogens via the breathing circuit to the anesthesia machine.

Contaminated Anesthesia Machines Are Unlikely to Transmit Bacterial Microorganisms to Patients Several investigators have used simulations to show that contaminated anesthesia machines are unlikely to transmit bacterial pathogens *(55,59–62)*. For example, Adriani and Rovenstine *(59)* were unable to grow microorganisms from air blown through soda lime canisters contaminated with large numbers of *E. coli* or *M. tuberculosis*. Ziegler and Jacoby *(60)* used a contaminated machine to ventilate a sterile reservoir bag for 30 minutes; cultures of the reservoir bag remained negative. After inoculating the expiratory port of a sterile circle system with 10^8 to 10^9 CFU of either *Enterobacter cloacae* or *Flavobacterium* species, du Moulin and Saubermann *(55)* blew 3 L of nitrous oxide and oxygen per minute through the valve for 3 hours. Every 30 minutes, they obtained samples from the valve and found progressively fewer bacteria in the cultures. They did not recover the indicator microorganisms from other parts of the machine. Ibrahim and Perceval *(62)* seeded cleaned circuits with viridans streptococci or staphylococcal bacteriophages, attached these circuits to machines, and blew air through them. Air sampling cultures obtained from the distal ends of the tubes were all negative.

Anesthesia circuits are not a major source of infections for surgical patients and bacterial filters are not an important preventive measure.

Two prospective clinical trials have been cited as evidence that anesthesia circuits are not a major source of infections for surgical patients. Garibaldi et al. *(63)* randomly assigned 257 patients to be anesthetized with disposable corrugated plastic circuits containing bacterial filters (0.22 μm) and 263 patients to be anesthetized with disposable corrugated plastic circuits without filters. The postoperative pneumonia rates for the two groups did not differ significantly, but the study was powered to detect a 50% difference in rates, which would be difficult to achieve with most interventions. Feeley et al. *(64)* found no difference in postoperative pneumonia rates between 138 patients anesthetized with sterile disposable circuits and 155 patients anesthetized using clean reusable circuits. However, the study had a power of only 17% to detect a 50% difference in rates.

Van Hassel et al. *(65)* reviewed 9 years of surveillance data and found lower respiratory tract infections in 5 of 2,300 (0.2%) patients undergoing operations under regional anesthesia and 31 of 23,500 (0.1%) patients undergoing general anesthesia with tubing that was cleaned only once a day (i.e., was shared by three to seven patients). They changed the soda lime every 3 days and they placed filters at the T pieces only when patients had suspected or overt respiratory tract infections, *M. tuberculosis*, or human immunodeficiency virus (HIV) infection. They concluded that "in our setting, patient factors are most important in the development of postoperative lower respiratory infections and that the role of bacterial filters as a preventive measure is negligible" *(65)*.

In summary, the studies reviewed in this section suggest the following: (a) colonized or infected patients are not likely to contaminate the anesthesia machine; (b) the anesthesia machine does not serve as a significant reservoir for bacterial microorganisms; (c) anesthesia circuits are not a major source of infections for surgical patients and bacterial filters are not an important preventive measure.

Data Suggesting that the Practice of General Anesthesia, Anesthesia Equipment, the Operating Room Environment, Anesthetic Medications, and Anesthesia Personnel Are Associated with HAIs

Endotracheal Tube Studies in experimental animals indicate that endotracheal tubes disrupt the ciliated tracheal epithelium, cause an inflammatory response, and impair mucociliary clearance, increasing the risk of subsequent infections *(66–71)*. In addition, the endotracheal tube can serve as a route by which bacterial pathogens from the patient's oropharynx, healthcare providers' hands, and the surrounding environment can be transmitted into a patient's trachea *(72,73)*. Indeed, several studies have shown that gram-negative bacteria or other potential bacterial pathogens that were not identified by preoperative cultures of the nasopharynx, pharynx, or larynx subsequently contaminated endotracheal tubes in the postoperative period *(72–74)*. In addition, nasal-tracheal intubation has been shown to cause transient bacteremia *(75,76)*. Thus, placement of endotracheal tubes can increase the risk of transmitting bacterial pathogens to patients and can contaminate a patient's lungs with his or her own flora, thereby increasing the risk of HAIs.

Anesthesia machine and circuit (Ambu bag, breathing circuit tubing, Y connector, inspiratory and expiratory valves, CO_2 absorber): Numerous authors cite an outbreak of follicular tonsillitis *(77)* and two outbreaks caused by *Pseudomonas aeruginosa (78,79)* as evidence that contaminated anesthesia machines transmit microorganisms. These reports provide some evidence that anesthesia equipment (anesthesia machine, Ambu bag, and circuit) could be reservoirs for bacterial pathogens and may play a role in bacterial transmission. However, the results of these investigations should be interpreted with caution, because the authors did not conclusively identify the source of the infecting microorganisms. Furthermore, the typing methods evaluated phenotypic, not genotypic, characteristics that do not discriminate between strains and modern molecular typing methods.

Albrecht and Dryden *(80)* also evaluated whether sterilizing the breathing circuits and using a disposable absorber affected the rate of postoperative pneumonia. They retrospectively reviewed the medical records of 220 randomly selected patients who underwent major abdominal operations requiring general anesthesia and who were not infected at the time of the operation. Twenty percent (10/50) of patients who underwent operations before the anesthesia equipment was sterilized, 26% (13/50) of patients who underwent operations when breathing circuits were sterilized but the absorbers were reused, and 6% (7/120) of patients who underwent operations after sterile breathing circuits and disposable absorbers were used acquired postoperative pneumonia. The investigators concluded that contaminated anesthesia machines transmitted bacteria to patients and they should, therefore, be

sterilized between cases. However, the results of this study should be interpreted with caution, because it was an unblinded, uncontrolled retrospective study and because the investigators did not specify their definition of postoperative pneumonia.

Other investigators have evaluated the ability of microorganisms to survive on anesthesia equipment. Investigators either obtained cultures from anesthesia equipment after routine use or conducted *in vitro* studies. In general, such experiments identified a wide variety of bacteria (saprophytic micrococci and bacilli, *Staphylococcus aureus*, coagulase-negative staphylococci, *E. coli*, *P. aeruginosa*, viridans streptococci, *Bacillus* species) contaminating all parts of used anesthesia machines (breathing circuits, rebreathing bags, inspiratory and expiratory valves) with the parts of the machine closest to the patient most heavily contaminated *(78,81–84)*. For example, Meeks et al. *(84)* obtained cultures from anesthesia equipment after use. They grew *Staphylococcus epidermidis* from 73% of face masks, 12% of Y connectors, 6% of breathing circuits, and 6% of rebreathing bags; *S. aureus* from 10% of face masks and 1% of rebreathing tubes; and *Pseudomonas* species from 36% of face masks, 67% of Y connectors, 42% of breathing circuits, and 79% of rebreathing bags. In the study by Livingstone et al. *(85)*, 33% (13/39) of the rubber masks used to anesthetize patients with tuberculosis yielded *M. tuberculosis*. Likewise, several investigators who obtained cultures from face masks used to administer nitrous oxide for dental procedures demonstrated that bacteria from a patient's nose and mouth contaminated the apparatus *(86–88)*.

Investigators have also investigated the potential filtering and bactericidal roles of soda lime canisters and found that they do *not* filter bacterial microorganisms effectively *(83,89,90)*. For example, Murphy et al. *(89)* aerosolized eight different bacterial species into a soda lime canister and found that up to 40% of the microorganisms were not retained in the canister. Investigators have also demonstrated that the soda lime in the canister is *not* uniformly bactericidal. Murphy et al. *(89)* found that, at room temperature, 1 gram of soda lime killed *Klebsiella pneumoniae, Candida albicans, S. aureus, P. aeruginosa, Serratia marcescens, E. coli,* and *S. pneumoniae* within 10 minutes, but 1% of the *Bacillus subtilis* CFU survived at 30 minutes. Dryden *(83)* demonstrated that 4% sodium hydroxide, Sodasorb extract, and Baralyme extract killed *P. aeruginosa* and *Proteus mirabilis* within 15 minutes, but *M. tuberculosis* survived for at least 3 hours in each of the solutions.

Investigators have also used laboratory models to simulate the patient–anesthesia machine interaction and concluded that air could move bacterial pathogens through the breathing circuit *(83,90,91)*. For example, Nielsen et al. *(91)* measured the bacterial content of anesthetic gases before and after passing them through clean and previously used breathing systems to determine whether anesthetic gases could become contaminated when blown through contaminated circuits. Gases passed through clean circuits contained 1.2 to 50.2 (median 4.2) CFU of bacteria per 100 L, compared with 3.3 to 129.8 (median 38.5) CFU of bacteria per 100 L for gas passed through used circuits (Mann–Whitney $p < .01$). The authors concluded that anesthetic gases can transfer microorganisms.

Investigators have also attempted to assess the origin of breathing circuit contamination. Rathgeber et al. *(92)* obtained cultures of breathing circuits used with filters and from those used without filters to assess the origin of microbiologic contamination. When a filter was used, the microorganisms isolated from the breathing circuits were different than the microorganisms detected in the patients' tracheal aspirates. When filters were not used, the same microorganisms were isolated from the patients' tracheal aspirates and from the tubing in 13% of the cases. Thus, the study results demonstrated that patients' bacterial microorganisms can contaminate the breathing circuits and that filters can prevent circuit contamination. However, the investigators were unable to show that filter use changed patient outcomes, because patients were not followed prospectively to determine whether they acquired postoperative pneumonia.

Investigators from the New South Wales (NSW) Health Department studied the potential role of anesthetic equipment in intraoperative viral transmission when they evaluated a cluster of patients who acquired hepatitis C virus (HCV) infection after having operative procedures at a private hospital in Sydney *(93)*. After two persons who had operations on the same day presented to the hospital with acute hepatitis C, NSW health officials tested all patients who had operative procedures during the same session. Three more patients were found to be anti-HCV positive. Surgical personnel were tested and were anti-HCV negative. Patient-to-patient transmission was likely, because all five patients were infected with hepatitis C of the same genotype. The common denominator between patients seemed to be the anesthesia equipment; the same anesthesia circuit was used without a filter and without decontamination for all 11 patients who had procedures during the implicated session. On the basis of these data, the investigators concluded that the HCV was transmitted through a contaminated anesthesia circuit. They hypothesized that the index case's respiratory secretions containing HCV were introduced into the anesthesia circuit and that the virus was transmitted in droplets through minor breaks in the oropharyngeal mucosa of subsequent patients. In response, NSW health officials recommended enforcing existing guidelines that a filter be used in the anesthesia circuit to prevent cross-transmission *(18,19,94)*.

A number of other agencies, including the AANA *(8)*, the Blood-borne Viruses Advisory Panel of the Association of Anaesthetists of Great Britain and Ireland *(22)*, the Department of Health of the Netherlands Committee on Infection Prevention *(23)*, and the Societé Francaise d'Anesthesie et Reanimation *(24)*, have recommended that an appropriate filter be placed between the patient and the breathing system and that either a new filter or a new breathing circuit should be used for each patient. At present, there is no consensus on whether hydrophobic pleated membrane filters are necessary or whether electrostatic filters are adequate. Most studies of filtration efficiency have indicated that the hydrophobic filters are more efficient *(95–97)*. However, a study of patients undergoing general anesthesia found no difference between hydrophobic filters and electrostatic filters *(98)*. Both filter types significantly decreased the incidence of bacterial contamination in the breathing circuits compared with the level of contamination in endotracheal tubes.

Laryngoscopes Inadequate disinfection of laryngoscope blades and handles has been associated with clusters of infection *(99,100)*. These clusters are discussed further in the section "Current Infection Prevention and Control Guidelines and Current Anesthesia Practice."

Equipment in the Anesthesia Work Area Loftus et al. (101,102) and Koff et al. (103) have documented that various pieces of equipment in the anesthesia work area are contaminated with bacterial pathogens. Other investigators have found extensive blood contamination in the anesthesia work area *(104)*. These findings are discussed further in the section "Exposure of Anesthesia Personnel to Patients' Blood and Body Fluids."

Air Air in operating rooms can become contaminated with bacteria. For example, Edmiston et al. *(105)* obtained air samples from a single operating room during 70 different vascular procedures. *S. aureus* and various coagulase-negative staphylococcal species were recovered from 64% and 86% of all samples, respectively. Gram-negative bacteria were recovered less frequently (33%). The magnitude of contamination increased with proximity to the surgical field. Some of the microorganisms were identical to those recovered from HCWs' nares, suggesting that the surgical masks were inefficient *(105)*.

Medications In addition to impairing host defenses, anesthetic medications can become contaminated with viral or bacterial pathogens, which can then be injected directly into the patient's intravascular space *(106–110)*. This has occurred when syringes become contaminated during use, when anesthesia personnel contaminate anesthetic medications either by contaminating multidose vials or by handling medications, such as propofol, improperly *(106–111)*. The role of contaminated medications is discussed further in the sections "Infections Associated with Intravenous Anesthesia and Outbreaks Associated with Anesthesia Personnel."

Anesthesia Providers Anesthesia providers can be colonized or infected with pathogens that can be transmitted to patients *(112–119)*. In addition, anesthesia providers' hands are often contaminated with pathogenic bacteria during all phases of anesthesia: induction, maintenance, and emergence (*120*,121). The role of microorganisms colonizing or infecting anesthesia providers and microorganisms carried on anesthesia providers' hands is discussed further in the sections "Infections Associated with Intravenous Anesthesia and Outbreaks Associated with Anesthesia Personnel."

In summary, the studies reviewed in this section suggest that (a) Bacteria can contaminate all parts of anesthesia circuits, but the highest numbers of bacteria contaminate the parts closest to the patient; (b) Anesthetic gases may carry bacteria from the machine to the patient or vice versa; (c) The soda lime removes bacteria imperfectly and, although it kills many bacterial pathogens, *M. tuberculosis* and *Bacillus* species survive prolonged exposure; (d) Filters decrease contamination of breathing circuits; (e) Anesthesia equipment such as endotracheal tubes, the anesthesia machine, laryngoscope handles/blades, syringes, and medications can serve as reservoirs for bacterial pathogens and may facilitate transmission to patients.

Thus, there are several ways that anesthesia practice could facilitate transmission of bacteria to patients during surgical procedures *(49–53)*. Given that surgical patients often have multiple comorbidities *(47)* and that numerous host defenses are breached or impaired by the surgical incision and by general anesthesia, patients may be particularly susceptible to microorganisms transmitted in the operating room *(48)*. This hypothesis is supported by the results of a prospective, observational study by Hajjar and Girard *(122)*. They found an incidence of 3.4 HAIs per 1,000 patients during the first 72 hours after the operations, suggesting that the source of the infections may have been in the operating room *(122)*. However, the investigators could not directly link the practice of anesthesia or anesthesia equipment to intraoperative transmission of bacterial pathogens to patients. Consequently, many anesthesia providers do not believe that anesthetic practice or the anesthesia work area is associated with HAIs *(123)*. In fact, the studies reviewed thus far provide little objective evidence linking either the practice of anesthesia or anesthesia equipment with direct transmission of bacterial microorganisms to patients.

Recently, Loftus et al. (101) developed and validated a method for assessing intraoperative bacterial transmission to the anesthesia work area and to the stopcocks on the patients' intravenous catheters. These investigators randomly selected 61 operating rooms and decontaminated the adjustable pressure-limiting (APL) valve complex and the agent dial (AD) before the first case of the day. After the case, they cultured the APL valves, the ADs, and the stopcock sets. The number of CFU per surface area sampled (CPSS) on the APL valves and the ADs increased significantly, and 32% (95% confidence interval [95% CI] 20.6–44.9%) of the stopcock sets became contaminated. Most of the contaminating bacteria were skin microorganisms, but these microorganisms can cause bloodstream infections. In addition, methicillin-resistant *S. aureus* (MRSA) was transferred to the APL valves for two patients; the stopcock set became contaminated with *E. cloacae* for one of these patients. VRE was transmitted to all three sites for one patient and pulsed-field gel electrophoresis documented that all three sites were contaminated by the same strain. Moreover, the probability that the stopcock set would become contaminated increased as the CPSS increased, even after adjusting for the CPSS at baseline and for covariates (odds ratio [OR] 1.67; 95% CI 1.10–2.53; $p = .02$).

Subsequently, these investigators extended their observations by assessing transmission of bacteria in 82 pairs of patients (i.e., the first and second cases done in 82 randomly selected operating rooms during the study days) (102). The investigators also cultured the dominant hands of the anesthesia providers before they touched the patients. The investigators used biotyping to determine whether microorganisms cultured from the anesthesia work area (i.e., APL valves and ADs) and from the anesthesia providers' hands were the same. Loftus et al. found that 11.5% of the stopcocks became contaminated, of which 47% were contaminated with isolates found on the anesthesia providers' hands. They identified intraoperative transmission to the anesthesia work area in 89% of the cases and 12% of these work areas were contaminated with isolates from the providers' hands. In one instance, they found

the same microorganism on the hands of the anesthesia provider before the start of the first case, on the stopcock at the end of the first case, on the anesthesia machine at the start of the second case, and on the stopcock and the machine at the end of the second case, suggesting that the anesthesia provider did not perform adequate hand hygiene and that the machine was not cleaned adequately between cases. Most transmission events involved coagulase-negative staphylococci ($n = 8$), or *Micrococcus* spp. ($n = 5$), but a *Streptococcus* spp. ($n = 1$), methicillin-susceptible *S. aureus* ($n = 1$), MRSA ($n = 1$), and *Pseudomonas* spp. ($n = 2$) were also transmitted. Given their methodology, the investigators felt that these percentages were minimal estimates of the actual transmission rates from the anesthesia providers' hands. Furthermore, they found that the number of rooms that attending anesthesiologists supervised simultaneously was an independent predictor of transmission events that could not be linked to providers, suggesting that the attending physicians may have transmitted microorganisms from one patient to another. The investigators also found that patients discharged from the operating room to an intensive care unit (ICU) had a higher incidence of transmission events that could not be linked to providers, suggesting that anesthesia providers may have omitted hand hygiene, because they thought they needed to expedite care for more seriously ill patients. Again, given the limitations of their methods, the investigators felt that their results represented a minimum estimate of the transmission events.

Koff et al. (103) extended this model further when they did an intervention to see whether increasing hand hygiene decreased environmental contamination. They significantly increased (27-fold; $p < .002$) hand hygiene adherence over the baseline rate by giving anesthesia providers dispensers for alcohol-based hand rub that could be attached to their clothing. In addition, they noted that contamination of the anesthesia work area and stopcocks decreased from 32.8% to 7.5% (OR 0.17; 95% CI 0.06–0.51; $p < .01$) and that the incidence of HAIs decreased from 17.2% to 3.8% (OR 0.19; 95% CI 0.00–0.81; $p = .02$).

Conclusions Regarding the Role of the Practice of General Anesthesiology and Anesthesia Equipment as Potential Sources of Infection Until recently, the clinical importance of microorganisms isolated from anesthesia machines and their role in postoperative infections had not been clearly defined. In fact, Hogarth *(124)* concluded following a thorough review of the available literature that there was little evidence to implicate anesthesia machines and breathing systems as either a source of pathogenic bacteria or a vector for transmitting these microorganisms to patients undergoing general anesthesia for surgical procedures. Even the outbreaks reported by Joseph *(77),* Tinne et al. *(78)*, and Olds et al. *(79)*, and the report by Chant et al. *(93)* provide little evidence for transmission of pathogens by anesthesia machines or equipment, because these studies did not use sensitive methods for identifying specific strains and because they did not address whether anesthesia providers complied with critical infection prevention and control practices, such as performing hand hygiene, changing gloves between procedures on the same patient, changing gloves between patients, and cleaning and disinfecting the anesthesia cart and equipment between cases *(125)*. Furthermore, most investigators assessing the role of the anesthetic equipment and staff in the transmission of microorganisms used simulations and did not assess real-life anesthetic procedures in operating rooms. Thus, prior studies do not allow us to determine whether the providers, the patients, or the anesthesia equipment was the source of the infecting microorganisms.

The studies by Loftus et al. (101,102) and Koff et al. (103) were the first to demonstrate that anesthesia environment *and* anesthesia providers *do* transmit bacteria to patients and to document that increasing hand hygiene decreases transmission of bacteria to the anesthesia work area and to stopcocks on patients' intravenous catheters. In addition, their work suggests that transmission of microorganisms in the operating room may not be benign in that the mortality rate was higher for patients whose stopcocks became contaminated (101) and HAI rates were higher in the preintervention period when hand hygiene was poor and environmental contamination was high (102). While their studies did not prove the direct link between poor hand hygiene in the operating room and poor patient outcomes, these studies describe a method that other investigators can use to further this work and they provide a rationale for implementing interventions. Moreover, anesthesia providers can incorporate these interventions easily into their work flow to improve hand hygiene.

Preventing Infections Associated with General Anesthesia Procedures Current recommendations for measures for preventing intraoperative transmission of pathogenic microorganisms are relatively sparse (Table 60-1). We support changing and/or disinfecting breathing circuits and masks between operative cases *(7,8)*. Because in-line circuit filters effectively prevent transfer of bacteria from the patient to the anesthesia machine and from the machine to the patient *(126–128),* we think filters should also be used routinely, particularly for patients with active pulmonary tuberculosis receiving general anesthesia *(29)*. Hand hygiene, cleaning, disinfection, and sterilization of equipment, and environmental cleaning are also important preventive measures. Further studies are needed to identify additional sources of pathogens in the operating room and additional risk factors for intraoperative transmission. Such studies could provide the evidence base for implementing intraoperative preventive measures.

INFECTIONS ASSOCIATED WITH INTRAVENOUS ANESTHESIA

Pathogenesis

Syringes Bacteria from the hands of healthcare workers can contaminate syringes and their contents. Blogg et al. *(111)* noted that 3 of 50 syringes (6%) used repeatedly in an operating room and 4 of 50 syringes (8%) used repeatedly in an ICU were contaminated with bacteria, including *S. aureus* (two syringes), *E. coli* (two syringes), *S. epidermidis*

Recommendations/Guidelines for Infection Control in Anesthesia Equipment

Item	*ASA (7)*	*AANA (8)*	*ANZCA (18)*	*AORN (10–13)*	*CDC (28)*	*Other*
Critical: Items that enter or contact an area that is normally sterile. Examples include, but are not limited to vascular needles, catheters and tubing; syringes; stopcocks; regional block needles and catheters; and urinary catheters.	Use sterile equipment to enter or contact any body area that is normally sterile. Clean reusable items thoroughly and sterilize before reuse. Ensure sterility at the time of use. Follow aseptic techniques when handling and using sterile equipment.	Use sterile items to enter sterile body area or vascular system.		Use sterile items to enter sterile tissue or the vascular system. Clean items thoroughly before disinfection.	Sterilize medical devices or patient-care equipment before use. Clean all items thoroughly before sterilizing or disinfecting.	
Semicritical: Items that come in contact with mucous membranes. Examples include but are not limited to laryngoscope blades, Magill forceps, endotracheal tube stylets, temperature probes, masks, breathing circuits and connectors, nasal and oral airways, self-inflating resuscitation bags, and esophageal stethoscopes.	Rinse items as soon as possible after use, decontaminate by cleaning and sterilize or treat with high-level disinfection. Keep endotracheal and endobronchial tubes free from contamination until they are used.	Sterilize items or treat with high-level disinfection.	Endotracheal tubes, nasal, and pharyngeal airways should be kept sterile until they are used. Reusable face masks must be thoroughly decontaminated and then disinfected before they are reused. Items placed in the upper airway that may cause bleeding, such as laryngoscope blades and temperature probes, must be disinfected before use. The breathing circuit should be sterilized or decontaminated and disinfected or	Reusable anesthesia equipment that comes in contact with mucous membranes, blood, or body fluid is considered semicritical and should be cleaned and then processed by high-level disinfection, pasteurization, or sterilization between each patient use.	Sterilize or at minimum treat items with high-level disinfection.	Separate used laryngoscopes and nondisposable items that are overtly contaminated from clean equipment *(374)*. The part of the breathing circuit between the patient and the filter must either be discarded or cleaned and disinfected after each patient. If a carbon dioxide absorber is also used, the part of the breathing circuit between the absorber and the filter must either be discarded or cleaned and disinfected at the end of each procedure list. If carbon dioxide absorbers are not used, the breathing circuit

Recommendations/Guidelines for Infection Control in Anesthesia Equipment (*Continued*)

Item	*ASA (7)*	*AANA (8)*	*ANZCA (18)*	*AORN (10–13)*	*CDC (28)*	*Other*
			protected by a new filter. When a filter is used the disposable items between the patient and the filter should be disposed of between each case and the reusable devices should be decontaminated and disinfected before they are reused. Ventilator circuits should be cleaned and disinfected regularly.			tubing that conducts the gas to and from the filter must either be discarded or cleaned and disinfected at the end of each procedure or operation list. If a filter is not used, the breathing circuit must either be discarded or cleaned and disinfected after each patient. All anesthetic apparatus that comes in contact with a patient or becomes contaminated with blood or body substances for example airways, endotracheal tubes, laryngoscopes, suckers, forceps, temperature probes, esophageal echo probes and face masks must be either discarded or cleaned and disinfected after each patient *(21)*. A new filter should be placed between the patient and the breathing system OR a new breathing system should be used for each patient. Expired gas sampling should be done on The breathing system side of the filter. Filters should not be used for pediatric anesthesia; new breathing systems should be used *(22)*.

Noncritical: Items that touch intact skin or do not make contact with the patient.						
Items that touch the patient. Examples include, but are not limited to blood pressure cuffs, electrocardiograph cables and electrodes, pulse oximeter and skin temperature sensors, stethoscopes, and headstraps.	Clean equipment with a disinfectant at the end of the day and whenever visibly contaminated.	Process equipment with intermediate or low-level disinfection.	Laryngoscope handles should be decontaminated between uses.	Clean and decontaminate items when contaminated or visibly soiled and at the end of the day.	Wash items with detergent or disinfectant, rinse, and dry.	
Items that do not touch the patient. Examples include, but are not limited to exterior surfaces of anesthesia machines, carts, monitors, and tables.	Clean horizontal surfaces of anesthesia machines and carts after each patient.	Clean environmental surfaces with warm water and detergent or with a low low- to intermediate-level disinfectant after each patient procedure; terminally disinfect at the end of the day or when contaminated with blood or body fluids.		Clean and decontaminate items when contaminated or visibly soiled and at the end of the day.		
Single-use items	Reuse is not recommended because there are insufficient data on the safety of this practice for anesthesia equipment. Reuse of single-use items shifts the responsibility/liability	Do not reuse, clean, repackage, or resterilize disposable equipment designed for one-time use and labeled as "single-use" items. Hospitals that reprocess	Items of airway equipment to be placed in direct contact with the respiratory tract and airways labeled by the manufacturer as disposable or for single use only should not be reused.	Single-use items (e.g., suction catheters, breathing circuits, endotracheal tubes, stylets) should be used once and discarded. (*a*) If a device cannot be cleaned, it cannot be reprocessed and reused;	Do not reprocess items or devices that cannot be cleaned and sterilized or disinfected without altering their physical integrity and function.	FDA compliance policy guide: "… the institution or practitioner who reuses a disposable medical device should be able to demonstrate: (a) that the device can be adequately cleaned

(*Continued*)

TABLE 60-1

Recommendations/Guidelines for Infection Control in Anesthesia Equipment (*Continued*)

Item	*ASA (7)*	*AANA (8)*	*ANZCA (18)*	*AORN (10–13)*	*CDC (28)*	*Other*
	from the manufacturer to the user. If single-use items are reprocessed, the users must develop a quality assessment program to ensure disinfection/sterilization is adequate and that the function and integrity are not compromised.	and reuse such products, not the manufacturer, are responsible for their safety and effectiveness. Refer to Food and Drug Administration (FDA) guideline. Disposable products that have been opened but not used or manipulated may be resterilized if the manufacturer approves the process.		(*b*) if sterility of a postprocessed device cannot be demonstrated, the device cannot be reprocessed and reused; (*c*) if the integrity and functionality of a reprocessed device cannot be demonstrated and documented to be as safe for patient care and/or equal to the original device specifications, the device cannot be reprocessed and reused. For further details the reader is referred to the AORN Guidance Statement: Reuse of Single-Use Devices *(11)*		and sterilized, (b) that the physical characteristics or quality of the device will not be adversely affected, and (c) that the device remains safe and effective for its intended use. [A]ny institution or practitioner who resterilizes and/or reuses a disposable medical device must bear full responsibility for the performance, its safety and effectiveness" *(375)*. Medical and Surgical Products Liaison Group and the Association of British Health-Care Industries advise against re-use unless specifically permitted by manufacturers *(376)* The New South Wales Health Department recommends that medical devices marked "single use only" should not be reused unless (*a*) testing documents that the devices are not physically or microbiologically less safe than new items;

					(*b*) reprocessing is controlled and in accordance with Good Manufacturing Processes defined by the Commonwealth Therapeutic Goods Administration; (*c*) reprocessing must be in accordance with the manufacturer's instructions; (d)standard information is needed for informed patient consent *(21)*.
Valves and CO_2 absorber	Clean and disinfect unidirectional valves and CO_2 absorber chambers periodically.	Disassemble, clean, and sterilize CO_2 valves prior to reuse. When a patient has a respiratory infection, use disposable devices (e.g., circle system and absorber with bacterial filter, laryngoscope, and airway products) whenever possible.	When a filter is used in the circuit, sterilization of the carbon dioxide absorber before every case is not necessary. The device including the unidirectional valve should be disinfected regularly.	Absorbers and valves should be cleaned when the soda lime is changed according to the manufacturer's written instructions. Particular attention should be paid to the valves. Routine sterilization or high-level disinfection of the internal components of anesthesia machines is considered unnecessary.	
Bellows	Clean and disinfect tubing and bellows at regular intervals, not after each use. Routine sterilization/ disinfection of the interior of anesthesia machines is not necessary or feasible.	Sterilize the anesthesia bellows and the bellows base or head after every case unless bacterial filters are used to protect the inspiratory, expiratory, and ventilator limbs of the circuit.	Clean and disinfect regularly.	Bellows should be cleaned regularly according to the manufacturer's written instructions. Bellows are thought to represent a low risk for transmission of infection and do not require cleaning and disinfection after each use.	

(*Continued*)

TABLE 60-1

Recommendations/Guidelines for Infection Control in Anesthesia Equipment (*Continued*)

Item	*ASA (7)*	*AANA (8)*	*ANZCA (18)*	*AORN (10–13)*	*CDC (28)*	*Other*
		When using disposable breathing circuits without bacterial filters, replace the ventilator bellows each time the circuit is replaced and the bellows base or head cleaned and sterilized.				
Filters for breathing circuits	There are insufficient outcome data to support routine use of bacterial filters. Use a filter for patients known or suspected to have active tuberculosis.	Use breathing circuits with bacterial filters for all cases.		.	Data do not support using bacterial filters to prevent nosocomial pulmonary infections *(32)*. Use filter if patient has suspected or confirmed active tuberculosis *(29)*.	If used, filters must be discarded after each patient *(26)*. At the current state of knowledge, a new bacterial/viral filter should be used for each case. The filter should be placed so as to protect the breathing circuit from possible contamination by the patient *(23)*.
Heated humidifiers		Clean and sterilize humidifiers after each use. Use sterile water.			Sterilize reusable humidifiers or subject them to high-level disinfection after each use *(32)*.	

ASA, American Society of Anesthesiologists; AANA, American Association of Nurse Anesthetists; ANZCA, Australia and New Zealand College of Anaesthetists; AORN, Association of PeriOperative Registered Nurses; CDC, Centers for Disease Control and Prevention

(three syringes), and viridans streptococci (one syringe). Lessard et al. *(51)* also obtained cultures from syringes used in their operating rooms and found 4 contaminated syringes among 100 that were refilled an average of 3.58 times compared with 3 contaminated syringes among 100 filled only once. Blogg et al. *(111)* also tested whether bacteria (25×10^6 CFU of *S. marcescens*) on the hands could contaminate syringes when they were refilled. All 15 plastic syringes and 35 of 65 (54%) glass syringes were contaminated after they were refilled twice.

To simulate the common syringe technique, several investigators injected liquid from tuberculin syringes through 26-gauge needles into suspensions of *E. coli (129–131)*, *S. aureus (131)*, poliovirus *(132)*, or ^{3}H-thymide *(131)*. After removing the needles, they examined the syringe contents and found that most were contaminated. Plott et al. *(133)* took this line of research one step further. They placed 10 mL of sterile water containing 10^6 plaque-forming units of vesicular stomatitis virus into a multidose vial. They then injected 1 mL of sterile water into the vial, withdrew the syringe, changed the needle, drew 1 mL of air into the syringe, injected the air into a second vial, and withdrew 1 mL of water. All of the second vials were contaminated with vesicular stomatitis virus.

Syringes can become contaminated with a patient's blood or with blood-borne pathogens after just one injection into a patient or into an intravenous line. Fleming and Ogilvie *(134)* found blood in 5 of 50 syringes (10%) used to inject a vaccine subcutaneously, and Hughes *(135)* identified red blood cells in 17 of 39 syringes (44%) used to inject saline intramuscularly. Hughes demonstrated that fluid was aspirated from the needle into the syringe when the needle was removed from the syringe. He hypothesized that the syringe used to administer penicillin was contaminated in this manner and subsequently transmitted serum hepatitis to 26 patients. Other investigators confirmed Hughes's hypothesis *(129,136)*. For example, Lutz et al. *(129)* calculated that 2×10^{-5} mL of fluid were aspirated into the syringe when they removed the needle. Although minuscule, this volume of blood is 200 to 2,000 times greater than the amount required to transmit hepatitis B virus to chimpanzees *(137)*.

Syringe contents may be contaminated with blood when the syringes are used to administer fluids into intravenous lines. Hein et al. *(138)* detected visible blood in 6 and occult blood in 8 of 100 injection ports for intravenous tubing. Similarly, Trepanier et al. *(139)* used Ames Multistix read by a Clinitek 200 module (sensitive to a 1:32,000 dilution) to detect blood in intravenous fluids withdrawn through injection ports. They detected blood in 3.33% (95% CI 2.26–4.73%) of samples withdrawn from the first port and in 0.3% (95% CI 0.01–1.84%) of those withdrawn from the third port. When they injected fluids into intravenous tubing through which blood was infusing, 34% (95% CI 24.8–44.1%) of the syringes were contaminated. Using 10-mL syringes, Parlow *(140)* injected 2-mL aliquots of normal saline into injection ports of intravenous lines used for patients undergoing general anesthesia. After injecting four aliquots per syringe, the investigator removed the needle, filtered the remaining 2 mL of saline, and stained the filter with Papanicolaou's stain. Three of 26 samples (11.5%) contained red blood cells.

Multidose Vials Many drugs used by anesthesia personnel are packaged in multidose vials. Ninety-eight percent of anesthesia personnel surveyed by Kempen used multidose vials opened by unknown persons, and 75% refilled common syringes from multidose vials and did not subsequently discard the vial *(141,142)*. Moreover, a study by Zacher et al. *(143)* suggests that bacteria contaminating the outside of a multidose vial can be injected into the vial if the vial is not disinfected.

Corley et al. *(144)* injected at least one billion *S. aureus* or *E. coli* microorganisms into vials containing succinylcholine chloride, chloroprocaine, tubocurarine, water for injection, and sodium chloride for injection. After 7 days, 99.6% to 100% of the microorganisms were killed. Of the three anesthetic agents tested, only succinylcholine chloride did not kill all of the bacteria. Highsmith et al. *(145)* evaluated whether 12 different pathogens persisted in eight drugs commonly packaged in multidose vials. Cultures of procainamide and methohexital were negative at 24 hours. Succinylcholine chloride, regular insulin, potassium chloride, and thiopental killed slowly or allowed limited survival of several microorganisms. If the bacteria were washed in 0.25% peptone broth (i.e., carried some nutrients with them when injected), all 12 microorganisms survived or proliferated in lidocaine. However, if the bacteria were washed in saline, lidocaine supported growth of only *Pseudomonas cepacia*. Bawden et al. *(146)* inoculated 1 to 100 CFU of *E. coli* or *P. aeruginosa* into 30-mL multidose vials of bacteriostatic water with 0.9% benzyl alcohol, 0.9% sodium chloride with 0.9% benzyl alcohol, and 1% lidocaine hydrochloride with 1 mg/ml of methylparaben. All cultures were positive at 1 hour, and *E. coli* was recovered from the lidocaine at 16 hours. Longfield et al. *(147)* inoculated 11 commonly used medications with suspensions of 10 bacterial species. When stored at 22°C, atropine and D-tubocurarine were sterile at 4 hours, but lidocaine and heparin still contained viable bacteria at 24 hours. At 4°C, bacteria persisted longer in all medications tested. Plott et al. *(133)* injected 10^6 plaque-forming units of vesicular stomatitis virus into sterile water, 1% lidocaine, and 1% lidocaine with 1:100,000 epinephrine. All cultures were positive at 1 hour and cultures of the sterile water and the lidocaine were positive at 1 day. None of the vials contained viable virus at 1 week.

The results of multiple culture surveys indicate that the proportion of multidose vials contaminated by bacteria has ranged from 0% to 27% *(144,146,148–155)*. In their review of 12 studies published between 1958 and 1983, Longfield et al. *(152)* noted that the studies reporting high rates were done before 1973. On the basis of four studies done after 1973, they estimated that 0.6% of used multidose vials were contaminated with bacteria. Longfield et al. suggested that the differences between the results of earlier and more recent studies might be explained by changes in both the types of drugs packaged in multidose vials and the chemicals used as preservatives. After reviewing 15 papers published between 1958 and 1986, Thompson et al. *(156)* estimated that 0.5% of used multidose vials become contaminated with bacteria.

Of the studies we evaluated, only one tested used multidose vials for viral contamination. Petty et al. *(148)* tested 121 used multidose vials for viruses, none of which were

positive. Only two studies evaluated used multidose vials for red blood cells. Melnyk et al. *(151)* evaluated 69 multidose vials; none of the vials were contaminated with bacteria, but one (1.4%) contained red blood cells. Arrington et al. *(157)* noted that many anesthesia staff members withdrew contents from a medication vial, injected the drug into intravenous tubing, and then used the same needle and syringe to withdraw medication for the next patient. Because they were concerned that this practice could contaminate medication vials, the authors tested vials at the end of the day for the presence of occult blood. The first group consisted of vials reused by staff members who used a single needle and syringe as described above. The second group consisted of vials used by the investigators who placed a new needle on the used syringe to withdraw medication from vials. Eleven of 492 (2.2%) vials in the first group and 1 of 369 (0.3%) in the second group contained occult blood. The authors concluded that their study supported the AANA *(8)* and CDC *(30)* guidelines that mandate use of a new needle and a new syringe for each patient and each time a vial is entered.

Epidemiology

A number of outbreaks have been caused by contaminated solutions or anesthetic agents (*106–110*,*158–171*,172,173,*174*). Of the 21 reports reviewed in Table 60-2, 20 were caused by drugs that were contaminated at the healthcare facility and only one was caused by a drug contaminated by the manufacturer. Nine outbreaks were caused by contaminated propofol *(106,108–110,162,163,167,174)*. Bennett et al. *(171)* investigated outbreaks associated with propofol at seven hospitals and found numerous breaks in aseptic technique. For example, anesthesia personnel did not clean vials before opening them and did not wear gloves. They also drew up the drug before the case, transferred syringes containing unused drugs between operating rooms and facilities, and reused syringes. In one hospital, the same strain of *S. aureus* was isolated from the patients and from a lesion on the scalp of the anesthesiologist who prepared the medication *(108)*. A case–control study implicated exposure to propofol as the risk factor, suggesting that the anesthesiologist contaminated the propofol solution. Kuehnert et al. *(108)* noted similar faulty technique. Anesthesia personnel often did not wash their hands before preparing the medications, drew up all the propofol doses required for an entire day at one time, and kept the syringes at room temperature throughout the day. In addition, they often used multidose vials that contained large volumes of propofol, and stored the unused doses in the open vial at room temperature.

Most anesthetic drugs are weak bases dissolved in acidic solutions that inhibit growth of bacteria and fungi *(175–177)*, and most contain a bacteriostatic agent. However, propofol is suspended in a lipid solution that supports bacterial and fungal growth *(176–184)*, and it does not contain a preservative. If anesthesia personnel do not follow aseptic technique when they remove propofol from the glass vial, they can contaminate the solution. The contaminating microorganisms can multiply in propofol while it is infused slowly or while prefilled syringes sit at room temperature. To avoid such problems, the manufacturer recommends that propofol "be drawn into a sterile syringe immediately after the ampoule is opened and administration should commence promptly. Each unit of [propofol] is intended for use in a single patient and the syringe and any unused portion of [propofol] must be discarded at the end of the surgical procedure" *(184,185)*.

Seeberger et al. *(186)* administer propofol using the following protocol. The anesthesiologist must (a) use only 20-mL ampoules of propofol; (b) use an alcohol-based hand rub before starting the procedure; (c) prepare the syringes, lines, and stopcocks just before the procedure; and (d) discard all unused propofol, and never use propofol from the same ampoule for more than one patient. In addition, an infection preventionist conducts continuing education, teaching anesthesia staff members about good infection prevention practice and monitoring their adherence. These investigators reported that between January 1, 1995, and June 30, 1996, they performed 1,407 anesthetic procedures using propofol and 5,026 using thiopentone. Subsequent follow-up revealed that the incidence of catheter-related sepsis of unknown origin was 0.2% for both groups and the incidence of superficial thrombophlebitis and of fever >38°C of unknown origin was <0.1% for both groups. On the basis of these data, they concluded that their precautions were adequate to prevent infections in patients undergoing intravenous anesthesia with propofol.

Other outbreaks reviewed in Table 60-2 illustrate how various breaks in aseptic technique, including narcotic pilfering *(164)* use of the same syringe for more than one patient (*165*,173), and assembling equipment in advance of the procedure *(108,166)*, have led to infections. Although outbreaks associated with contaminated solutions or drugs occur rarely, large numbers of patients can be infected. Most of the reported outbreaks have been related directly to poor aseptic technique, including the unacceptable practices of administering the same solution to more than one patient and entering a single use *(174)* or a multidose vial (173) with a used syringe and needle. Of note, outbreaks of viral hepatitis (seven hepatitis C, four hepatitis B) still occur related to unacceptable practices—reuse of needles or syringes (either for more than one patient or for the same patient by entering a vial with used equipment and administering the remaining medication to other patients) *(165*,*168*,172,173,*174*) and misuse of multidose vials (*107*,*109*,*169*,*170*,173). Rather than saving money, these unacceptable practices actually increase the costs of medical care (due to the costs of investigating outbreaks and treating patients who become infected), harm patients, and destroy careers.

Preventing Infections Related to Intravenous Anesthesia

Table 60-3 summarizes the guidelines that anesthesia societies, government agencies, and others have developed regarding practices that will limit the risk of infection related to intravenous anesthesia. Given the information in the preceding section, we believe that very few infections would occur in association with intravenous anesthesia if anesthesia providers knew the guidelines and followed them.

TABLE 60-2

Outbreaks Related to Intravenous Anesthesia

Author (Reference)	*Year*	*Contaminated Product*	*Infection*	*Number of Patients*	*Microorganism*	*Comments*
Sack *(158)*	1970	Intravenous solution used for numerous patients	Bacteremia	5	*K. pneumoniae, A. cloacae*	Multiple-dose solution used by same anesthesiologist.
Siboni *(159)* Borghans *(160)*	1979	Fentanyl	Bacteremia	16	*P. cepacia*	Intrinsic contamination despite methyl- and propyl-p-hydroxybenzoates included as preservatives.
Maldonado *(161)*	1989	Lidocaine multidose vial	Hepatitis	5	Hepatitis B	Vial used for numerous patients by one anesthesiologist.
CDC *(162)* Daily *(106)*	1990	Propofol infused per pump	Fungemia, end-ophthalmitis	4	*C. albicans*	Breaks in aseptic technique noted in anesthesia practice.
CDC *(162)*	1990	Propofol infused per pump	Fever, hypertension	2	*M. osloensis*	Same infusion, syringe, and pump used for both patients.
CDC *(162)* Villarino *(163)*	1990	Propofol infused per pump	Bacteremia, surgical site infections	13	*S. aureus*	Same phage type isolated from the patients and the hands of the nurse anesthetist, same infusion used for numerous patients.
CDC *(162)*	1990	Propofol infused per pump	Fever, surgical site infections	8	*S. aureus*	Same phage type isolated from the patients and from the anesthesiologist's throat.
Maki *(164)*	1991	Fentanyl in predrawn syringes	Bacteremia	3	*P. pickettii*	Narcotic tampering in pharmacy contaminated the medication.
Froggatt *(165)*	1991	Common syringe used on numerous patients	Hepatitis	6	Hepatitis B	Medication syringes contaminated by blood from a Hepatitis B carrier and used on subsequent patients.
Rudnick *(166)*	1991	Preassembled pressure-monitoring equipment	Bacteremia	9	*P. aeruginosa, E. cloacae, K. pneumoniae*	Pressure-monitoring equipment contaminated with floor-washing solution.
Veber *(110)*	1994	Propofol injections	Bacteremia	4	*K. pneumoniae*	Contents of one vial used for four patients over 18 h.
Kuehnert *(108)*	1997	Propofol injections	Bloodstream infection	5	*S. aureus*	Contents of one vial used on successive patients.
Kidd-Ljunggren *(107)*	1999	Local anesthetic injections	Hepatitis	2	Hepatitis B	A permanent aspiration needle was left in the bottle of local anesthetic. The desired amount was drawn into a syringe. If the patient needed more pain relief, the same syringe was used to obtain the agent. The multidose vial was NOT discarded between patients.
Henry *(167)*	2001	Propofol injections	Bloodstream infection (5) Surgical site infection (2)	7	*S. marcescens*	One anesthesiologist was associated with all cases but only 14% of the controls. All cases received propofol compared with 24% of controls. No cultures of the environment or the anesthesiologist were positive for the etiologic agent.
Massari *(109)*	2001	Propofol	Hepatitis	4	Hepatitis C	Risk factors for infection included being operated on during the same morning session on the same day as the probable source patient. All five patients were infected with genotype 1b. A multidose vial of propofol was the shared by all five patients.

TABLE 60-2

Outbreaks Related to Intravenous Anesthesia (*Continued*)

Author (Reference)	*Year*	*Contaminated Product*	*Infection*	*Number of Patients*	*Microorganism*	*Comments*
Meier *(168)*	2002	Sedative injections	Hepatitis	>50	Hepatitis C	Nurse anesthetist in a pain clinic used the same needle and syringe to give sedative injections into ports of intravenous lines.
Anonymous *(169)*	2002	Sedative injections	Hepatitis	28	Hepatitis C	Anesthesiologist in an endoscopy clinic obtained sedative from a multidose vial and gave several injections to the same patient with a single needle and syringe. The multidose vial was used for more than one patient. A patient with chronic hepatitis C, genotype 2C, underwent endoscopy at the beginning of the epidemic period.
Carbonne *(170)*	2003	Fentanyl injections	Hepatitis	2	Hepatitis C	A patient had chronic hepatitis C, subtype 1b. Repeat doses of fentanyl were obtained from a multidose vial with a used syringe and needle. Two patients whose operations followed this patient's operation acquired hepatitis C of the same genotype.
Comstock (173)	2004	Three different sedation medications	Hepatitis	102	Hepatitis C	A nurse prepared one syringe and needle for each of three sedation medications for a single pain clinic session. She injected drugs through heparin locks and she believed these devices were sterile.
Germain (172)	2005	Fentanyl	Hepatitis	3	Hepatitis B and C	Same syringe and needle probably were used to give the source patient fentanyl from two different vials. Fentanyl vial 2 was used for the index case and for cases 2 and 3, but not for a patient who did not become infected. The fentanyl was injected directly into peripheral intravenous catheters without antireflux valves.
CDC *(174)*	2008	Propofol	Hepatitis	≥6; 40,000 involved in the recall	Hepatitis C	A clean needle and syringe were used to draw medication from a single-use vial of propofol, which was injected directly through an intravenous catheter. If a patient required more sedation, the needle was removed from the syringe and replaced with a new needle. The new needle and the used syringe were used to draw more propofol. Backflow from the patient's intravenous catheter or when the needle was removed might have contaminated the syringe with HCV and subsequently contaminated the vial. Propofol remaining in the vial was used to sedate the next patient.

Note: Reference *(171)* describes a case–control study done at seven hospitals that had outbreaks related to misuse of propofol. Thus, references *(106,162,163)* share cases with reference *(171)*.

TABLE 60-3

Recommendations and Guidelines Regarding Medication Use in Anesthesia

Item	*ASA (8)*	*AANA (9)*	*ANZCA (19)*	*CDC (30)*	*Other*
Preservative-free medications	Use as single-patient, single-dose item. Open at the time of use; discard immediately after use. Swab rubber septum or neck with alcohol before entering. Use sterile needles and syringes to aspirate contents.	Clean the ampule before opening. Use a filtered needle to draw up the medication. Cleanse rubber stoppers before each use.			
Medications drawn up into a syringe	Do not give medications from a syringe to more than one patient. Discard medication drawn into a syringe within 24 h.			Do not administer medications from a syringe to multiple patients, even if the needle or the cannula on the syringe is changed.	
Multidose vials	Use aseptic technique. Cleanse rubber stopper. Use sterile needle and syringe each time vial is entered.	Restrict use of multiple-dose vials to one patient only unless strict aseptic technique is used. A new sterile syringe and needle should be used each time the vial is penetrated.	Because of the potential for crossinfection, the use of the contents of multiple-dose vials and ampoules for more than one patient is not recommended except in a dispensing situation where different doses are drawn up before the administration of the first dose to a patient. Likewise it is recommended that the contents of a single dose ampoule are to be used for one patient only.	If multidose vials must be used, both the needle or cannula and syringe used to access the multidose vial must be sterile. Do not keep multidose vials in the immediate patient treatment area and store in accordance with the manufacturer's recommendations; discard if sterility is compromised or questionable.	Single-use ampoules or vials of medication must be used for all injections unless alternative systems are set in place to prevent crossinfection(19). A medication may be taken from a multidose vial or ampoule only if the medication or solution is not readily available in another form. If any medication is taken from a multidose vial or ampoule, a sterile needle and syringe must be used to withdraw the contents. The needle and syringe must be discarded once they have been used. Precautions must be taken to ensure that contaminated materials or fluids are not injected into a multidose vial or ampoule *(21)*.

(*Continued*)

TABLE 60-3

Recommendations and Guidelines Regarding Medication Use in Anesthesia (*Continued*)

Item	*ASA (8)*	*AANA (9)*	*ANZCA (19)*	*CDC (30)*	*Other*
Single-dose vials and ampules				Use single-dose vials for parenteral medications whenever possible. Do not administer medications from single-dose vials or ampules to multiple patients or combine leftover contents for later use.	
Intravenous fluids, tubing, connectors, and disposable pressure transducers	Single use only.	Single use only.		Do not use bags or bottles of intravenous solution as a common source of supply for multiple patients. Use fluid infusion and administration sets (i.e., intravenous bags, tubing and connectors) for one patient only and dispose appropriately after use. Consider a syringe or needle/cannula contaminated once it has been used to enter or connect to a patient's intravenous infusion bag or administration set.	

Stopcocks, injection ports, and other portals of access to sterile fluids	Maintain with sterile technique. Keep free of blood and cover with a sterile cap or a syringe when not in use. Clean injection ports with appropriate disinfectant before entry.	Use sterile technique for all access ports.	
Use of syringes for more than one patient	Syringes are single-patient use items. Do not give medications from a syringe to more than one patient. Consider the syringe contaminated after entry into an intravascular line.	Consider syringes and needles as single-use disposable items. Do not reuse needles and syringes. Dispose of all needles and syringes after every use. Once used they are contaminated.	Needles, cannulae, and syringes are sterile, single-use items; they should not be reused for another patient or to access a medication or solution that might be used for a subsequent patient.
Noninjectable drugs and ointments and sprays	Discard multidose containers if contaminated or if contamination is suspected. Use unit dose packages whenever possible.	Acknowledge the risk of cross-contamination but do not specify practice.	
Other			Use aseptic technique to avoid contamination of sterile injection equipment.

INFECTIONS ASSOCIATED WITH NEURAXIAL BLOCKADE

Pathogenesis of Infections Associated with Central Neuraxial Blockade

Microorganisms from exogenous or endogenous sources can enter the subarachnoid and/or epidural space. Epidural catheters used for short-term postoperative analgesia have been found to be contaminated shortly after insertion; the most common microorganism is coagulase-negative staphylococci. Similar to central-venous catheters, bacterial migration from the insertion site along the epidural catheter track is the most common way epidural catheters become colonized *(187)*. Microorganisms may also reach the central nervous system by direct inoculation when the catheter is inserted or by hematogenous spread from a distal site.

North and Brophy *(188)* described a case in which microorganisms from the healthcare provider were most likely inoculated directly when the catheter was inserted. In this case, *S. aureus* of the same phage type was isolated from both the epidural abscess and the nose of the anesthesiologist; *S. aureus* with a different phage type was isolated from the patient's nose *(188)*. Several other groups have reported similar cases. Trautmann et al. *(189)* identified a case of meningitis caused by a *S. aureus* strain that was identical by pulsed-field gel electrophoresis to the *S. aureus* isolate in the anesthesiologist's nose. Schneeberger et al. *(190)* reported a cluster of meningitis cases caused by several streptococcal species after subarachnoid neural blockade administered by one anesthesiologist. The anesthesiologist routinely talked to his patients and did not wear a mask during the procedures. The anesthesiologist complained of recurrent pharyngitis and tonsillitis at the time the first two cases occurred. The investigators concluded that respiratory droplets may have transmitted mouth flora from the anesthesiologist to the patients and, thus, they suggested that all anesthesia personnel wear face masks when performing subarachnoid neural blockade. Assuming that the respiratory tract of anesthesia personnel could be a source of infection, Philips et al. *(191)* conducted a simulation to assess the efficacy of masks. They seated anesthesia staff in a room with controlled ventilation and asked the volunteers to speak directly at blood agar plates placed 30 cm away. The number of bacteria on the plates was significantly lower when masks were worn *(191)*.

Microorganisms can also enter the epidural space by hematogenous spread from other body sites, most often skin infections *(192)*, or by migrating along the catheter tract (*187*,*193–195*). A study by Wulf and Striepling *(196)* suggested that hematogenous spread can occur from infected sites to the epidural space. They performed autopsies on 10 patients who had continuous epidural neural blockade for 2 to 21 days after operative procedures. At postmortem examination, seven of nine patients, who had both infections at other sites and an epidural neural blockade, had evidence of epidural infection. The investigators did not find evidence of epidural infection in the nine control patients who had similar underlying infections but did not have an epidural neural blockade. Pinczower and Gyorke *(197)* reported a case of L1 osteomyelitis caused by *P. aeruginosa* in a 76-year-old man who had a lower respiratory tract infection caused by the same microorganism. Bengtsson et al. *(198)* reported three cases of spinal space infection in 4 years. The three cases occurred in different hospitals, and three different anesthesiologists did the epidural neural blockades. All three patients had coexisting lower-extremity contaminated wounds, and two of the three spinal infections were caused by microorganisms that infected the patients' own wounds. The investigators concluded that infected lower-extremity wounds were a contraindication for epidural anesthesia. On the other hand, Newman *(199)* did not find any epidural catheter-related infections among over 3,000 patients who had epidural neural blockades for postoperative or posttraumatic analgesia, yet some of these patients had lower-extremity infections. Thus, Newman concluded that lower-extremity infections were not a contraindication to epidural anesthesia.

Several investigators have done studies to determine the likelihood that microorganisms infecting a distal site could enter the central nervous system. For example, Carp and Bailey *(200)* did cisternal punctures on rats with *E. coli* bacteremia and 24 hours later the investigators examined the spinal fluid to determine whether the animals' central nervous systems were infected. Control rats (nonbacteremic rats, bacteremic rats that did not have cisternal punctures, and bacteremic rats treated with a single dose of gentamicin before the cisternal puncture) all had sterile spinal fluid. Twelve (30%) of 40 bacteremic rats that were not treated with gentamicin and that underwent cisternal punctures acquired *E. coli* meningitis. The authors acknowledged that their study had several limitations: *E. coli* rarely causes meningitis after neuraxial blockade; the "relative size of the dural tear produced by a 26-gauge needle… is clearly greater in rats compared to that in humans;" the cisternal site is rarely used in clinical anesthesia; and the agents used for neuraxial blockade have a bacteriostatic effect *(200)*. The investigators did not feel that giving a dose of gentamicin before the puncture was a limitation, because febrile obstetric and surgical patients are often treated with antimicrobial agents before they undergo neuraxial blockade. However, unlike researchers, clinicians often do not know the susceptibility patterns of microorganisms infecting their patients before they undergo invasive procedures.

Studies by Goodman et al. *(201)*, Teele et al. *(202)*, and Jakobsen et al. *(203)* are also relevant to the question of whether patients who have infections at other sites or who are bacteremic at the time of a neuraxial blockade are at increased risk of infection. Goodman et al. *(201)* evaluated 531 women, who received either epidural or subarachnoid anesthesia before delivery and who had pathologic evidence of chorioamnionitis. Of these patients, 4 (80%) of 5 women with documented bacteremia, 11 (24%) of 45 women who were febrile, and 174 (76%) of 229 women who had leukocytosis did not receive antimicrobial agents before their blocks, but none of them acquired neurological infections even though many of them were not treated with antimicrobial agents. The investigators concluded that neuraxial blockade "may be safe in parturients with chorioamnionitis without prior antibiotic therapy" *(201)*.

In contrast, Teele et al. *(202)* found a significant association between lumbar puncture performed during

bacteremia and a subsequent diagnosis of bacterial meningitis in children <1 year of age. The investigators retrospectively reviewed the medical records of 271 children who had 277 episodes of bacteremia with *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Neisseria meningitidis* and who were sent home before blood culture results were available. None of the 46 patients who had lumbar punctures during their first visits had laboratory evidence at that point of meningitis. Nine (3%) of the 271 children, all of whom were <1 year old, acquired meningitis; seven (78%) of these nine children had lumbar punctures during their initial evaluations and two (12%) did not ($p < .001$). Treatment with antimicrobial agents may have decreased the risk of meningitis; 2 (11%) of 17 bacteremic children <1 year old who had a lumbar puncture during the initial visit and who were treated with antimicrobial agents acquired meningitis compared with five (83%) of the six patients who had lumbar punctures but were not treated with antimicrobial agents ($p = .003$). The investigators discussed two important limitations of their study. First, clinicians may be able to identify patients who are most likely to acquire meningitis. Second, patients who subsequently acquire meningitis may look sicker than other patients and, thus, clinicians may perform lumbar punctures on these patients more frequently than they do on other patients. Moreover, researchers have not determined whether data from diagnostic lumbar punctures can be extrapolated to spinal anesthesia or whether the antibacterial effect of local anesthetics *(204)* decreases the risk of infection in this context compared with the risk from injections of opioids or clonidin alone.

Jakobsen et al. *(203)* evaluated 69 patients (120 extradural catheters) who were treated for abscesses or infected wounds. three (4%) patients had inadvertent dural punctures treated with blood patches, 16 (23%) had septic episodes while their catheters were in place, and 1 (1%) patient had a positive blood culture. Twelve (10%) catheters were removed because of exit site infections, but none of these patients received antimicrobials. None of the patients acquired epidural abscesses or meningitis; 1 (1%) patient acquired a discitis caused by *S. epidermidis*.

In summary, most of the studies assessing the source of infecting microorganisms in patients undergoing regional anesthesia procedures have been small, and the source of most infections was never identified. Data from several case series and from an animal model do not indicate clearly whether or not bacteremia or infections at distal sites increase the risk of infections associated with regional anesthesia procedures or whether these procedures are contraindicated in bacteremic patients. Thus, anesthesiologists should assess the risks and benefits of various approaches to methods of providing anesthesia before performing regional blocks in patients suspected of having infections and should consider treating these patients empirically with antimicrobial agents.

Rarely, contaminated anesthetics are injected into the patient's subarachnoid or epidural space. For example, North and Brophy *(188)* reported an infection in which *S. aureus* strains with matching phage types were recovered from an abscess and a multidose lidocaine vial. Green and Pathy *(205)* questioned whether staff can draw up opioids in a sterile fashion from ampules, but did not provide evidence to support their concern. They suggested that these drugs be drawn through a filter into a syringe that is then double wrapped and sterilized in ethylene oxide. Raedler et al. *(206)* obtained cultures of 114 spinal and 20 epidural needles after use for single-injection lumbar anesthesia. Twenty-four cultures (17.9%) grew microorganisms: 15.7% coagulase-negative staphylococci, 1.5% yeasts, and 0.8% each enterococcus, pneumococcus, and micrococcus. However, no infections occurred in the study population. The anesthesiologists who performed these procedures wore "operating room dress" and used sterile gloves and sterile drapes. These authors concluded that it is easy to contaminate the needle and that anesthesiologists need to improve their hygienic measures.

Other investigators evaluated specimens from catheters or syringes. In four studies, 0% to 29% of the catheters were contaminated *(207–210)* and James et al. *(207)* found that 5 of 101 syringes used to inject an anesthetic agent were contaminated. Ross et al. *(211)* drew up bupivacaine 0.25% into control syringes and into syringes used to induce continuous lumbar epidural neural blockade (test syringe) in 18 obstetric patients. After each dose from the test syringe, cultures were obtained from the contents of both the test and control syringes. Six of 18 test syringes were contaminated with bacteria, compared with 1 of 18 control syringes. In the five studies cited above, none of the patients acquired infections *(207–211)*. Hence, the authors could not correlate contaminated catheters or syringes with infection.

Yaniv and Potasman *(212)*, Dawson *(213)*, Baer *(214)*, and Videira *(215)* reviewed infections after neuraxial anesthesia. Dawson's review of studies on infections associated with epidural anesthesia *(213)*, and two papers on postdural puncture meningitis (PDPM) *(214,215)* indicate that there is no consensus regarding patient risk factors for infectious complications and that the aseptic practices used by anesthesia providers for these procedures differ substantially. In addition, the literature includes conflicting reports about the association of the risk of infection with the duration of catheterization and with the site of the catheter. Horlocker's review of complications associated with spinal and epidural anesthesia *(216)* and Baer's review of PDPM *(214)* address several issues regarding infections after these procedures.

Infections Associated with Epidural Neural Blockade

Epidemiology Infections Associated with Epidural Anesthesia—Estimated Incidence: Data from two reviews of epidural abscesses suggest that only a small proportion of these infections are related to epidural catheters *(192,217)*. The incidence of infections after epidural neural blockade has been difficult to determine. Various groups have assessed the frequency of infections after epidural neural blockade, but their results differ substantially *(218–223)*. When reviewing 350 reports in the literature, Dawkins *(219)* found no reports of infection after thoracic or lumbar epidural block, but he identified eight reports of infection after 3,767 sacral epidural blocks used for operative procedures and for obstetrics (0.2% or 212/100,000). More recently, Dawson *(213)* reviewed the literature and found rates of deep infection ranging from 0% to 0.7% and rates of

superficial infection ranging from 1.8% to 12%. Studies by Aromaa et al. *(220)* and Wang et al. *(221)* produced very different estimates of the incidence: 3.5/100,000 procedures and 51.8/100,000, respectively. Wang *(221)* also found that the rate was substantially lower at university hospitals (17.7/100,000) than at private hospitals (125.6/100,000) ($p < .01$). The risk of persistent neurological deficit was 23/100,000 *(221)*. Ruppen et al. (224) conducted a meta-analysis of complications related to obstetric epidural blockades. They identified 11 cases of deep epidural infection in 13 studies that included 1.2 million patients for an estimated rate of 0.9/100,000. If they included only studies done after 1990, the rate was 0.77/100,000. Several studies have estimated the 95% confidence intervals for the rates of infection associated with epidural neuraxial blockade. These estimates have ranged from 0 to 10 infections per 100,000 procedures *(222)* to 0 to 30 infections per 100 *(223)*. We are not sure why the estimates vary so much. However, the methods, size, and patient populations varied substantially from study to study. In addition, readers must interpret these estimates in light of two recent studies. Ptaszynski et al. *(225)* found the incidence of spontaneous spinal epidural abscesses to be 0.88/100,000 (95% CI 0.27–1.48/100,000). Reihsaus et al. *(226)* conducted a meta-analysis and found that only 5.5% of 915 patients with spinal epidural abscess (representing an incidence estimate of 0.2–2/10,000) had a prior epidural anesthetic.

A number of case series have assessed infections associated with epidural neural blockades for short-term pain relief during and after obstetrical or surgical procedures *(210,222,223,228–239)*. We found six case series that discussed infectious complications of obstetrical epidural anesthesia. Three small series (~12,000 patients) did not identify any infections *(230–232)*. Two larger studies found rates of 0.2/100,000 *(228)* and 1/100,000 procedures *(229)*. In contrast, Brooks et al. *(240)* found four infections among 4,832 (83/100,000) patients undergoing epidural neuraxial blockades for surgical procedures or for labor and delivery. Data from other case series suggest that epidural catheters inserted for long-term pain control become infected more frequently than those used for short periods of time *(241–246)*. However, in two of these studies *(241,242)*, patients received only opioids rather than local anesthetics or a combination of drugs, which may confound the interpretation of the results. Du Pen et al. *(241)* and Coombs *(242)* found that 9% (38) to 11% (39) of patients with long-term catheters acquired superficial infections. Du Pen et al. *(241)* and Zenz et al. *(243)* found rates of deep infections of 1% (38) to 2%.

Case Reports Although infections rarely complicate short-term epidural neural blockade, case reports in the literature indicate that such infections do occur and that they can be severe. We reviewed case reports of 59 patients who acquired infections after epidural neuraxial blockade with anesthetic agents alone or anesthetic agents and steroids *(239,247–257)*. We excluded patients who received steroids alone. Among the 49 (83%) patients who had epidural catheters and for whom the duration of catheterization was specified, the median duration was 3 days (range 50 minutes to 6 weeks). The median time to onset of the first signs or symptoms of infection was 4 days (range 14 hours to 5 months) after catheter placement. Forty-two (71%) of 59 patients in these case reports acquired epidural abscesses and *S. aureus* was the predominant etiologic agent (Table 60-4). The infection prevention and control precautions used during the procedures were not specified for 31 (53%) of the patients and were described in vague terms (e.g., "aseptic technique" or "according to protocol") for 13 (22%).

In 1998, Kindler et al. *(218)* published a literature review in which they identified 42 patients with catheter-related epidural infections between 1974 and 1996. Epidural abscess was the initial diagnosis in only 15 (36%) patients. Similarly, we also found evidence that the diagnosis was delayed by at least 1 day (sometimes days to weeks) in 35 (59%) of 59 infections. Of these 35 patients, 17 (49%) recovered (fully or nearly fully), 17 (49%) had residual neurological deficits, and no information was provided about 1 patient (3%). In contrast among the 22 patients for whom there was no evidence of a delay between the onset of symptoms and the diagnosis, 15 (68%) recovered, 4 (18%) had residual neurological deficits, and no information was provided about 3 patients (14%; $p = .05$) (see the reviews by Herwaldt et al. *(239)*, Baer *(214)*, Ruppen et al. (224), and by Sarrubi and Vasquez *(258)* for further information about the cases and for information about additional cases *(214)*).

Infections Associated with Subarachnoid Neural Blockade

Epidemiology Data from a passive surveillance system and from nine case series (Table 60-5) suggest that the rate of meningitis is approximately 4.6 per 100,000 subarachnoid neural blockades *(215,222,239,259–266)*. In contrast, Aromaa and colleagues *(220)* evaluated administrative data in Finland and identified only four infections (the authors did not specify the types of infection) in 550,000 patients undergoing subarachnoid anesthesia for an incidence of 7.2/1,000,000.

Case Reports Although infections infrequently complicate subarachnoid neural blockade, case reports in the literature indicate that such infections can be serious. We reviewed reports of 26 patients who acquired infections after subarachnoid neural blockade *(239,267)*. The median time to onset of signs or symptoms of infection was 24 hours (range 1 hour to 2 months) for all infections combined. The median onset time of symptoms from meningitis was only 17 hours (range 1 hour to 10 days) compared with 4 days (range 1 day to 2 months) for other infections. Compared with infections after epidural neural blockade, infections associated with subarachnoid neural blockade were more likely to be caused by streptococci and patients were more likely to recover fully (Table 60-4). Few reports provided detailed information about the infection prevention precautions used during the implicated procedures. Eight (31%) reports did not provide any information and two (8%) provided only vague descriptions ("sterile conditions," "aseptic technique").

Infections Associated with Combined Epidural and Subarachnoid Neural Blockade

Epidemiology and Case Reports At present, there are few reports in the literature about infectious complications

TABLE 60-4

Summary of Data from Case Reports on Infections Associated with Epidural and Subarachnoid Anesthesia/Analgesia

Demographics	*Epidural (n = 59)*	*Subarachnoid (n = 26)*	*Combined (n = 10)*
Median Age	51 y	27 y	33.5 y
Female	35 (59%)	10 (39%)	7 (70%)
Health status			
Previously healthy	14 (39%)	9 (35%)	7 (70%)
One or more underlying diseases[a]	30 (41%)	5 (19%)	3 (30%)
No information provided	15 (20%)	12 (46%)	
Indication for procedure			
Obstetrical analgesia	14 (24%)	6 (23%)	7 (70%)
Surgical procedure	21 (36%)	16 (62%)	2 (20%)
Nonsurgical pain	24 (41%)	4 (15%)	
Other			1 (10%)
Type of infection			
Meningitis	7 (12%)	19 (73%)	6 (60%)
Epidural abscess	42 (71%)	4 (15%)	4 (40%)
Discitis/osteomyelitis/spondylitis	4 (7%)	2 (8%)	
Other	6 (10%)	1 (4%)	
Microorganism	(*n* = 54)	(*n* = 23)	(*n* = 10)
S. aureus	39 (72%)	2 (9%)	4 (40%)
S. species	4 (7%)	12 (52%)	3 (30%)
Pseudomonas aeruginosa	4 (7%)	4 (17%)	
Other	7 (9%)	5 (22%)	3 (30%)
Outcome			
Death	3 (5%)	1 (4%; from underlying disease)	
Neurologic deficit	20 (34%)	2 (8%)	
Complete or nearly complete recovery	31 (53%)	22 (84%)	9 (90%)
Not specified	5 (8%)	1 (4%)	1 (10%)

Note: The data in this table are summarized from references (*239*,*269*,296). Data from single-shot epidurals that did not involve placement of a catheter and steroid injections were excluded

[a]For example, coronary artery disease, hypertension, peripheral vascular disease, diabetes mellitus, chronic obstructive lung disease, cancer, trauma secondary to an automobile accident, etc.

of combined epidural and subarachnoid neural blockade. Cascio and Heath *(268)* identified one (~0.1%) case of meningitis after about 700 combined epidural and subarachnoid neural blockades. We reviewed nine case reports describing 10 infections after combined procedures *(239,268,269)*. The median age of the patients was 33.5 years. All seven female patients had obstetrical procedures; two of the male patients had surgical procedures and one had lithotripsy. The median time to onset of signs or symptoms of infection was 1.5 days (range 8 hours to 9 days) for all infections and 18 hours (range 8 hours to 3 days) for meningitis. Signs or symptoms of epidural abscesses were first noted 1 to 9 days after the procedures. Evidence of symptom progression was noted in five cases, and in three of those cases the diagnosis was delayed at least 1 day. Streptococcal species caused three (50%) of six cases of meningitis and *S. aureus* caused the four epidural abscesses. Nine (90%) patients recovered fully. Infection prevention precautions were specified for eight cases, and these reports did not note obvious breaks in technique.

In summary, infections are infrequent but serious complications of neuraxial regional anesthetic procedures. The incidence of these infections is not well defined and varies substantially by study. The case series and surveillance studies from which the estimates were derived do not discuss possible confounding factors such as the patients' comorbidities, the duration of labor or of the surgical procedures, or the frequency of distal infections such as chorioamnionitis. The investigators often did not describe the infection prevention precautions used by the anesthesiologists whose patients were described. Thus, we cannot determine whether the patient populations and the practices in the different reports were similar. Moreover, the reports did not include control patients; consequently, the investigators could not identify patient or practice factors that increase the risk of infection.

Infections Associated with Peripheral Nerve Blocks

Epidemiology and Case Reports In recent years, continuous regional anesthetic techniques using peripheral

TABLE 60-5

The Frequency of Meningitis after Subarachnoid Neural Blockade

Author (Reference)	*Year*	*Number of Patients in the Series*	*Number of Patients with Meningitis*	*Cases of Meningitis per 100,000*

Total		>173,188	8	≈4.6

nerve blocks have become more popular for postoperative pain management, especially for orthopedic procedures *(270,271)*. Auroy et al. *(222)* did not identify any infections after 43,946 peripheral blocks reported through their passive surveillance system. Bergman *(272)* identified one (0.3%) patient who acquired a local *S. aureus* skin infection after 48 hours from among 368 patients who had 405 axillary catheters. The patient recovered fully with antimicrobial treatment. Meier *(273)* evaluated 91 patients who had continuous interscalene catheters for an average of 5 days, and 8 (9%) patients acquired superficial skin infections. These investigators did not provide information about the aseptic techniques used for catheter insertion.

We reviewed two case reports of serious infections after peripheral nerve blocks. Nseir et al. *(274)* described a case of fatal necrotizing fasciitis caused by group A streptococcus following an axillary brachial plexus block in an elderly woman with insulin-dependent diabetes, hypertension, and chronic atrial fibrillation. The patient underwent right carpal tunnel decompression; an axillary brachial plexus block was used during the procedure. The patient was discharged the same day. Four days later, the patient had axillary pain and edema followed by symptoms of toxic shock syndrome; the patient expired within 48 hours despite medical and surgical management. Adam et al. *(275)* identified a *S. aureus* psoas abscess in a 35-year-old woman who had a 3-in-1 femoral blockade for an arthroscopic arthrolysis of the knee. The catheter was removed 4 days postoperatively. The following day the patient had fever and 4 days after the catheter was removed she complained of left lower quadrant abdominal pain.

Cuvillion et al. *(276)* obtained cultures of 208 femoral catheters when they removed the catheters after 48 hours; 54% were colonized with potentially pathogenic bacteria (71% *S. epidermidis*, 10% *Enterococcus* spp., and 4% *Klebsiella* spp.). These investigators also reported three episodes of transient bacteremia, but they did not identify abscesses or episodes of clinical sepsis.

Capdevila *(277)* observed 1,416 patients with continuous peripheral nerve catheters and found three patients with local inflammation and one psoas abscess caused by *S. aureus* in a diabetic woman. Wiegel et al. *(278)* described nine patients (0.6%) who had local inflammation at the catheter insertion sites and three (0.2%) who had local infections (all at the femoral sites) among patients who had 628 femoral and 549 sciatic continuous blocks. Neuburger et al. *(279)* followed patients with 3,491 peripheral nerve catheters (936 axillary, 473 interscalene, 125 vertical infraclavicular, 74 psoas compartment, 900 femoral, and 964 sciatic) and found 146 minor, 83 moderate, and 29 severe infections. The risk of infectious complications was significantly ($p < .001$) higher for interscalene blocks compared with blocks at the other sites. Infections occurred on average 4 to 5 days after catheter insertion. The authors speculated that sebaceous glands might increase the risk of infection with interscalene blocks; hence, they recommended that the skin in this area be kept wet with disinfectant for 10 minutes before the catheter is placed. However, the observations from this study may not be generalizable because the infection rate was quite high. For example, Borgeat et al. *(280)* followed 700 patients with interscalene blocks and found the rate of minor to moderate infections to be 0.8% compared with approximately 5% in the study by Neuberger et al. *(279)*. Borgeat et al. *(280)* found the rate of severe infections to be 0.1% compared with 1.3% in the study by Neuburger et al. *(279)*. If interscalene blocks are more likely to be complicated by infection than are other peripheral nerve blocks, mechanical stress secondary to catheter movement might be a factor that increases the risk of infection associated with catheters placed in this area.

Preventing Infections Associated with Central Neuraxial Blockade and with Peripheral Nerve Blocks

The literature regarding infection prevention precautions for neuraxial and peripheral nerve blocks documents that practice varies substantially and that some precautions are quite controversial (*214,281–288*,289). Nevertheless, most infections after epidural and subarachnoid neural blockade are caused by bacteria that colonize the skin, respiratory tract, or water. Consequently, we believe anesthesia staff should take precautions to limit contamination from

these sources. Hepner recently wrote the following in an editorial: "Evidence has clearly shown that aseptic techniques are effective in reducing contamination and complications in other sterile procedures such as central venous lines. Likewise, data clearly show that lack of some sterile technique such as the use of masks creates situations (higher bacterial counts) that may be potentially harmful. If we are to avoid the complications that 60 years into the future will seem obvious, we must institute uniform sterile safety practices that have been proven, or seem by common logic to be prudent, and continue to study techniques used in other areas to determine their utility" (290).

Given the very low rates of infection associated with epidural and subarachnoid neural blockade, we believe it will be very difficult to prove that infection prevention interventions—such as full-barrier precautions (i.e., the anesthesiologist wears a cap, mask, sterile gloves, and sterile gown and uses a large drape to cover the patient and the patient's bed)—reduce the risk of infection. However, these procedures are at least as invasive as placing central venous catheters and the consequences of subsequent infections are at least as bad as those for catheter-associated bloodstream infections.

In addition, risk factors for infections after neuraxial and peripheral nerve blocks have not been studied in robust epidemiological studies. The only case–control study of risk factors for infections associated with epidural neural blockade done for postoperative pain relief identified only one remediable risk factor—administering the anesthetic agent with a syringe rather than a bag [OR (for use of a bag) 0.17; 95% CI 0.02–1.34, $p = .05$] *(291)*.

Several investigators have evaluated the agents used to prepare the skin before epidural neuraxial blocks. However, these studies all had methodologic flaws *(292–295)*. For example, three of four studies that we reviewed did not report power calculations, and the study by Adam et al. *(292)* comparing 3% povidone-iodine with 1% chlorhexidine was not randomized. Kasuda et al. *(293)* randomly assigned 70 patients to receive either 0.5% chlorhexidine or 10% povidone-iodine. After a median of 49 ± 7 hours, the authors removed the catheters and obtained cultures of the insertion sites and catheter tips. The rates of positive cultures were similar in both groups. Kinirons et al. *(294)* (the only investigators who reported a power calculation) cultured catheters removed from 96 children who had epidural catheters for longer than 24 hours. Coagulase-negative staphylococci were the only microorganisms that grew and the colonization rate was lower for the catheters removed from children whose skin was prepared with 0.5% alcoholic chlorhexidine (1/52 catheters, 0.9/100 catheter days) compared with those removed from children whose skin was prepared with povidone-iodine (5/44 catheters, 5.6/100 catheter days) (relative risk 0.2; 95% CI 0.1–1.0). These investigators did not identify any epidural space infections. Sato et al. *(295)* evaluated the efficacy of 0.5% alcoholic chlorhexidine and 10% povidone-iodine in a group of 60 patients who were undergoing back operations under general anesthesia. After prepping and draping the site, the investigators obtained skin biopsies that they evaluated by culture and microscopy. Cultures from skin prepared with the chlorhexidine product were less likely to be positive (5.7%) than were cultures from skin prepared with povidone iodine (32.4%; $p < .01$). *S. epidermidis, Staphylococcus hyicus,* and *Staphylococcus capitis* grew from skin cultures. However, microscopy of the hair follicles was equally likely to be positive in skin prepared with chlorhexidine (14.3%) and skin prepared with povidone-iodine (11.8%).

Recently, the ASA (9), the American Society of Regional Anesthesia (ASRA) (14–17), and the German Society of Anesthesiology and Intensive Care (Deutsche Gesellschaft für Anästhesiologie und Intensivmedizin e.V." [DGAI]) *(25)*, as well as Brooks et al. *(240)* and Schulz-Stubner et al. (296) have published recommendations for preventing infections associated with neuraxial procedures (Table 60-6). In addition to providing advice on preventing infections, the ASA recommended the following procedures for diagnosing and managing infectious complications associated with neuraxial techniques: (9) (i) Evaluate patients with indwelling neuraxial catheters daily to identify early signs and symptoms (e.g., fever, backache, headache, erythema, and tenderness at the insertion site) of infectious complications. (ii) Investigate signs or symptoms promptly to minimize the severity of an infection. (iii) If an infection is suspected, (a) Remove an *in situ* catheter and consider culturing the catheter tip. (b) Obtain appropriate blood tests. (c) Obtain appropriate cultures. (d) Perform imaging studies and consult with appropriate specialties promptly if the patient may have an abscess or if the patient has neurologic dysfunction. (iv) Administer appropriate antimicrobial therapy at the earliest signs or symptoms of a neuraxial infection. (v) Consider consulting a physician with expertise in the diagnosis and treatment of infectious diseases. (vi) Consult a surgeon if an abscess is identified to determine whether percutaneous drainage of the abscess or a surgical procedure (e.g., laminectomy) is warranted.

To date, guidelines for placement of catheters for peripheral nerve blocks have not been published. Given that complex catheter systems, which require several manipulations during insertion, are used for these procedures *(297)*, we believe that aseptic technique similar to that recommended for placement of central venous catheters is warranted *(298)*.

OUTBREAKS ASSOCIATED WITH ANESTHESIA PERSONNEL

Anesthesia personnel have been the reservoir of infection in at least 11 outbreaks (Table 60-7) (*112–119,299–302)*. Group A β-hemolytic streptococci disseminated from anesthesia personnel caused five outbreaks of surgical site infections and one outbreak of puerperal sepsis (see Chapters 21 and 55). Anesthesia personnel carried group A β-hemolytic streptococci in the following sites: anus (two outbreaks), anus and throat (one outbreak), throat (one outbreak), and skin lesions (two outbreaks). The source of one outbreak was particularly difficult to identify, because the carrier, an anesthesia technician, was present in the operating room only between cases and not during the operations *(119)*. In two outbreaks of *S. aureus* surgical site infections, the microorganism was disseminated by anesthesiologists with psoriasis *(112,113)*. Clearly, the barrier between the anesthesia area and the operative site does not always prevent spread of microorganisms from anesthesia personnel to patients.

TABLE 60-6

Recommendations/Practice Advisories for Prevention of Infections Associated with Neuraxial Anesthetic Procedures

Practice	*ASA (9)*	*ASRA (14,15,16–17)*	*DGAI (25)*	*CDC*	*Other*
Patient selection	Before performing neuraxial techniques, conduct a history and physical examination relevant to the procedure and review relevant laboratory studies to identify patients who may be at risk of infectious complications. Determine whether a neuraxial technique is appropriate on a case-by-case basis and include an assessment of the patient's evolving medical status when considering these techniques. Consider alternatives to neuraxial techniques for patients at high risk of infectious complications. Consider administering pre-procedure antimicrobial therapy before performing a neuraxial procedure on a patient who is known or suspected to be bacteremic. Avoid doing lumbar punctures in patients with epidural abscesses.	The decision to perform a regional anesthetic technique must be made on an individual basis considering the anesthetic alternatives, the benefits of regional anesthesia, and the risk of central nervous system infection (which may theoretically occur in any bacteremic patient; which theoretically are more likely to occur in the immunocompromised patient) (16,17). Despite conflicting results, many experts suggest that, except in the most extraordinary circumstances, central neuronal block should not be performed in patients with untreated systemic infection (16). Available data suggest that patients with evidence of systemic infection may safely undergo spinal anesthesia, provided appropriate antibiotic therapy is initiated before dural puncture and the patient has shown a response to therapy, such as a decrease in fever (placement of an epidural or intrathecal catheter in this group of patients remains controversial) (16). Available data suggest that spinal anesthesia may be safely performed in patients at risk for low-grade transient bacteremia after dural puncture (16). Central neuronal block has been shown to be safe in patients with recurrent herpes simplex infections (HSV), though exacerbations of HSV-1 have been reported in association with intrathecal and epidural opioids (17).			

		There are inadequate data available regarding the safety of spinal and epidural anesthesia in the presence of primary HSV-2 infection. However, viremia, fever, and meningitis have been reported. These findings would suggest a conservative approach (17). Minimal data suggest that neuraxial and peripheral techniques (including epidural blood patch) can be performed safely in HIV-infected patients. The presence of preexisting neurologic pathology is common in these patients and must be considered (16,17).			
Hand hygiene	Remove jewelry (e.g., rings and watches), wash hands.	Thorough hand washing greatly reduces the risk of crosscontamination and should occur before performing any regional anesthetic technique. Alcohol-based antiseptic solutions will provide maximal degree of antimicrobial activity with extended duration when compared with nonalcoholic antimicrobial or nonantimicrobial preparations. The duration and method of washing (standard hand washing vs. full surgical scrub) required to reduce infectious complications is currently unknown (14). Higher microbial counts have been identified in healthcare workers who do not remove jewelry before hand washing. Therefore, it may be prudent to remove all jewelry items (rings, watches, and so on) before hand washing to reduce the risk of contamination (14).	Hand hygiene is considered obligatory. The preferred method is an alcohol-based solution used for 60 s.	The reader is referred to the CDC's hand hygiene guideline *(31).*	Hand hygiene—preferably with an alcohol-based hand rub–should be performed before and after every patient contact and before all invasive procedures (296).

(*Continued*)

TABLE 60-6

Recommendations/Practice Advisories for Prevention of Infections Associated with Neuraxial Anesthetic Procedures (*Continued*)

Practice	*ASA (9)*	*ASRA (14,15,16–17)*	*DGAI (25)*	*CDC*	*Other*
Masks	Wear a mask covering both mouth and nose and consider changing the mask before each case.	The use of surgical masks during regional anesthesia will maximize sterile barrier precautions. Although the routine use of masks has not been found to reduce infectious complications related to regional anesthesia, they do remain a vital protective measure against blood-borne pathogen exposure as recommended by OSHA.	Masks should be worn by all members of the puncture team.	Wear a surgical mask when placing a catheter or injecting material into the spinal canal or epidural space *(30)*.	Masks should be worn during regional anesthesia procedures (296).
Barrier precautions	Wear a cap and sterile gloves. Use sterile drapes.	Sterile surgical gloves should be used and considered a supplement to, not replacement for, hand washing. The use of surgical gloves is advocated not only to protect patients from crosscontamination but also to protect healthcare workers from bloodborne pathogen exposure as required by OSHA (14). Several intensive-care unit based investigations have shown that the use of surgical gowns does not reduce colonization, infection or mortality rates beyond that achieved with gloves alone. However there is currently insufficient data to make recommendations with regard to routine use during regional techniques within the operating room environment (14).	Gowns are recommended when placing catheters for continuous regional anesthesia and large drapes should be used to prevent contamination of the sterile field.		Full-barrier precautions (i.e., the anesthesiologist wears a cap, mask, sterile gloves, sterile gown and uses a large drape to cover the patient) should be used for catheter placement, especially for catheters that will be in place > 24 h and stimulating catheters that require frequent manipulations (296).

Skin preparation	Use individual packets of antiseptics to prepare the skin. Use chlorhexidine (preferably with alcohol) for skin preparation, allowing adequate drying time. If chlorhexidine is not available, use povidone iodine with alcohol.	Alcohol-based chlorhexidine antiseptic solutions significantly reduce the likelihood of catheter and site colonization and maximize the rapidity and potency of bactericidal activity when compared to other solutions. Therefore alcohol-based chlorhexidine solutions should be considered the antiseptic of choice before regional anesthetic techniques (14).	Alcohol-based solutions should be used for 1–10 min, according to manufacturers recommendations	2% Chlorhexidine in 80% alcohol skin prep or alternatively 10% povidone iodine, 80% alcohol, or a mixture of 70–80% alcohol with povidone iodine can be used to prepare the site (alcohol should not be used for subarachnoid blocks) (296).
Dressings	Use sterile occlusive dressings at the catheter insertion site.			The exit site should be dressed with a transparent dressing and should be viewed every 8 h or as necessary *(239)*.
Tunnels or port systems				Catheters for long-term use should be tunneled or have a port system (296).
Catheter management	Limit the number of times a neuraxial delivery system is disconnected and reconnected to minimize the risk of infectious complications. Consider removing catheters that are disconnected accidentally when a healthcare worker is not present. Remove catheters when no longer clinically necessary.			Disconnected nonstimulating catheters can be cut and reconnected after disinfection (296). The anesthesiologist should evaluate whether the infusion should continue if the system becomes disconnected *(239)*.
Prophylactic antimicrobial agents		Because implanted devices used for chronic pain therapy extend to the neuraxis and infection can prove to be catastrophic, routine antimicrobial prophylaxis is warranted in all patients (15). Discitis is a deep-seated difficult infection to treat and can prove to be catastrophic, thus routine antibiotic prophylaxis is warranted (15).	Prophylaxis with antimicrobial agents is not recommended for regional anesthetic procedures.	Prophylactic antimicrobial agents should not be used routinely to decrease the risk of infections associated with regional anesthesia (296).

(*Continued*)

TABLE 60-6

Recommendations/Practice Advisories for Prevention of Infections Associated with Neuraxial Anesthetic Procedures (*Continued*)

Practice	*ASA (9)*	*ASRA (14,15,16–17)*	*DGAI (25)*	*CDC*	*Other*
Patients with infections at other sites		Available data suggest that patients with evidence of systemic infection may safely undergo spinal anesthesia, provided appropriate antimicrobial therapy is initiated before the dural puncture and the patient has responded to therapy (e.g., decreased temperature). Placement of an indwelling epidural (or intrathecal) catheter in patients with infections remains controversial (16).			Patients with documented bacteremia or distal infections who need neuraxial blocks should be treated with appropriate antimicrobial agents before the procedure is done (296).
Filters	Consider using bacterial filters during extended continuous epidural infusion	Currently the literature does not support the routine use of bacterial filters with short-term (e.g., days) epidural or perineural catheter infusions (14).	Filters are recommended; routine filter changes are not recommended.		A 0.22-μm 96-h filter should be included in the infusion system (296). A 0.22-μm 96-h filter should be included in the infusion system. The tubing, filter, and solution should be changed or the system should be discontinued every 96 h *(239)*.
Administration of the anesthetic agent					The primary anesthesia and the adjuvant bolus dose should be given with a larger syringe that remains attached to the catheter until a continuous analgesia infusion is begun *(239)*.

Medication preparation		Only freshly prepared drug solutions should be used and multi-dose vials should be avoided.	Infusions and medications should be prepared by a pharmacist or an equally qualified individual according to Community Health Accreditation Program (CHAP) standard (296).
Patient follow-up	A delay in diagnosis and treatment of major central nervous system infections of even a few hours may significantly worsen neurologic outcome (16)	The puncture site for catheters should be inspected and palpated daily. If clinical signs of infection occur, a regional anesthetic catheter should be handled similar to central venous catheters.	Anesthesia personnel should observe their patients closely for signs and symptoms of infection and should consider infection in the differential diagnosis of patients who had a regional block and subsequently present with fever or with pain at the site (296).

CDC *(117)*	1976	Anesthesiologist	<48 h	Surgical site; bacteremia and meningitis	61	Group A β-hemolytic streptococci	Asymptomatic throat and anal carrier	Not specified	16 d
Paul *(118)*	1990	Anesthesiologist	24 h-16 d	Surgical site	4	Group A β-hemolytic streptococci	Asymptomatic throat carrier	Not specified	30 d
Mastro *(119)*	1990	Anesthesia technician	6–240 h	Surgical site	20	Group A β-hemolytic streptococci	Disseminated from a carrier with psoriasis and seborrhea on scalp and ears	23 m	40 m
Bosch *(299,300)*	1998, 2000	Anesthesiologist	Not specified	Hepatitis	171	Hepatitis C	Anesthesiologist addicted to morphine and infected with hepatitis C gave himself morphine injections and then gave patients the drug through the same syringe and needle.	Not specified	Not specified
Ross *(301)*	2000	Anesthesia assistant		Hepatitis	Five patients and the anesthesia assistant	Hepatitis C	Index patient may have infected the anesthesia assistant who participated in her operation. Six weeks later, the anesthesia assistant had acute icterus.	Not specified	3 m
Cody *(302)*	2002	Anesthesiologist	7 wk	Hepatitis	1	Hepatitis C	Mode of transmission is unclear. Anesthesiologist probably acquired hepatitis C from a chronically infected patient.	Not specified	Not specified

Most outbreaks are inadvertent, even if they are related to poor infection prevention and control practices. However, outbreaks such as those reported by Maki et al. *(164)* and Bosch *(299,300)* demonstrate that on occasion, hospital personnel deliberately put patients at risk. In the outbreak reported by Maki et al. *(164)*, a pharmacy technician replaced stolen fentanyl with nonsterile distilled water. The outbreak described by Bosch is even more frightening. On numerous occasions, an anesthesiologist addicted to morphine and infected with hepatitis C first gave himself morphine and then administered the remaining drug to the patients through the same syringe and needle. He thereby infected at least 171 patients *(299,300)*. In two recent outbreaks, the anesthesia provider acquired hepatitis C from a patient and spread the virus to other patients *(301,302)*.

EXPOSURE OF ANESTHESIA PERSONNEL TO PATIENTS' BLOOD AND BODY FLUIDS

Asai et al. *(303)* screened routinely all patients undergoing elective operations for blood-borne pathogens. Of 6,437 patients screened in a 2-year period, 534 (8.3%) were infected with at least one of these agents. Thus, anesthesiologists frequently care for patients who are infected with these agents.

The proportion of operative procedures in which anesthesia personnel are exposed to blood has varied by study. White and Lynch *(304)* observed 1,054 blood contacts during 8,502 operative procedures. Anesthesia personnel were exposed to blood in 82 (0.96%) of the cases. The authors noted that fingers, hands, and arms were exposed 70 times, usually when anesthesia personnel inserted intravenous catheters. The face or neck was exposed eight times by blood from the operative field. Legs or feet were exposed four times when blood or bloody irrigation fluid ran off the surgical drapes. In 75 episodes, blood contaminated intact skin, and in 2 episodes blood contaminated nonintact skin. Five (6%) punctures occurred. Panlilio et al. *(305)* observed 206 operative procedures and noted that anesthesia staff were exposed to blood in 13 (6.3%). Popejoy and Fry *(306)* observed blood contact during 190 of 684 operations (28%). Circulating nurses and anesthesia personnel contacted patients' blood more frequently than did surgeons, but surgeons had more frequent percutaneous exposures. The authors noted that "although the anesthesiology staff and circulating nurses reported the greatest number of blood contact events, they were the only individuals who did not consistently wear gloves. Independent observations suggested that they were rarely gloved during the study period."

Several prospective studies indicate that anesthesia personnel are stuck with needles in 0.13% to 0.4% of operative procedures *(306–308)*. During a 3-month period studied by Maz and Lyons *(308)*, a higher proportion of the more experienced anesthesiologists stuck themselves with needles than did the less experienced personnel: 4 of 15 consultants (27%), 2 of 7 senior registrars (29%), 1 of 6 registrars (17%), 1 of 7 senior house officers (14%), and 1 of 7 clinical assistants (14%). Six of the nine needles were contaminated, and only three of the injuries were reported to the proper hospital authorities. In contrast, Jagger et al. *(309)* observed that residents injured themselves more frequently than did attending physicians in all specialties. Moreover, Heald and Ransohoff *(310)* estimated the rate of needlestick injuries in anesthesia residents to be 2.5 injuries per resident year. This rate was lower than that for residents in orthopedics (5.6 injuries per resident year), general surgery (5.5 injuries per resident year), and obstetrics and gynecology (4.5 injuries per resident year) but higher than that for residents in internal medicine (0.75 injuries per resident year).

Greene et al. *(311)* studied percutaneous injuries reported by anesthesia personnel from nine hospitals participating in the EPINet surveillance program. All contaminated percutaneous injuries in these personnel resulted from needles, 87% (34 of 39) of which were hollow bore. Seventy-eight percent of these injuries occurred between uses or after use of the device and are, therefore, considered potentially preventable. In contrast to injuries experienced by anesthesia personnel, fewer than 30% of the injuries to nonanesthesia personnel in the operating rooms were caused by hollow-bore needles. Thus, anesthesia personnel may be less likely to experience percutaneous injuries than are surgeons; however, the needles used by the former usually have hollow bores. In addition, anesthesia personnel use hypodermic needles and large-bore cannula introducers, both of which can carry more blood than suture needles. Thus, the percutaneous injuries experienced by anesthesia personnel may be more likely to transmit blood-borne pathogens than are those experienced by surgeons. A study by Jagger et al. *(309)* confirmed these findings. Most percutaneous injuries observed in this study occurred in the operative site and to nonanesthesia staff; 1.5% of the injuries occurred at the anesthesia cart or machine. However, 16.7% of the injuries sustained by anesthesia personnel were caused by blood-filled, hollow-bore needles.

Greene et al. *(312)* evaluated contaminated percutaneous injuries (CPIs) among anesthesia personnel at 11 hospitals over a 2-year period. These investigators found that 30% of all CPIs were high-risk exposures, that is, the sharp device was a blood-contaminated hollow-bore needle. Seventy-four percent of these injuries were potentially preventable. They noted that only 26% of CPIs were reported and that reporting rates varied by job category. Student nurse anesthetists reported 64% of their injuries compared with 29% for anesthesia residents, 23% for certified nurse anesthetists, and 19% for staff anesthesiologists. After correcting for under reporting, these investigators calculated a CPI rate of 0.27 CPIs per year per person or 0.42 CPIs per year per full-time equivalent. Patel and Tignor *(313)* determined device-specific sharps injury rates. Injuries with hollow-bore needles on Luer-lock syringes occurred at a rate of 1.29/100,000 devices used for anesthesiologists compared with 7.35/100,000 devices used for surgeons. Injuries from intravenous catheters occurred at rates of 1.18/100,000 devices for anesthesiologists and 12.87/100,000 devices for surgeons.

Anesthesia personnel perform numerous procedures during which they may be exposed to patients' blood or body fluids. For example, they insert intravascular catheters, intubate and extubate patients' tracheas, and

TABLE 60-8

Blood Contact During Routine Anesthesia Procedures *(314)*

Procedure	*Percentage Associated with Blood Contact (%)*
Injecting a drug intramuscularly	8
Extubating a patient	9
Suctioning the oral cavity, pharynx, or trachea	13
Catheterizing a peripheral vein	18
Doing a lumbar puncture	23
Catheterizing the epidural space	34
Doing an arterial puncture	38
Establishing or discontinuing a blood transfusion	43
Inserting a central venous catheter	87

suction tracheal and oral secretions. Using a questionnaire, Kristensen et al. *(314)* found that 50% of anesthesiologists had contact with blood during a 1-week period, compared with approximately 40% of orthopedic surgeons and approximately 30% of general surgeons. Furthermore, Kristensen et al. *(315)* determined that anesthesia personnel contacted patients' blood or body fluids during 36% of common anesthesia procedures (Table 60-8). On the basis of a questionnaire survey, Harrison et al. *(307)* observed that 65 "anesthetic and related staff" contacted patients' blood or body fluids in 35 of 270 (13%) operations, most frequently while cannulating a vessel.

In addition to contact with visible blood from vessels, the operative site, or contaminated needles, anesthesia personnel are exposed to blood from several less obvious sources. For example, Crisco and DeVane *(316)* found blood in the mouths of 56 of 168 patients (33%) after tracheal intubation; blood was visible in 12 (7%) and occult in 44 (26%). Thirty-nine patients (23%) had blood on their cheeks, tongue, and posterior soft palate, and for 29 patients (17%) blood was noted on the laryngoscope blade. After tracheal extubation, 58 patients (35%) had overt blood and 59 (35%) had occult blood in their mouths. Blood was found on the distal tip of 113 endotracheal tubes (67%). Similarly, Kristensen et al. *(314)* noted visible blood on 16 of 29 endotracheal tubes (55%; 95% CI 36–74%) and occult blood on 6 of 29 endotracheal tubes (21%; 95% CI 8–40%). Five of 28 suction catheters (18%; 95% CI 6–37%) were contaminated by visible blood, and 10 (36%; 95% CI 19–56%) were contaminated by occult blood. Brimacombe et al. *(317)* determined that cuffed oropharyngeal airways (14%) were more likely than laryngeal mask airways) (LMAs) (3%) to be contaminated with visible blood. Parker and Day *(318)* found visible blood on 12% of LMAs and 16% of endotracheal tubes after use. However, when they tested for occult blood, these investigators found that 76% and 78%, respectively, were contaminated.

In addition, anesthesia personnel may unwittingly contact a patient's blood or body fluids when they touch the anesthetic record *(319)* or equipment such as the anesthesia machine or touch screens *(320)*. Hall *(321)* sampled surfaces on "clean" anesthesia machines, carts, and monitors. Of 418 samples, 134 were positive for occult blood and three sites were contaminated with visible blood (see section "Current Anesthesia Practice," for further studies about this topic). Perry and Monaghan *(104)* found visible and occult blood on anesthesia equipment: 35.5% of the tests were positive before the first case of the day, 29.5% were positive after the first case, and 29.5% after the second case. Occult blood was more common than visible blood. They found blood on ventilator controls (25.0%), flowmeter knobs (33.9%), vapor controls (26.8%), electrocardiography cables (64.3%), pulse oximeter probes (19.6%), and blood pressure cuffs (26.8%). Taken together, these studies indicate that anesthesiologists contaminate the environment in which they work with blood, that the equipment is not cleaned adequately, and that anesthesia personnel can unwittingly contact blood during all their activities, not just when they access the vascular system.

INFECTIONS CAUSED BY OCCUPATIONAL EXPOSURE

Hepatitis B Virus

The prevalence of serologic markers for hepatitis B virus (HBV) has ranged from 3.5% to 49% in anesthesia personnel *(322–329)* compared with only 4.4% to 13.7% in the general population *(330,331)*. The highest rate of HBV seropositivity, 49%, was noted in an inner city hospital *(327)*, where 27 of 70 anesthesiologists were from areas of the world with a high prevalence of hepatitis B infection and a large proportion of the patients were in high-risk groups. Most point prevalence studies suggest that the proportion of seropositive personnel increases with the duration of anesthesia practice *(322–324,326–328)*. However, in one multicenter point prevalence study, Berry et al. *(325)* found that hepatitis B seropositivity did not increase with additional years of practice.

Anesthesia personnel were infected with HBV during two outbreaks *(332,333)*. In both outbreaks, the index case was not known to be infected with HBV, routine precautions were taken in the operating room, and the healthcare workers denied touching the patient's blood. Thus, the mode of transmission was not identified.

Hepatitis C Virus

Anesthesia personnel have acquired hepatitis C from patients; some of these staff members subsequently transmitted this virus to patients (see "Outbreaks Associated with Anesthesia Personnel" and Table 60-7) *(301,302)*. Bakir et al. *(334)* described a 33-year-old male Tunisian anesthesiologist who acquired hepatitis C while "training abroad". While he was assisting in the care of an accident victim, he instinctively put his bare hand, which had minor cuts, onto a bleeding wound. Three months later, he had jaundice,

asthenia, hepatitis, and elevated serum transaminases. His hepatitis C serology converted to positive and the infection did not respond to treatment with interferon or ribavirin. Greene et al. *(312)* estimated that the 30-year risk for anesthesiologists acquiring hepatitis C was 0.45% per full-time equivalent (FTE). They estimated that 155 anesthesiologists would acquire hepatitis C over a 30-year period.

Human Immunodeficiency Virus

Although the absolute risk of acquiring HIV infection from occupational exposure has not been determined for anesthesia personnel specifically, one anesthesiologist was infected when he stuck himself with an HIV-contaminated needle *(335)*. Buergler et al. *(336)* used data in the literature to estimate the risk for anesthesiologists and surgeons of acquiring HIV infection over a 30-year career. They assumed that (a) the risk of needle sticks per year ranges from 0.86 to 2.5 for anesthesiologists and 3.8 to 6.2 for surgeons, (b) the risk of seroconversion from a needlestick ranges from 0.42% to 0.50%, (c) the prevalence of HIV infection in the population would remain constant during the 30-year period and would range from 0.32% to 23.6%, and (d) protective measures would be of no benefit. Using these assumptions, Buergler et al. estimated a cumulative risk for anesthesiologists of 0.05% to 4.5% compared with 0.17% to 13.9% for surgeons. Buergler's estimates have been controversial *(337,338)*. Subsequently, Greene et al. *(312)* used different assumptions and estimated the 30-year risk to be only 0.049%, with 17 HIV infections occurring in anesthesiologists during this time period. Regardless of which estimate most closely approximates reality, both estimates suggest that the risk of acquiring HIV infection is measurable. Furthermore, despite the less invasive nature of anesthesia practice, the risk for anesthesiologists overlaps with that of surgeons, and, as we noted previously, many exposures among anesthesia personnel are considered high risk because they involve hollow-bore needles that had been in the vascular space.

Herpes Simplex Virus

Herpetic whitlow, infection of the fingers with herpes simplex virus (HSV), occurs rarely in the general population but is a recognized hazard for healthcare workers (see also Chapter 44). Herpes simplex infects the fingers when breaks in the skin are exposed to secretions containing the virus. Serologic surveys indicate that 80% to 90% of the United States population has been infected with HSV *(339,340)*. Cross-sectional culture surveys indicate that, at any one time, 2% to 9% of adults and 5% to 8% of children asymptomatically shed HSV in saliva; longitudinal studies suggest that 32% of children and 80% of adults asymptomatically shed HSV in saliva at some points in their lives *(341–343)*. Anesthesia personnel frequently contact patients' oral secretions and therefore might be at increased risk for acquiring herpetic whitlow *(344)*. Although the frequency of this infection in anesthesia personnel is unknown, individual anesthesiologists and nurse anesthetists have acquired herpetic whitlow from infected patients *(345–347)*.

PREVENTION AND CONTROL OF INFECTION IN THE PRACTICE OF ANESTHESIA

Current Infection Control Guidelines and Current Anesthesia Practice

As noted previously, several agencies and societies, including the ASA (7,9), the AANA *(8)*, AORN *(10–13)*, CDC (28,*29–33*,*298*), the Australia and New Zealand College of Anaesthetists (ANZCA) *(18)*, the Australian Society of Anaesthetists *(19),* the Australian Medical Association *(20)*, the New South Wales Health Department *(21)*, and the Association of Anaesthetists of Great Britain and Ireland *(22)*, Department of Health of the Netherlands Committee on Infection Prevention *(23)*, the Societe Francaise d'Anethesie et de Reanimation *(24)*, and the German Society of Anesthesiology and Intensive Care *(25),* have published infection prevention and control guidelines for the practice of anesthesia (Tables 60-1 and 60-3). Nevertheless, several anesthesiologists have voiced concern about their colleagues' disregard for basic infection control practices. They criticize their colleagues for using common syringes, handling intravenous tubing ports and multidose vials without aseptic technique, recapping needles, failing to maintain separate clean and dirty work spaces, not cleaning and disinfecting equipment after each patient, and not wearing protective barriers *(141,142,320,348–355)*.

Crow and Green *(356)* observed 18 surgeons and 10 anesthesiologists during 36 herniorrhaphies to determine whether they complied with 44 "aseptic precautions". Anesthesiologists violated those aseptic precautions nearly twice as often as did the surgeons. During the 36 operations, anesthesiologists were observed touching the sterile field (2 occurrences), working while ill (3 occurrences), inadequately separating the operative field from the anesthesia area (3 occurrences), wearing their masks improperly (7 occurrences), leaning over the sterile field (8 occurrences), not washing their hands before the case (24 occurrences), and not covering their hair completely (25 occurrences).

Tait and Tuttle *(357)* surveyed anesthesiologists to determine how many complied with practices recommended for preventing transmission of infectious agents to patients; 493 of 1,149 (43%) completed the survey. Ninety-five percent reported washing their hands after caring for patients they considered to be at high risk for infection, but only 58% washed their hands if they felt the patient was at low risk of infection. Eighty-eight percent changed breathing circuits between patients, 99% cleaned laryngoscope blades after each patient, 69% disinfected or sterilized blades, and 60.5% never or rarely disinfected their work surfaces. Forty-seven percent acknowledged that they reused syringes, and 53% said they never reused these devices. el Mikatti et al. *(358)* did a similar survey in the United Kingdom. They had a better return rate (145 of 213 [68%]) than did Tait and Tuttle *(357)*, but a lower percentage (20%) of the respondents admitted to ever reusing syringes. In Taiwan, 6% of respondents to the survey by Or et al. *(359)* acknowledged reusing syringes frequently. Ryan et al. (289)

surveyed anesthesia providers in New Zealand and found that 2.2% admitted to occasionally using a single syringe for more than one patient. Similarly, Carbonne et al. (360) in France found that 2% of the respondents to their survey admitted using a single syringe for more than one patient. Sixty-six percent of the anesthesia providers in Iran who responded to the survey by Askarian et al. *(123)* reported that they routinely used unused anesthetic agents for subsequent patients.

The proportion of anesthesiologists who reported that they always disinfected the septum of a multidose vial (27.8% United States [Tait and Tuttle] *(357)*, 39.4% United Kingdom [el Mikatti] *(358)*) and who work while sick (upper respiratory tract infection—96% United States, 94% United Kingdom; gastrointestinal infection—60.1% United States, 42.9% United Kingdom; herpes infection—22% United States, 32.6% United Kingdom) was similar in both surveys. Both Tait and Tuttle *(357)* and el Mikatti et al. *(358)* asked anesthesiologists to describe, using a scale of 0 to 10 (0, no chance of transmission; 10, a significant chance for transmission), the potential for anesthesiologists to transmit pathogens from patient to patient. The median score for anesthesiologists surveyed by Tait and Tuttle *(357)* was 4.7 compared with only three for those surveyed by el Mikatti et al. *(358)*. Thus, the anesthesiologists responding to these surveys thought their potential to transmit pathogens was low. More recently, anesthesia providers in New Zealand rated the likelihood that they could transmit pathogenic microorganisms to patients at a "7" (289). In Iran, Askarian et al. *(123)* found that anesthesia providers' assessments of whether anesthesia could cause infection in patients was significantly related to whether or not they always cleaned oral airways.

Several investigators documented that anesthesia equipment in some institutions is not cleaned and disinfected adequately. Simmons obtained cultures of 20 "clean" handles, all of which grew microorganisms *(361)*. Although *S. epidermidis, Micrococcus* species, and *Bacillus* species were the most common microorganisms, cultures from 12 of the 20 handles grew group A streptococcus. In addition, one handle each grew *S. aureus*, enterococcus, and *P. aeruginosa* with *Citrobacter*. Phillips and Monaghan *(362)* tested 65 laryngoscope blades and handles that were "patient-ready" (i.e., had been cleaned and disinfected and were ready to use on the next patient). No visible blood was noted, however, 13 (20%) blades and 26 (40%) of the handles had positive tests for occult blood; blades and handles tested in the afternoon were significantly more likely to be positive compared with those tested in the morning. Morell et al. *(363)* found similar results; 10.5% of "clean" laryngoscope blades and 50% of "clean" laryngoscope handles were contaminated with occult blood.

Several studies suggest a possible reason that these items are contaminated with blood. Many anesthesia personnel do not routinely clean and disinfect laryngoscope blades, endotracheal tube stylets, and breathing circuits between patients (*141*,*349*,*353*,*359*,360). Esler et al. *(364)* did a postal survey of all 289 Royal College tutors in anesthesiology in Great Britain, 239 (82.7%) of whom responded. Of the respondents, 22% autoclaved laryngoscope blades after every use, 19% autoclaved them "often," 41% autoclaved them after high-risk cases, and 18% did not autoclave them. Fifty percent did not dismantle the laryngoscope before cleaning. One-third of the respondents did not clean the laryngoscope handle. Forty-nine percent cleaned the handles, 13% autoclaved the handles after high-risk cases, and 5% autoclaved the handle after each case. One-third of the respondents said they would not put a randomly selected, ready-to-use laryngoscope from their institutions into their own mouths! Of note, laryngoscope blades are semicritical items and, therefore, need to be cleaned and treated at least with high-level disinfection after each use.

It has been difficult to document that these breaches in infection control practice compromise patients' care. However, Foweraker *(99)* identified four children in a pediatric cardiology ICU who were infected with *P. aeruginosa*. All four isolates had different phage types. However, the investigators found a laryngoscope blade that had dried secretions around the bulb. *P. aeruginosa* with the same phage type as the strain infecting the one child who died was isolated from the blade. Of note, the staff in this unit did not follow their own cleaning policy. Similarly, Neal et al. *(100)* reported that eight neonates acquired infections with the same *P. aeruginosa* strain. Dried secretions were found on two neonatal laryngoscopes, and *P. aeruginosa* with the same phage and serotype as the epidemic strain was isolated from cultures of these devices. The laryngoscopes were washed in hot water and detergent and wiped with alcohol. They were then stored loose in a drawer. Nelson et al. *(365)* reported that *Listeria monocytogenes* possibly was transmitted from one neonate to another by a laryngoscope that was wiped with alcohol and not sterilized as the hospital's policy required. These studies suggest that bacterial pathogens and possibly blood-borne pathogens could be transmitted to patients or to anesthesia personnel via contaminated anesthesia equipment. Laryngoscope blades touch the oral mucosa, and thus, could transmit blood-borne pathogens from patient to patient. Laryngoscope handles and anesthesia carts and machines do not contact patients directly, and thus may not put patients at risk. However, anesthesia personnel may contaminate their hands when touching these surfaces, putting themselves at risk and putting patients at risk if the staff members do not perform hand hygiene. Further studies are needed to determine whether these items could be a source of infections for individual patients or anesthesia staff or a source for outbreaks such as that reported by Chant et al. *(93)*.

Anecdotal reports, questionnaires, and studies observing their practice consistently show that many anesthesia personnel do not routinely wear protective equipment to prevent contact with blood and body fluids (*123*,289,*307, 357,358*,360,*366,367*). Only 16% of anesthesia personnel responding to O'Donnell and Asbury's *(366)* mail survey stated that they wore gloves for routine daily work. In a similar study, only 9% of anesthesia personnel wore gloves when intubating patients, and 8% wore gloves when inserting peripheral cannulas *(306)*. However, 63% wore gloves to insert arterial lines, and 89% wore gloves to insert central venous catheters *(307)*. Tait and Tuttle *(357,367)* surveyed anesthesiologists to determine how many complied with guidelines to protect themselves from exposures to blood-borne pathogens. Only 7% of anesthesiologists reported

that they wore gowns and 49.3% reported that they always wore gloves while administering anesthesia. In contrast, only 14.5% of the anesthesiologists responding to el Mikatti et al.'s *(358)* survey said they always wore gloves. Anesthesiologists who responded to Tait and Tuttle's *(367)* survey reported that they were more likely to wear gloves if they felt the patient was at high risk for infection with blood-borne pathogens. Anesthesiologists who recently entered practice were more likely than their more experienced colleagues to wear gloves for contact with patients felt to be at low risk for infection with a blood-borne pathogen *(367)*. Eighty-eight percent reported that they sometimes and 10% reported that they always recapped needles; nearly 66% reported using a two-handed technique while recapping. Thirty-two percent of the respondents reported sustaining injuries with contaminated needles in the preceding 12 months; only 45% stated that they reported the incident or sought treatment *(367)*.

In summary, studies consistently indicate that many anesthesia personnel disregard both traditional infection prevention and control procedures and those recommended by their own societies. Furthermore, despite the risk of transmitting HBV, HCV, HIV, and other blood-borne diseases, anesthesia personnel continue to use common syringes and procedures that might transmit blood-borne pathogens. In 1990, Kempen and Treiber *(354)* pointedly stated that "the widespread reeducation of personnel regarding hygiene (universal precautions) due to the AIDS epidemic may have missed anesthetic personnel, as many prevailing anesthetic practices appear quite cavalier regarding nosocomial viral transmission." In 2001, Berry *(368)* published an editorial in which he commented on a report by Ross et al. *(301)* in which the authors described transmission of hepatitis C from a patient to an anesthesia assistant, who then spread this microorganism to other patients. Berry wrote, "The report clearly demonstrates the potential for occupational HCV transmission both from and to patients via tasks performed by anesthesiologists. The disregard of appropriate aseptic techniques and the failure to use Standard Precautions likely were responsible for the adverse outcomes" *(368)*. Little has changed!

Preventing Infections in Anesthesia Personnel

Several investigators noted that anesthesia personnel could prevent most of their contact with blood and body fluids by wearing gloves *(305–307,309,315)*. Hence, if anesthesia personnel wore gloves and used other barriers, they could protect themselves against most occupationally acquired infections including HBV, HCV, HIV, and herpetic whitlow (Table 60-9).

However, anesthesia providers often have not studied important guidelines and policies. For example, 51.5% of respondents to the survey by Ryan et al. (289) acknowledged that they had never read their hospitals' infection prevention policies and 32.4% had never read the guidelines published by the ANZCA. McNamara and Stacey *(369)* surveyed anesthesia staff at five hospitals in southeast England and found that only 49% knew the published guidelines. Only 29% of the respondents wore gloves routinely. The primary reason anesthesiologists gave for not wearing gloves was that gloves decreased their sense of feel. Some anesthesia personnel are concerned that they may increase their risk of injury and that they may contaminate their patients or the environment if they wear gloves while performing procedures. A study by Ben-David and Gaitini *(370)* suggests that these fears may be unfounded. These investigators observed fewer needlestick injuries and less environmental contamination when personnel wore gloves than when they did not. Although the differences did not reach significance, these data indicate that gloves did not increase the number of injuries or the frequency of contamination.

HBV infection can be prevented by immunizing persons at high risk and by using appropriate barriers. Hepatitis B vaccine, available in the United States since 1982 *(371)*, was accepted slowly by anesthesia personnel. In 1985, only 19% of anesthesia residents surveyed by Berry et al. *(325)* had been immunized. In 1991, approximately 90% of the anesthesia residents but only 60% of the attending anesthesiologists ($p < .001$) surveyed by Rosenberg et al. *(355)* had been vaccinated. Two other surveys of anesthesiologists conducted in the late 1980s found vaccination rates of 71% to 74% *(307,308)*, but the rate in Iran was only 61.5% in 2000 *(123)*.

A case report describes an incident in which respiratory secretions splashed into an anesthesiologist's unprotected eyes during an intubation *(372)*. Subsequently, he acquired bilateral conjunctivitis, fever, myalgia, and pharyngitis. Adenovirus type 14 was isolated from the patient and the anesthesiologist. The authors concluded that face protection would have prevented this exposure, and they recommended that anesthesia personnel wear face protection when intubating patients.

A poignant case report illustrates how performing routine tasks can put anesthesia personnel at risk for HIV infection *(335)*. An anesthesiologist with 20 years of experience inserted a central venous catheter into a patient known to be infected with HIV. After inserting the catheter, the anesthesiologist picked up the 16-gauge needle in his right hand and reached across his left arm to discard it. In the process, he stuck the contaminated needle into his left forearm. Despite beginning azidothymidine (AZT) within 2 hours of the injury, he seroconverted 10 weeks later. In an article *(335)* and videotape *(373)* describing the accident, this unfortunate anesthesiologist shared several important lessons. First, the catastrophic procedure was 1 he had performed hundreds of times. Second, he was working under adverse conditions that forced him to reach across his body with the contaminated needle. Third, and to our mind most important, the accident occurred after he had finished the procedure. He concentrated intently while inserting the line in order to complete the task successfully, but his vigilance dropped while discarding the contaminated needle. Although this is only one case, we conclude that anesthesia personnel should protect themselves by optimizing their work conditions and by concentrating intently during and after procedures, even the most routine.

In summary, numerous studies indicate that anesthesia personnel are exposed frequently to patients' blood and body fluids. Thus for their own safety, anesthesia providers must implement Standard Precautions in a manner that is appropriate for their work flow.

TABLE 60-9

Recommendations/Guidelines to Protect Anesthesia Providers

Item	*ASA (8)*	*AANA (9)*	*Other*
Standard Precautions	Use gloves, fluid-resistant mask, face shield, and gown routinely with all patients. Choose barrier commensurate with the expected extent of exposure.	Use Standard Precautions for all patients. Wear gloves, gowns, mask, and protective eyewear for contact with blood and body fluids. Use transmission-based precautions for patients known to be infected or colonized with epidemiologically important pathogens (see guidelines for specifics).	For the anesthetist's protection, protective gloves are worn whenever the hands may contact blood, saliva, or any other body fluid and are to be removed after such a procedure to minimize contamination of the work place *(18)*. Universal precautions must be adopted for all anesthetic practices *(19)*. Readers are referred to the Hospital Infection Control Practices Advisory Committee's guideline on isolation precautions *(30)*.
Hand hygiene	Wash hands after touching blood or body fluids whether or not gloves are worn. Wash hands immediately after removing gloves.	Wash hands before and after all contact with patients or specimens, after handling body substances, and after removing gloves.	Frequent hand washing by the anesthetist and the anesthetic technician is a most important infection control measure. Hands should be washed before handling a new patient or equipment to be used on a new patient, after leaving a patient, whenever they become contaminated and before any invasive procedure *(18)*. Decontaminate hands means to reduce bacterial counts on hands by performing antiseptic hand rub or antiseptic hand wash *(31)*. Decontaminate hands before having direct contact with patients. Decontaminate hands before donning sterile gloves when inserting a central intravascular catheter. Decontaminate hands before inserting indwelling urinary catheters, peripheral vascular catheters, or other invasive devices that do not require a surgical procedure *(31)*.

Handling needles	Do not recap, bend, break, or remove contaminated needles from syringes by hand. If necessary to recap a needle, use a single-handed technique or a mechanical protection device. Encourage use of needleless systems or shielded needle products. Puncture-resistant containers should be at all work locations.	Do not recap needles or manipulate them in any way. Place used syringes in nearby puncture-resistant containers that are stored upright and labeled as biohazards. Use a mechanical device or one-handed technique if no alternative is available. Alternatives to needles are available for checking sensory awareness.	
Blood exposures	Develop detailed protocol at each facility.	Each facility is obligated to provide postexposure testing, counseling, monitoring, and surveillance.	
Emergency ventilation devices	Mouth pieces, resuscitation bags, and other ventilation devices should be available.	Place equipment needed for emergency resuscitation in areas where the need for resuscitation is probable and predictable. Use ventilation devices rather than mouth-to-mouth resuscitation.	
Personnel with cutaneous lesions	Anesthesiologists should refrain from direct patient contact when they have breaks in the skin or exudative, weeping lesions unless the open area can be protected. Unprotected lesions are a risk to the healthcare worker and the patient.		Personnel with skin abrasions, cuts, or dermatitis must be excluded *(19)*.
Hepatitis B vaccine	Vaccinate all anesthesiologists who do not have documented immunity.	Refers to the OSHA standard.	Immunization Practices Advisory Committee states that healthcare workers whose work involves contact with blood should be vaccinated *(33)*.
		Offer student CRNAs the vaccine at no cost.	OSHA requires that employers offer the vaccine at no cost to individuals who are exposed to blood *(377)*.
Laser plumes	Hold evacuator nozzles close to the operative field before and 30 s after the tissue is vaporized to prevent transmission of viruses.		

ASA, American Society of Anesthesiologists; AANA, American Association of Nurse Anesthetists; CDC, Centers for Disease Control and Prevention; OSHA, Occupational Safety and Health Administration; CRNA, certified nurse anesthetist

CONCLUSION

Until recently, studies assessing the risk of infection related to anesthesia procedures had produced little objective evidence to confirm that the practice of anesthesia—general or regional—and the use of anesthesia equipment can be associated with transmission of pathogens and with HAIs. Recently, Loftus et al. (101,102) and Koff et al. (103) found that bacterial pathogens can be transmitted to the anesthesia work area and to patient's intravenous lines. They also found that improving hand hygiene could decrease environmental contamination and the incidence of HAI. They demonstrated that strategic, scientific, evidence-based approaches that are specific for a unique hospital setting and integrated into the normal work flow could improve anesthesia providers' adherence with aseptic practice and, thereby, also improve patient safety.

We hope that more anesthesia providers will do studies designed to address specific infection prevention issues associated with anesthesia practice so that the evidence base will increase. Anesthesia providers understand the unique challenges presented by the environment in which they work and by the nature of the work they do (e.g., the limited amount of work space, the rapid pace of the work, and the need to multitask). They are well suited to assess the infectious risks posed by their work and to design preventive measures specific for their work and their environment. Infection prevention staff members can support these efforts by sharing their expertise and by giving the anesthesia providers the rates of infection among patients who have had anesthetic procedures. Together, they could design and conduct studies to identify risk factors specific to the specialty and the environment and specific interventions that address these factors. Such partnerships are likely to yield better results than are campaigns that take a "one-size-fits-all" approach. We hope that this chapter will encourage anesthesia providers and infection prevention staff members to engage in this important patient safety work.

CHAPTER 61

Healthcare-Associated Infections that Complicate Invasive Procedures in Cardiology

Winfried Ebner and Markus Dettenkofer

Few prospective studies on healthcare-associated infections related to invasive procedures in cardiology have been done, and most studies have been done retrospectively. In very few investigations were the etiologies, pathogenesis, and epidemiology specifically addressed, primarily because most studies were retrospective. There seem to be, however, no major differences between healthcare-associated infections associated with invasive devices in cardiology and other foreign body–associated infections, which are extensively covered in Chapters 17, 18, and 65. Therefore, this chapter mainly describes the incidence rates and types of infections.

INFECTIONS ASSOCIATED WITH CARDIAC CATHETERIZATION AND PERCUTANEOUS CORONARY INTERVENTIONS

Cardiac catheterization and percutaneous coronary interventions (PCIs), the latter including percutaneous transluminal coronary angioplasty (PTCA), coronary stent implantation, intraaortic balloon pump (IBP) insertion and laser thermal angioplasty, are frequently performed examinations in modern medical care. However, besides technical complications, infections may arise.

Cardiac Catheterization

In early publications, bacteremia was reported to occur in 4% to 18% of patients undergoing cardiac catheterization *(1,2)*. However, in these studies, blood for culture was obtained from the intravascular catheter or the vessel from which the catheter was removed. Sande et al. *(3)* determined the true frequency of bacteremia during and after cardiac catheterization and the frequency of fever by obtaining 214 blood cultures from 106 patients from a vein in the arm on the side opposite to that of the catheter. All venous samples were sterile; therefore, no bacteremia could be demonstrated during cardiac catheterization.

The mortality and morbidity associated with cardiac catheterization were analyzed over a period of 9 years (1971–1979) by Gwost et al. *(4)*. No infection and only two pyrogenic reactions occurred in 1,771 patients. Furthermore, there were only three cases of bacteremia or bacterial endocarditis after 12,367 catheterization procedures reported in an early cooperative study *(5)*. Ricci et al. *(6)* found only five documented infections after review of 7,690 medical records of cardiac catheterizations over a 40-month period.

Between 1980 and 1988, 12,251 arterial punctures for cardiac catheterization, PTCA, or pure diagnostic intra-arterial angiography (IAA) were performed by Würsten et al. *(7)*. The only infectious complications documented were prolonged healing of a wound in the groin and a severe graft infection necessitating ligation of the common femoral artery.

In a retrospective study from January 1991 to December 1998, Munoz et al. (8) found a bacteremia rate of 0.11% in 22,006 invasive nonsurgical cardiologic procedures (0.24% after PTCA, 0.6% after diagnostic cardiac catheterization, 0.8% after electrophysiologic studies). Multivariate analysis identified the presence of congestive heart failure (OR 21.0; CI 95% 6.8–66.0) and age older than 60 years (OR 1.9; CI 95% 1.9–6.3) as independent risk factors for a blood stream infection after nonsurgical cardiologic procedures.

The incidence of bacteremia and other infections associated with cardiac catheterization, therefore, seems to be very low. Even if synthetic vascular grafts have to be catheterized, the infection rate is very low. Mohr et al. *(9)* investigated 109 percutaneous catheterizations of synthetic vascular grafts in 89 patients to determine the risk of major complications. Ninety-six catheterizations were performed through the inguinal portion of the aortofemoral graft. There were no instances of graft infection, and only one superficial infection developed at a cutaneous puncture site, which did not involve the graft.

A large prospective study to assess the frequency of bacteremia due to cardiac catheterization and PCI was performed by Banai et al. (10) who examined patients undergoing a total of 960 interventional procedures. They analyzed blood cultures, withdrawn from the arterial sheath immediately after arterial puncture and at the end of the procedure. A third blood culture was withdrawn from a peripheral

vein 4 hours later. The incidence of positive blood cultures immediately after the procedure was 7.3% after diagnostic catheterization and 4.6% after PCI (balloon angioplasty and stent implantation). After 4 hours, positive blood cultures were noted in 3.9% and 4.1%, respectively. However, only four cases of bacteremia were considered to be clinically significant (1 × *Staphylococcus aureus*, 3 × *Klebsiella* spp.). Moreover, all of these cases were related most likely to an intravenous line and not to the cardiac procedure itself. The data of Banai et al. suggest that clinically significant bacteremia is a rare complication of cardiac catheterization and also of PCI (explaining the low incidence of coronary stent infection; see below).

A further prospective study *(11)* investigated the frequency of bacteremia after more complex PCI in 147 consecutive patients. Procedures included balloon angioplasty, cutting balloon angioplasty, rotational coronary atherectomy, and single and multiple stent implantations. All procedures were performed via the femoral route. Blood cultures were taken immediately at the end of the procedure from the side arm of the arterial sheath. A second blood culture was taken after 12 hours prior to sheath removal. 17.7% of the patients had bacteria isolated from the first blood culture with coagulase-negative staphylococci being the most common microorganisms (57.7%). After 12 hours, 12.0% of the patients yielded microorganisms in the blood culture; 70.5% of them were coagulase-negative staphylococci. Four of the 147 patients developed a temperature >38°C; all had negative blood cultures. No patient developed clinical evidence of septicemia, endarteritis, or endocarditis during hospital stay or after discharge. The authors suggested that the relatively high incidence of bacteremia was due to the complex nature of PCI. However, the statistical analysis did not show a difference in the number of devices used in those patients with and in those without bacteremia.

Percutaneous Transluminal Coronary Angioplasty

PTCA today is one of the most common procedures in nonsurgical invasive cardiology.

No infection was reported during early and long-term follow-up (at least 1 year) of 3,079 patients after coronary angioplasty in the early 1980s *(12)*. In a prospective study, 164 PTCAs resulted in one *S. aureus* infection (0.6%) that could be related to the procedure *(13)*.

Malanoski et al. *(14)* identified a risk of 0.25% for *S. aureus* bacteremia (SAB) among 1,944 PTCA procedures performed during 25 months at one institution. Cleveland and Gelfand *(15)* summarized the reported cases of invasive staphylococcal infections associated with PTCA and described three more patients with invasive staphylococcal disease after PTCA of which two patients had received single intravenous antibiotic prophylaxis with cefazolin. This may well be explained by the fact that the predominant risk of infection may not have been the procedure itself but more likely the retention of the femoral sheath for more than 24 hours.

McCready et al. *(16)* noted that septic complications after cardiac catheterization and PTCA are quite uncommon, but they described nine cases of septic complications after this procedure resulting in two deaths. Their study suggests that repeated puncture of the same femoral artery and the femoral artery sheath being left in for more than 1 day are risk factors for septic complications *(15,16)*. Cardiac abscess after PTCA has also been described in a patient in whom a problematic and repeated procedure probably led to a direct colonization and subsequent infection of an intimal dissection of the right coronary artery *(17)*.

Siddiqui and Lester *(18)* described a case of septic arthritis and bilateral endogenous endophthalmitis associated with PTCA. Several cases of septic endarteritis with *S. aureus* after PTCA have been described by different authors *(19,20)*. In another case report, an epidural abscess occurred in a patient after PTCA. The explanation was that the residual arterial sheath, whose tip was near the aortic bifurcation, was injected with an infected bolus, thus facilitating infection through the lumbar radicular arteries *(21)*. The absence of specific signs may easily cause a delay in recognizing the infection *(18,21,22)*. As mentioned above, it has been considered that retention of the sheath for more than 24 hours could be a risk factor for infection. However, prospective studies are not available on this issue *(15,23)*. Salinas et al. *(24)* reported a case of infective coronary aneurysms 7 days after a balloon angioplasty.

Endocarditis following PTCA is such a rare complication that there are merely individual case reports. Wang et al. *(25)* reported a case of *Candida parapsilosis* endocarditis. Barbetseas et al. *(26)* reported a case of a patient with infective endocarditis of a prosthetic valve in the aortic position after receiving PTCA. Shibata et al. *(27)* reported a case of a 73-year-old man who developed infectious endocarditis caused by *S. aureus* after PTCA. A postmortem examination revealed multiple myocardial microabscesses and myocardial infarction resulting from an embolic vegetation.

Although infections after PTCA are rare, some have resulted in death *(28)*. Infections may become evident several weeks after the procedure *(14)*. Even ultrasonography and computed tomography may fail to reveal vascular infection, and, when there is clinical suspicion of infection, it may be prudent to initiate early surgical exploration *(29)*. Some authors recommend use of the contralateral inguinal site if PTCA is to follow a recent catheterization *(15–17,30,31)*, whereas others found no correlation between ipsilateral inguinal puncture and infectious complications *(13)*. At present, this question cannot be answered, because none of the cited studies have the statistical power to be able to detect significant differences between contralateral and ipsilateral repuncture.

Risk factors for bacteremia and other infectious complications during cardiac catheterization, mainly during PTCA, are age older than 60 years, congestive heart failure, duration of procedure, number of catheterizations at the same site, difficult vascular access, and an arterial sheath in place for more than 1 day (8,*16*,32,*33*,*34*). The most common microorganisms that cause PTCA-related bacteremia are *S. aureus*, coagulase-negative staphylococci, and group B streptococci (32).

Cutting Balloon Angioplasty Kobeiter et al. *(35)* monitored the long-term results in 19 patients undergoing cutting balloon angioplasty over a period of 32 months. They observed no case of infection. The authors postulate a randomized trial to be necessary to confirm the favorable results.

Coronary Stent Implantation

Gunther et al. *(36)* described in 1993 the first case of lethal complications resulting from a myocardial abscess near the stent in the right coronary artery. A second case of fatal outcome resulting from stent infection with *Pseudomonas aeruginosa,* which led to infective mitral endocarditis and saccular aneurysm of the coronary artery, was described by Leroy et al. *(37)*. Studies in a swine model suggest that metallic stents have the potential of becoming infected after bacterial challenge unlike arteries that have undergone angioplasty without stenting *(38)*. Seven stent-artery complexes implanted in the iliac arteries of 14 swine were culture positive after an intravenous bacterial challenge with *S. aureus,* whereas only 1 of 14 arteries that underwent angioplasty were positive for *S. aureus* ($p = .03$) *(38)*. The pathophysiology behind the stent infection is unknown; perhaps the stents or endothelial injury served as a nidus for bacterial adherence. Bouchart et al. *(39)* suggested that multiple repeat procedures through the same arterial sheath may increase the risk for bacterial infection of the coronary stent.

Dieter et al. *(40)* reported the case of a patient who developed an infected aortic aneurysm after placement of a coronary artery stent. They pointed out that infectious complications have been rare, but that the associated mortality is alarmingly high (41). The authors analyzed four cases of stent infections, two with *P. aeruginosa* and two with *S. aureus* as causative microorganisms. Despite aggressive measures (surgical removal of the infected stent and artery complex), three of the four patients died. The authors pointed out, that the clinician must be sensitive to fever, return of angina pectoris, and bacteremia in patients who have undergone coronary stent placement. With regard to the generally low infection rate, the prophylactic use of antibiotics is not recommended.

Recently also Schoenkerman et al. (42) described stent infections as a rare, but dramatic sequela of coronary stent implantation. They reported three cases of infections, two with mycotic aneurysms and one with purulent pericarditis. Two of these three cases were associated with drug-eluting stents (DES). In all cases, *S. aureus* was the causative microorganism. The authors suggested the possibility that recent infection with *S. aureus* within 16 days prior to PCI may be an additional risk factor for the complication of coronary stent infection.

Kaufmann et al. *(43)* reviewed all published cases of coronary stent infections, that is, all patients who presented with symptoms of infection within the first 4 weeks after PCI. They stated that, although the implantation of medical devices in general represents one of the most important risk factors for healthcare-associated infections, the reports of coronary stent infections are exceedingly rare. The authors summarized 10 case reports. One patient received a DES; all other patients had a bare metal stent (BMS) implanted. In seven patients, *S. aureus* was the causative microorganism, and in four the stent was completely or partially removed. Three patients died despite initiation of antibiotic and surgical treatment. The very low number of published cases suggests that coronary stent infections represent a rather uncommon complication of PCI. But the exact incidence of infection is unknown.

According to Kaufmann et al. *(43)*, fever is the hallmark of coronary stent infection. Chest pain is present in only half of the patients. They concluded that blood cultures should be taken in all patients presenting with fever within the first (four) weeks after stent implantation even in the absence of chest pain, ECG abnormalities, or elevation of cardiac enzymes.

Infections in Drug-Eluting Stents Kaufmann et al. *(43)* speculated that DES, introduced in the first decade, may predispose more to infection than BMS because of their immunomodulating and antiproliferative effects. They stated, however, that this seems not to be the case. There are only a few documented cases of stent infection after DES insertion. Recently, Lee et al. (44) found in their retrospective study on 1,023 consecutive patients who underwent PCI with DES a mortality of 9.4%. Of the 96 patients who died, no one died from PCI-related infection.

Aoki et al. *(45)* reviewed all published case reports of coronary artery aneurysms after DES implantation since 2004 and compared them with published case reports of aneurysms after BMS implantation. They stated that the incidence of coronary artery aneurysms after DES implantation is low within the first 9 months (aneurysms have been reported from 3 days to up to 4 years) with an incidence of 0.2% to 2.3%. This is a rate similar to the aneurysm rate after BMS implantation (0.3% to 3.9%). The clinical course is variable ranging from natural resolution to life-threatening complications.

Gonda et al. *(46)* reported the unique case of a DES infection with MRSA in a 75-year-old male 11 months after the procedure. In the cardiac magnetic resonance angiography, they found a nonenhancing fluid collection surrounding the DES, suggesting the presence of an abscess, which was confirmed in the following surgical intervention.

Intraaortic Balloon Pump

In an early study published in 1978, the overall complication rate for 100 consecutive patients treated with the IBP was 23%, with five patients developing surgical site infections and two developing septicemia *(47)*. Surgical site problems contributed to the death of one patient. Another patient died with septicemia and an infected aortotomy closure site 4.5 months after the original procedure.

Goldberg et al. *(48)* compared the percutaneous and surgical techniques of IBP insertion in 101 patients. In the percutaneous group (51 patients), no infection developed, but, in the surgical group, three patients developed sepsis with bacteremia (including one patient who required vein patch repair of the femoral artery and one patient who developed a surgical site infection requiring debridement).

An outbreak of *Pseudomonas cepacia* bacteremia associated with a contaminated water reservoir of an IBP was reported by Rutala et al. *(49)*.

Forty-five patients who died after insertion of an intraaortic balloon device were studied at necropsy *(50)*. Thirty-six percent had one or more complications related to the use of the device, one of which was a local surgical site infection not suspected during life. In two other patients in whom the balloon was implanted for septic shock, there was no evidence of bacterial seeding of either the balloon catheter or the prosthetic introducer graft. In a study of 240 consecutive percutaneous intraaortic balloon counterpulsations, Eltchaninoff et al. *(51)* identified

only one case of *S. aureus* bloodstream infection and one superficial infection. In the retrospective study by Meco et al. (52), 7 of 116 patients (6%) requiring postoperative IBP support had infection of the insertion site.

Yang et al. *(53)* investigated 112 used intraaortic balloons for physical integrity, gas leakage, mechanical performance, surface chemistry and morphology, and physical stability. These devices were all used clinically only once, and the duration of use *in vivo* ranged from 6 to 312 hours. Macroscopic examination of the balloons and the outer catheters revealed no obvious change in either shape or color. No discernible abrasions or cracks were observed. However, 61% of the balloons were creased and 40% of the central lumina and 21% of the sheaths showed visible bending flaws. Moreover, 65% of the balloons and 38% of the central lumina were contaminated by visible residual organic debris. The authors concluded that the presence of residual organic debris that cannot be eliminated is an indication that such intraaortic balloons should not be reused.

In their prospective study, Crystal et al. *(54)* found an incidence of fever of 47%, true bacteremia of 15%, and sepsis of 12% in 60 patients treated with an intraaortic balloon counterpulsation pump. The authors suggested evaluating the benefit of antibiotic prophylaxis. However, no studies addressing this issue have been published so far.

Laser Thermal Angioplasty

Laser thermal–assisted balloon angioplasty is used in the treatment of patients with advanced peripheral vascular disease and in high-risk patients who are poor candidates for operative reconstructions. White et al. *(55)* followed 28 patients, including 27 who had advanced peripheral vascular disease, for 3 years after laser thermal-assisted balloon angioplasty. Eighteen patients were successfully recanalized, but five amputations were required within 1 month and another six were needed between 8 and 12 months. Early amputations were necessitated by failure of wound healing. Whether this was due to infection, however, was not mentioned in the report.

Diethrich *(56)* reviewed his experience in treating 1,849 lesions in 894 patients and found no infection. The most common surgical procedures performed were laser angioplasty, patch angioplasty, arterectomy, thrombectomy, femoral-popliteal bypass, and profundoplasty. If laser-assisted angioplasty, however, is performed in the treatment of prosthetic graft stenosis, the wound infection rate is higher. Diethrich et al. *(57)* followed 25 symptomatic patients with 28 peripheral prosthetic arterial bypass grafts; two patients suffered from recurrent thrombosis and one developed an inexplicable graft infection 5 months after laser treatment. The latter patient, however, had undergone graft thrombectomy elsewhere 3 months before laser therapy, and the 5-month interval between angioplasty and the identification of the infection would make the laser's role in the etiology doubtful.

Vascular Closure Devices

Bacteremia after PCI is estimated to range between 4.6% (10) and 17.7% (11) depending on the complexity of the PCI performed. According to Ramsdale et al. *(11)*, these data support the routine removal of femoral artery sheaths early after PCI, now that effective femoral artery closure devices are available. However, it should be mentioned that infectious complications with percutaneous vascular closure devices are reported. Franco et al. *(58)* presented the case of a 43-year-old male patient undergoing cardiac catheterization and closure with a vascular closure device. He required a second catheterization with access gained on the same side and developed bacteremia and an infected hematoma with erosion of the femoral artery. A second case involved a 57-year-old male patient, who developed a localized infection over the accessed groin site. The authors stated that the overall infectious complication rate of closure devices was 0.3%.

A meta-analysis of 31 prospective randomized trials (59) including 7,528 patients investigated the rate of complications comparing vascular closure devices and manual/mechanical compression after diagnostic angiography and/or endovascular procedures. The use of vascular closure devices was associated with a significantly shorter time of hemostasis, but also with a significantly increased risk of groin infection (0.9% vs. 0.3%; RR 2.49, CI 95% 1.06–5.88 [12 studies including 3,210 patients]).

Prophylactic Antibiotics in PCI

With regard to the findings in their prospective study, Ramsdale et al. (see above, 11) stated that routine antibiotic prophylaxis prior to PCI is routinely not necessary. However, patients who are at increased risk of infective endocarditis such as those with valvular heart disease should receive prophylactic antibiotics prior to PCI ("single shot"). Furthermore, extra care should be taken with aseptic technique, and the femoral artery sheaths should be removed early after the procedure.

Infection Control Guidelines for the Cardiac Catheterization Laboratory

In 2006, the Members of the Catheterization Lab Performance Standard Committee for the Society for Cardiovascular Angiography and Interventions (60) published infection control guidelines for the cardiac catheterization laboratory. Based on the corresponding guidelines of the Centers for Disease Control and Prevention, this committee outlined recommendations regarding hair removal, skin cleaning and disinfection, drapes, the use of antibiotics, wound dressings, hand hygiene, the use of gloves and gowns, caps, masks, eye protection, and vaccination of the staff. Cleaning of the laboratory environment, the ventilation system, the handling of fixed and disposable laboratory equipment, and the disposal of waste are further topics that were addressed. In addition, catheterization technique, sheath removal, and vascular closure devices are laboratory-specific aspects covered by this guideline.

INFECTIONS ASSOCIATED WITH IMPLANTABLE DEVICES IN CARDIOLOGY

Pacemaker Insertion

Insertion in Children Pacemaker treatment is more complicated in children than in adults, largely because of electrode problems. If infections such as recurrent septicemia occur, the whole system usually has to be removed *(61)*.

Walsh et al. *(62)* reviewed their 21-year experience with pacemaker implantation in children. Forty-one patients

aged 11 days to 19 years at initial pacemaker implantation were followed up to 248 months. Complications included infection in six cases, and one patient died of a pacemaker-associated infection. Between 1971 and 1986, 85 pacemakers were implanted at the St. Justine Hospital in Montreal in 57 patients then aged from 1 day to 23 years (mean, 10.3 years). The patients were followed for periods ranging from 15 days to 13.5 years. Only one patient developed a pacemaker-associated infection *(63)*.

Nordlander et al. *(64)* reviewed their clinical experience of pacemaker treatment in children. Pacemaker systems had been implanted in 23 children aged 2 days to 14 years since 1983. Only three local infections developed. They concluded that endocardial pacing is the method of choice even for small children.

Pacemakers can even be implanted in newborns and very small infants. Villain et al. *(65)* implanted pacemakers in neonates. In eight children, a permanent pacemaker was implanted in the first 2 days of life, and, in six children, the pacemaker was implanted at the age of 2 to 3 months. Only one pacemaker had to be replaced because of infection at 28 months. In another investigation, 24 children, 15 kg or less in weight, underwent implantation of a permanent pacemaker using the transvenous technique. During a median follow-up period of 3 years and 6 months, two children developed infection *(66)*.

Cohen et al. (67) evaluated possible predictors of pacemaker infections in children. They reported a total of 7.8% infections (30 infections in 385 pacemaker implantations). In a multivariate analysis, trisomy 21 and pacemaker revisions were found to be predictors of infection.

Insertion in Adults Several older publications described infectious complications of pacemakers in adults *(68–73)*. The time from insertion to infection varied from 7 to 31 days, and the only causative microorganisms were *S. aureus* and *S. epidermidis*. Pocket infections usually occurred earlier than septicemia, and the incidence of septicemia was much lower than that of pocket infections. Later series have shown infection rates between 0.6% and 2.1% *(74,75)*. In their case report and review of the literature, Voet et al. *(76)* reported an incidence between 0.3% and 12.6%. This may involve infection of the pocket or the electrodes and may be associated with bacteremia with or without endocarditis. Systemic factors contributing to a higher incidence of infection are diabetes mellitus, thin skin, the use of corticosteroids, age, intravenous catheters, neoplasms, the use of anticoagulants, temporary pacing, dermatologic diseases, and other infectious foci.

In their retrospective risk factor analysis of permanent pacemaker infection in 29 case patients and 58 control subjects, Sohail et al. (77) used multivariable logistic regression analysis and observed that long-term corticosteroid use and the presence of >2 pacing leads were independent risk factors for infection. Long-term corticosteroid use was defined as ≥20 mg of prednisone (or equivalent), administered for ≥1 month during the preceding year. Twenty-four of 29 infected patients had pocket infections, and 3 had pacemaker related endocarditis. *Staphylococcus* species (69%) were the most common pathogens.

Klug et al. (78) prospectively recorded all infectious complications in 6,319 consecutive patients who were recipients of pacemakers or cardioverter-defibrillators. At 12 months, device-related infections were reported in 42 patients (0.68%). In the multivariable logistic regression analysis, the occurrence of infection was positively correlated with fever within 24 hours before the implantation (OR 5.83; CI 95% 2.0–16.98), use of temporary pacing before implantation (OR 2.46; CI 95% 1.09–5.13), and early reinterventions (OR 15.04; CI 95% 6.7–33.73). Immunosuppression, diabetes mellitus, and the use of anticoagulants or skin diseases could not be confirmed as risk factors. The median time to infection was 52 days. Implantation of a new system and antibiotic prophylaxis protected against infection.

One of the most serious infectious complications is pacemaker endocarditis. Arber et al. *(79)* reported 44 cases and reviewed the literature. Kurup et al. *(80)* reported the rare case of *Candida tropicalis* pacemaker endocarditis. Between 1980 and 2000, 7 of 1,920 patients with pacemaker implantation developed endocarditis in the study by Erdinler et al. *(81)*. The most common pathogen was *S. aureus*. Mezilis et al. *(82)* described two patients with metastatic pacemaker infections, one caused by *P. aeruginosa* 5 months after implantation and a second by *Streptococcus pneumoniae* 8 years after implantation. Pacemaker infections can also be caused by rare microorganisms such as *Staphylococcus schleiferi*, a member of the human skin flora *(83)*, or by *Mycobacterium fortuitum (84)*. A prospective study by Da Costa et al. *(85)* compared microorganisms isolated at the time of insertion and any infective complication by using ribotyping. Their study supported the hypothesis that pacemaker-related infections are mainly due to local contamination. In general, early infections after implantation tend to be caused by *S. aureus,* whereas late infections are caused by coagulase-negative staphylococci *(76)*. The same most common microorganisms were also found by Margey et al. (86) in their retrospective study over a period of 7 years and a total of 2,029 permanent pacemakers and 1,076 ICD implantations. The infection rate was 1.25%. *S. aureus* was the causative microorganism in 30.8% and coagulase-negative staphylococci in 20.5% of the cases. Important to note is that the rate of infection with methicillin-resistant *S. aureus* (MRSA) was 5.1%. In the univariate comparison of cardiac device infection survivors and those dying from infection, the presence of documented MRSA infection was significantly different between the groups with MRSA predicting mortality ($p < .004$; RR 37.0; CI 95% 5.3–250).

Although most infections have been limited to the pocket, pacemaker endocarditis accounts for approximately 10% of pacemaker infections (87).

Implantable Cardioverter-Defibrillator

The automatic implantable cardioverter-defibrillator (ICD) has been found to be useful in the management of life-threatening ventricular arrhythmias. Marchlinski et al. *(88)* reported that primary infectious complications were associated with 6% of cardioverter-defibrillator implantations. In another series by Marchlinski et al. *(89)* following 26 patients for 13 months, 1 patient developed a superficial incisional surgical site infection 14 days after device implantation and 1 patient acquired a late infection

of the generator pocket 3 months after repositioning of a migrated lead and 14 months after initial generator placement. Treatment necessitated removal of both the generator and leads. A partial removal is reserved for patients in whom the risk of complete removal is too high and infection is confined to a part of the ICD (i.e., generator only) *(90)*.

Mela et al. *(91)* stated that infection is an uncommon (0–6.7% reported in the literature) but serious complication after ICD implantation, because complete device removal is often necessary. In their review of 1,700 procedures, they found a total of 21 ICD-related infections (1.2%); one-fourth of these had systemic signs of infection. Patients with abdominal systems had significantly more infections than patients with pectoral systems (3.2% vs. 0.5%). In a prospective study, Chamis et al. *(92)* determined an incidence of 45.4% (15/33) cardiac device–associated infections among patients with an ICD or a permanent pacemaker who developed *S. aureus* bacteremia (SAB). In patients with early SAB (<1 year after device placement), they found that 75% of the events were related to the device; in patients with late SAB (>1 year), 28.5% were confirmed to be related to the ICD or pacemaker (43% were possible cardiac device infections).

The most common pathogens of infections related to ICD are coagulase-negative staphylococci and *S. aureus* (68% and 23%, respectively, in the study by Chua et al. [*93*]).

The decision whether or not to reimplant an ICD after removal of an infected one has been controversial. Some authors recommend reimplantation as early as 36 hours after explantation in patients with only local symptoms of infection. The need for reimplantation should be reassessed in every case *(93)*. With regard to infections, but also to other complications, the single-chamber ICD (SC-ICD) seems to be superior to the dual-chamber ICD (DC-ICD), which may be explainable by the longer operation time and the placement of the second lead of the DC-ICD (infectious complications: 4.1% with the DC-ICD vs. 0% with the SC-ICD) *(94)*.

The greater risk of infection concerning more complex devices (dual/triple chamber vs. single ICD and pacemaker [see below]) was also documented by Nery et al. (95) in their retrospective study on 2,417 patients who had pacemaker or ICD implantation during a period of approximately 4 years. A total of 24 infections were identified (1%): 60% of these were diagnosed within 90 days of the last surgical procedure. Frequent clinical presentations were pocket infection (15/24) and bacteremia (5/24). Besides the above-mentioned greater risk regarding more complex devices, univariate analysis showed that patients with infection were more likely to have had a device replacement, rather than a new implant, and were more likely to have had a prior lead dislodgement. Of the 24 patients with device-related infection, 2 were diagnosed with a superficial wound infection. Complete system removal was performed in the 22 patients with deep infection. The authors stated that to date, there are significant data that support the premise that device replacement and/or pocket reoperation are the strongest independent risk factors for cardiac device infection.

In their retrospective study, Remmelts et al. (96) investigated whether there is a difference in the infection rate depending on the location where an implantable cardioverter-defibrillator is inserted (operating room vs. cardiac catheterization laboratory). Infections were defined as pocket infection or device-related endocarditis. Six hundred sixty-seven consecutive patients were reviewed (366 with implantation in the operating room and 301 in the cardiac catheterization laboratory). No difference in the infection rate was found.

Antibiotic Prophylaxis before the Implantation of Pacemakers and Cardioverter-Defibrillators

Several earlier studies on the merits of antibiotic prophylaxis at the time of permanent pacemaker implantation have yielded inconclusive results. A meta-analysis by Da Costa *(97)* of all available randomized trials (up to 1998) to evaluate the effectiveness of this measure to reduce infection rates after permanent pacemaker implantation suggested that systemic antibiotic prophylaxis significantly reduces the incidence of potentially serious infective complications. The studies support the use of prophylactic antibiotics at the time of pacemaker insertion to prevent short-term pocket infection, skin erosion, or septicemia *(97)*. A recent double-blinded trial (98) examined the benefit of prophylactic antibiotics (1 g of cefazolin vs. placebo) immediately before the implantation of a pacemaker or a cardioverter-defibrillator (or generator replacement) in 1,000 consecutive patients. The primary end point was any evidence of infection at the surgical incision, or systemic infection related to the procedure. The trial was interrupted after 649 enrolled patients due to a significant difference in favor of the antibiotic arm (0.63% vs. 3.28%; RR 0.19; $p = .016$). Patients with a high risk of infection, e.g., patients with prosthetic heart valves with a potentially higher risk for endocarditis, and patients who needed early reintervention due to lead dislodgement, were excluded from this study.

Management of Cardiovascular Implantable Electronic Device (CIED) Infections—A Scientific Statement of the American Heart Association (AHA)

In 2010, the AHA (87) published a scientific statement as an update on CIED infections and their management. The evidence-based recommendations were categorized into a classification system estimating the size of treatment effect and the level of evidence.

The classification system ranges from class I (benefit >>> risk) over class IIa (benefit >> risk) and class IIb (benefit ≥ risk) to class III (risk ≥ benefit). The level of evidence is defined as level A (data derived from multiple randomized clinical trials or meta-analysis), level B (data derived from a single randomized trial or nonrandomized studies), and level C (consensus opinion of experts, case studies, standard of care).

The most important recommendations are summarized as follows:

Diagnosis of CIED and Associated Complications

- At least two sets of blood cultures should be drawn before prompt initiation of antimicrobial therapy (IC).
- Generator-pocket tissue Gram stain and culture and lead-tip culture should be obtained (IC).

- A TEE should be done in patients who have had recent antimicrobial therapy before blood cultures were obtained (IC).
- Adults suspected of having CIED-related endocarditis should undergo TEE, even if TTE has demonstrated lead-adherent masses. In pediatric patients with good views, TTE may be sufficient (IB).

Antimicrobial Management

- The antimicrobial therapy should be based on the identification and *in vitro* susceptibility results of the causative pathogen (IB).
- Duration of therapy should be 10 to 14 days after CIED removal for pocket-site infection (IC), at least 14 days after CIED removal for bloodstream infection (IC), at least 4 to 6 weeks for complicated infection (endocarditis, septic thrombophlebitis, osteomyelitis, persisting bloodstream infection despite device removal) (IB).

Removal of Infected CIED

- Device and lead removal is recommended for all patients with definite CIED infection, as evidenced by valvular and/or lead endocarditis or sepsis (IA), for all patients with CIED pocket infection (IB), for all patients with valvular endocarditis without definite involvement of the leads and/or device (IB), and for all patients with occult staphylococcal bacteremia (IB).

New CIED Implantation after Removal of an Infected CIED

- A careful evaluation whether there is need for a new device should be done (IC).
- The replacement device implantation should not be ipsilateral to the extraction site. Alternative locations include the contralateral side, the iliac vein, and epicardial implantation (IC).

Antimicrobial Prophylaxis

- Prophylaxis with an antibiotic that has *in vitro* activity against staphylococci should be administered (IA).

INFECTIONS AFTER MINIMALLY INVASIVE VALVE SURGERY

Valve surgeries, including valve repairs and valve replacements, are the most common type of minimally invasive surgery in cardiology, which is increasingly utilized. Studies comparing minimally invasive and conventional median sternotomy approaches for primary valve surgery have demonstrated similar early mortality. However, less need for transfusion and better postoperative pulmonary function have been observed with minimally invasive surgery *(99)*. In their prospective study comparing the outcome of 337 sternotomies (160 undergoing aortic valve and 177 mitral valve surgery) and 161 minithoracotomies (61 aortic valve and 100 mitral valve surgery), Sharony et al. *(99)* found a significant difference with regard to the occurrence of deep wound infections (0% in the minimal surgery group vs. 2.4% in the sternotomy group [$p = .05$]). Additionally, hospital length of stay was shorter and the 5-year survival rate was borderline favorable in the minimally invasive group.

A retrospective review of 1,005 patients who underwent minimally invasive aortic valve operations (aortic root replacement, ascending aortic replacement, reoperative surgery) was done by Tabata et al. (100). The incidence of deep sternal wound infection was 0.5%, and for pneumonia 1.3%. In the subgroup of the elderly (≥80 years), the rate of deep wound infection was 1.1% (2/179). The authors concluded that the minimal access approaches in aortic valve surgery are safe and feasible with excellent outcomes.

For mitral valve surgery and its minimal access approach, Modi et al. (101) reviewed the literature and included one randomized controlled trial and 10 case–control studies published between 1998 and 2005 in their meta-analysis. Three studies reported data for septic wound complications *(102–104)*. There was a significant difference comparing minithoracotomy and conventional sternotomy in the study of Grossi et al. (*103*) (0.9% vs. 5.7%; $p = .05$). The incidence of septic wound complications increased in the elderly (≥70 years) to 1.8% and 7.7%, respectively *(102)*. One of the three studies reported no significant difference *(104)*. In the synopsis of the available studies, Modi et al. (101) stated that minimal mitral valve surgery is associated with less morbidity in terms of reduced need for reoperation for bleeding, a trend to shorter hospital stay, less pain, and faster return to preoperative function levels than conventional sternotomy-based surgery.

A recently published propensity-matched comparison of 2,124 patients undergoing mitral valve surgery through a minimally invasive approach and 1,047 patients undergoing a conventional sternotomy found a similar infection rate between both groups regarding 590 well-matched patient pairs (56% of cases) *(105)*. Overall, the authors reported a deep sternal wound infection rate of 14/2,124 (0.66%) versus 4/1,047 (0.38%) and in the matched patients of 6/590 (1.02% in the minimally invasive group) versus 4/590 (0.68% in the conventional group). Regarding infectious complications like sepsis and septicemia, there was a significant difference overall (17/2,124 [0.8%] vs. 31/1,047 [3.0%] with $p < .0001$). This significance could not be documented regarding the propensity-matched patients (8/590, 1.4% in the minimally invasive group vs. 12/590, 2.0% in the conventional group).

REUSE OF DISPOSABLE CARDIAC CATHETERS

In Canada and many European countries, the reuse of disposable catheters has been common practice until the end of the last century. Today, the legal situation in Europe is quite diverse. In some European states, reprocessing is regulated or accepted if validated procedures/high-quality standards are strictly adhered to by reprocessors (as in Germany). Other states such as the United Kingdom or France do not recommend reprocessing. Consequently, reprocessors cannot offer their services in these states. However, it is likely that uncontrolled reprocessing is widely performed.

In the United States, this practice had been discontinued mainly because of legal concerns, but some centers have started to reuse cardiac catheters involving professional

third-party reprocessors *(106,107)*. Several studies have examined the risks of infection with reuse of catheters. Jacobson et al. *(108)* prospectively studied 341 patients who underwent cardiac catheterization and/or coronary angiography to examine the correlation of adverse effects with the number of times catheters were cleaned, sterilized with ethylene oxide (ETO), and reused (maximum of four uses and less when any defects were noted). The overall incidences of adverse reactions were hypotension 27%, fever 3%, chills 3% (all three 0.6%). There were no statistically significant increases in these reactions associated with the reuse of catheters. The authors concluded that careful processing and reuse of catheters did not obviously increase the risk of infection.

Frank et al. *(109)* prospectively studied 414 patients who had undergone cardiac catheterization or angiography to determine whether there was an increased risk of bacterial contamination or pyrogenic reactions in patients who had procedures with reused cardiac catheters. One hundred sixty-one patients were studied with 426 single-use catheters and 152 with 384 multiple-use catheters that were resterilized once or twice, and 101 patients with 325 multiple-use catheters reprocessed up to ten times. No significant differences between the three groups with respect to fever could be observed. Infectious complications associated with cardiac catheterization or angiography did not occur in any case. It was concluded that careful cleaning, disinfection, and resterilization of intravascular catheters with ETO do not increase the risk of infection. O'Donoghue and Platia *(110)* surveyed retrospectively 13,395 electrophysiologic (EP) studies using 44,950 reused pacing catheters in nine medical centers. They found one superficial skin infection and eight positive blood cultures. However, blood cultures were only performed when infection was suspected, and no information was given on the denominator. The authors concluded that infections were very rare and not significantly different in the catheter reuse group (1,245 EP studies; 3,125 catheters; 3 medical centers) compared with the single-use group and that reuse was safe and cost-effective.

Few studies in the literature provide information on specifically how reuse affects catheter material and function. Zapf et al. *(111)* presented data concerning mechanical stability of polyethylene catheters (elasticity and maximum tensile strength) when exposed up to 60 times to ETO and concluded that reuse of catheters seems to be possible without loss of mechanical safety. Bentolila et al. *(112)* studied the effects of reuse on the physical characteristics of five types of angiographic catheters with special emphasis on the possibility that reuse could be associated with blood contamination by loose particles. Samples were taken both from new catheters and from catheters used up to 10 times. Routine cleaning and sterilization procedures showed no adverse effect on the maximum tensile strength and elongation at break of catheters. Some biologic debris was occasionally present in reused catheters. On the other hand, new catheters exhibited a substantially higher loose particle count than catheters that had been properly cleaned and resterilized.

One of the main concerns with using resterilized catheters is reaction to endotoxin, which may cause chills, fever, and hypotension. Lee et al. *(113)* reported reactions in 13% (8/62) of patients undergoing cardiac catheterization over a 3-month period. New catheters, however, may also contain traces of endotoxin. To establish a baseline for the endotoxin contamination of commercially prepared angiographic catheters, Kundsin and Walter *(114)* purchased 106 catheters from three manufacturers that were packaged, sterile, and ready for insertion. All catheters contained endotoxin ranging from 6.9 to 55.6 pg per catheter. Twenty-five new sterile catheters were pyrogenic, whereas 106 were not. The authors also tested 13 catheters that were reprocessed in a cardiac catheterization laboratory. All were found to be pyrogenic, containing as much as 7,800 pg per catheter of endotoxin. Recommendations were then made for processing catheters to eliminate pyrogens.

Buchwalsky et al. *(115)* reported experience in 50,000 interventions, including PTCA, using different reprocessed cardiac catheters. Neither the duration of the intervention nor the catheter-dependent complication rates increased for reused in comparison with single-use catheters. Avitall et al. *(116)* prospectively investigated, over a period of 1 year, the electrical, mechanical, and physical changes after reuse of 69 catheters used in 336 ablation procedures and concluded that they can be reused an average of five times if careful examination of the ablation tip electrode under appropriate magnification (×30) is performed before each use. The catheters should also be tested for deflection and electrical integrity.

Recommendations for Reprocessing of Cardiac Catheters

In the United States, the Food and Drug Administration (FDA) announced in 2000 that it intended to phase in active enforcement of all its premarket and postmarket requirements for devices to ensure that the cleaning, disinfection, and sterilization of reprocessed single-use devices (SUDs) afforded the same level of safety and effectiveness for patients as new catheters did (*www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/ReprocessingofSingle-UseDevices/default.htm*). Postmarket requirements such as registration, listing, medical device reporting, medical device tracking, medical device corrections and removals, the quality system regulation, and labeling are applicable to third-party and hospital reprocessors. This policy led to the comment of a "requiem for reuse of SUDs in U.S. hospitals" *(117)*. In Germany, the Robert Koch-Institute (RKI) issued its guideline on reprocessing of medical devices (*www.rki.de/cln_151/nn_206124/DE/Content/Infekt/Krankenhaushygiene/Kommission/kommission__node.html?__nnn=true*). According to this guideline, cardiac catheters are ranked as highly critical medical devices, which require special caution when such devices are reprocessed, and an active external quality control system is required to be in place.

Cleaning and Sterilizing of Cardiac Catheters If hospitals decide to reprocess cardiac catheters within their own facilities, the following process may be applied. If these recommendations are followed carefully and are accompanied by strict quality controls, no infectious complications or endotoxic reactions should occur. Resterilization bears the potential for residual chemical contamination with ETO *(118)*. Therefore, residual ETO levels may be substantially reduced by allowing a 14-day waiting period after resterilization or by

incorporating a detoxification period immediately after ETO exposure [repeated cycles of steam flushes *(119)*].

- Flush immediately after use with water or heparinized saline and soak for 20 to 25 minutes.
- Remove and brush the tip and soak in a detergent solution for 30 minutes.
- Push guidewire gently through the catheter lumen to remove any biologic material or debris.
- Hand wash and rinse for 5 minutes with detergent solution and rinse intensely with sterile water.
- Blow completely dry with compressed air.
- Inspect carefully for any damage or defect or the presence of organic matter or debris and mark with an indelible marking pen.
- Repackage in sealed envelope and add proper identification.
- Sterilize with ETO.
- Aerate catheters for at least 14 days at room temperature.

Reuse of Coronary Angioplasty Catheters

One of the pioneer studies on reuse of PTCA catheters was done by Plante et al. *(120)*. In this study, two centers were compared: one using new and the other reused catheters. Comparison of the centers led to the conclusion that reuse was associated with a higher rate of adverse clinical events (7.8% vs. 3.8%). This result is in contrast to findings published by Browne et al. *(106)*, who investigated the reuse of PTCA balloon catheters. The study enrolled 107 patients; 106 had a successful laboratory outcome, and 1 required coronary artery bypass graft surgery after failed rescue stenting. The authors concluded that reuse of disposable coronary angioplasty catheters after carefully controlled reprocessing appeared to be safe and effective with success rates similar to those of new products and no detectable sacrifice in performance.

With respect to reuse of PTCA equipment, Krause et al. (121) reviewed the literature, interpreted the state of knowledge (2000), and presented the main arguments in favor and against reuse. According to the authors, the following conclusions can be drawn:

1. Even assuming that no additional clinical risk is associated with PTCA-catheter reuse, the decision to adopt or reject a reuse policy has to be based on the individual situation at each hospital. Factors to consider include technical and personnel resources of the institution, frequency of PTCA procedures, and the economical and legal environments.
2. The review of the literature showed that authors tend to come to two contradictory conclusions as far as patient safety is concerned. One group of authors claimed that PTCA catheters are already being reused in many countries and that there is no evidence for an increased risk. The other group sees a risk in the presence of organic debris in reused catheters, which raises both health and legal issues.

Krause et al. stated that it is unlikely that clinical trials will ever come up with a clear answer to the problem (121).

CHAPTER 62

Infection Risks of Endoscopy

John Holton

Endoscopic procedures are used worldwide for both diagnostic and therapeutic interventions. Considering the numbers of endoscopies that must be performed annually, the incidence of infection is comparatively low and estimated at one per 1.8 million examinations (*1,2,*3), although increasing concern has been expressed at cross-contamination during the decontamination process *(4)*. Endoscopic procedures are becoming increasingly complex, particularly in the field of keyhole surgery; however, percutaneous endoscopic surgical procedures have impacted beneficially on the postoperative wound infection rate and by reducing hospital stay have also had an economic benefit. It is therefore important that the potential cross-infectious hazards from the instruments are reduced to a minimum by correct decontamination procedures particularly as endoscopes are the commonest medical device associated with outbreaks of infection (*5,6,*7).

Many endoscopic procedures are carried out with all-metal instruments and they are thus comparatively easy to decontaminate by autoclaving. There are still, however, large numbers of endoscopies performed with instruments that are flexible and heat sensitive. It is this group of instruments that presents a considerable challenge to effective decontamination, in part because of their complex internal structure, with several very narrow bore channels and difficult to clean valves and valve seats. An additional factor to be considered is the heavy workload on a clinic and consequently a short turnaround time between patients, thereby potentially making effective decontamination problematic.

Currently, there are circumstances that set a particular challenge to the safe decontamination, not only of flexible but also rigid endoscopes, and these circumstances relate to viral and prion contamination of instruments (8). These circumstances take the emphasis for the safe reuse of instruments away from simply killing adherent microorganisms to removal of contaminating "soil" that may contain microbial nucleic acids, hazardous protein, and endotoxin. The availability of the polymerase chain reaction (PCR) has demonstrated that following decontamination procedures *(9)* it is possible to still detect the presence of microbial nucleic acid and that, although it may not be an infective hazard, it may well be hazardous for the patient by other mechanisms. These considerations and the concern regarding biofilms have led to a reevaluation of current decontamination procedures by professional organizations and to the circulation of new protocols to deal with contaminated endoscopes (10,*11*,12,13,*14–17*,18,*19*,20,*21,22*,23).

To standardize the decontamination procedure for endoscopes, the instruments are now almost universally processed in automated washer/disinfectors. This does not obviate the need for an initial manual cleaning, which is vital to the whole decontamination process, but does ensure that all endoscopes are decontaminated in an identical fashion and frees the endoscopy nurses for other duties in the clinic. There is, however, a downside to the use of automated washer/disinfectors, which relates to recontamination of endoscopes by the machine after the disinfection stage. This is due to the growth of microorganisms within a biofilm present in the tanks and pipes of the washer/disinfector and thus recontamination during the final rinse prior to removal of the instrument from the machine *(24)*. This problem has led to the reporting of pseudo-outbreaks of tuberculosis following bronchoscopy and to actual infection of patients with environmental gram-negative microorganisms. The manufacturers of automated washer/disinfectors have had to redesign the internal architecture of the machines and to otherwise modify them by including a self-disinfection cycle. The problem has also led to the development of systems for the provision of sterile water to the machine from the potable water supplies.

Aldehydes, for example, 2% glutaraldehyde, are still probably the commonest disinfectants used worldwide for flexible endoscopes *(25–29)* although in some countries, including the United Kingdom, they have been withdrawn from the market and this has of necessity led to the use of other disinfectants. Glutaraldehyde does have two major disadvantages despite its efficacy as a disinfectant. It is now recognized to be a major cause of occupational allergy, giving rise to both pulmonary and skin hypersensitivity *(30,31)*. Its other main disadvantage is that it acts as a fixative, and with concern expressed over prion proteins and the emphasis placed on soil removal from endoscopes, this characteristic in a disinfectant is unwelcome. The disinfectants that have replaced glutaraldehyde (in the United Kingdom) are very effective in killing microorganisms but are far more corrosive both to the endoscope and to the washer/disinfector.

The area of endoscope decontamination is thus currently in a state of flux, and further developments are anticipated with respect to the processes of decontamination, the nature of disinfectants, and the materials from which endoscopes are manufactured.

TYPES OF ENDOSCOPES

Endoscopes are constructed from a diverse range of materials including plastic, metal, glass, and adhesives. They generally have a complex internal construction with narrow bore channels, external ports, and valves. Many different endoscopes are now produced for a variety of medical interventions, both therapeutic and diagnostic, including bronchoscopy, arthroscopy, laparoscopy, colonoscopy, gastroscopy, and cystoscopy. The endoscopes may be flexible or rigid, the latter usually made entirely of metal and are thus relatively easily decontaminated compared to the flexible endoscopes. They may be used as direct viewing instruments or for the collection of biopsy specimens, as video endoscopes, or as endoscopes with an ultrasound attachment used for diagnostic purposes.

Endoscopes can be classified as critical instruments—those that penetrate the skin or sterile body cavities—or as semicritical instruments—those that are in contact with mucous membranes. However, this distinction is not clear-cut, as many semicritical instruments may be in contact with pathologic lesions, where the local defenses are breached, or they are used to take specimens, thus breaching local defense mechanisms.

Critical Instruments

These instruments include laparoscopes, vascular and neurological endoscopy, cystoscopes, and arthroscopes. Some of these instruments such as the cystoscopes and laparoscopes may be rigid in construction, made out of metal, and are thus autoclavable.

Laparoscopes are used for visualizing the peritoneal cavity, penetrate the skin, and are increasingly used as surgical equipment involved in intraperitoneal operations such as cholecystectomy, hysterectomy, hernia repair, and tubal ligation. Similar instruments may also be used in the thoracic cavity for some surgical procedures, in cosmetic surgery for rhytidectomy, and in general surgery for thyroidectomy. Angioscopy is used for atherectomy, embolectomy, and direct inspection of vessels. Endoscopes are used in neurology for III ventricle ventriculoscopy, in cases of hemorrhage-related obstructive hydrocephalus, and for transsphenoidal resection of pituitary adenoma. Arthroscopes are also rigid and autoclavable and are used for inspecting joint spaces and surgical procedures including meniscectomy. These instruments are also used percutaneously. Hysteroscopes are used for visualizing the uterus, for removing polyps, for biopsies, and for resection of submucous fibroids. Cystoscopes are often rigid, although ureteroscopes are flexible. These instruments are used for visualizing the urinary tract, taking biopsies, removing small tumors and calculi, and dilating stenosed regions of the urinary tract. They may be passed into the renal tract through the urethra or directly into the renal pelvis percutaneously.

In general, the flexible operative endoscopes are heat labile and should be sterilized by ethylene oxide or gas plasma. The rigid ones may be autoclaved.

Semicritical Instruments

These instruments include gastroscopes, duodenoscopes, sigmoidoscopes, proctoscopes, colonoscopes, bronchoscopes, and laryngoscopes. Gastroscopes, duodenoscopes, and colonoscopes are long, flexible instruments, usually with four channels (suction, biopsy, air, and water) and corresponding ports and valves. The suction and biopsy channels are often combined within the insertion tube. Their intricate construction makes them difficult to clean, and the materials from which they are made make them difficult to decontaminate. These instruments are inserted through one of the natural orifices of the body, which has a rich normal flora. Bronchoscopes are thus categorized as semicritical despite the fact they enter a sterile body cavity. These instruments are used both diagnostically and for minor surgical procedures such as polyp removal or diathermy.

Accessories

A wide range of accessories is available for both critical and semicritical endoscopes including forceps, snares, diathermy, bougies, sphincterotomy knives, and lasers. Many of these accessories can be autoclaved, but increasingly manufacturers are supplying single-use disposable accessories. Laser and ultrasonic probes are expensive and not able to be autoclaved.

ETIOLOGY

The commonest microorganisms that cause endoscopy-associated infections or pseudoinfections are opportunistic gram-negative bacteria and mycobacteria that are associated with moisture or biofilms on an endoscopy processing apparatus *(32,33)*. Microorganisms that have frequently been isolated include *Pseudomonas* species *(34)*, *Serratia marcescens*, *Klebsiella*, *Escherichia*, and *Salmonella* species *(35–42)*. *Salmonella* sp. is easily diagnosed as cross-infection due to a poorly decontaminated endoscope because this microorganism would not normally be found in the environment of an endoscopy room as a contaminant. Cross-contamination with *Salmonella* would be likely to cause an infection, even in relatively healthy individuals, in comparison to the environmental opportunist microorganisms commonly linked to failed endoscope decontamination, such as *Klebsiella* and *Pseudomonas*. Most of the cases of transmission of *Salmonella*, and there have been relatively few, date from the 1970s to 1980s, and in all cases, disinfectants were used that would be regarded as inappropriate by current standards. The agents that were used to decontaminate the endoscopes were skin antiseptics—chlorhexidine, cetrimide, povidone-iodine, hexachlorophene, and quaternary ammonium compounds. The majority of reported infections occurred prior to 1983, with only three more cases reported by 1992 and none to the current time. Since the late 1980s, glutaraldehyde and more recently other agents have been used to decontaminate endoscopes, with the effect that there are fewer reported incidents of cross-infection from an endoscope contaminated with enteric gram-negative bacteria.

Bronchoscopy has been associated with contamination or infection caused by *Mycobacterium tuberculosis*, *M. kansasii*, *M. chelonae,* and *M. abscessus (24,43–47)*. Cystoscopy has been associated with infections by *Escherichia*, *Enterococcus*, and *Proteus* species *(48)*. Percu-

taneous endoscopy has been associated with skin flora and *Staphylococcus aureus* surgical site infections *(49)*.

There is little evidence of viral transmission after endoscopy. Both bronchoscopes and gastroscopes become contaminated with human immunodeficiency virus (HIV) when used on patients with the acquired immune deficiency syndrome (AIDS), yet there is no evidence of transmission following endoscopy. Studies have shown that mechanical cleaning of endoscopes removes even high concentrations of HIV and that glutaraldehyde rapidly inactivates the virus *(50)*. There is a single well-documented case of hepatitis B virus (HBV) transmission between patients *(51)*, but most studies have not been able to document transmission. Of 394 patients followed up after exposure, none showed clinical evidence of infection *(52)*. There have been three reported cases of hepatitis C virus (HCV) transmission, one following endoscopic retrograde cholangiopancreatography (ERCP), and two following colonoscopy, and in all cases decontamination was found to have been ineffectively carried out *(53)*. In a study of 19 patients with HCV using molecular techniques to detect the virus, a blood sample taken from the patient was positive prior to the procedure, and 53% of the endoscopes were contaminated with the virus immediately after removal, but after both mechanical cleaning and mechanical cleaning followed by immersion in a disinfection, none were contaminated *(54)*. Thus, current decontamination procedures appear to be sufficiently robust to prevent viral transmission following endoscopy.

Less frequently identified pathogens that may be transmitted by endoscopic procedures include *Helicobacter pylori (55,56)*, *Shewanella* spp. *(57)*, *Trichosporon asahii (58)*, and *Strongyloides (59)*. Other microorganisms that may be transmitted by endoscopy include *Clostridium difficile*, *Cryptosporidia*, and enteroviruses.

PATHOGENESIS

Infections are derived either from an external source (exogenous) or from the patient's own microflora (endogenous). (Fig. 62-1) Endoscopically transmitted infection reported in the literature has been mainly exogenous, from inadequately decontaminated endoscopes, although endogenous infections have also been reported, particularly in association with urologic or percutaneous procedures.

Exogenous Spread of Infection

There are two main reasons for microorganisms being transmitted to a patient from an endoscope, which are to some extent related. On the one hand, the endoscope may be inadequately decontaminated. On the other hand, microorganisms produce and reside in a biofilm when in a moist environment, such as an endoscope or an endoscope washer/disinfector (AEW). Many bacteria secrete a carbohydrate substance, frequently called "slime," which forms the glycocalyx or matrix (the biofilm) within which the microorganisms can survive (*60*,61). Often, biofilms contain complex microbial communities. The dynamics of the biofilm are still poorly understood, but what is certain is that microorganisms within the biofilm are more resistant to biocides than adherent but non–biofilm-associated bacteria or planktonic bacteria *(62,63)*. Additionally, biofilms and the associated bacteria are resistant to hydrodynamic shear forces. Both these characteristics make eradication of microorganisms from endoscopes or endoscope washer/disinfectors difficult and predispose to failure of decontamination processes. The net result is that microorganisms are still present on the endoscope, or the endoscope becomes recontaminated following the decontamination procedure *(64,65)* by poor quality rinse water. Thus, in Fig 62-1, the endoscope (E1) will become contaminated

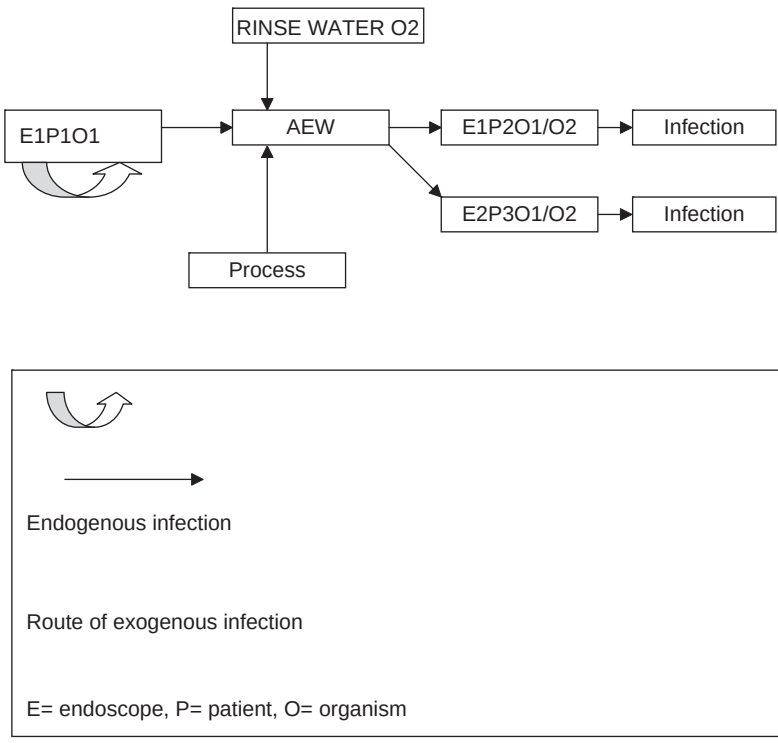

FIGURE 62-1 Routes of transmission of microorganisms by endoscopy.

during the procedure with microorganisms (O1) from the first patient (P1). The endoscope will then be decontaminated in an Automated Endoscope Washer/Disinfector (AEW) and if the procedure is inappropriate or poorly carried out the microorganism will not be removed or killed and when the same endoscope is used on another patient (E1P2O1) an infection may occur. The AEW may also act as a source of contamination of endoscopes. Microbes derived from patients (O1) or from contaminated rinse water (O2) may reside in the biofilm and contaminate endoscopes processed in the machine thereby infecting other patients (E2P3O1/2).

Airborne infection from staff members in the endoscopy room during percutaneous surgical procedures, although possible, is unlikely owing to the small incision produced. During endoscopic surgery, the video screen may act as a source of contamination of the surgeon's hands, as the electrostatic field generated by the screen facilitates the transfer of microorganisms from the screen to the gloved hands of the surgeon *(66)*.

On the other hand, spread of infection from the patient to the staff is a very real risk during bronchoscopy, particularly when dealing with patients who have tuberculosis. Similar concern has been expressed about staff members acquiring infection with HIV when performing endoscopy on patients who are infected *(67)*. In one study of 427 urologic procedures, contamination of the surgeon's skin or mucous membranes occurred in 32%. Thirty-three percent were endoscopic procedures and in these, contamination of the face or eyes occurred in 46% *(68)*. Although in practice the risks of infection are small, the risks of contamination in some procedures are high, and appropriate physical precautions have been almost universally introduced.

In addition to the transfer of microorganisms to the patient, who may then become colonized, whether or not the patients develop an infection is due to other contributory factors such as their underlying medical condition, the treatment they may be receiving, and whether they already have a focus of infection such as an obstructed bile duct *(69)*.

Endogenous Spread of Infection

Endogenous infection may be due to transfer of microorganisms from one site to another during the insertion or removal of the endoscope. Mouth flora may be transferred to the stomach or to the bronchi during gastroscopy or bronchoscopy. Mouth, stomach, or duodenal flora may be transferred to the biliary or pancreatic system during ERCP. Intestinal flora may contaminate the oral cavity on removal of a gastroduodenoscope or ERCP. Similarly, skin flora may be introduced into the peritoneal cavity, pleural cavity, or joint; vaginal flora may be introduced into the uterus; and fecal, skin, or urethral flora may be introduced into the bladder or kidneys during urological procedures.

INFECTIONS ASSOCIATED WITH ENDOSCOPY

The insertion, manipulation, or removal of the endoscope may be associated with bacteremia, usually with the patient's own microflora but rarely from microorganisms contaminating the endoscope. More usually, pseudoinfections have been reported in the literature, due to contamination of a patient's specimen by a microorganism derived from the endoscope. Percutaneous procedures may be followed by surgical site infections or joint infections, peritonitis, bacteremia, or empyema.

Between 1974 and 2004, there were 140 outbreaks related to endoscopy reported in the world literature (70). Forty-nine percent were from the United States and 51% from 19 countries other than the United States. Bronchoscopy accounted for 47% of infections and 94% of pseudoinfections in the United States and 21% of infections and 76% of pseudoinfections outside the United States. Gastrointestinal endoscopy accounted for a similar percentage of infections, but only 6% of pseudoinfections within the United States and 76% of infections and 24% of pseudoinfections outside the United States. Overall, bacteria were the principal cause of infections and pseudoinfections.

The commonest cause of toxic reactions was glutaraldehyde, which has now been withdrawn from use in the United Kingdom. The most frequent cause of outbreaks related to inadequate decontamination practices followed by contamination of the AEW in the United States and the use of contaminated water outside the United States. Over this period of study, the primary cause of decontamination failure fell from 72% to 47% in the United States and 81% to 70% elsewhere. Since 1990, equipment malfunction has been identified as a cause of failure in the United States (8%) and elsewhere (4%) and AEW contamination accounting for 25% and 4% in the United States and elsewhere, respectively. A key outcome of this study was that by better adherence to decontamination guidelines, 90% to 97% of the outbreaks could have been prevented both within and outside the United States. During this period of study, there were 14 deaths, 1.9% of the total number of exposed patients in the United States and 6 deaths elsewhere (1% of contaminated patients). The mean length of an endoscopy-related outbreak was 182 days in the United States and 202 days elsewhere.

These data represent an underestimate as an unknown number of endoscopy-related incidents may go unreported, and in about half of the reported cases insufficient data was recorded and particularly the denominator (number of patients undergoing endoscopy) is unknown. Since this study, there have been nine further outbreaks reported from 2005 to 2008 that occurred outside the United States *(71)*.

Endoscope-Assisted Surgery

Laparoscopic Surgery Surveys of infective complications following minimally invasive procedures are few, and there is little evidence to show they are due to contaminated endoscopes as opposed to complications of the procedure. Surveys between 1975 and 1980 of, in one case, over 100,000 laparoscopies *(72)* showed an infection rate of 3% to 4%, with only seven possibly being due to nonsterile equipment. In a second survey of over 10,000 laparoscopies *(73)*, three cases of surgical site infection were reported, none of which were thought to be due to contaminated equipment. In 1991, a prospective study

of 1,518 laparoscopic cholecystectomies showed an infection rate of 0.9% to 2.0% *(74)*. In 1999, a retrospective survey of 1,702 laparoscopic cholecystectomies *(75)* showed an infection rate of 2.3%, with a surgical site infection rate of 0.4%. The commonest infective complication following this procedure is septic complications after spillage of gallstones in the peritoneal cavity *(76–78)*, and not due to a failure of decontamination procedures. In 2002, a Cochrane Review of laparoscopic appendectomy compared to open appendectomy covering 45 studies *(79)* showed that wound infection following the laparoscopic procedure was half as likely as with the open procedure, but that intra-abdominal abscess was three times as likely. It was not suggested that failed decontamination procedures were the cause of any of the infective complications.

In a report from India, local skin infection with *M. tuberculosis* followed laparoscopic surgery in eight patients *(80)*. The endoscopes were soaked in an open tray for 20 minutes, a technique no longer used in developed countries and that emphasizes the importance of correct modern decontamination procedures.

In a study of 801 patients treated by laparoscopic distal pancreatectomy, an infection rate of 0.6 was recorded. Fewer patients have undergone total pancreaticoduodenectomy, and of 85 so reported although the morbidity was high (34%) the rate of infection was not reported *(81)*.

Minimally invasive surgery has so far involved percutaneous entry into the abdominal cavity to perform the operative procedure with a lower infection rate compared to conventional surgery. However, the development of natural orifice transluminal endoscopic surgery (NOTES) where flexible endoscopes are used to perform intra-abdominal and intrathoracic operations may alter that, as entry into the abdominal cavity is via the vagina *(82)* or stomach *(83)*. As the endoscope transverses a heavily colonized mucosal site, the procedure may be associated with a higher postoperative infection rate as there is a potential to introduce microorganisms into a sterile cavity. However, in both series, no infections were recorded and the transvaginal approach is frequently used by gynecologists without adverse infection risks. This suggests that terminal sterilization of surgical endoscopes is not required, although a protocol has been developed to sterilize these surgical endoscopes using peracetic acid *(84)* Further, a single-port endoscopic procedure for cholecystectomy (SPEC) has been developed in pigs *(85)* as an alternative to NOTES, and as there are fewer breaks in the skin, this may even further reduce the possibility of infection.

Arthroscopy

Infections following arthroscopy are uncommon, with, in one survey of 12,505 procedures, an infection rate of 0.04% being reported *(86)*. Postprocedure infections do occur, usually with skin flora and usually due to environmental contamination rather than poor decontamination of the arthroscope. In one study, three joint infections occurred in 155 arthroscopies *(87)*, but following alteration of environmental factors, there were no subsequent infections in 222 procedures. In one more recent study, *Candida albicans* infection occurred following arthroscopy. Infectious complications can also follow other endoscopic orthopedic procedures, and in one case lumbar discitis occurred following laparoscopic sacrocolpopexy *(88)*, although there was no indication this was due to failed decontamination. Infection has also been reported following meniscus repair performed by arthroscopy. Three patients developed a septic arthritis with *Staphylococcus epidermidis*, and the likely source was the cannulae. *In vitro* studies demonstrated these cannulae could only be sterilized by an ultrasonic bath, jet washing of the lumen, and steam sterilization. *(89)*.

Cystoscopy

Cystoscopes were among the first endoscopes to be used, and initially inadequate disinfection was responsible for infection. Many of the cystoscopes can be autoclaved, although flexible heat-sensitive cystoscopes are also used. In the 1950s, it was shown that patients were developing infections within a few days of the procedure *(90)*. A number of disinfectants were introduced, and since the use of 2% glutaraldehyde and antibiotic prophylaxis, the postprocedure infection rate is small. In a study of 161 cystoscopies, an infection rate of 7.5% was reported with microorganisms derived from endogenous flora, giving no suggestion that failed decontamination procedures were to blame *(91)*. In a study of 420 patients following flexible cystoscopy, 110 patients donated a postprocedure urine specimen 3 days following the investigation, with 2.7% showing evidence of infection *(92)*. Percutaneous urologic procedures, such as nephrostomy or insertion of a ureteral endoprosthesis, in one study had a complication rate of 7%, with 0.87% being due to urinary tract infection. Minor complications of skin inflammation occurred in 5.3%, but in no case was it thought to be due to poor decontamination procedures *(93)*. An outbreak of *Pseudomonas aeruginosa* infection following cystoscopy was identified in New Mexico involving 23 patients. Most of the patients had a urinary tract infection postprocedure, but 4 also had bacteremia. A multivariate analysis indicated cystoscopy was the most likely common factor (OR: 46.5). On examination, the cystoscope was positive for the microorganism and there were several breaches of the decontamination protocol identified *(94)*. Another study in a urology unit indicating inadequate disinfection as a cause of an outbreak demonstrated that forceps were the likely source. In this case, 10 isolates of *Pseudomonas* recovered from the forceps were indistinguishable by pulse-field gel electrophoresis *(95)*.

Endoscopic Vascular Surgery

Infections are also a complication of cardiovascular cannulation, although there is no suggestion that these infections are due to failed decontamination procedures, as the cannulas are sterile, single-use items. In a retrospective study between 1991 and 1998 of 22,006 procedures, there were 25 cases of bacteremia (0.11%) with 0.24% following percutaneous transluminal coronary angioplasty, 0.06% following cardiac catheterization, and 0.08% following electrophysiologic studies. The majority of the infections were with gram-negative bacteria *(96)* (see also Chapter 61).

In one study, 103 patients undergoing coronary artery bypass graft (CABG) had the saphenous vein removed by minimally invasive endoscopic procedure. Eight

point seven percent of the standard operative control population (9/105) developed a wound infection, whereas only 2 out of 103 developed an infection after in the endoscopic procedure *(97)*. A further study demonstrating the lower infection rate using minimally invasive endoscopic procedures compared open surgical repair of the abdominal aorta compared to endovascular repair. The patient with an open procedure was twice as likely to develop an infection compared to the one having endovascular repair *(98)*.

Endoscopic Neurosurgical Procedures

Third ventricular endoscopy (ETV) has been used for obstructive hydrocephalus of several etiologies including removal of tumors, Chiari malformation, aqueduct narrowing, spina bifida, and following a cerebral hemorrhage. In one study of 34 procedures for obstructive hydrocephalus following cerebral hemorrhage, spanning a 15-year period of endoscopic neurosurgery, no cases of infection were reported postprocedure *(99)*. Although this study is small, if the general trend of lower post procedure infection rates for other types of surgery is observed, then ETV will compare well with placement of an extraventricular drain (EVD) where infection rates of 10% are common *(100)*. Further, some studies report infection rates as high as 45% for EVD. In another study of 190 patients treated by EVT for obstructive hydrocephalus *(101)*, there were no cases of postprocedure infection reported, and in many cases an EVD or VP shunt was not needed, thus avoiding recognized infectious complications. In a study of ETV for colloid cyst removal in 55 patients, the infection rate was 0% compared to 5 of 27 patients in the control surgical procedure *(102)*. Finally, after endoscopic removal of subcortical tumors in 21 patients, only one postoperative infection was identified. *(103)*. The use of endoscopic procedures in neurosurgery not only results in a lower infection rate postprocedure, but there are no reports of contaminated endoscopes linked to outbreaks.

Miscellaneous Endoscopic Surgical Procedures

In a study of 251 patients who underwent thyroidectomy using an endoscopic transcervical approach, the infection rate was 2.6% compared to 7.35% in conventional surgery *(104)*. A 10-year prospective study of endoscopic rhytidectomy in 54 patients did not record any case of postoperative infection or of cross-infection *(105)*.

Semicritical Endoscopes

Gastrointestinal Endoscopy Infections associated with gastrointestinal endoscopy are uncommon, and several surveys dating from the 1970s have shown a rate of <1%. In a survey of over 240,000 gastrointestinal endoscopies, only 24 infective complications were reported, including four fatal cases, two of cholangitis and two of pancreatitis *(106)*. In a further study, 116 infective complications were reported, which included bacteremia, hepatitis B, endocarditis, aspiration pneumonia, and Creutzfeldt-Jakob disease (CJD) *(25)*. The microorganisms isolated included enteric gram-negative bacteria such as *Serratia* and *Salmonella*, environmental bacteria such as *Pseudomonas*, and gram-positive bacteria such as *S. aureus*. In a survey in the United Kingdom of 164,000 endoscopies, the infection rate was 0.74% for ERCP, but of those infected, there was a high mortality rate of 26% *(107)*. Percutaneous endoscopic gastrostomy (PEG) is a procedure for establishing enteral feeding *(108)*. In one study of 166 PEG procedures, the complication rate was 16.3%, with wound infections occurring in 5.4%, including one case of necrotizing fasciitis. Esophagoscopy has been linked to the transmission of *Pseudomonas* with, in some cases, evidence of infection and death following septicemia *(109)*. In a study of 760 children undergoing PEG between 1994 and 2005, there was a 4% complication rate (skin infection) postprocedure in hospital rising to 20% out of hospital *(110)*.

Lower respiratory tract infection has also followed gastroscopy, again with *Pseudomonas*, which probably relates to aspiration of oral secretions associated with a contaminated endoscope *(111)*.

Following sigmoidoscopy, a 10% prevalence of bacteremia that was detectable over a period of 15 minutes has been reported, although no obvious infective complications were noted *(112)*. Transient bacteremia has also been reported in other studies *(113–116)*. A false sense of security may be given if using disposable rigid sigmoidoscopes as microorganisms may contaminate the nondisposable bellows or light head. In one study of 21 sigmoidoscopies, a number of enteric bacteria were detected in these two locations *(117)*.

Procedures involving sclerotherapy with *N*-butyl-2 cyanoacrylate have been shown to have a high rate of bacteremia and peritonitis, ranging from 5% to 53% and 0.5% to 3%, respectively *(118)*, and in some cases endocarditis or abscess has occurred following endoscopy *(119–121)*. An alternative approach is the use of a covered needle (Clisco needle) whose tip does not become contaminated during insertion of the endoscope *(122)*. Culture of the tip of covered needles compared to noncovered needles showed a lower contamination rate for the covered needle and by implication this may lower the rate of postprocedure bacteremia. However, endoscopic variceal ligation is replacing sclerotherapy as the method of choice to control bleeding. This procedure has a 3% to 14% risk of bacteremia, with 11/67 patients developing bacteremia and 2/67 developing peritonitis *(123)*.

Endoscopic Retrograde Cholangiopancreatography

Infection following ERCP is more common than with other forms of gastrointestinal endoscopy, particularly when the biliary tree is obstructed. A postal survey of 10,000 endoscopies showed an infection rate of 3%. Most complications were due to pancreatitis, but cholangitis and cases of infected pancreatic pseudocyst also occurred, as did a small number of cases of aspiration pneumonia *(124)*. Exogenous infection leading to septicemia, following the use of a contaminated endoscope for ERCP, has also been reported. The microorganism isolated from the patient's blood, the endoscope, and the water reservoir was *P. aeruginosa (125)*. In a survey of 690 ERCPs, fever occurred in 12 patients and 5 of these died of septicemia *(126)*. Microorganisms isolated were *Pseudomonas*, *Klebsiella*, *Proteus*, and *Escherichia*. Several other reports have documented infections following ERCP, frequently in association with biliary stasis, and thus likely to be of endogenous origin, but also following the use of inappropriate disinfectants as mentioned previously, or more recently, incidents have been reported

following recontamination of the endoscope from the endoscope washer/disinfector. In both cases, outbreaks due to *Pseudomonas* have been reported *(127–130)*. In one report, the post-ERCP infection rate in one hospital increased from 1.6% to 3.6% following the use of a new automated washer/disinfector. The microorganisms causing the bacteremia were *Pseudomonas* and enteric gram-negative bacteria. Seven epidemic strains causing infection were genomically related as shown by macrorestriction DNA analysis and accounted for 55% of the episodes. Effective decontamination of the washer/disinfector led to a reduction in the infection rate to preincident levels *(131)*.

In a report from the United States, *Pseudomonas* was isolated from 10 patients following ERCP. Five developed sepsis and one died *(132)*. The same strain (serotype 10) was isolated from the endoscope and persisted in the unit for 9 months. Factors involved in its persistence were probably inadequate decontamination of the endoscope, recontamination from the rinse water of the washer/disinfector, and inadequate drying of the endoscope. *Pseudomonas* has also been implicated in other cases of infection in association with high counts of the microorganism in the biopsy channel and samples of rinse water from the washer disinfector immediately after disinfection with glutaraldehyde *(64,133,134)*. The mechanism of persistence in this case was lack of circulation of the disinfectant to all areas in the washer/disinfector and the formation of a biofilm containing the microorganism, which acted as a source of recontamination.

Bronchoscopy

A bronchoscope is less complex than a gastrointestinal endoscope, having fewer channels to decontaminate. However, bronchoscopes are used to obtain bronchoalveolar lavage (BAL) specimens in which the pulmonary tree is washed out with saline. There is thus the potential to contaminate the specimen from an inadequately decontaminated endoscope, giving a false clinical impression that the patient is infected.

The most frequently reported pseudoinfection is with mycobacterial species, but they have also been reported with *Pseudomonas* found in bronchial washings following bronchoscopy *(32)*. In a study in 1982, 11 of 19 specimens were contaminated with the same serotype 10, which was also isolated from the bronchoscopy channels *(135)*. In another study, 82/103 BAL specimens were contaminated by *P. aeruginosa (136)*, but again no infections were reported. As with gastrointestinal endoscopy in the 1970s and early 1980s, the disinfectants used were inappropriate. Other outbreaks involving multiresistant *P. aeruginosa* have also been reported more recently *(137–139)*.

Microorganisms other than *Pseudomonas* have also been linked to outbreaks of pseudoinfections as well as true infective complications. Following bronchoscopy on a patient with *S. marcescens* pneumonia, the microorganism was found in the tracheal washings of three other patients *(140)*. Other sources of outbreaks of pseudoinfection have been linked to contaminated sterile water *(141)* and lens cleaner *(142)*. In one case, incorrect connectors had been used to link the machine to the bronchoscope. Also, defects in the bronchoscope may be involved. In one report, three outbreaks were identified involving 418 patients contaminated by various Enterobacteriaceae (*Klebsiella* sp., *Proteus* sp., and *Morganella* sp.). The likely source of the contamination was traced to a faulty biopsy channel port *(143)*. Proteus species have also been associated with pseudoinfections following bronchoscopy *(144)*, and bronchoscopes have also been the vehicle for a pseudo-outbreak with *Legionella pneumophila,* which became contaminated from tap water *(145)*.

Gram-negative bacteria are relatively susceptible to disinfectants, compared to the more hardy mycobacteria. Additionally, mycobacteria are also found in water supplies and can grow in biofilm in pipe work. It is therefore not surprising that infections with *M. tuberculosis* and many pseudoinfections with other mycobacterial species have been reported. A retrospective survey of 8,750 bronchoscopies showed that contamination occurred in eight, but there was no evidence of infection *(146). M. tuberculosis* has been isolated from washings of a bronchoscope after it had been decontaminated in povidone-iodine, and transmission was documented from one patient to another in a separate episode. In this case, the bronchoscope had also been disinfected in povidone-iodine, and *in vitro* studies showed that this was an ineffective agent for mycobacteria *(147)*. In 1 month in 1999, five *M. tuberculosis* BAL specimens were reported in one hospital that overall had a low rate of tuberculosis. A retrospective survey for the whole year showed that 19 bronchoscopies had been performed with 10 of 18 BAL specimens positive. Two patients were infected prior to endoscopy and two became infected after the procedure. Six patients had positive specimens but did not develop infection. The majority of the isolates were indistinguishable on restriction fragment length polymorphism analysis. In one of the three endoscopes that was used during this period, a small hole was discovered in the sheath, and as leak testing had not been performed regularly, this had allowed a contaminated endoscope to be unwittingly used *(148)*.

There have been numerous reports of pseudoinfections with other mycobacterial species, and on some occasions this has led to inappropriate treatment. In one study, *M. xenopi* was isolated from 13 clinical specimens, although none had clinical evidence of mycobacterial infection. Five of these patients received antituberculosis therapy *(149)*. An important factor was rinsing bronchoscopes with tap water and gargling with tap water prior to sputum collection. In another study over a period of 37 months, 35% of mycobacterial isolates were *M. xenopi*. Four of the patients had *M. xenopi*–associated disease; the remaining were pseudoinfections. An important risk factor was rinsing bronchoscopes after disinfection in tap water *(150)*. Other mycobacterial species have also been associated with bronchoscopy. A pseudo-outbreak of *M. abscessus* occurring in 15 patients was traced to the use of an automated washer/disinfector *(24)*. Pseudo-outbreaks in association with the use of automated washer disinfectors have also been reported with *M. chelonae* and *Methylobacterium mesophilicum (151)*. Colonization by the microorganisms was linked to bronchoscopy, and the microorganisms were also isolated from the endoscopes, washer disinfectors, and glutaraldehyde taken from the washer/disinfector. Some strains of *M. chelonae* are known to be resistant to glutaraldehyde.

A pseudo-outbreak of nontuberculous mycobacteria involving 41 patients over a 6-month period yielded 16 specimens with acid-fast bacilli that were mainly *M. chelonae* or *M. gordonae*, although one specimen was *M. avium* and one *M. tuberculosis*. Of the apparently positive patients, four were treated for suspected tuberculosis. The source of the contamination for most of the isolates was the water reservoir in the machine, although the source of two of the *M. gordonae* isolates was a laboratory solution *(152)*. In one study 13 strains of *M. chelonae* were isolated from BAL fluid where the bronchoscopes were decontaminated in the same machine as colonoscopes. The outbreak was stopped by manually decontaminating the instrument *(153)*.

True infections following bronchoscopy are uncommon. The complication rate of 24,521 bronchoscopic procedures assessed from 192 replies of a questionnaire was 0.08% with a mortality of 0.01% *(154)*, with fever in eight patients and pneumonia in two. In a prospective study of 100 bronchoscopies, fever occurred in 16% and lung infiltration in 6% *(155)*. In a prospective study of fever and bacteremia following bronchoscopy in immunocompetent children, of 91 children investigated, 48% developed fever within 24 hours, but bacteremia was not detected *(156)*. In those children who developed fever, 40.5% of the BAL specimens had a significant bacterial growth.

These cases emphasize the importance of correct use and regular maintenance of the AEW, and adherence to recognized guidelines for reprocessing the instrument. Also, defects in the bronchoscope may be involved and should be guarded against by regular maintenance of the endoscope.

Miscellaneous Microorganisms and Sources

Bacillus species have been found in bronchial washing in one hospital, although none of the patients were infected. The source seemed to be the automatic suction valve *(157)*. Fears have been raised that anthrax may be transmitted by endoscopy, although studies of the efficacy of current disinfectants indicate that they would be effective in killing the microorganism *(158)*. An outbreak of *Aeromonas hydrophila* pseudoinfection was reported. The endoscopes were decontaminated with a disinfectant containing a quaternary ammonium compound and glutaraldehyde phenate. The use of 2% glutaraldehyde eradicated the problem *(159)*. *Strongyloides stercoralis* has been transmitted by gastroscopy *(59)*, and also cross-infection with *H. pylori* may occur *(55,56)*. Fungal infections and pseudoinfections have been reported with *Trichosporon* species *(58)* and *Aureobasidium* species; the latter was linked to the reuse of plastic stopcocks *(160)*. Finally, in 169 patients following ERCP, 12.7% were positive for *Cryptosporidium* oocytes *(161)*. This is a particular risk for AIDS patients, especially as the microorganism is resistant to most disinfectants. (See Chapter 9 for more information on pseudoinfections.)

CONTROL OF INFECTION

As mentioned, endoscope-associated infection can be either endogenous or exogenous in origin. Endogenous infections may be prevented by appropriate skin preparation or chemoprophylaxis prior to the procedure. As indicated by recent reviews, several aspects of the prevention of exogenous infection from endoscopes have taken on current importance *(162–169)*. Exogenous infections would be prevented by effective decontamination procedures. In this latter category, infections that have followed endoscopy have arisen from the use of inappropriate disinfectants, breakdown in the decontamination process, or recontamination from an automated washer/disinfector.

Two common reasons associated with transmission is failure to conform to an adequate decontamination process and equipment failure (*71*,170). Important hazard points in the reprocessing of endoscopes are provision of trained endoscope decontamination staff, regular AEW and endoscope maintenance, adherence to effective decontamination protocols, drying of the endoscopes, machine decontamination at the start of a session, endoscope reprocessing at the start of a session and sterile rinse water. Also important for identifying and mapping outbreaks is surveillance such as tracking of instruments and accessories and surveillance cultures (Fig. 62-2).

Key factors aimed at reducing the already low case-to-case transmission of microorganisms is the development of endoscope channels that can be adequately manually cleaned prior to the automated phase of the decontamination process, including the removal of biofilm, the development of flexible materials that can withstand pressurized steam, and the rapid detection of contamination prior to use. The key factor, however, in relation to decontamination failure is lack of adherence to accepted protocols. This is emphasized by a study in which a questionnaire was sent to 367 Society of Gastroenterology Nurses and Associates (SGNA) members in the United States, which showed that there was a wide variation in quality assurance practices (particularly in the manual decontamination steps) and the use of disposable accessory equipment *(171)*.

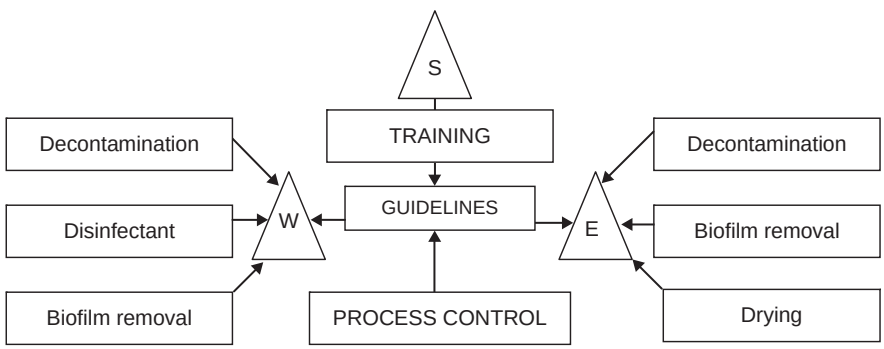

FIGURE 62-2 The three critical areas related to transmission of exogenous infection and the main components of the decontamination cycle. W, the AEW as a source; S, process control as a source; E, the endoscope as a source.

A review of case-to-case transmission of infections in the United States as a result of mainly reprocessing errors has been reported *(172)* and the resultant clinical and economic effects of infection demonstrated. The main type of endoscopy reported to transmit infection in this study was bronchoscopy. The reasons for the failure were processing faults, equipment compatibility problems, and AEW failure, and although there was no evidence of cross-transmission or infection, it was indicative of the need to be stringent in the application of policy guidelines.

In the United Kingdom, a study of decontamination failures was stimulated by an incident where an auxiliary channel of an endoscope had not been identified since the endoscope had been purchased and had been used undecontaminated on 1,300 patients. As a result of this incident, a look back of the 1,300 patients was instigated *(173)*, and an Endoscopy Task force was established to examine decontamination failures in the United Kingdom between 2003 and 2004 *(174)*. In the initial case, none of the 1,300 patients had any evidence of being infected with a bloodborne virus. A further eighteen incidents were investigated: eight incidents were failure to decontaminate auxiliary channels (incompatibility of endoscope with the AEW (4); manual cleaning only of the auxiliary channel (3); detergent not flushed down the channel (1); seven incidents were related to use of an AEW (4) in which the incorrect detergent had been used and in three there had been a fault of the machine alarm); in one incident the endoscope had only been cleaned manually; in another the reprocessing of a bronchoscope was incorrect and in the final incident a single use item was reused. In all these incidents, over 23,000 patients had been exposed. As a result of this investigation, an NHS National Decontamination Training Programme was established.

In another case, a faulty pump of an AEW used to inject disinfectant into the endoscope channels led to exposure of 236 individuals of which 197 patients were followed up. Despite the prevalence of HIV (23%), HCV (39%), and HBV (33%) in this cohort prior to exposure, analysis and testing of potential chain of transmission did not reveal any seroconversions despite there being acute cases of HIV, HCV, or HBV in the population *(175)*. A similar episode occurred with a failed AEW in France leading to the exposure of 72 patients of which 59 patients were followed up and there were no cases of seroconversion at 3 and 6 months *(176)*.

A further report noted an increase in *Pseudomonas* isolated from BAL specimens from 10% to 30%. In 414 patients, 39 developed respiratory infections or bacteremia and the cause of the failed decontamination was a loose biopsy port cap *(177)*. A similar problem with ill-fitting biopsy port caps led to contamination with *S. marcescens* and *P. aeruginosa* in 60 patients *(178)*.

In Britain, there is a particular concern that CJD may be transmitted on endoscopes, and this has led to interest in the efficacy of soil removal from endoscopes. Additionally, as current decontamination procedures incorporate the use of automated washer/disinfectors and as there have been pseudoinfections linked to recontamination of an adequately disinfected endoscope from a washer/disinfector, attention has focused on the provision of sterile water for the final rinse of the endoscope. One final event in Britain has been the removal of 2% glutaraldehyde from the marketplace due to problems with sensitization. This has led to the realization that monitoring of staff health is an important issue, as is the assessment of new disinfectants.

Flexible endoscopes are complex, reusable instruments that require unique consideration with respect to decontamination. In addition to the external surface of the endoscope, their internal channels are exposed to body fluids and other contaminants. In contrast to rigid endoscopes and some reusable accessories, flexible endoscopes are heat labile and cannot be autoclaved or washed ultrasonically. The main obstacle to effective decontamination of instruments is the complex internal structure of the channels and the inevitable damage that occurs to the channel lining, which then provides a source of microbes during the decontamination process (*179*) and the development of biofilm in the channels.

The scheme introduced by Spaulding *(180)* to separate medical devices into critical, semicritical, or noncritical categories depending on their relationship with mucosal surfaces or sterile body cavities does not adequately cover the issues raised by the development of complex, heat-sensitive endoscopes, some of which are introduced into body cavities. This has led to difficulties in sometimes choosing an adequate disinfection regimen and to controversy over the correct regimen for others. According to the Spaulding scheme, arthroscopes and laparoscopes, because they are critical items, should be sterilized. However, mostly these items are decontaminated by high-level disinfection, and the data show that infection following the use of these items is minimal. There is no evidence to suggest that sterilization of these items will reduce the rate of infection, and to do so would involve the use of either ethylene oxide or gas plasma.

Decontamination of Endoscopes

Decontamination is a process that renders the endoscope safe to use on another patient and consists of a mandatory cleaning step followed either by a disinfection or sterilization process. Cleaning removes many of the microorganisms as well as biologic fluids from the surfaces of the endoscope. Thorough cleaning with a detergent (neutral or enzymatic) is one of the main requirements for the effective reprocessing of endoscopes and accessories and is essential to maximize the effectiveness of the subsequent disinfection or sterilization step. Cleaning should comprise an initial mechanical cleaning of the endoscope once removed from the patient, followed by an obligatory clean in an automated washer or washer/disinfector followed by sterilization or high-level disinfection. The cleaning step should include all channels and valves as well as the insertion tube. The channels should be vigorously brushed and the brush sterilized or discarded *(181)*. The decontamination of reusable accessories was found to be cheaper in one study compared to the use of disposable accessories *(182)*; however, the advantage of using disposable accessories is the lower risk of cross-contamination and the avoidance of the need to track the accessories and record their use in the patient's notes.

Sterilization is defined as the destruction or removal of all viable microorganisms including spores. The Food and Drug Administration (FDA) defines sterilization as a 12-log

reduction in the bacterial spore count. The adherence of prions presents a special challenge. In practice, assessment of sterilization in the laboratory requires the killing of spores of *Bacillus subtilis* or *Bacillus stearothermophilus*. According to the Spaulding criteria, cystoscopes, arthroscopes, and laparoscopes should be sterile, but in practice high-level disinfection is frequently used. However, wherever possible, instruments that penetrate a sterile body cavity should be sterilized.

Disinfection is more difficult to define. It implies the removal or destruction of vegetative microorganisms excluding spores; the process reduces the bioload on the endoscope to a safe level, although this may vary with circumstances. In laboratory tests, the disinfectant must pass one of the National tests, which usually involves the reduction of a panel of vegetative microorganisms including viruses and mycobacteria by 10^5 in 5 minutes in either clean or dirty conditions, that is, without or with the addition of an organic soil.

Surface Contamination of Endoscopes

Microbiological Assessment of Endoscope Contamination: Surveillance Cultures The use of surveillance cultures is incorporated into many guidelines. However, some consider them to be onerous without any benefit and have suggested fewer sampling times and also rejecting the need to assess endotoxin levels. Routine surveillance cultures are of necessity *post hoc*, but if carried out regularly can identify potential problems and allow remedial action early. Samples are taken from specific locations in both the AEW and the ready-to-use endoscopes and cultured to assess the presence of viable bacteria and are used as an assessment of contamination levels.

After removal of the endoscope from a patient, it is inevitably contaminated with microorganisms and organic matter. An important consideration is how effectively the decontamination process reduces this contamination. In a study in Italy over a 2-year period, surveillance of contamination of gastroscopes demonstrated that 60.5% were contaminated on the outer surface and the channels were contaminated in 41.3% *(183)*. Similar figures were found for colonoscopes. The microorganisms most frequently isolated were *Pseudomonas* and *Staphylococcus* species. A study investigating the contamination of the air and water channels in endoscopes when they were either brushed or not brushed prior to reprocessing showed that the air channel in 42 endoscopes in both groups was not contaminated and the water channel in only one endoscope was contaminated in the group that was not brushed prior to reprocessing *(184)*. There was, however, organic matter present in both channels as determined by amido black staining. This was markedly reduced by effective brushing of the channels. Investigations using sterile, single-use biopsy forceps that had been passed through the channel of an endoscope at different stages of the decontamination cycle showed the effectiveness of the decontamination process *(185)*. The endoscopes were tested prior to use, directly postprocedure, after manual cleaning, and after manual cleaning and exposure to 2% glutaraldehyde, and showed overwhelming contamination with microorganisms immediately after removal from the patient. Microorganisms were present in 25% of cases after manual cleaning and 0% after exposure to glutaraldehyde.

In a study of 312 surveillance cultures taken between 1992 and 1994, 11.6% (15/129) of cultures were positive, the majority (93%) from duodenoscopes. However, between 1995 and 1997, 14.5% (18/124) were positive of which only one-third were from duodenoscopes and 55.6% were from upper GI endoscopes. The latter residual contamination was due to faulty cleaning by nontrained staff *(186)*.

A prospective study of the efficacy of decontamination by assessing ready-to-use endoscopes showed that both gastroscopes ($n = 1{,}376$, contamination rate 1.8%) and colonoscopes ($n = 987$, contamination rate 1.9%) were equally contaminated with oro/faecal flora in low numbers. HCV was detected on one occasion by using PCR on the washings. Significant findings were: (i) the more frequently used an endoscope, the more likely it was to be contaminated postdecontamination, (ii) colonoscopes used on patients with gastrointestinal disease were more likely to be contaminated postdecontamination, and (iii) of the culture-negative endoscopes, 40% were positive by PCR for coliforms—this as a surrogate marker for the presence of biofilm (187).

If surveillance cultures on endoscopes are performed, it is important that retrograde flushing of the channels is undertaken as the number of positive samples increases from 3–8% to 25–31% compared to antegrade flushing *(188)*. The cost of surveillance cultures has been analyzed over a 5-year period during which 2,374 screening tests (287 from the AEW, 631 from bronchoscopes for mycobacteria, and 1,456 from all endoscopes) were taken at a cost of 51,000 Eu. Only six samples were positive, and the authors suggest that process control would be more cost-effective than product control (189). The problem is, however, unlike autoclaving where temperature and pressure are monitored, the parameters for chemical disinfection are more insubstantial because of nonuniformity during the process and accuracy of values measured.

Alternative, more rapid methods to assess efficacy of decontamination have been suggested, by using ATP levels or utilizing PCR *(190)*. Using the assessment of ATP levels, in one study 109 endoscopes were sampled (from the surface of the insertion tube and the channel orifice at the tip, at various times during the reprocessing cycle (predecontamination, postmanual cleaning, postdisinfection, and during storage). Although the level of ATP (as detected by a luminometer) fell during reprocessing, there was a poor correlation between the luminometer reading and the level of bacterial contamination as assessed by culture. Also, the test only detected rather high levels of bacteria (10^5–10^6 CFU) *(191)*. An alternative study sampled 63 endoscopes from eight locations, and recognizing that the coefficient of variance of ATP was lower than that of culture, did not correlate luminometer values with colony counts but set benchmarked values for contamination. Using these values, the main sites of contamination were suction channels predisinfection and endoscope tips postdisinfection *(192)*.

Microorganisms may reside in endoscopes even though they have undergone disinfection, and one report detailed an outbreak associated with *Pseudomonas* where the channels were heavily soiled with biofilm *(193)*.

Biofilm Despite the adherence to guidelines for reprocessing endoscopes, biofilm will develop in the endoscope and the AEW. There is no simple recognized

way of detecting the presence of biofilm or of determining reduction or eradication of the biofilm after attempted removal. Techniques do exist for assessing the biofilm and the spatial distribution of bacteria therein by the use of florescent *in situ* hybridization and 2/3D image analysis, and these have been applied to medical specimens *(194,195)*. An alternative method to assess microbes in biofilm is by the use of Syto 13 nucleic acid stain *(196)*. Specific biofilm-detaching agents have been investigated, and in one study the surface covered by the biofilm was assessed by crystal violet and the quantification of microorganisms by culture. The agent, which was 0.5% solution containing minerals, phosphates, amylases, lipases and proteases, was more active than current detergents at removing biofilm *(197)*.

Infection Risk and Drying of the Endoscope Another area of dispute is the need for reprocessing after storage in which there are differences between National Guidelines. If the endoscopes are not dried, then there is a growth of *Pseudomonas* that could present a potential source of infection. However, if stored in a drying cabinet, then the number of microorganisms fell with time, whereas if not stored in a drying cabinet, the number remained stable or even increased *(198)*. In another study, all ready-to-use endoscopes were assessed before reprocessing and after overnight storage. Out of 194 endoscopes tested, the contamination rate was 15.5%, and the median time from reprocessing the previous day was 18 hours. The most frequent microorganism isolated was coagulase-negative staphylococci, and the authors suggested that reprocessing at the beginning of the list is omitted *(199)*. In a further study of the effect of drying on the bioburden of duodenoscopes, endoscopes that had been processed in an automatic washer were sampled through the suction channel at 2, 24, and 48 hours postdisinfection (200). Fifty percent of the endoscopes were contaminated mainly with *Pseudomonas* species and mainly after 48 hours. After an additional drying period was introduced, the contamination fell to 0%, thus emphasizing the importance of drying the endoscope, particularly the channels, prior to storage. Similar results were obtained in a different study *(201)*. In this case, the bioburden following removal of the endoscope was 7.0×10^9, which was reduced to 1.3×10^5 by cleaning. Gram-negative bacilli were the most numerous contaminants (*E. coli* and *Bacteroides*) found immediately after removal and *Pseudomonas* after cleaning. In addition to microbial contamination, the endoscopes are also contaminated with organic matter. An investigation of the suction channel from a variety of endoscopes (bronchoscope, duodenoscope, colonoscope) was assessed immediately after removal from the patient and after mechanical cleaning but prior to disinfection or sterilization (202). The highest level of soiling was not unexpectedly found immediately after removal from the patient with high levels of protein, sodium, hemoglobin, bilirubin, carbohydrate, endotoxin, and bacteria. Colonoscopes were the most contaminated. After mechanical cleaning, the levels of most contaminants fell by 5- to 10-fold with a 3- to 5-log reduction in bacterial contamination. Although cleaning does reduce the level of bioburden and organic contamination, a significant amount still remains.

Transmissible Spongiform Encephalopathies and Endoscopy

Transmissible spongiform encephalopathies (TSE) are a group of neurologic conditions that lead to dementia and are caused by a protein agent called a prion, PrP^{sc}, which is an abnormal variant of a normal cellular protein PrP^{c} *(203)*. Prion proteins are resistant to inactivation by a wide range of sterilization and disinfection processes. The best known of the TSEs is CJD and a modified variant (vCJD) that was first reported in the United Kingdom in 1996 and that has different clinical and histopathologic appearances. This new-variant CJD is thought to have been transmitted to the human population via food products from beef cattle that were suffering from bovine spongiform encephalopathy (BSE or mad cow disease). Cattle are thought to have contracted BSE by having been fed on processed animal feed. The prion protein of vCJD is found in a wide distribution in the body including muscle, blood, and lymphoid tissue. Patients with vCJD do not give a history of contact with neurological tissue (dura mater, growth hormone), and because they may be asymptomatic, present a special risk for endoscopic procedures *(204)*. Thus, they are of particular concern in endoscopy in which biopsies are taken from the small intestine where there is a high concentration of Peyer's patches or ear, nose, and throat (ENT) endoscopy involving the tonsillar tissue *(205)*. The European Society of Gastrointestinal Endoscopy and the UK government have issued advice on preventing transmission of vCJD by endoscopy (8,206). The particular concern is the contamination of endoscopes by proteins that are resistant to removal or destruction, because current routine methods of sterilization or high-level disinfection are incapable of inactivating the prion. This places a greater emphasis on the physical cleaning steps prior to sterilization/disinfection and an argument for the use of disposable accessories, particularly biopsy forceps (see also Chapters 47 and 80).

Methods to destroy the prion protein are too harsh (e.g., autoclaving, concentrated sodium hydroxide) to be used on endoscopes. Some processes can inactivate the prion protein but can be damaging to instruments, particularly flexible ones. Autoclaving at 134° to 137°C for 18 minutes may be effective in some cases. Immersion in 1 N sodium hydroxide or 20,000 parts per million (ppm) free chlorine or 96% formic acid for 1 hour will inactivate prions but in the routine situation are not practicable (see also Chapter 80).

Alternative methods of inactivation and removing prions have been advocated: (i) Vaporized hydrogen peroxide (1.5 mg/L at 25°C for 3 hours) in conjunction with an enzymatic agent (Klenzym—0.8% at 43°C for 5 minutes); (ii) an alkaline cleaner (HAMO 100 detergent—1.6% at 43°C for 15 minutes); and (iii) a phenolic agent (EnvironLpH—5% at 20°C for 30 minutes) can reduce infectivity by >5.6 log. Neither the enzymatic cleaner on its own nor 20% peracetic acid at 55°C for 12 minutes have any effect on reducing infectivity, but vaporized hydrogen peroxide, on its own, reduces infectivity by 66% *(207)*. Another study *(208)* demonstrated that proteinase K + Pronase + sodium dodecyl sulfate (incubation at 40°C for 60 minutes) effectively removed prion proteins from steel. This study, however, used a concentrated human vCJD preparation compared to a preparation of the scrapie agent used by Fichet et al. (*207*).

A combination of copper sulfate and hydrogen peroxide (500 μM/L/7.5% 30 minutes) is also effective in decontaminating prions, reducing them by >5.25 log and can be used on thermosensitive endoscopes. It is also active against a wide range of viruses (adeno and polio virus), bacteria (*Pseudomonas*, *Enterococcus*, and *Mycobacteria*), and fungi (*Candida*) (209). More recently, a broad-spectrum agent consisting of 0.2% SDS + 0.3% NaOH + 20% 1 propanol has been reported and reduces prion infectivity by >5.5 log and is also active against a wide range of bacteria, viruses, and fungi *(210)*.

Washer/Disinfectors and Sterile Water

Washer/disinfectors are now recommended as part of the decontamination process rather than a manual wash, as they are more effective and more consistent, and reduce the potential contact with sensitizing agents *(211,212)*. Owing to both the reports of outbreaks of pseudoinfection with gram-negative bacteria and mycobacteria and the importance of removing contaminating organic material from endoscopes, the key role of the washer/disinfector has become an issue. Guidelines have been promulgated on the purchase of washer/disinfectors and the criteria that should be taken into consideration (213). Essentially, the machine must clean, disinfect, and rinse all channels, provide a supply of sterile water for terminal rinsing, contain and filter disinfectant fumes, be equipped with a self-disinfection cycle that irrigates all channels of the washer/disinfector, and finally provide a readout that can be incorporated into the patient's notes.

A controversial issue is the provision of sterile water for the terminal rinsing of endoscopes. In the United Kingdom, HTM 2030 *(214)* provides precise details on the routine testing of washer/disinfectors to achieve sterile rinse water, even down to the level of allowable endotoxin. However, doubt has been expressed as to its importance, particularly with respect to gastrointestinal endoscopes *(215)*, and concerns have been expressed as to the suitability and practicality of the standards *(216)*. The concern is the ability to actually obtain sterile rinse water, given the difficulty in controlling the formation of biofilm, which makes eradication of the microorganism from the internal channels of the washer disinfector very difficult *(217)*. A study of a new washer/disinfector that was fitted with a water-filtration system to provide a supply of sterile water showed that only 24% of the samples of final rinse water were culture negative over a 6-month period *(218)*. In some cases, fungal contamination was found *(219)*. Current methods of trying to obtain sterile water for rinsing include the use of pharmaceutical grade water (which is expensive and impractical), filters, UV light, raised water temperature, and the addition of a biocide.

Decontamination Processes

Items penetrating a sterile body cavity ideally should be sterile, although, as discussed above, there is some controversy over this. Nevertheless, rigid instruments can be autoclaved. Alternative methods include ethylene oxide, gas plasma, and low-temperature steam/formaldehyde or prolonged insertion in a disinfectant. In a cost analysis of sterilization methods for endoscopic instruments, ethylene oxide was the most expensive with gas plasma next and formaldehyde the cheapest. However, plasma sterilization was the quickest with the fastest turnaround time *(220)*.

If instruments have been used on a case of CJD, the UK recommendations are that they should be incinerated or kept in reserve for future use on a known case of CJD. For operations on known CJD patients, disposable equipment should be used as far as possible. If there is some doubt whether a patient has CJD or not, the instrument or endoscope should be quarantined until a histological diagnosis is available.

High-Level Disinfection of Flexible Endoscopes

High-level disinfection of flexible endoscopes involves initial manual cleaning, followed by the use of an automated washer/disinfector that initially mechanically washes the endoscope followed by a period of immersion in a suitable disinfectant. Until recently, 2% glutaraldehyde has been the most commonly used disinfectant. Its advantages are a long in-use life, a broad spectrum of activity, and compatibility with equipment. Its disadvantages are its capacity to cause sensitization in healthcare staff and that it fixes proteins to surfaces. This latter characteristic is unwanted in the light of concerns about prions. Further, some reports have highlighted the emergence of glutaraldehyde-resistance mycobacterial species from the biofilm in washer/disinfectors *(221)*.

Several other agents are now available for high-level disinfection of flexible endoscopes *(222,223)*. Generally, they are more active than glutaraldehyde, providing shorter contact times, but they are also more corrosive to equipment, more expensive, and have a shorter in-use life.

Orthophthalaldehyde

Orthophthalaldehyde (OPA) is a substitute for 2% glutaraldehyde. It has a lower vapor pressure than glutaraldehyde and is thus less likely to cause adverse reactions in healthcare staff, although it does have the same sensitization capacity as glutaraldehyde to exacerbate dermatitis or asthma. It has a similar spectrum of activity to glutaraldehyde, inactivating a broad range of bacteria, viruses, and fungi. It is active against HIV and HBV and is more active than glutaraldehyde against mycobacterial species *(224)*. Its activity against *Cryptosporidia* is, like glutaraldehyde, poor *(225)*. It is similar to glutaraldehyde in its in-use life and in its capacity to fix proteins. An environmental survey of 17 decontamination rooms where OPA was used was undertaken. In some of the rooms, open trays of OPA were used and in others decontamination was with an AEW. As one might anticipate, the environmental levels of OPA were higher in the rooms with open trays compared to the AEW (1.43 ppb compared to 0.35 ppb, respectively). Occupational exposure was also highest in these rooms (0.66 ppb compared to 0.33 ppb). Disinfection-related complaints were skin complaints (10%), eye complaints (9%), and respiratory complaints (16%) *(226)*.

Peracetic Acid

Peracetic acid is available as a liquid disinfectant or as part of a decontamination system incorporating a washer/disinfector (Steris Corporation, Mentor, OH) *(227,228)*. Peracetic acid has a broad spectrum of activity and has greater mycobactericidal activity than glutaraldehyde and is active against glutaraldehyde-resistant mycobacteria *(227,229–232)*. In a comparison with ethylene oxide, peracetic acid

was more effective at decontaminating lumina *(233)*, and in a prospective study of contamination in bronchoscopes there was no incidence of cross-contamination in 220 procedures. Additionally, artificial contamination with *M. gordonae* was effectively inactivated by peracetic acid *(234)*. It has a shorter in-use life and must be replaced daily. It also is corrosive to flexible endoscopes, and washer/disinfectors have to be modified in order to use the disinfectant.

In situ generation of peracetic acid linked to an AEW was assessed by artificially contaminating endoscopes (externally and internally) with *P. aeruginosa*, a glutaraldehyde-resistant *M. chelonae*, spores of *Clostridium difficile*, a vancomycin-resistant *Enterococcus* sp, and an MRSA *(235)*. In all cases, the process reduced all microorganisms to undetectable levels. This is particularly encouraging for *C. difficile* spores as spores are, by their nature, more resistant to disinfectants than vegetative bacteria. Moreover, a review of the literature on the transmission of *C. difficile* by endoscopy did not reveal any case of transmission linked to endoscopy *(236)* as long as accepted guidelines are adhered to.

Chlorine Dioxide

Chlorine dioxide is an effective disinfectant that has a broad spectrum of activity including spores and mycobacteria and some modest activity against cysts of gastrointestinal pathogens such as *Giardia* and *Cryptosporidia (237–240)*. It is corrosive and gives off irritant fumes, and some endoscope manufacturers do not recommend that chlorine dioxide be used on their products.

Superoxidized Water

Superoxidized water is the anodal product of the electrolysis of a salt solution. It is vital that the parameters of the electrolysis are adhered to, as an effective agent is only produced by electrolysis of a 0.05% solution of saline at 950 mV. The disinfectant has a broad range of activity *(241,242)* but is inactivated in the presence of organic matter and adversely affects the polymer coating of some endoscopes. The polymer of endoscopes can be protected with a coating of Optiflex or Scope Protection System (Sterilox Technologies Inc., Mount Olive, NJ). Its active half-life is <24 hours and should be used only once and then discarded. The disinfectant could be ideally tailored to be a component of an endoscope/washer disinfector and be continuously produced at the point of use.

Hydrogen Peroxide

Hydrogen peroxide has also been advocated as a disinfectant for endoscopes. In this study, 2% accelerated hydrogen peroxide (AHP) was used, which is a stabilized form and has a shelf life of 2 weeks and provides high-level disinfection within 5 minutes but only has sterilizing activity after 6 hours. It is a broad acting biocide and hydrolyzes to water and oxygen with a reduced occupational sensitivity hazard *(243)*.

Other Agents

Alcohol is an effective antimicrobial against vegetative bacteria including mycobacteria and viruses except for enteroviruses *(237,244)*. Alcohol does not have activity against bacterial spores. Because of the risk of fire, alcohol is not used as a primary disinfectant for endoscopes, but it is useful for flushing the channels as it enhances the drying of the endoscope. Prolonged exposure to alcohol can damage the polymer of the endoscope as well as the lens cement. Other compounds such as iodophors, peroxygen compounds, and quaternary ammonium compounds have been used in the past to decontaminate endoscopes and have been associated with cross-contamination. Newer formulations of some of these agents have been developed, but few data are available on their efficacy, and they are currently not recommended for high-level disinfection of flexible endoscopes.

Gas Plasma Technology

The Sterrad sterilization system (Johnson & Johnson, Irvine, CA) is a low-temperature method that utilizes hydrogen peroxide converted to a plasma, in a vacuum, by MHz electromagnetic radiation. The equipment resembles an autoclave, and like an autoclave a vacuum is drawn prior to injection of hydrogen peroxide. This is then converted to a plasma, and the free radicals kill a wide range of microorganisms including spores and mycobacteria *(245–247)*. For sterilization of endoscopes that have narrow channels, special adaptors are required for the end of each channel, or the channels will not be effectively decontaminated *(241)*. An organic load can also lead to the failure of decontamination *(248)* (see also Chapters 80 and 81).

A comparison of the four models of Sterrad (ASP Johnson & Johnson) indicated that the 50, 100, 100S, and 200 models were all comparable in sterilizing endoscopes *(249)*.

CONCLUSION

Infective complications of endoscopy are relatively rare. Few problems of infection occur with operative endoscopes that are sterilized or given high-level disinfection even though they penetrate sterile sites. The majority of infections associated with percutaneous and operative endoscopes relate to endogenous infection. These are principally bacteremia, endocarditis, or abscesses.

Although the incidence of crossinfection is low, outbreaks related to contaminated endoscopes are still reported in the literature. The principal cause of these cases is failure to adhere to recognized and accepted guidelines, and in order to reduce the already low risk of transmission this is an issue that can be addressed by education and continuous refresher training. Another main concern relates to biofilm, whether in the automated reprocessor or in the endoscope, and this problem is being addressed by development of agents, which will remove biofilm. Another important consideration is the ability to remove prions from the endoscopes, and again, agents are being developed that can destroy and or remove them. A third reason for failed reprocessing of endoscopes is a manufacturing fault in the endoscope. This is a problem more difficult for the end user to address.

Important for monitoring the reprocessing cycle, surveillance cultures of the reprocessor and the endoscope will give early warning of a failure and allow remedial action. Additionally, the tracking of instruments, which should be mandatory in any process control, will facilitate epidemiological investigation.

High-level disinfectants that have replaced aldehydes in some countries are more rapidly acting than glutaraldehyde

but have a shorter shelf life and are more corrosive. The long-term effects of these new disinfectants on staff are unknown, reinforcing the need for continual staff monitoring of the long-term health effects. Similarly, long-term follow-up of patients in the community will provide a more accurate assessment of the burden of postendoscopy infection.

CHAPTER 63

Control of Infections Associated with Hemodialysis

Priti R. Patel, Nicola D. Thompson, and Matthew J. Arduino

In 2007, there were approximately 340,000 maintenance hemodialysis patients receiving care at some 5,240 outpatient hemodialysis facilities (1). This represents about 92% of the end-stage renal disease (ESRD) population receiving renal replacement therapy (hemodialysis, peritoneal dialysis, or renal transplantation) in the United States. Approximately 2,999 (1%) hemodialysis patients perform self or assisted therapy in their homes. The ESRD program is administered by the Centers for Medicare and Medicaid Services (CMS) of the Department of Health and Human Services and is the only Medicare entitlement that is based on the diagnosis of a medical condition.

Maintenance hemodialysis patients are at increased risk for infection because uremia is known to make patients with ESRD more susceptible to infectious agents through defects in cellular immunity, neutrophil function, and complement activation *(2,3)*. In addition, since the process requires vascular access for extended periods and an extracorporeal circuit in an environment where multiple patients receive hemodialysis concurrently, repeated opportunities exist for transmission of infectious agents. Transmission of infectious agents, directly or indirectly through contaminated devices, equipment, supplies, dialysis fluids, injectable medications, environmental surfaces, or hands of healthcare personnel have all been demonstrated. Furthermore, hemodialysis patients require frequent hospitalizations and surgery, which increases their opportunities for exposure to healthcare-associated infections. This chapter describes (a) the major infectious diseases that can be acquired in the maintenance dialysis center setting, (b) important epidemiologic and environmental microbiologic considerations, and (c) infection control strategies.

MICROBIAL CONTAMINANTS IN HEMODIALYSIS SYSTEMS

Hemodialysis systems are complex and have components that contain a variety of fluid pathways that transport water, dialysate, dialysate effluent, and blood. These systems can become colonized or contaminated with a variety of microorganisms. There are many situations where certain types of water bacteria (gram negatives, environmental mycobacteria, and other gram positives) and fungi can persist and actively multiply in aqueous environments associated with hemodialysis equipment. This can result in the production of massive concentrations of microorganisms, primarily gram-negative bacteria, which can directly or indirectly affect patients by septicemia or endotoxemia *(4–17)*.

Gram-negative water bacteria are commonly found in water supplies used for hemodialysis. These bacteria, in conjunction with fungi, can adhere to surfaces and form biofilms (glycocalyces), which are virtually impossible to eradicate *(6,18–24)*. Control strategies are designed not to eradicate bacteria but to prevent establishment of biofilms *(25)*, reduce bacterial concentration to relatively low levels, and prevent their regrowth.

Although certain genera of gram-negative water bacteria (e.g., *Burkholderia*, *Delftia*, *Enterobacter*, *Flavobacterium*, *Hydrogenophaga*, *Methylobacterium*, *Pseudomonas*, *Ralstonia*, *Serratia*, *Sphingomonas*, and *Stenotrophomonas*) are most commonly encountered, virtually any bacterium that can grow in water can be a problem in a hemodialysis unit. Several species of environmental mycobacteria may also contaminate water treatment systems, including *Mycobacterium chelonae*, *M. abscessus*, *M. fortuitum*, *M. gordonae*, *M. mucogenicum*, *M. scrofulaceum*, *M. kansasii*, *M. avium*, and *M. intracellulare*; these microorganisms do not contain bacterial endotoxin but are comparatively resistant to chemical germicides *(26–31)*. Some investigators have also reported isolating fungi from water used to prepare dialysate (*18*,*19*,32,*33*).

Gram-negative water bacteria can multiply even in water containing relatively small amounts of organic matter, such as water treated by distillation, softening, deionization, or reverse osmosis, reaching levels of 10^5 to 10^7 microorganisms/mL *(6)*; these levels are not associated with visible turbidity. When treated water is mixed with dialysis concentrate, the resulting dialysis fluid is a balanced salt solution and growth medium almost as rich in nutrients as conventional nutrient broth *(6,34)*. Gram-negative water bacteria growing in dialysis fluids can reach levels of 10^8 to 10^9 microorganisms/mL, without producing visible turbidity.

Bacterial growth in water used for hemodialysis depends on the types of water treatment system used, dialysate distribution systems, dialysis machine type, and

The findings and conclusions in this chapter are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

TABLE 63-1

Factors Influencing Microbial Contamination in Hemodialysis Systems

Factors	*Comments*
Water Supply (Water Source)	
Ground water	Contains endotoxin and bacteria
Surface water	Contains high levels of endotoxin, bacteria, and other microorganisms
Water treatment at the dialysis center	
None	Not recommended
Filtration	
Prefilter	Particular filter to protect equipment; does not remove microorganisms
Absolute filter (depth or membrane)	Removes bacteria but unless changed frequently or disinfected, bacteria will accumulate and grow through the filter; acts as a significant reservoir of bacteria and endotoxin
Granular activated carbon (GAC)	Removes organics and available chlorine or chloramine; significant reservoir of water bacteria and endotoxin
Water treatment devices	
Ion exchange (softener, deionization)	Softeners and deionizers remove cations and anions, contaminants from source water; significant reservoir for bacteria and endotoxin
Reverse osmosis	Removes bacteria, endotoxin, chemicals, and must be cleaned and disinfected; most systems employed for dialysis applications operate under high pressure
Ultraviolet germicidal irradiator	Kills most bacteria, but there is no residual, some UV-resistant bacteria can develop
Ultrafilter	Removes bacteria and endotoxin; operates on normal line pressure; can be positioned distal to storage tank and deionizer; must be disinfected or changed
Water and dialysate distribution system	
Distribution pipes	
Size	Oversized diameters and length decrease fluid flow and increases bacterial reservoir in the form of biofilms for both treated water and central delivery systems (bicarbonate concentrate or bicarbonate dialysate)
Materials	Pipe materials influence bacterial colonization and biofilm formation, as well as what types of chemical disinfectants can be used
Construction	Rough joints, dead ends, and unused branches can act as bacterial reservoirs
Elevation	Outlet taps should be located at highest elevation to prevent loss of disinfectant
Storage tanks	Generally undesirable because of large surface area and can act as a reservoir for water bacteria; a properly designed tank can minimize this risk
Dialysis machines	
Single pass	Disinfectant should have contact time with all parts of the machine that are in contact with treated water or dialysate
Recirculating single pass, or recirculating batch	Recirculating pumps and machine design allow for massive contamination levels if not properly disinfected. Overnight disinfection has been recommended

method of disinfection (Table 63-1) *(6,20,26,35,36)*. Each component is discussed separately below.

Microbial Contamination of Water

Water used for the production of dialysis fluid must be treated to remove chemical and microbial contaminants. The Association for the Advancement of Medical Instrumentation (AAMI) has published guidelines and recommended practices for the chemical and microbial quality of water used to prepare dialysis fluid and reprocess hemodialyzers (Table 63-2) (*37*,*38*,39). Some components of the water treatment system may allow for amplification of water bacteria (Table 63-1). For example, ion exchangers such as water softeners and deionizers do not remove endotoxin or microorganisms, and provide many sites for significant bacterial multiplication *(40–42)*. Granular activated carbon adsorption media (i.e., carbon filters) are used primarily to remove certain organic compounds and available chlorine (free and combined) from water *(43–45)*, but they also significantly increase the level of water bacteria, yeast, fungi, and endotoxins *(46–48)*.

A variety of filters are marketed to control bacterial contamination of water and dialysis fluids. Most are inadequate, especially if they are not either routinely disinfected or frequently changed. Particulate filters, commonly called prefilters, operate by depth filtration, which allows

TABLE 63-2

AAMI Microbial Quality Standards for Dialysis Fluids

	Microbial Bioburden		*Endotoxin*	
Type of Fluid	*Maximum Contaminant Level*	*Action Level*	*Maximum Contaminant Level*	*Action Level*
Water for all purposes	200 CFU/mL	50 CFU/mL	2 EU/mL	1 EU/mL
Conventional dialysate	200 CFU/mL	50 CFU/mL	2 EU/mL	1 EU/mL
Ultrapure dialysate	1 CFU/10 mL		0.03 EU/mL	
Dialysate for infusion	1CFU/1,000 L[a]		0.03 EU/mL	

[a]Compliance with a maximum bacterial level of 10^{-6} CFU/mL cannot be demonstrated by culturing, but by processes developed by the machine manufacturers.

larger particles to be trapped near the surface of the filter while smaller particles penetrate the larger open areas to be trapped nearer the center of the filter in the smaller openings. Depth filters remove larger particulates from the water but do not remove bacteria or endotoxin; these filters can become colonized with gram-negative water bacteria, resulting in higher levels of bacteria and endotoxin in the filter effluent than in the feed water. Absolute filters, including membrane types, remove 100% of particles above the stated pore sizes (≥1 μm) and temporarily remove bacteria from passing water; however, some of these filters tend to clog, and gram-negative water bacteria can "grow through" the filter matrix and colonize downstream surfaces within a few days. Further, absolute filters do not reduce levels of endotoxin in the effluent water. All of these filters should be changed regularly in accordance with the manufacturer's directions and disinfected in the same manner and at the same time as the rest of the water distribution system.

Ultraviolet germicidal irradiation (UVGI) is sometimes used to reduce microbial contamination in water, but the use of UVGI has some special considerations. The lamp should be appropriately sized for the flow rate of water passing through the device, and the energy output should be monitored to insure effectiveness of the lamp. Manufacturers of the lamp may require a routine replacement schedule. Some bacterial populations may develop resistance to UVGI *(49)*. In recirculating dialysis distribution systems, repeated exposure to UVGI is used to ensure adequate disinfection; however, this approach allows for selection of UVGI-resistant microorganisms. In addition, bacterial endotoxins are not affected.

Reverse osmosis is an effective water treatment modality that is used in more than 97% of US hemodialysis centers, either alone or in combination with deionization *(50)*. Reverse osmosis possesses the singular advantage of being able to remove a variety of substances including microorganisms and endotoxin from supply water based primarily on particle size and adsorption to the membrane. However, low numbers of microorganisms may penetrate the membrane or by other means (leaks around seals) colonize downstream portions of the water distribution system. Consequently, the reverse osmosis unit must be disinfected routinely.

A water treatment system that produces chemically adequate water while avoiding high levels of microbial contamination is highly recommended. The components in a typical water system should include (a) prefilters, (b) a water softener, (c) carbon adsorption tanks (at least two in series), (d) a particulate filter or absolute filter (to protect the reverse osmosis membrane), and (e) a reverse osmosis unit. If one includes a deionization unit as a polisher (postreverse osmosis unit) or a storage tank, the final component in the system should be an ultrafilter to remove both microorganisms and endotoxin *(51,52)*. As the incoming tap water passes through the system components, it becomes more chemically pure, but the level of microbial contamination increases, which is why the use of reverse osmosis and ultrafiltration is important. Additional components or processes may be included in the pretreatment chain (Table 63-1) depending on the pH, potable water disinfectant, and the chemical quality of the incoming municipal water *(52)*. If the system is adequately disinfected and properly maintained, the microbial content of water should be well within the recommended limits.

Distribution Systems

Water that has passed through the water distribution system (product water) is then distributed to individual dialysis machines, where it is combined with dialysate concentrates (bicarbonate and acid concentrates), and to a reprocessing area if a facility reprocesses hemodialyzers for reuse. It may also be combined with concentrates at a central location where the resulting dialysis fluid is supplied to the individual machines. Plastic pipe (most often schedule 80 polyvinyl chloride) is then used to distribute water or dialysis fluids to the dialysis machines. Distribution systems should include the use of a loop-based system and no dead end pipes (dead legs). Outlets to dialysis machines should have a relatively short path with the least amount of fittings and the use of valves with minimal dead space. Voids, dead ends, and large surface areas serve as sites for microbial colonization. Large-diameter pipes decrease fluid velocity and increase the wetted surface area available for microbial colonization *(34,53)*, and long pipe runs increase the available surface area for colonization; therefore, both of these situations should be avoided if possible. Gram-negative water bacteria in fluids remaining in pipes overnight can rapidly multiply and colonize wetted surfaces of the distribution system, producing microbial populations and endotoxin in quantities proportional to the total volume of the surface area. Such colonization results in the formation of protective biofilm, which is difficult to remove and protects the bacteria and other microorganisms from disinfection (54).

Routine disinfection of the water or dialysate distribution system should be performed on a regular basis so that the microbial quality of the fluids is within the acceptable standards range. The minimum frequency of disinfection may be at least monthly *(34,51)*. However, AAMI standards and recommended practices are community consensus standards, and do not specify a schedule for disinfection other than to suggest that routine disinfection be conducted. In many instances, microbiologic monitoring can be used to determine the frequency of testing and disinfection of the distribution system *(51,52)*.

To prevent disinfectant from draining from pipes by gravity before adequate contact time, distribution systems should be designed with all taps at equal elevation and at the highest point of the system. Furthermore, the system should be free of rough joints, dead ends, oversized pipes, and long pipe runs. Fluid trapped in such stagnant areas can serve as reservoirs for bacteria and fungi that later contaminate the rest of the distribution system *(55)*.

Storage tanks greatly increase the volume of fluid and surface area of the distribution system. If used, these should be designed with a conical-shaped bottom so that water exits the storage tank at its lowest point (and allows the tank to be drained), fitted with a tight sealing lid, and equipped with a spray head, and possesses an air vent containing a bacteriologic filter. Storage tanks should also be routinely cleaned, disinfected, and drained. In order to remove biofilm, use of strong oxidizers may aid in stripping biofilm from surfaces; however, physical scrubbing of the inner surfaces of the tank may be necessary. When using a storage tank, an ultrafilter should be incorporated before water is pumped into the distribution system *(51,52)*.

Hemodialysis Machines

In the 1970s, most dialysis machines were of the recirculating or recirculating single-pass type; their design contributed to relatively high levels of gram-negative bacterial contamination in dialysis fluid. Currently, virtually all dialysis machines in the United States are single-pass machines. Single-pass machines tend to respond to adequate cleaning and disinfection procedures and, in general, have lower levels of bacterial contamination than do recirculating machines. Levels of contamination in single-pass machines depend primarily on the microbiologic quality of the incoming water and the method of machine disinfection *(6,51)*.

Disinfection of Hemodialysis Systems Routine disinfection of isolated components of the dialysis system frequently produces inadequate results. Consequently, the total dialysis system (water treatment system, distribution system, and dialysis machine) should be included in the disinfection procedure.

Disinfection of dialysis systems usually employs sodium hypochlorite solutions, hydrogen peroxide solutions, commercially available peracetic or peroxyacetic acid (PAA) disinfectants, ozone, and in some systems hot-water pasteurization. Sodium hypochlorite solutions are convenient and effective in most parts of the dialysis system when used at the manufacturer's recommended concentrations. Also, the test for residual available chlorine to confirm adequate rinsing is simple and sensitive. However, because chlorine is corrosive, it is usually rinsed from the system after a relatively short dwell time of 20 to 30 minutes. The rinse water invariably contains microorganisms that can multiply to significant levels if the system is permitted to stand overnight *(34)*. Therefore, disinfection with chlorine-based disinfectants is best performed before the start of the first patient treatment session rather than at the end of the day. In centers dialyzing patients in multiple shifts with either batch or recirculating hemodialysis machines, it may be reasonable to disinfect with chlorine-based disinfectants between shifts and with another disinfectant or process (e.g., PAA) at the end of the day. Single-pass machines may be disinfected at the end or beginning of the treatment day.

Aqueous formaldehyde, PAA, hydrogen peroxide, or glutaraldehyde solutions can produce good disinfection results *(20,56,57)*. These products are not as corrosive as hypochlorite solutions and can be allowed to dwell in the system for long periods of time when the system is not in operation. However, formaldehyde, which has good penetrating power, is considered an environmental hazard and potential carcinogen and has irritating qualities that may be objectionable to staff *(58)*. The U.S. Environmental Protection Agency (EPA) has also limited the amount of formaldehyde that can be discharged into the wastewater stream, which has drastically reduced the use of this chemical in the dialysis community as a disinfectant. PAA and hypochlorite-based products are commercially available and are designed for use with dialysis machines when used according to the manufacturers' labeled instructions. Glutaraldehyde use is limited because it is considered to be a sensitizer and may pose a risk to healthcare workers; it is more frequently used for dialyzer reprocessing and only in a minority (<4%) of facilities in the United States (59).

Some dialysis systems (both water treatment and distribution systems, some hemodialysis machines) use hot-water disinfection (pasteurization) for control of microbial contamination. In this type of system, water heated to >80°C (176°F) is passed either through the water distribution system and the fluid pathway of the hemodialysis machine, or just through the hemodialysis machine at the end of the day. These hot-water systems are excellent for controlling microbial contamination.

Monitoring of Water and Dialysis fluid

Microbiologic and endotoxin standards for water and dialysis fluids were originally based on the results of culture assays performed during epidemiologic investigations *(34,35,52,53,60)*. However, as knowledge improved about the long-term effect of dialysis fluids on patient inflammatory responses, the recommended microbial standards have been revised (Table 63-2) (*37,38,*39). There is increasing evidence that the microbial quality of hemodialysis fluids plays a role in the chronic inflammatory response syndrome impacting anemia management, serum albumin level, and rate of loss of residual renal function in dialysis patients (61,*62–66*,67,*68*,69,*70–75*). Increasing data suggest that use of ultrapure water and dialysate would benefit maintenance dialysis patients. However, there have been no randomized controlled studies to evaluate and confirm the impact on health outcomes.

Water samples should be collected from a source as close as possible to where water enters the dialysate proportioning unit. In most cases, this is the tap (not from the hose

connecting the tap to the dialysis machine) at the dialysis station, but may also be a sampling port on the hemodialysis machine. Water samples should be collected at least monthly (more frequent monitoring may be necessary) from several locations within the dialysis unit. Samples should also be collected after any modifications or maintenance has been made to the water treatment system or water distribution system. Dialysate samples should be collected during or at the end of the dialysis treatment from a source close to where the dialysis fluid either enters or leaves the dialyzer. Dialysate samples should be collected at least monthly from a representative number of dialysis machines. Samples of water and dialysate should also be collected whenever pyrogenic reactions are suspected *(53)*. If centers reprocess hemodialyzers for reuse on the same patient, water used to prepare disinfectant and rinse dialyzers should also be assayed monthly. The maximum contaminant levels are 200 CFU/mL and 2 EU/mL (Table 63-2) (*37*,*38*,39).

Specimens should be assayed within 30 minutes of collection or refrigerated at 4°C and assayed within 24 hours of collection. Conventional laboratory methods, such as the spread plate or membrane filter technique, can be used. Calibrated loops should not be used because they sample only a small volume, are inaccurate, and often do not have the sensitivity to detect the current action or maximum contamination limits. Blood and chocolate agar media should not be used because the microorganisms have adapted to nutrient-poor environments and thus require specific media designed for the recovery of microorganisms from water. In addition, microorganisms that are found in bicarbonate dialysis fluids require a small amount of sodium chloride. Consequently, to cover both conditions needed, trypticase soy agar (soybean casein digest agar) is currently recommended; however, standard methods agar, plate count agar, or tryptose glucose yeast extract agar may also be used (39,*76*,*77*). The assay should be quantitative, not qualitative, and a standard technique for enumeration should be used. Colonies should be counted after 48 hours of incubation at 36°C (39,*51–53*,*78*,*79*). Total viable counts are the objective of plate counts. Endotoxin testing should be conducted using either the *Limulus* amebocyte lysate assay, Gel-clot method, or one of the kinetic methods.

In an outbreak investigation, the assay methods may need to be both qualitative and quantitative; detection of nontuberculous mycobacteria and, in some cases, fungi in water or dialysate may be desirable. In such instances, plates should be incubated for 5 to 14 days at both 36°C and 28°C to 30°C.

DIALYSIS-ASSOCIATED PYROGENIC REACTIONS

Gram-negative bacterial contamination of dialysis water or components of the dialysis system (water, dialysate, water used for reprocessing) can cause pyrogenic reactions. Pyrogenic reactions are defined as objective chills (visible rigors), fever (oral temperature ≥37.8°C [100°F]), or both in a patient who was afebrile (oral temperature up to 37°C [98.6°F]) and had no signs or symptoms of an infection before the start of the dialysis treatment session *(11,80,81)*. Depending on the type of dialysis system and the level of contamination, fever and chills may start 1 to 5 hours after dialysis has been initiated. Other symptoms may include hypotension, headache, myalgia, nausea, and vomiting. Pyrogenic reactions can occur without bacteremia; because presenting signs and symptoms cannot differentiate bacteremia from pyrogenic reactions, blood cultures are necessary.

During 1990 to 2002, an annual average of 20% to 24% of the hemodialysis centers in the United States reported at least one pyrogenic reaction in the absence of septicemia in patients undergoing maintenance dialysis (*50*,59,*82–90*). Pyrogenic reactions can result from passage of bacterial endotoxin (lipopolysaccharide [LPS]) or other substances in the dialysate across the dialyzer membrane (*91–94*,95) or from the transmembrane stimulation of cytokine production in the patient's blood by endotoxin in the dialysate *(92,96–98)*. In other instances, endotoxin can enter directly into the bloodstream with fluids that are contaminated with gram-negative bacteria *(99)*. The signs and symptoms of pyrogenic reactions without bacteremia generally abate within a few hours after the dialysis has been stopped. If gram-negative sepsis is associated, fever and chills may persist, and hypotension is more refractory to therapy *(4,99)*.

When a pyrogenic reaction occurs, the following steps are usually recommended: (a) careful physical examination of the patient to rule out other causes of chills and fever (e.g., pneumonia, vascular access infection, urinary tract infection); (b) blood cultures, and other diagnostic tests (e.g., chest radiograph), and other cultures as clinically indicated; (c) collection of dialysate from the dialyzer (downstream side) for quantitative and qualitative microbiological culture; and (d) recording of the incident in a log or other permanent record. Determining the cause of these episodes is important, because they may be the first indication of a remediable problem.

The higher the level of bacteria or endotoxin in dialysis fluid, the higher is the probability that the bacteria or their products will pass through the dialyzer membrane, thus producing bacteremia or a pyrogenic reaction by stimulating cytokine production in a patient. In an outbreak of febrile reactions among patients undergoing hemodialysis, attack rates were directly proportional to the level of microbial contamination in the dialysis fluid *(6)*. Prospective studies also demonstrated a lower pyrogenic reaction rate among patients when they underwent dialysis with dialysis fluid from which most bacteria had been removed, compared to patients who underwent dialysis with fluid that was highly contaminated (mean 19,000 CFU/mL) *(5,80,100)*.

Among nine outbreaks of bacteremia, fungemia, and pyrogenic reactions not related to dialyzer reuse investigated by the Centers for Disease Control and Prevention (CDC), inadequate disinfection of the water distribution system or dialysis machines was implicated in seven (Table 63-3) *(4,9,55,101–105)*. The most recent outbreaks occurred at dialysis centers using dialysis machines that had a port (waste-handling option or WHO port) that allowed disposal of the extracorporeal circuit priming fluids. One-way check valves in the WHO had not been maintained, checked for competency, or disinfected as recommended, thus allowing backflow from the effluent dialysate path into and contamination of the port and the attached blood line (103,*104*,*105*).

TABLE 63-3

Outbreaks of Dialysis-Associated Illnesses Investigated by the Centers for Disease Control and Prevention, 1975–2008

Description	*Cause(s) of Outbreak*	*Corrective Measure(s) Recommended*	*Reference*
Bacteremia, Fungemia, or Pyrogenic Reactions not Related to Dialyzer Reuse			
Pyrogenic reactions in 49 patients	Untreated city water contained high levels of endotoxin	Install a reverse osmosis system	*(4)*
Pyrogenic reactions in 45 patients	Inadequate disinfection of the fluid distribution system	Increase disinfection frequency and contact time of the disinfectant	(55)
Pyrogenic reactions in 14 patients; 2 bacteremia; 1 death	Reverse osmosis water storage tank contaminated with bacteria	Remove or properly maintain and disinfect the storage tank	*(35)*
Pyrogenic reactions in six patients; seven bacteremias	Inadequate disinfection of water distribution system and dialysis machines; improper microbial assay procedure	Use correct microbial assay procedures; disinfect water treatment system and dialysis machines following manufacturer's recommended procedures	*(301)*
Bacteremia in 35 patients with central venous catheters (CVCs)	CVCs used as facilities primary vascular access; median duration of infected catheters was 311 d; improper aseptic techniques	Uses CVCs when only absolutely necessary for vascular access; use appropriate aseptic technique when inserting and performing routine catheter care	*(302)*
Three pyrogenic reactions and 10 bacteremias in patients treated on machines with a port for disposal of dialyzer priming fluid (waste-handling option or WHO port)	Incompetent check valves allowing backflow of fluid from the waste side of the machine into attached blood tubing; bacterial contamination of the WHO	Routine disinfection and maintenance of the dialysis machine including the WHO; check competency of WHO prior to patient treatment	(103)
Bacteremia in 10 patients treated on machines with WHO port	Incompetent backflow to allow backflow from dialysate effluent side of the machine in the WHO port and attached bloodlines	Routine maintenance, disinfection, and check for valve competence of the WHO port	*(104)*
Outbreak of pyrogenic reactions and gram-negative bacteremia in 11 patients	Water distribution system and machines were not routinely disinfected according to manufacturer's recommendations. Water and dialysate samples were cultured using a calibrated loop and blood agar plates—results were always as no growth	Disinfect machines according to manufacturer's recommendations and include reverse osmosis water distribution system in the weekly disinfection schedule; microbiological assay should be performed via membrane filtration or spread plate using Trypticase Soy agar	*(9)*
Phialemonium curvatum access infections in four dialysis patients; two of these patients died of systemic disease	Observations at the facility noted some irregularities in site prep for needle insertion. All affected patients had synthetic grafts. One environmental sample was positive for *P. curvatum* (condensate pan of HVAC serving the unit)	Review infection control practices and clean and disinfect HVAC system where water accumulated. Perform surveillance on all patients	*(303)*
Phialemonium curvatum blood stream infections in two patients	Water system and dialysis machines with WHO ports not routinely maintained; water system contained dead legs and lab used wrong assays	Conduct routine maintenance and disinfection of machines and WHO ports; redesign water system to eliminate dead legs; have a routine schedule for disinfection of the water system	*(105)*
Bacteremia/Pyrogenic Reactions Related to Dialyzer Reprocessing			
Mycobacterial infections in 27 patients	Inadequate concentration of dialyzer disinfectant	Increase formaldehyde concentration used to disinfect dialyzers to 4%	*(27)*
Mycobacterial infections in five high-flux dialysis patients; two deaths	Inadequate concentration of dialyzer disinfectant and inadequate disinfection of water treatment system	Use higher concentration of peracetic acid for reprocessing dialyzers and follow manufacturers labeled recommendations; Increase frequency of disinfecting the water treatment system	*(304)*

(*Continued*)

TABLE 63-3

Outbreaks of Dialysis-Associated Illnesses Investigated by the Centers for Disease Control and Prevention, 1975–2008 (*Continued*)

Description	*Cause(s) of Outbreak*	*Corrective Measure(s) Recommended*	*Reference*
Bacteremia in six patients	Inadequate concentration of dialyzer disinfectant; water used to reprocess dialyzers did not meet AAMI standards	Use AAMI quality water; insure proper germicide concentration in the dialyzer	CDC unpublished data
Bacteremia and pyrogenic reactions in six patients	Dialyzer disinfectant diluted to improper concentration	Use disinfectant at the manufacturers' recommended dilution and verify concentration	*(79)*
Bacteremia and pyrogenic reactions in six patients	Inadequate mixing of dialyzer disinfectant	Thoroughly mix disinfectant and verify proper concentration	*(10)*
Bacteremia in 33 patients at two dialysis centers	Dialyzer disinfectant created holes in the dialyzer membrane	Change disinfectant (product was withdrawn from the market place by the manufacturer)	*(305,306)*
Bacteremia in six patients; all blood isolates had similar plasmid profiles	Dialyzers were contaminated during removal and cleaning of headers with gauze; staff not routinely changing gloves; dialyzers not reprocessed for several hours after disassembly and cleaning	Do not use gauze or similar material to remove clots from header; change gloves frequently; process dialyzers after rinsing and cleaning	*(307)*
Pyrogenic reactions in three high-flux dialysis patients	Dialyzer reprocessed with two disinfectants; water for reuse did not meet AAMI standards	Do not disinfect dialyzers with multiple germicides; more frequent disinfection of water treatment system and conduct routine environmental monitoring of water for reuse	*(308)*
Pyrogenic reactions in 14 high-flux dialysis patients; one death	Dialyzers rinsed with city (tap) water containing high levels of endotoxin; water used to reprocess dialyzers did not meet AAMI standards	Do not rinse or reprocess dialyzers with tap water; use AAMI quality water for rinsing and preparing dialyzer disinfectant	*(309)*
Pyrogenic reactions in 18 patients	Dialyzers rinsed with city (tap) water containing high levels of endotoxin; water used to reprocess dialyzers did not meet AAMI standards	Do not rinse or reprocess dialyzers with tap water; Use AAMI quality water for rinsing and preparing dialyzer disinfectant	*(11)*
Pyrogenic reactions in 22 patients	Water for reuse did not meet AAMI standards; improper microbiological technique was used on samples collected for monthly monitoring	Use the recommended assay procedure for analysis of water and dialysate; disinfect water distribution system	*(8)*
Bacteremia and candidemia among patients in seven dialysis units (MN and CA)	Dialyzers were not reprocessed in a timely manner; some dialyzers refrigerated for extended periods of time before reprocessing; Company recently made changes to header cleaning protocol	Reprocess dialyzers as soon as possible; follow joint CDC and dialyzer reprocessing equipment and disinfectant manufacturer guidance for cleaning and disinfecting headers of dialyzer	CDC unpublished data
Transmission of Viral Agents			
26 patients seroconvert to HBsAg+ during a 10-mo period	Leakage of coil dialyzer membranes and use of recirculating bath dialysis machines	Separation of HBsAg+ patients and equipment from all other patients	*(181)*
19 patients and 1 staff member seroconvert to HBsAg+ during a 14-mo period	No specific cause determined; false-positive HBsAg results caused some susceptible patients to be dialyzed with infected patients	Laboratory confirmation of HBsAg+ results; strict adherence to glove use and use of separate equipment for HBsAg+ patients	*(310)*
24 patients and 6 staff seroconverted to HBsAg+ during a 10-mo period	Staff not wearing gloves; surfaces not properly disinfected; improper handling of needles/sharps resulting in many staff needlestick injuries	Separation of HBsAg+ patients and equipment from susceptible patients; proper precautions by staff (e.g., gloves; handling of needles and sharps)	*(181)*

TABLE 63-3

Outbreaks of Dialysis-Associated Illnesses Investigated by the Centers for Disease Control and Prevention, 1975–2008 (*Continued*)

Description	*Cause(s) of Outbreak*	*Corrective Measure(s) Recommended*	*Reference*
13 patients and 1 staff member seroconvert to HBsAg+ during a 1-mo period	Extrinsic contamination of intravenous medication being prepared adjacent to an area where blood samples were handled	Separate medication preparation area from area where blood processing for diagnostic tests is performed	*(186)*
Eight patients seroconverted to HBsAg+ during a 5-mo period	Extrinsic contamination of multidose medication vial shared by HBsAg+ and HBV-susceptible patients	No sharing of supplies, equipment, and medications between patients	(CDC, unpublished data)
Seven patients seroconverted to HBsAg+ during a 3-mo period	Same staff caring for HBsAg+ and HBV-susceptible patients	Separation of HBsAg+ patients from other patients; same staff should not care for HBsAg+ and HBV susceptible patients	*(181)*
Eight patients seroconverted to HBsAg+ during 1 mo	Not consistently using external pressure transducer protectors; same staff members cared for both HBsAg+ patients and HBV-susceptible patients	Use external pressure transducer protectors and replace after each use; same staff members should not care for HBV-infected and susceptible patients on the same shift	*(300)*
14 patients seroconvert to HBsAg+ during a 6-wk period	Failure to review results of admission and monthly HBsAg testing; inconsistent hand washing and use of gloves; adjacent clean and contaminated areas; <20% of patients vaccinated	Proper infection control precautions for dialysis facilities; routine review of serologic testing; hepatitis B vaccination of all patients	*(184)*
Seven patients on the same shift seroconvert to HBsAg+ during a 2-mo period	Same staff members cared for HBsAg+ and HBV-susceptible patients on the same shift; common medication and supply carts were moved between stations, and multidose vials were shared; no patients vaccinated	Dedicated staff for HBsAg+ patients; no sharing of equipment or supplies between any patients; centralized medication and supply areas; hepatitis B vaccination of all patients	*(184)*
Four patients seroconverted to HBsAg+ during a 3-mo period	Transmission appeared to occur during hospitalization at an acute-care facility; no patients vaccinated	Hepatitis B vaccination of all patients	*(184)*
11 patients seroconverted to HBsAg+ during a 3-mo period	Staff, equipment, and supplies were shared between HBsAg+ and HBV-susceptible patients; no patients were vaccinated	Dedicated staff for HBsAg+; no sharing of medication or supplies between any patients; hepatitis B vaccination of all patients	*(184)*
Two patients converted to HBsAg+ during a 4-mo period	Same staff cared for HBsAg+ and HBV-susceptible patients; no patients vaccinated	Hepatitis B vaccination of all patients; dedicate staff for the care of HBsAg+ patients; no sharing of supplies or medication between patients	*(184)*
Six patients converted to HBsAg+ during a 6-mo period	Transmission occur during hospitalization at an acute-care facility; same staff cared for HBsAg+ and HBV-susceptible patients; no patients vaccinated	Hepatitis B vaccination of all patients; review HBsAg status of chronic hemodialysis patients who require hospitalization; no sharing of equipment, supplies, or medication between patients	*(187)*
36 patients with liver enzyme elevations consistent with Non-A, Non-B hepatitis	Environmental contamination with blood	Utilize proper precautions (e.g., gloving of staff; environmental cleaning); monthly liver function tests (e.g., ALT)	*(308)*
35 patients with elevated liver enzymes consistent with Non-A, Non-B hepatitis during a 22-mo period; 82% of probable cases were anti-HCV+	Inconsistent use of infection control precautions, especially hand washing	Strict compliance to aseptic technique and dialysis center precautions	*(311)*

(*Continued*)

TABLE 63-3

Outbreaks of Dialysis-Associated Illnesses Investigated by the Centers for Disease Control and Prevention, 1975–2008 (*Continued*)

Description	*Cause(s) of Outbreak*	*Corrective Measure(s) Recommended*	*Reference*
HCV infection developed in 7/40 (18%) HCV-susceptible patients; shift specific attack rates of 29–36%	Multidose vials left on top of machine and used for multiple patients; routine cleaning and disinfection of surfaces and equipment between patients not routinely done; arterial line for draining prime dripped into a bucket that was not routinely cleaned or disinfected between patients	Strict compliance with infection control precautions for all dialysis patients; routine HCV testing	(*252*,253)
HCV infection developed in 5/61 (8%) HCV-susceptible patients	Sharing of equipment and supplies between chronically infected and susceptible patients; gloves not routinely used; clean and contaminated areas not separated	Strict compliance with infection control precautions for all dialysis patients; CDC does not recommend separation of equipment/supplies between HCV-infected and susceptible patients	(*252*,253)
HCV infection developed in 3/23 (13%) HCV-susceptible patients; shift specific attack rate 27%	Supply carts moved between stations and contained both clean and blood-contaminated items; medications prepared in the same area used for disposal of used injection equipment	Strict compliance with infection control precautions for all dialysis patients	(*252*,253)
HCV infection developed in 7/52 (13%) HCV-susceptible patients; shift specific attack rates 4–21%	Medication cart moved between stations and contained both clean and blood-contaminated items; single-dose medication vials used for multiple patients; cleaning and disinfection of surfaces and equipment between patients not routinely done	Strict compliance with infection control precautions for all dialysis patients	(*252*,253)
HCV infection developed in 9/90 (10%) HCV-susceptible patients.	Cleaning and disinfection of surfaces and equipment between patients not routinely done; gloves not routinely used; medications not stored in separate clean area	Strict compliance with infection control precautions for all dialysis patients; routine HCV testing	*(254)*
HCV infection developed in 8/107 (7.5%) HCV-susceptible patients	Poor medication handling and infusion practices	Proper training of personnel on aseptic technique and compliance with infection control precautions for dialysis setting	*(255)*

Hemodialyzer Reuse

From 1976 to 1997, the percentage of maintenance dialysis centers in the United States that reported reuse of disposable hollow-fiber dialyzers increased steadily; the largest increase (126%) occurred during the period between 1976 and 1982, when percentage of facilities reprocessing dialyzers increased from 18% to 43%, and the percentage of facilities reprocessing peaked at 82% in 1997 (*90*). However, the percentage of facilities reporting reusing dialyzers had declined to 63% in 2002 (59). This decline was primarily driven by a large dialysis chain's decision to discontinue the practice of reuse and to only use single-use dialyzers.

In 1986, AAMI Standards for reprocessing hemodialyzers *(106)* were adopted by the United States Public Health Service (USPHS) and were incorporated into regulation by the CMS. In general, dialyzer reuse appears to be safe if performed according to strict and established protocols *(22)*. In the United States, dialyzer reuse has not been associated with the transmission of blood-borne pathogens such as hepatitis B virus (HBV), hepatitis C virus (HCV), or human immunodeficiency virus (HIV) *(107,108)*. However, the reprocessing of dialyzers has been associated with pyrogenic reactions *(107)*. These adverse events may be the result of the use of incorrect concentrations of chemical germicides, failure to maintain appropriate water quality, or improper cleaning (e.g., header cleaning practices). Manual reprocessing of dialyzers that does not include a test for membrane integrity, such as a pressure-leak test, may fail to detect membrane defects and may be a cause of both pyrogenic reactions and bacteremia *(107,108)*.

The procedures used to reprocess hemodialyzers generally constitute high-level disinfection rather than sterilization *(22,109)*. There are several liquid chemical germicides that have been used for high-level disinfection of dialyzers. Formaldehyde is a chemical solution from chemical supply houses and is not specifically formulated for dialyzer disinfection. There are commercially available chemical germicides specifically formulated for this purpose (e.g., PAA, chlorine-, and glutaraldehyde-based products) that are approved by the U.S. Food and Drug Administration (FDA) as sterilants or high-level disinfectants for reprocessing hemodialyzers. During the period between 1983 and 2002, the percentage of centers using formaldehyde for reprocessing dialyzers decreased from 94% to 20%, while the percentage using PAA increased from 5% to 72%. Only a minority of facilities (4%) reported using either glutaraldehyde or heat disinfection (59).

In 1983, most centers used 2% aqueous formaldehyde with a contact time of approximately 36 hours to disinfect dialyzers *(110)*. In 1982, a dialysis center using this regimen experienced an outbreak of infections caused by nontuberculous mycobacteria *(27)*. It was subsequently shown that the 2% formaldehyde regimen was not effective against nontuberculous mycobacteria. Rather, a regimen of 4% formaldehyde with a minimum contact time of 24 hours was required to inactive high numbers of these microorganisms and was recommended as the minimum solution for reprocessing dialyzers *(22,107,109)*. A similar outbreak of systemic mycobacterial infections in five hemodialysis patients, resulting in two deaths, occurred when high-flux dialyzers were contaminated with *M. abscessus* during manual reprocessing and disinfected with a commercial disinfectant prepared at a concentration that did not ensure complete inactivation of mycobacteria *(28)*. These two outbreaks of infections in dialysis patients emphasize the need to use dialyzer disinfectants at concentrations that are effective against more chemically resistant microorganisms, such as mycobacteria.

Outbreaks of pyrogenic reactions have often resulted from reprocessing hemodialyzers with water that did not meet AAMI standards (Table 63-3). In most instances, the water used to rinse dialyzers or to prepare the dialyzer disinfectants exceeded the allowable AAMI microbial or endotoxin standards, because the water distribution system was not disinfected frequently, the disinfectant was improperly prepared, or routine microbial assays were improperly performed.

High-Flux Dialysis and Bicarbonate Dialysate

High-flux dialysis uses dialyzer membranes with hydraulic permeability that is 5 to 10 times greater than conventional dialyzer membranes. There has been concern that bacteria or more likely endotoxin in the dialysate may penetrate these highly permeable membranes.

Another concern is that high-flux membranes require the use of bicarbonate rather than acetate dialysate. Acetate dialysate is prepared from a single concentrate with a high salt molarity (4.8 M) that does not support the growth of most bacteria. Bicarbonate dialysate, however, must be prepared from two concentrates, an acid concentrate (acetic acid) with a pH of 2.8 that is not conducive to microbial growth and a bicarbonate concentrate with a relatively neutral pH and a salt molarity of 1.2 M. Because the bicarbonate concentrate will support rapid growth *(79)*, its use can increase microbial and endotoxin concentrations in the dialysate and theoretically may contribute to an increase in pyrogenic reactions, especially when used during high-flux dialysis.

Some of the concern appeared justified by results of surveillance data during the 1990s showing a significant association between use of high-flux dialysis and reporting of pyrogenic reactions among patients during dialysis *(111)*. However, a prospective study of pyrogenic reactions in patients receiving more than 27,000 conventional, high-efficiency, or high-flux dialysis treatments with dialysate containing high concentrations of bacteria and endotoxin found no association between pyrogenic reactions and the type of dialysis treatment *(5)*. Although there seem to be conflicting data on the relationship between high-flux dialysis and pyrogenic reactions, centers providing high-flux dialysis should ensure that dialysate meets AAMI microbial standards (Table 63-2).

BACTERIAL AND FUNGAL INFECTIONS

Annual adjusted mortality rates among hemodialysis patients are between 203.3 (patients on dialysis <2 years) and 245.1 (patients on dialysis >5 years) deaths per 1,000 patient years at risk (1). Infection is the second leading cause of mortality in this patient population (32.7/1,000 patient years at risk); septicemia is the leading cause of infectious mortality *(112)*. In a number of published studies that have evaluated bacterial infections in outpatient hemodialysis, bacteremia occurred in 0.6% to 1.7% of patients per month and vascular access infections (with or without bacteremia) in 1.3% to 7.2% of patients per month (*113–123*). A review of four studies published during 2002 estimated that 1.8% of hemodialysis patients have bacteremia each month, amounting to at least 50,000 cases nationally per year *(124)*.

Because of the importance of bacterial infections in hemodialysis patients, CDC initiated a voluntary ongoing surveillance project in 1999 in which all US maintenance hemodialysis centers are eligible to enroll *(122)*. Bloodstream infections as well as hospital admissions and intravenous antimicrobial administrations are counted. Since infections treated with outpatient oral antimicrobials are excluded, this system likely only detects more severe infections. During 2006, 32 dialysis centers reported data on 28,047 patient months (125). Bloodstream infection rates per 100 patient months were reported as 0.5 (AV fistula), 0.9 (grafts), 4.2 (cuffed catheters), and 27.1 (temporary catheters) (125). Previous infection rates per 100 patient months in hemodialysis patients have been reported as 3.2 for all vascular access infections (including access infections both with and without bacteremia), 1.8 for vascular access–associated bacteremia, 1.3 for wound infections not related to the vascular access, 0.8 for pneumonias, and 0.3 for urinary tract infection. Among patients with fistulas or grafts, wounds were the most common site for infection *(122)*. Among patients with hemodialysis catheters, infections of the vascular access site were the most common site for infection (*122*,125).

In a study of 27 French hemodialysis centers, 28% of 230 infections in hemodialysis patients involved the vascular access, whereas 25% involved the lung, 23% the urinary tract, 9% the skin and soft tissues, and 15% other or unknown sites *(119)*. Thirty-three percent of infections involved either the vascular access site or were bacteremia of unknown origin, many of which might have been caused by unrecognized access infection or colonization. Thus, the vascular access site was the most common site for infection but accounted for only one-third of infections.

Pathogens causing infection can either be exogenous (i.e., acquired from contaminated dialysis fluids, injectable medication, hands of healthcare workers, equipment, etc.) or endogenous (i.e., caused by invasion of bacteria present in or on the patient). Exogenous pathogens have caused numerous outbreaks, most of which resulted from inadequate dialyzer reprocessing procedures (e.g., contaminated water or inadequate disinfectant concentration) or inadequate disinfection and maintenance of the water treatment and distribution system. During 1995 to 2006, five outbreaks were traced to contamination of the WHO port on one type of dialysis machine (103,*104*,*105*, *126–128*). Recommendations to prevent such outbreaks are published elsewhere *(129)*. The endogenous infection category includes pathogens such as *Staphylococcus aureus*, which cause a greater number of intravascular infections. An increase in incidence of these infections above baseline might be less likely to be recognized as an outbreak, but is often due to suboptimal infection control practices and aseptic technique.

Contaminated medication vials are also a source of bacterial infection for patients. In 1999, an outbreak of *Serratia liquefaciens* bloodstream infections and pyrogenic reactions among hemodialysis patients was traced to contamination of vials of erythropoietin. These vials, which were intended for single use, were contaminated by repeated puncture to obtain additional doses and by pooling of residual medication into a common vial (130).

Vascular Access Infections

Access site infections are particularly important, because they can cause disseminated bacteremia or loss of the vascular access. Local signs of vascular access infection include erythema, warmth, induration, swelling, tenderness, break down of skin, loculated fluid, and purulent exudates *(116,117,122,131)*. In the CDC surveillance project, the initial reported rate of access-associated bacteremia per 100 patient months was 1.8 overall and varied by access type: 0.25 for fistulas, 0.53 for grafts, 4.8 for permanent (tunneled, cuffed) catheters and 8.7 for temporary (nontunneled, noncuffed) catheters *(122)*. A more recent 10-year summary of the data collected through this surveillance system (1995–2005) reported that the overall vascular access infection rate was 3.1 per 100 patient months and varied from 0.6 for fistulas to 10.1 for temporary catheters *(132)*.

Vascular access infections are caused (in descending order of frequency) by *S. aureus* (32–53% of cases), coagulase-negative staphylococci (CNS: 20–32% of cases), gram-negative bacilli (10–18%), gram-positive cocci other than staphylococci (including enterococci; 10–12%), and fungi (<1%) *(122,132)*. The proportion of infections caused by *S. aureus* is higher among patients with fistulas or grafts, and the proportion caused by CNS is higher among patients dialyzed through catheters (125).

The primary risk factor for access-related infection is access type, with catheters having the highest risk for infection, grafts having intermediate risk, and native arteriovenous (AV) fistulas having the lowest risk (*115*,*116*,120,125,*132*). Other potential risk factors for vascular access infection include (a) location of the access in the lower extremity; (b) recent vascular access surgery; (c) trauma, hematoma, dermatitis, or scratching over the access site; (d) poor patient hygiene; (e) poor needle insertion technique; (f) older age; (g) diabetes mellitus; (h) immune suppression; (i) iron overload, (j) intravenous drug use; and (k) the chronic inflammatory state (*116*,*117*,*133–138*).

Based on relative risk of both infectious and noninfectious complications, it is recommended that native AV fistulas be used more commonly and hemodialysis catheters less commonly; a goal of no more than 10% of patients maintained with permanent catheters is recommended *(139–143)*. To minimize infectious complications, patients should be referred early for creation of an implanted access, thereby decreasing the time they are dialyzed through a temporary catheter. Additionally, catheters should be used only in patients for whom a permanent access is impossible. During the period between 1995 and 2002, the percentage of patients dialyzed through fistulas increased from 22% to 33%, with most of the increase occurring after 1999 (59). During the same period, use of grafts decreased from 65% to 42%, and the use of catheters increased from 13% to 33%. However, data from CMS's ESRD Clinical Performance Measures (CPM) project indicate that 75% of new dialysis patients begin dialysis using a hemodialysis catheter; in 2006, 93.1% of patients with no pre-ESRD nephrologist care started dialysis with a catheter, while 76.9% of patients who had seen a nephrologist for 1 year or less and 65.2% of patients who saw a nephrologist for 1 year or more started dialysis with a catheter *(112)*.

Recommendations for preventing vascular access infections have been developed by the National Kidney Foundation *(139–143)* and CDC (144). Selected recommendations for preventing hemodialysis catheter-associated infections include (a) not using antimicrobial prophylaxis before insertion or during use of the catheter; (b) not routinely replacing the catheter (in the absence of infection); (c) using sterile technique (cap, mask, sterile gown, large sterile drape, and sterile gloves) during catheter insertion; (d) limiting use of noncuffed catheters to 3 to 4 weeks; (e) using the catheter solely for hemodialysis unless there is no other alternative; (f) restricting catheter manipulation and dressing changes to trained personnel; (g) replacing catheter-site dressing at each dialysis session or if damp, loose, or soiled; (h) disinfecting skin before catheter insertion and dressing changes (a chlorhexidine-based preparation is preferred); and (i) ensuring catheter-site care is compatible with catheter material (144,*145*).

There have been a number of studies looking at the use of various antimicrobial locks to prevent catheter-related bloodstream infection (CRBSI) among hemodialysis patients. Two recent meta-analyses of these studies concluded that (a) antimicrobial catheter lock solutions reduce CRBSIs and the (b) use of these lock solutions should be

considered in routine clinical practice in conjunction with other prevention modalities (146,147). However, the long-term consequence of using antibiotics routinely in catheter locking solutions is unknown. While results of these studies appear to be promising, CDC does not recommend the routine use of antimicrobial lock solutions for hemodialysis catheters, because antimicrobial use can lead to antimicrobial resistance (144,148).

The Infectious Diseases Society of America (IDSA) previously recommended treatment with nasal mupirocin in hemodialysis patients who were documented *S. aureus* carriers, had catheter-related blood stream infections with *S. aureus*, and continued to need a hemodialysis catheter *(149,150)*. However, updated IDSA guidance, published in 2009 *(151)*, no longer recommends intranasal antimicrobial/decolonization based on studies suggesting this is not effective in preventing infections and concerns about emerging resistance. In CRBSI due to *S. aureus*, *Pseudomonas* spp., or *Candida* spp., the catheter should always be removed and a temporary catheter inserted at another site. If no alternative sites are present, the infected catheter should be exchanged over guidewire. Once blood cultures are negative, a new permanent catheter maybe placed. For uncomplicated CRBSI due to pathogens other than *S. aureus, P. aeruginosa, Bacillus* spp., *Micrococcus* spp., proprionibacteria, mycobacteria, or fungi, treatment should be attempted without catheter removal, with the use of both systemic and antimicrobial lock therapy *(151)*.

Pneumonia

Hospital admissions for pneumonia have been declining overall for dialysis patients; however, pneumonia rates for hemodialysis patients are 1.8 to 2.2 times those of transplant recipients or peritoneal dialysis patients. Hospital admissions for pneumonia are also 102% higher among hemodialysis patients when compared to the general population (1). In one study of a group of 433 dialysis patients over a 9-year period, pneumonia was the third most common type of infection (following vascular access infections and infections below the knee) and accounted for 13% of all infections *(152)*. One- and five-year survival probabilities are 0.55 and 0.17, respectively. Pneumonia is common among hemodialysis patients, carries a poor prognosis, and is often the antecedent to cardiovascular death *(153,154)*. A recent analysis of new hemodialysis patients found pneumonia to be associated with chronic obstructive pulmonary disease, inability to transfer or ambulate, hemodialysis as initial therapy, advanced age (≥75 years), and body mass index ≥30 kg/m *(154)*.

Antimicrobial-Resistant Bacteria

Hemodialysis patients have been in the forefront of the epidemic of antimicrobial resistance, especially vancomycin resistance. One of the earliest reports of vancomycin-resistant enterococci (VRE) was from a renal unit in London, United Kingdom, in 1988 *(155)*. The prevalence of VRE stool colonization among dialysis patients has varied from 1.5% among pediatric dialysis patients in the United Kingdom *(156)* and 2.4% of adult dialysis patients at three dialysis centers in Indianapolis, IN *(157)*, to 9.5% at a University hospital in Baltimore, MD *(158)*. In one center with a prevalence of 9%, (10/111) three patients developed VRE infections in the following year *(159)*. It appears that hospital acquisition of VRE contributes substantially to the increasing prevalence of VRE in the chronic hemodialysis patient population *(160)*. Among enterococci causing blood stream infections in hemodialysis patients, up to 26% have been reported to be resistant to vancomycin *(122,161,162)*.

Vancomycin resistance in staphylococci has also been reported in dialysis patients. Five of the first six US patients infected with vancomycin intermediate-resistant *S. aureus* were receiving either peritoneal dialysis or hemodialysis *(163,164)*. Additionally, the first patient found to be infected with a fully vancomycin-resistant *S. aureus* (VRSA) strain was a maintenance hemodialysis patient; the VRSA was isolated from a diabetic foot wound and from a temporary catheter exit site *(165)*. In the period between 2002 and 2009, there was a total of nine cases of VRSA identified in the United States; three of the case patients had chronic renal failure and two were hemodialysis patients *(166,167)*. Five of the seven VRSA cases occurred in southeastern Michigan and contained a plasmid carrying the *vanA* gene, which had been donated from a VRE *(168)*.

The percentage of hemodialysis facilities reporting methicillin-resistant *S. aureus* (MRSA) infection or colonization among patients in the facility has increased from 40% in 1995 *(89)* to 76% in 2002 (59). In a recent CDC study assessing invasive MRSA infection among dialysis patients, the incidence was found to be 42.5 cases/1,000 population (169), 100-fold higher than the incidence of these infections in the general population (0.2–0.4 cases/1,000 population). Additionally, a study in the United Kingdom of vascular access infections found that MRSA was responsible for 30% of all catheter-related infections *(170)*.

In order to combat emerging antimicrobial resistance in dialysis patients, one must understand the transmission kinetics involved with each microorganism. For certain patients, including those infected with MRSA or VRE, Contact Precautions are used in the hospital setting (171). However, for several reasons, Contact Precautions are not recommended in hemodialysis centers for patients infected or colonized with pathogenic bacteria. First, although contact transmission of pathogenic bacteria is well documented in hospitals, similar transmission has not been well documented in hemodialysis centers. At least one study demonstrated that significant transmission and acquisition of pathogens occurred when hemodialysis patients were admitted to the acute-care setting, while similar transmission was not documented in the hemodialysis centers *(160)*. However, it is possible that transmission of pathogenic bacteria in dialysis centers is less likely to be recognized, possibly because it occurs less frequently than in the acute-care setting or results in undetected colonization rather than overt infection. Furthermore, because dialysis patients are frequently hospitalized, determining whether transmission occurred in either the outpatient or inpatient setting may be difficult. A second reason that Contact Precautions are not recommended in outpatient maintenance hemodialysis centers is that contamination of the patient's skin, bedclothes, and environmental surfaces with pathogenic bacteria is less likely to occur in these settings (where patients may spend up to 9–15 hours per week), as compared to hospitals (where patients spend 24 hours a day). Finally, the routine use of infection control practices

recommended for hemodialysis facilities, which are more stringent than the Standard Precautions routinely used in hospitals, should prevent transmission of these pathogens.

HEPATITIS B VIRUS

Recommendations for the control of HBV transmission in hemodialysis settings were first published in 1977 *(172)* and, by 1980, their implementation was associated with a sharp decrease in the incidence of HBV infection among both patients and staff members *(173,174)*. In 1982, the hepatitis B vaccine was recommended for all susceptible hemodialysis patients and staff members *(175)*.

Epidemiology

During the early 1970s, HBV infection was endemic in maintenance hemodialysis units and outbreaks were common. Subsequently, the incidence and prevalence of HBV infection among maintenance hemodialysis patients in the United States have declined dramatically, and by 2002, were 0.12% and 1%, respectively (59). Newly acquired HBV infections were reported by 2.8% of U.S. hemodialysis centers, and 27.3% of centers reported one or more patients with chronic HBV infection (59).

The chronically infected patient provides a reservoir for maintenance of the disease in the population and is central to the epidemiology of HBV transmission. HBV is transmitted by percutaneous (i.e., puncture through the skin) or mucosal (direct contact with mucus membranes) exposure to infectious blood or body fluids. All hepatitis B surface antigen (HBsAg)-positive persons who are also positive for hepatitis B e antigen (HBeAg) have an extraordinary level of HBV circulating in their blood, approximately 10^8 to 10^9 virions/mL *(176,177)*. With virus titers this high in blood, body fluids containing serum or blood may also contain high levels of HBV and are potentially infectious. Furthermore, HBV at titers of 10^2 to 10^3 virions/mL can be present on environmental surfaces in the absence of any visible blood and still cause infection *(176,178–180)*.

HBV is relatively stable in the environment and has been shown to remain viable for at least 7 days on environmental surfaces at room temperature *(176,178,180)*. HBsAg has been detected in dialysis facilities on hemostats, scissors, dialysis machine control panels, and door knobs *(180)*. Thus, blood-contaminated surfaces that are not routinely cleaned and disinfected represent a source for HBV transmission, even in the absence of visible blood. Dialysis staff members can transfer virus from these surfaces to susceptible patients, resulting in patient infection *(176,178,180)*.

Most HBV outbreaks among hemodialysis patients (Table 63-3) were caused by cross-contamination to patients via (a) environmental surfaces, supplies (e.g., hemostats, clamps, etc.), or equipment that were not routinely cleaned and disinfected after each use; (b) multiple-dose vials or intravenous solutions that were not used exclusively for one patient; (c) medications for injections that were prepared adjacent to areas where blood samples were handled; and (d) staff members who simultaneously provided care for both infected (HBsAg-positive) patients and susceptible patients *(99,181–187)*. Once the factors that promote HBV transmission among hemodialysis patients were identified, recommendations for control were published in 1977 *(172)*. These recommendations included: (a) serologic screening of patients for HBV infection, including monthly testing of all susceptible patients for HBsAg; (b) isolation of all HBsAg-positive patients in a separate room during hemodialysis; (c) assignment of staff members to HBsAg-positive patients and not to HBV-susceptible patients during the same shift; (d) assignment of dialysis equipment to HBsAg-positive patients that is not shared with HBV-susceptible patients; (e) assignment of a supply tray to each patient (regardless of serological status); (f) cleaning and disinfection of nondisposable items (e.g., hemostats, clamps, scissors) before use on another patient; (g) glove use whenever patient or hemodialysis equipment is touched and glove changes between each patient (and station); and (h) routine cleaning and disinfection of equipment and environmental surfaces.

The segregation of HBsAg-positive patients and their equipment from HBV-susceptible patients resulted in a 70% to 80% reduction in the incidence of HBV infections among hemodialysis patients *(174,188,189)*. The success of isolation practices in preventing transmission of HBV infection is linked to other infection control practices, including routine serologic surveillance and routine cleaning and disinfection. Frequent serologic testing for HBsAg detects patients recently infected with HBV so that isolation procedures can be implemented before cross-contamination can occur. Environmental control by routine cleaning and disinfection procedures reduces the opportunity for cross-contamination, either directly from environmental surfaces or indirectly by hands of personnel.

Since the publication of recommendations for HBV control, HBV infection outbreaks have continued to occur in maintenance hemodialysis centers (*179–187*,*190*, *191*,192,*193*,*194*). Investigations of these and other outbreaks have documented failures to use recommended infection control practices, including (a) failure to routinely screen patients for HBsAg or routinely review results of testing to identify infected patients; (b) assignment of staff members to the simultaneous care of both infected and susceptible patients; (c) sharing of supplies, particularly multidose medication vials, among patients *(184)*. In addition, annual surveillance data from the United States in 2002 found only about 56% of hemodialysis patients have received the hepatitis B vaccine *(58)*. A more recent survey of 1,052 dialysis facilities found that 62% of patients had received three or more doses of the vaccine series *(195)*. Factors among maintenance hemodialysis patients for acquiring HBV infection include the presence of ≥1 HBV-infected patient in the hemodialysis facility who was not isolated, as well as a vaccination rate <50% among patients *(82)*.

HBV infection among maintenance hemodialysis patients has also been associated with hemodialysis provided in the acute-care setting *(184,187)*. Transmission appears to stem from the sharing of staff members, multiple-dose medication vials, and other supplies and equipment among patients with chronic HBV infection and susceptible patients. These episodes were recognized only after the patients had returned to their outpatient dialysis facilities, and routine HBsAg testing was resumed. Transmission from HBV-infected maintenance hemodialysis

patients to patients undergoing hemodialysis procedures for acute renal failure has not been documented, possibly because these patients are dialyzed for short durations and have limited exposure. However, such transmission could go unrecognized because acute renal failure patients are unlikely to be tested for HBV infection.

Other risk factors for acquiring HBV infection include injection drug use, sexual and household exposure to HBV-infected contacts, exposure to multiple sexual partners, male homosexual activity, and perinatal exposure. Dialysis patients should be educated about these and other risks and, for those patients with active HBV infection (HBsAg positive), informed that their sexual partners and household contacts should be vaccinated *(196–198)*.

Screening and Diagnostic Tests

Several well-defined antigen-antibody systems are associated with HBV infection, including HBsAg and antibody to HBsAg (anti-HBs); hepatitis B core antigen (HBcAg) and antibody to HBcAg (anti-HBc); and hepatitis B e antigen (HBeAg) and antibody to HBeAg (anti-HBe). Serologic assays are commercially available for all of these except for HBcAg because no free HBcAg circulates in the blood. One or more of these serologic markers are present during different phases of HBV infection (Table 63-4) *(199)*. HBV infection can also be detected using qualitative or quantitative tests for HBV DNA *(200,201)*; these tests are most commonly used for HBV-infected patients being managed with antiviral therapy *(202–206)*.

The presence of HBsAg is indicative of ongoing HBV infection and potential infectiousness. In newly infected individuals, HBsAg is present in serum on average 30 days (range 6–60 days) after exposure to HBV and persists for variable periods. Transient HBsAg positivity (typically lasting <18 days, but documented for up to 28 days) can be detected in some patients following vaccination and is clinically insignificant *(207–210)*. Anti-HBc develops in all HBV infections, appearing at the onset of symptoms or liver test abnormalities in acute HBV infection, rising rapidly to high levels, and persisting for life. Acute or recently acquired infection can be distinguished by presence of the immunoglobulin M (IgM) class of anti-HBc, which persists for approximately 6 months. However, persons with exacerbations of chronic HBV infection can test positive for IgM anti-HBc *(211)*. The positive predictive value of the IgM anti-HBc test is low in asymptomatic persons; therefore, its use for diagnosis of acute hepatitis B should be limited to persons with evidence of acute hepatitis, an epidemiologic link to a person with HBV infection *(212)*, or to assess an isolated anti-HBc positive (i.e., anti-HBc positive, HBsAg negative, and anti-HBs negative) test result in a hemodialysis patient (171).

In individuals who recover from HBV infection, HBsAg and HBV DNA are usually eliminated from the blood, and anti-HBs appears. The persistence of anti-HBs indicates immunity from HBV infection. After recovery from natural infection, most individuals will be positive for both total anti-HBc and anti-HBs, whereas only anti-HBs develops in patients who are successfully vaccinated against hepatitis B. Individuals who do not recover from HBV infection and become chronically infected remain HBsAg positive (and total anti-HBc positive) and HBV DNA positive, although a small proportion of these patients (0.3–2%) eventually clear HBsAg and might develop anti-HBs *(213)*.

In some individuals, the only HBV serologic marker detected is total anti-HBc (i.e., isolated anti-HBc). Among most asymptomatic persons in the United States tested for HBV infection, an average of 2% (range: <0.1–6%) test positive for anti-HBc *(214)*; among injecting drug users, however, the rate is 24% to 28% *(215,216)*. In general, the frequency of isolated anti-HBc is directly related to the prevalence of previous HBV infection in the population and can have several explanations. This pattern can occur after HBV infection among individuals who have recovered but whose anti-HBs levels have waned; or among individuals who have failed to develop anti-HBs. Individuals in the latter category include those who circulate HBsAg at levels not detected by commercial serological assays

TABLE 63-4

Interpretation of Serological Test Results for Hepatitis B Virus Infection

Serologic Markers				
HBsAg[a]	*Total Anti-HBc*[b]	*IgMc Anti-HB*[c]	*Anti-HBs*[d]	*Interpretation*
–	–	–	–	Susceptible, never infected
+	–	–	–	Acute infection, early incubation[e]

[c]Immunoglobulin M.
[d]Antibody to hepatitis B surface antigen.
[e]Transient HbsAg positivity (typically lasting ≤18 d) might be detected in some patients following vaccination.

(low-level chronic HBV infection). However, HBV DNA has been detected in <10% of these individuals with isolated total anti-HBc. In many persons with isolated anti-HBc, the result appears to be a false-positive reaction (217). Data from several studies have demonstrated that a primary anti-HBs response develops in most of these individuals after a three-dose series of hepatitis B vaccine *(218,219)*. Infected individuals who are positive only for anti-HBc are unlikely to be infectious to others except under unusual circumstances in which they are the source for direct percutaneous exposures to large quantities of virus (e.g., blood transfusion or organ transplant) *(220–222)*.

A third antigen, HBeAg, can be detected in the serum of individuals with acute or chronic HBV infection. The presence of HBeAg correlates with viral replication and high levels of virus (i.e., high infectivity). Anti-HBe correlates with loss of replicating virus and with lower levels of virus. However, all HBsAg-positive patients should be considered potentially infectious, regardless of their HBeAg or anti-HBe status.

HEPATITIS C VIRUS

HCV is a single-stranded RNA virus that belongs to the family *Flaviviridae (223)*. HCV was first recognized as non-A, non-B hepatitis virus (NANBH) in 1974 until cloning of the etiologic agent in 1989 *(224–226)*. HCV is another efficiently transmitted blood-borne viral pathogen in the dialysis setting. It is not as efficiently transmitted as HBV in this setting, and recommended infection control practices prevent transmission among hemodialysis patients without the need for isolation (171,*227–229*). Despite recommendations for HCV control in hemodialysis centers, both outbreaks and new acquisition of HCV infection continue to occur among maintenance hemodialysis patients.

Epidemiology

Data are limited on the current incidence and prevalence of HCV infection among maintenance hemodialysis patients. In 2002, 63% of dialysis centers tested patients for anti-HCV. In the facilities that tested for anti-HCV, the incidence rate in 2002 was 0.34%, and the prevalence of anti-HCV among patients was 7.8%, a decrease of 25.7% since 1995 (59). Only 11.5% of dialysis facilities reported having at least one patient who became anti-HCV positive during 2002 (i.e., tested positive in 2002 but has previously been anti-HCV negative). Higher incidence rates have been reported from cohort studies of dialysis patients in the United States (<1–3%), Japan (<2%), and Europe (3–15%) *(230–237)*. Higher prevalence rates (10% to 85%) also have been reported in individual facilities in the United States and other countries *(233,237–242)*.

HCV is moderately stable in the environment, and can survive drying and environmental exposure to room temperature for at least 16 hours *(243)*. HCV is most efficiently transmitted by direct percutaneous exposure to blood, and like HBV, the chronically infected patient is central to the epidemiology of HCV transmission. Risk factors associated with HCV infection among hemodialysis patients include blood transfusions from unscreened donors, low staff-to-patient ratios, and years on dialysis *(230,236,244–248)*. The number of years on dialysis is the major risk factor that is independently associated with higher rates of HCV infection. As the time patients spent on dialysis increased, their prevalence of HCV infection increased from an average of 12% for patients receiving dialysis <5 years to an average of 37% for patients receiving dialysis >5 years (*240,247–252*,253).

These studies, as well as investigations of dialysis-associated outbreaks of HCV infection, indicate that HCV transmission most likely occurs because of inadequate infection control practices (253). During 1998 to 2009, eight outbreaks of HCV infection were reported among patients in chronic hemodialysis centers in the United States; six of these were investigated by CDC (253,*254–256*). In these outbreaks, multiple transmissions of HCV occurred during periods ranging from 6 months to 7 years (attack rates: 7.5–17.5%), and HCV seroconversions were associated with receiving dialysis immediately after or at a machine adjacent to a chronically infected patient. Multiple opportunities for cross-contamination among patients were observed, including (a) equipment and supplies that were not cleaned and disinfected between patient use; (b) use of common medication carts to prepare and distribute medications at patient stations; (c) sharing of multiple-dose vials, which were placed at patients' stations on the top of the hemodialysis machine; (d) contaminated priming buckets that were not routinely changed or cleaned and disinfected between patients; (e) machine surfaces that were not routinely cleaned and disinfected between patients; and (f) blood spills that were not cleaned up promptly. In one of these outbreaks, there were multiple infections clustered among patients treated on the same dialysis shift (attack rate of 27%), suggesting a common exposure event. Multiple opportunities for cross-contamination from chronically infected patients also were observed in the unit where this outbreak occurred. In particular, supply carts were moved from station to station and contained both clean supplies and blood-contaminated items, including small biohazard containers, sharps disposal boxes, and used vacutainers containing patients' blood.

Other risk factors for acquiring HCV infection include injection drug use, exposure to an HCV-infected sexual partner or household contact, and perinatal exposure *(257–259)*. The efficiency of transmission via sexual or household exposure to infected contacts is low *(259)*, and the magnitude of risk and the circumstances under which these exposures result in transmission are not well defined.

Screening and Diagnostic Tests

FDA-licensed or approved anti-HCV screening tests used in the United States include three immunoassays: two enzyme immunoassays (EIA) and one enhanced chemiluminescence immunoassay (CIA) *(260–263)*. Although no true confirmatory test has been developed, supplemental tests for specificity are available. The FDA-licensed or FDA-approved supplemental tests include a serologic anti-HCV assay, the strip immunoblot assay (Chiron RIBA HCV 3.0 SIA, Chiron Corp., Emeryville, CA), and a nucleic acid test for HCV RNA (including reverse transcriptase polymerase chain reaction [RT-PCR] amplification and transcription mediated amplification [TMA]) *(264)*.

Anti-HCV testing includes initial screening with an EIA immunoassay. However, interpretation of the results of EIAs that screen for anti-HCV is limited by several factors:

(a) these assays will not detect anti-HCV in approximately 10% of persons infected with HCV, (b) these assays do not distinguish between acute, chronic, or past infection, (c) in the acute phase of hepatitis C, there may be a prolonged interval between onset of illness and seroconversion, and (d) in populations with a low prevalence of infection, the rate of false positivity for anti-HCV is high. Among hemodialysis patients, the proportion of false-positive screening test results averages approximately 15% *(260,262)*. For this reason, one should not rely exclusively on a positive anti-HCV screening test to determine whether a person has been infected with HCV. If the screening test is positive, supplemental testing with a test with high specificity should be performed to verify the results *(260)*. Alternatively, laboratorians can choose to perform reflex supplemental testing based upon the result of screening test-positive signal-to-cutoff ratios.

Routine testing of hemodialysis patients for anti-HCV on admission to a unit and every 6 months has been recommended since 2001 (171). For routine HCV testing of hemodialysis patients, the anti-HCV screening immunoassay is recommended, and if positive, supplemental testing using RIBA or HCV RNA (Table 63-5). With RIBA, the serologic assay can be performed on the same serum or plasma sample collected for the screening anti-HCV assay. The detection of HCV RNA requires that serum or plasma samples be collected and handled in a manner suitable for NAT and that testing be performed in a laboratory with appropriate facilities established for NAT testing *(260)*. In certain situations, the HCV RNA results can be negative in persons with active infection. As the titer of anti-HCV increases during acute infection, the titer of HCV RNA declines *(262,263)*. Thus, HCV RNA is not detectable in certain persons during the acute phase of their infection, but this finding can be transient and chronic infection can develop *(264)*. In addition, absence of HCV RNA positivity has been observed among patients with chronic HCV infection *(265–267)*. Therefore, the significance of a single negative HCV RNA result is unknown, and the need for further investigation or follow-up is determined by verifying anti-HCV status. Although, in rare instances, detection of HCV RNA might be the only evidence of HCV infection, a study conducted among almost 3,000 hemodialysis patients in the United States found that only 0.07% were HCV RNA positive but antibody negative (CDC, unpublished data).

TABLE 63-5

Interpretation of Test Results for Hepatitis C Virus Infection

Anti-HCV[a] Positive

- An anti-HCV positive result is defined as anti-HCV screening test positive and recombinant immunoblot assay (RIBA) positive or nucleic acid test (NAT) positive or signal-to-cutoff (s/co) ratio level indicative of a true positive antibody result; or anti-HCV screening test positive, NAT negative, RIBA positive (http://www.cdc.gov/hepatitis/HCV/LabTesting.htm) *(258)*.
- An anti-HCV positive result indicates past or current HCV infection.
- An HCV RNA-positive result indicates current (active) infection, but significance of single HCV RNA negative result is unknown; it does not differentiate intermittent viremia from resolved infection.
- All anti-HCV positive persons should receive counseling and undergo medical evaluation, including additional testing for the presence of virus and liver disease.
- Anti-HCV testing generally does not need to be repeated, once a positive anti-HCV result has been confirmed.

Anti-HCV Negative

- Anti-HCV negative result is defined as an anti-HCV screening test negative[b]; or anti-HCV screening test positive, RIBA negative; or anti-HCV screening test positive, NAT negative, RIBA negative.
- An anti-HCV negative individual is considered uninfected.
- No further evaluation or follow-up for HCV is required, unless recent infection is suspected or other evidence exists to indicate HCV infection (e.g., abnormal liver enzyme levels in immunocompromised persons or persons with other etiology for their liver disease).

Anti-HCV Indeterminate

- An indeterminate anti-HCV result is defined as anti-HCV screening test positive, RIBA indeterminate; or anti-HCV screening test positive, NAT negative, RIBA indeterminate.
- An indeterminate anti-HCV screening test result indicates that the HCV antibody status cannot be determined.
- Can indicate a false-positive anti-HCV screening test result, the most likely interpretation in those at low risk for HCV infection; such persons are HCV RNA negative.
- Can occur as a transient finding in recently infected individuals who are in the process of seroconversion; such individuals usually are HCV RNA positive.
- Can be a persistent finding in an individual chronically infected with HCV; such persons are usually HCV RNA positive.
- If NAT is not performed, another sample should be collected for repeat anti-HCV testing (≥1 mo later).

[a]Anti-HCV, antibody to hepatitis C virus.
[b]Interpretation of screening immunoassay test results based on criteria provided by the manufacturer *(259)*.

HEPATITIS DELTA VIRUS

Delta hepatitis is caused by the hepatitis delta virus (HDV), a relatively small defective virus that causes infection only in persons with active HBV infection. The prevalence of HDV infection is low in the United States, with rates <1% among HBsAg-positive persons in the general population and >10% among HBsAg-positive persons with repeated percutaneous exposures (e.g., injecting drug users, persons with hemophilia) *(268)*. Areas of the world with high endemic rates of HDV infection include southern Italy, parts of Africa, and the Amazon basin *(269–273)*.

Few data exist on the prevalence of HDV infection among chronic hemodialysis patients, and a few studies have reported nonexistent to low prevalence among

hemodialysis patients *(273,274)*. In endemic areas, prevalence rates may be relatively high among hemodialysis patients who are HBsAg positive *(275–278)*. Only one transmission of HDV during hemodialysis has been reported in the United States *(274)*. In this episode, transmission occurred from a patient who was chronically infected with HBV and HDV to an HBsAg-positive patient after a massive bleeding incident; both patients received dialysis at the same station.

HDV infection may occur as either coinfection with HBV or as a superinfection in a person with chronic HBV infection. High mortality rates are associated with both types of dual infection. A serologic test that measures total antibody to HDV is commercially available.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

During 1985 to 2002, the percentage of US hemodialysis centers that reported providing chronic hemodialysis for patients with HIV infection increased from 11% to 39%, and the proportion of patients with known HIV infection increased from 0.3% to 1.5% (59). Although the proportion of patients with HIV infection has remained fairly stable during the past decade, the number of infected patients has increased, as has the number of centers treating patients with HIV infection. HIV is transmitted by blood and other body fluids. No patient-to-patient transmission of HIV has been reported in a US hemodialysis center. However, there have been reports of transmission of HIV among patients in other countries. All of these outbreaks have been attributed to several breaks in infection control: (a) reuse of access needles and inadequately disinfected equipment, (b) sharing of syringes among patients, and (c) and sharing of dialyzers among different patients *(279–283)*. HIV infection is usually diagnosed with assays that measure antibody to HIV, and a repeatedly positive EIA test should be confirmed by Western blot or other confirmatory test.

PREVENTING INFECTIONS AMONG CHRONIC HEMODIALYSIS PATIENTS

Preventing transmission of blood-borne viruses and pathogenic bacteria from both recognized and unrecognized sources among chronic hemodialysis patients requires implementation of a comprehensive infection control program. The components of such a program include infection control practices specifically designed for the hemodialysis setting, including routine serologic testing and immunization, surveillance, and training and education. CDC has published recommendations describing these components in detail (171).

The infection control practices recommended for hemodialysis units (Table 63-6) will reduce opportunities for patient-to-patient transmission of infectious agents, directly or indirectly via contaminated devices, equipment and supplies, environmental surfaces, or hands of personnel. These practices should be carried out routinely for all patients in the chronic hemodialysis setting because of the increased potential for blood contamination during hemodialysis and because many patients are colonized or infected with pathogenic bacteria.

Such practices include additional measures to prevent HBV transmission because of the high titer of HBV and its ability to persist in an infectious state on environmental surfaces (Table 63-6). It is the potential for environmentally mediated transmission of HBV, rather than internal contamination of dialysis machines, that is the focus of infection control strategies for preventing HBV transmission in dialysis centers. For patients at increased risk for transmission of pathogenic bacteria, including antimicrobial-resistant strains, additional precautions also might be necessary in some circumstances. Furthermore, surveillance for infections and other adverse events is required to monitor the effectiveness of infection control practices, as are training and education of both staff members and patients to ensure that appropriate infection control behaviors and techniques are carried out.

In each maintenance hemodialysis unit or facility, policies and practices should be reviewed and updated to ensure that infection control practices recommended for hemodialysis units are implemented and rigorously followed. Intensive efforts must be made to educate new staff members and reeducate existing staff members regarding these practices. Readers should consult CDC recommendations for details on these practices (171). The following is a summary of the selected issues.

Routine Testing

All chronic hemodialysis patients should be routinely tested for HBV and HCV infection, and the results promptly reviewed to ensure that patients are managed appropriately based on their test results. Test results (positive and negative) must be communicated to other units or hospitals when patients are transferred for care. Positive test results should be reported to the appropriate public health department, as required by state notifiable disease reporting mandates. Routine testing for HDV or HIV infection for purposes of infection control is not recommended in populations with low endemicity (e.g., the United States).

Before admission to the hemodialysis unit, the HBV serologic status (i.e., HBsAg, total anti-HBc, and anti-HBs) of all patients should be known. For patients transferred from another unit, test results should be obtained before the patient transfer. If a patient's HBV serologic status is not known at the time of admission, testing should be completed within 7 days. The hemodialysis unit should ensure that the laboratory performing the testing for anti-HBs can define a 10-mIU/mL concentration to determine protective levels of antibody.

Routine HCV testing should include use of both a screening immunoassay to test for anti-HCV and supplemental or confirmatory testing with an additional, more specific assay. The use of an HCV RNA test as the primary test for routine screening is not recommended, because few HCV infections will be identified in anti-HCV negative patients. However, if ALT levels are persistently abnormal in anti-HCV negative patients in the absence of another etiology, testing for HCV RNA should be considered. Blood samples collected for HCV RNA testing should not contain heparin, which interferes with the accurate performance of this assay.

TABLE 63-6

Recommended Infection Control Practices for Hemodialysis Units

Infection Control Precautions for All Patients

- Wear disposable gloves when caring for the patient or touching the patient's equipment at the dialysis station; remove gloves and perform hand hygiene (if hands are visibly soiled wash with soap and water) between each patient or station.
- Items taken into the dialysis station should be disposed of, dedicated for use only on a single patient, or cleaned and disinfected before taken to a common clean area or used on another patient.
  - Nondisposable items that cannot be cleaned or disinfected (e.g., adhesive tape, cloth covered blood pressure cuffs) should be dedicated for use only on a single patient then discarded.
  - Unused medications (including multidose vials) or supplies (syringes, alcohol swabs, etc.) taken to the patient's station should be used only for that patient and should not be returned to a common clean area or used on other patients.
- When multidose medication vials are used (including vials containing diluents), prepare individual patient doses in a clean (centralized) area away from dialysis stations and deliver separately to each patient. Do not carry multidose medication vials from station to station.
- Do not use common medication carts to deliver medications to patients. Do not carry medication vials, syringes, alcohol swabs, or supplies in pockets.
- Clean areas should be clearly designated for the preparation, handling, and storage of medications and unused supplies and equipment. Clean areas should be clearly separated from contaminated areas where used supplies and equipment are handled. Do not handle and store medications or clean supplies in the same or adjacent area to where used equipment or blood samples are handled.
- Use external transducer protectors (venous or arterial) for each patient treatment to prevent blood contamination of the dialysis machine's pressure-monitoring equipment. Change these external transducer protectors between each patient treatment and when they become wetted[a], and do not reuse them. The redundant internal transducer protectors do not need to be changed routinely between patients. If the external transducer protectors are contaminated with blood, the internal transducer protector should be checked before dialyzing the next patient.[a]
- Clean and disinfect the dialysis station (chairs, beds, tables, machines, etc.) between patients.
  - Give special attention to cleaning control panels on the dialysis machine and other surfaces that are frequently touched and potentially contaminated with patient's blood.
  - Discard all fluid and clean and disinfect all surfaces and containers associated with the prime waste (including buckets attached to the machines).

For dialyzers and blood tubing that will be reprocessed, cap dialyzer ports and clamp tubing. Place all used dialyzers and tubing in a leak-proof container for transport from station to reprocessing or disposal area.

Schedule for Routine Testing for Hepatitis B Virus (HBV) and Hepatitis C Virus (HCV) Infections

Patient Status	*On Admission,*[b]	*Monthly*	*Semi-Annual*	*Annual*
All patients	HBsAg, Anti-HBc (total), Anti-HBs, Anti-HCV, ALT			
HBV susceptible, including vaccine nonresponders		HBsAg		
Anti-HBs positive (≥10 mIU/mL), anti-HBc negative				Anti-HBs
Anti-HBs and Anti-HBc positive		No additional testing is needed		
Anti-HCV negative		ALT	Anti-HCV	

[a]Results of HBV testing should be known before patient begins dialysis.
HBsAg, hepatitis B surface antigen; Anti-HBc, antibody to hepatitis B core antigen; Anti-HBs, antibody to surface antigen; Anti-HCV, antibody to hepatitis C virus; ALT, alanine aminotransferase.

Hepatitis B Vaccination

- Vaccinate all susceptible patients against hepatitis B
- Test for anti-HBs 1–2 mo after the last dose
  - If anti-HBs is <10 mIU/mL, consider patient susceptible, revaccinate with an additional three doses, and retest for anti-HBs
  - If anti-HBs is >10 mIU/mL, consider immune and retest annually
    - Give booster dose of vaccine if anti-HBs declines to <10 mIU/mL and continue to retest annually

Management of HBsAg-Positive Patients

- Follow infection control practices for hemodialysis units for all patients.
- Dialyze HBsAg-positive patients in a separate room using separate machines, equipment, instruments, and supplies.
- Staff members caring for HBsAg-positive patients should not care for HBV-susceptible patients at the same time (e.g., during the same shift or during patient change over).

[b]FDA Safety Alert: Potential Cross-Contamination Linked to Hemodialysis Treatment (http://www.fda.gov/MedicalDevices/Safety/AlertsandNotices/PublicHealthNotifications/UCM062283); (Adapted from CDC. Recommendations for preventing transmission of infections among chronic hemodialysis patients. *MMWR Morb Mortal Wkly Rep* 2001;50(RR5):1–43.)

Hepatitis B vaccination is an essential component of prevention in the hemodialysis setting. All susceptible patients and staff should receive hepatitis B vaccine. Susceptible patients who have not yet received hepatitis B vaccine, are in the process of being vaccinated, or have not adequately responded to vaccination should continue to be tested regularly for HBsAg. Detailed recommendations for vaccination and follow-up of hemodialysis patients have been published elsewhere (171).

Management of Infected Patients

Hepatitis B Virus HBsAg-positive patients should undergo hemodialysis in a separate room designated only for HBsAg-positive patients. They should use dedicated machines, equipment, and supplies, and most importantly staff members should not care for both HBsAg-positive and susceptible patients during the same shift or while the HBsAg-positive patient is in the treatment area. Dialyzers should not be reused on HBsAg-positive patients because HBV is efficiently transmitted through occupational exposure to blood; reprocessing dialyzers from HBsAg-positive patients might place HBV-susceptible staff members at increased risk for infection.

HBV chronically infected patients (i.e., those who are HBsAg-positive, total anti-HBc positive, and IgM anti-HBc negative) are infectious to others and are at risk for chronic liver disease. They should be counseled on how to prevent transmission to others, especially for those who are their household and sexual partners. Household contacts and sexual partners should be advised to receive hepatitis B vaccine. The HBsAg-positive patient should also be evaluated according to current medical practice guidelines (by consultation or referral, if appropriate) for possible treatment and for the presence or development of chronic liver disease. It is recommended that individuals with chronic liver disease be vaccinated against the hepatitis A virus (HAV), if susceptible, to prevent any additional injury to the liver.

HBV chronically infected patients do not require any routine follow-up testing for purposes of infection control. However, annual testing for HBsAg is reasonable to detect the small percentage of HBV-infected patients who might lose their HBsAg.

Hepatitis C Virus HCV-positive patients do not have to be isolated from other patients or dialyzed separately on dedicated machines. The purpose of routine testing is to detect potential transmission within centers and ensure that appropriate practices are being properly and consistently used. Furthermore, HCV-positive patients can participate in dialyzer reuse programs. Unlike HBV, HCV is not transmitted efficiently through occupational exposures. Thus, reprocessing dialyzers from HCV-positive patients should not place staff members at increased risk for infection (59,*88*).

All HCV-positive persons should be evaluated according to current medical practice guidelines (by consultation or referral, if appropriate) for possible treatment and the presence or development of chronic liver disease. They also should receive information concerning how they can prevent further harm to their liver and prevent transmitting HCV to others *(284,285)*. Persons with chronic liver disease should be vaccinated against hepatitis A, if susceptible.

Hepatitis Delta Virus Because HDV depends on an HBV-infected host for replication, prevention of HBV infection will prevent HDV infection in a person susceptible to HBV. Patients known to be infected with HDV should be isolated from all other dialysis patients, especially those who are HBsAg positive and HDV susceptible.

Human Immunodeficiency Virus Infection control precautions recommended for all hemodialysis patients are sufficient to prevent HIV transmission between patients. HIV-infected patients do not have to be isolated from other patients or dialyzed separately on dedicated machines. In addition, they can participate in dialyzer reuse programs, because HIV is not transmitted efficiently through occupational exposures. Reprocessing dialyzers from HIV-positive patients should not place staff members at increased risk for infection.

Bacterial/Fungal Contact transmission can be prevented by hand hygiene *(286)*, proper glove use, and disinfection of environmental surfaces. Infection control precautions recommended for all hemodialysis patients are adequate to prevent transmission from most patients infected or colonized with pathogenic bacteria, including antimicrobial-resistant strains. However, additional precautions should be considered for treatment of patients who might be at increased risk for transmitting pathogenic bacteria. Such patients include those with either an infected skin wound with drainage that is not contained by dressings (the drainage does not have to be culture positive for MRSA or VRE or any specific pathogen) or fecal incontinence or diarrhea uncontrolled with personal hygiene measures. For these patients, the following additional precautions apply (171):

1. Staff members treating the patient should wear a separate gown over their usual clothing and remove the gown when finished caring for the patient.
2. Dialyze the patient at a station away from the main flow of traffic and with as few adjacent stations as possible (e.g., at the end or corner of the unit).

Vancomycin is used commonly in dialysis patients, in part because vancomycin can be conveniently administered to patients when they come in for hemodialysis treatments. Prudent antimicrobial use is an important component of CDC recommendations for preventing the spread of vancomycin resistance *(287)*. Vancomycin is not indicated for therapy (chosen for dosing convenience) of infections due to ß-lactam–susceptible gram-positive microorganisms in patients with renal failure (148,*287*,*288*). Depending on the situation, alternative antimicrobials (e.g., cephalosporins) with dosing intervals greater than 48 hours, which would allow postdialytic dosing, could be used. Recent studies suggest that cefazolin given three times a week in the dialysis unit provides adequate blood levels and could be used to treat many infections in hemodialysis patients *(289,290)*.

Disinfection, Sterilization, and Environmental Cleaning

Good cleaning, disinfection, and sterilization procedures are important components of the infection control program in the hemodialysis center. The procedures do not differ from those recommended for other healthcare settings

(291,292), but the high potential for blood contamination makes the hemodialysis setting unique. Additionally, the need for routine aseptic access of the patient's vascular system makes the hemodialysis unit more akin to a surgical suite than to a standard hospital room. Medical items are categorized as critical (e.g., needles and catheters), which are introduced directly into the bloodstream or normally sterile areas of the body; semicritical (e.g., fiberoptic endoscopes), which come in contact with intact mucous membranes; and noncritical (e.g., blood pressure cuffs), which touch only intact skin *(292,293)*.

Cleaning and housekeeping in the dialysis center have two goals: to remove soil and waste on a regular basis, thereby preventing the accumulation of potentially infectious material, and to maintain an environment that is conducive to good patient care *(293)*. Crowding of patients and overtaxing of staff members may increase the likelihood of microbial transmission. Adequate cleaning may be difficult if there are multiple wires, tubes, and hoses in a small area. There should be enough space to move completely around each patient's dialysis station without interfering with the neighboring stations. Where space is limited, elimination of unneeded items; orderly arrangement of required items; and removal of excess lengths of tubes, hoses, and wires from the floor can improve accessibility for cleaning. Because of the special requirements for cleaning in the dialysis center, staff should be specially trained in this task.

After each patient treatment, frequently touched environmental surfaces, including external surfaces of the dialysis machine and the dialysis chair, should be cleaned (with a detergent/detergent germicide) and disinfected (with a hospital-grade disinfectant germicide) in a two-step process. A recent study in the Netherlands where the investigators used luminol to detect nonvisible blood contamination demonstrated the importance of environmental cleaning *(294)*. It is the cleaning step that is most important for interrupting the cross-contamination transmission routes *(295,296)*. Antiseptics, such as formulations with povidone iodine, hexachlorophene, or chlorhexidine, should not be used for environmental cleaning, because these are formulated for use on skin and are not designed for use on hard surfaces.

There is no evidence to suggest that medical waste is more infectious than residential waste or has caused disease in the community *(297)*. However, wastes from a hemodialysis center that are actually or potentially contaminated with blood should be considered infectious and handled accordingly. Eventually, these items of solid waste should be disposed of properly in an incinerator or sanitary landfill, depending on state or local laws.

Standard protocols for sterilization and disinfection are adequate for processing any items or devices contaminated with blood. Historically, there has been a tendency to use "over kill" strategies for instrument sterilization or disinfection and housekeeping protocols. This is not necessary. The floors in a dialysis center are routinely contaminated with blood, but the protocol for floor cleaning is the same as for floors in other healthcare settings. Usually, this involves the use of a good detergent germicide; the formulation can contain a low- or intermediate-level disinfectant.

Blood-borne viruses, such as HBV and HIV, are inactivated by any standard sterilization systems such as standard steam autoclave cycles of 121°C (249.8°F) for 15 minutes, ethylene oxide gas *(296)*, and low-temperature hydrogen peroxide gas plasma *(298)*. Large blood spills should be cleaned to remove visible material; the presence of organic soil can interfere with the activity of the disinfectant. Once the visible soil has been removed, the area should receive low- to intermediate-level disinfection following the label directions of the germicide manufacturer.

Blood and other specimens, such as peritoneal fluid, from all patients should be handled with care. Peritoneal fluid can contain high levels of HBV and should be handled in the same manner as the patient's blood *(299)*. Consequently, if the center performs inpatient peritoneal dialysis, the same criteria for separating HBsAg-positive patients who are undergoing hemodialysis apply to those undergoing peritoneal dialysis.

Blood contamination of venous pressure monitors has been implicated in HBV transmission *(300)*. Therefore, external pressure transducer filters should be used for each patient treatment; these filters should not be reused.

In single-pass artificial kidney machines, the internal fluid pathways are not subject to contamination with blood. Although the fluid pathways that exhaust dialysis fluid from the dialyzer may become contaminated with blood in the event of a dialyzer leak, it is unlikely that this blood contamination will reach a subsequent patient. Therefore, disinfection and rinsing procedures should be designed to control contamination with bacterial rather than blood-borne pathogens.

For dialysis machines that use a dialysate recirculating system (such as some ultrafiltration control machines and those that regenerate the dialysate), a blood leak in a dialyzer, especially a massive leak, can result in contamination of a number of surfaces that will contact the dialysis fluid of subsequent patients. However, the procedures that are normally practiced after each use of a recirculating machine—draining of the dialysis fluid, subsequent rinsing, and disinfection—will reduce the level of contamination to below infectious levels. In addition, an intact dialyzer membrane will not allow passage of bacteria or viruses. Consequently, if a blood leak does occur with either type of dialysis machine, the standard disinfection procedure used for machines in the dialysis center to control bacterial contamination will also prevent transmission of blood-borne pathogens.

Future Directions Infection control strategies that prevent and control HBV infection among hemodialysis patients have been well established. Areas that need further research include determining the ideal hepatitis B vaccine dosage regimen for predialysis and postdialysis pediatric patients and for predialysis adult patients, as well as the optimal timing for follow-up testing and administration of booster doses among vaccine responders. With regard to HCV infection, further studies are needed to clarify the specific factors responsible for transmission of HCV among hemodialysis patients and to evaluate the effect of the current recommendations on prevention and control of HCV infection in this setting.

Many areas related to the occurrence of bacterial and fungal infections in maintenance hemodialysis patients

need additional information. Studies are needed on the prevalence and epidemiology of these infections among chronic hemodialysis patients and the patient-care practices (e.g., those related to vascular access care and cannulation) that would be most useful in preventing infections. Since dialysis patients play a prominent role in the epidemic of antimicrobial resistance, more research regarding optimal strategies to ensure judicious use of antimicrobials in these patients should be conducted. Additional research topics would also include determining the frequency of transmission of pathogens within the dialysis unit and whether additional precautions are necessary to prevent such transmission.

CHAPTER 64

Infections Associated with Peritoneal Dialysis

John J. Szela and Jeffrey D. Band

HISTORICAL PERSPECTIVES

Although peritoneal dialysis has been used to treat acute renal failure for many years, it has only been over the past 25 to 30 years that peritoneal dialysis has become an alternative to hemodialysis for treatment of chronic renal failure. In 2007, more than 26,000 patients in the United States were maintained on chronic peritoneal dialysis (1). Six percent of the United States dialysis population is undergoing peritoneal dialysis as a form of dialytic therapy.

Two factors have largely contributed to the initial growth of peritoneal dialysis in the treatment of chronic renal failure. First, the introduction of an implantable, cuffed, indwelling silicone catheter by Tenckhoff and Schecter *(2)* in 1968 permitted secure and safe access to the peritoneal cavity. Prolonged continuous or intermittent dialysis was now possible. Second, a continuous, portable, and relatively simple dialysis technique was introduced by Popovich et al. *(3)* in 1976, called continuous ambulatory peritoneal dialysis (CAPD). Modification and simplification of this technique by Oreopoulos et al. *(4)* in 1978 resulted in fewer interruptions, increased portability, and reduced costs, leading to its popularity and acceptance.

However, peritonitis and, less commonly, catheter exit-site or tunnel infections initially led to cautious growth of this new form of chronic dialytic therapy. Rates of peritonitis as high as two to five episodes per patient year were reported in the past *(5–7)*. Better patient selection, improved education, and important changes in delivery systems and connectors designed to prevent touch contamination during bag exchanges have significantly reduced rates of peritonitis *(8–10)*. However, the major limitation of chronic peritoneal dialysis is peritonitis and its sequelae. Peritonitis is the most common reason for hospitalization *(11)* and for discontinuation of this form of dialysis *(12)*. Fortunately, hospitalization rates have declined for peritoneal dialysis patients secondary to decreased peritonitis rates and use of intraperitoneal (as opposed to intravenous) antimicrobics when needed.

Infections in patients on peritoneal dialysis are largely preventable. Knowledge of the epidemiology and pathogenesis of these infections and sources of infecting microbes is essential to design effective prevention and control strategies.

METHODS OF PERITONEAL DIALYSIS

Peritoneal dialysis may be performed in various settings and with a number of techniques. It involves infusing a dialysis solution composed of balanced salts and various concentrations of glucose into the peritoneal cavity by means of a catheter and achieving ultrafiltration by hyperosmolality; retained metabolites traverse the peritoneum from the bloodstream to the solution.

Acute Peritoneal Dialysis

Acute peritoneal dialysis is generally limited to the patient with newly diagnosed acute renal failure or to other circumstances in which dialysis is anticipated for only a few days. It has now largely been replaced by continuous renal replacement therapy. Its origins date back to the 1920s *(8)*. A rigid catheter is inserted into the peritoneal cavity at the bedside after making a small incision, and manual exchanges are performed every 1 to 3 hours as necessary *(13)*. The procedure confers a significant risk of complications, including bowel perforation. Infection is common, especially in cannulations persisting for more than a few days. Some reasons include same location of entry and exit site, lack of an implanted cuff barrier to bacterial migration, migration of the catheter with resultant serosal injury, and the need for frequent exchanges; each poses a risk of contamination.

Chronic Peritoneal Dialysis

Patients with chronic renal failure require maintenance peritoneal dialysis to alleviate symptoms of uremia and correct other metabolic abnormalities. Chronic peritoneal dialysis did not become an acceptable therapeutic alternative to hemodialysis until the mid-1960s, when a semipermanent implantable silastic catheter was developed by Palmer et al. *(14)* and modified by Tenckhoff et al. *(2,5)*. The Tenckhoff catheter is still the most frequently used peritoneal dialysis catheter today (15). Repeated insertions of a peritoneal catheter were no longer necessary to deliver dialysate. The catheter, composed of pliable silicone and usually containing two extraperitoneal Dacron cuffs, is inserted through one incision and tunneled through a subcutaneous tract until the outer end emerges from a new exit site. The Dacron cuffs initiate an inflammatory response

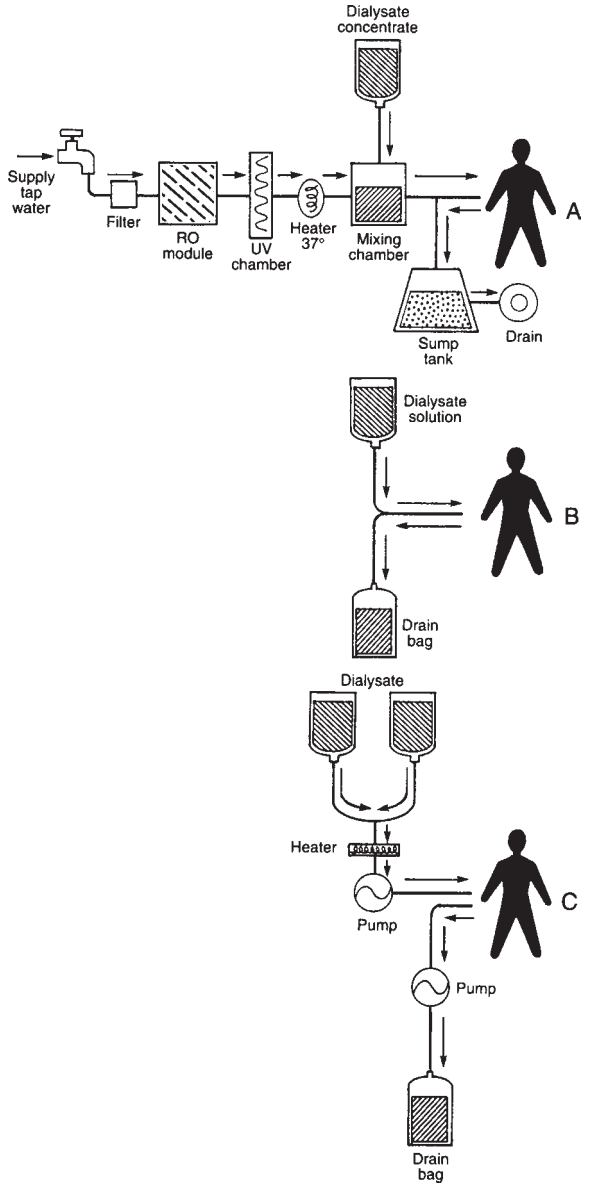

FIGURE 64-1 Schematic diagrams of peritoneal dialysis systems. **A:** Chronic intermittent peritoneal dialysis (CIPD) by automated machine. **B:** Continuous ambulatory peritoneal dialysis (CAPD). **C:** Continuous cycling peritoneal dialysis (CCPD) by roller pumps.

in the subcutaneous tissue near the exit site and deep in the abdominal wall, helping to seal the catheter in place, prevent fluid leaks, and limit bacterial migration around the catheter. Chronic peritoneal dialysis can be performed either intermittently or, as is common today, continuously (Fig. 64-1).

Chronic Intermittent Peritoneal Dialysis

Chronic intermittent peritoneal dialysis (CIPD) uses prolonged periods in which continuous dialysis is performed, thus permitting at least 48 hours of freedom from dialysis. To perform dialysis, a closed automated dialysis system is used to deliver dialysate to the patient *(5–7)*. To simplify the process and to reduce costs, an automated peritoneal dialysis system was developed that used reverse osmosis (RO) capable of producing sterile pyrogen-free water from tap water, which is then mixed with dialysis concentrate *(7)*. These machines gained widespread popularity in the mid-1970s. Although RO proved to be effective in removing bacterial counts by as much as four logs *(16)*, additional backup systems using heat or ultraviolet (UV) irradiation were added to ensure sterile water. Rates of peritonitis were reduced with these closed systems; however, the machines were found to be quite demanding in terms of maintenance, care, monitoring, and disinfection and may themselves provide a reservoir for pathogens *(17)*. With the meteoric rise of simpler procedures (described later), these machines have largely been replaced.

Continuous Ambulatory Peritoneal Dialysis

CAPD is a form of closed-system continuous dialysis that is machine free. Patients on CAPD manually exchange dialysate, usually four times daily, by using dialysate delivered by gravity into the peritoneal cavity. Empty bags, connected to the catheter by extension tubing, collect the effluent, also by gravity, at the end of the dwell time. Fluid from the last exchange of the day dwells overnight in the peritoneal cavity. The technique was pioneered by Popovich et al. *(3)* in 1976 but initially suffered from high rates of peritonitis and patient inconveniences because of bottled dialysate. Oreopoulos et al. *(4)* modified the process and replaced the bottled dialysate with plastic dialysate bags, improving convenience, reducing manipulations, and lowering rates of infectious complications. CAPD is, thus, performed without the necessity of machines, is portable, and is simple to learn and perform *(10,18–21)*.

Continuous Cycling Peritoneal Dialysis

A variant of CAPD, continuous cycling peritoneal dialysis (CCPD) combines the principles of continuous automated dialysis during the night with those of prolonged dwell time dialysis during the day by use of a machine cycler allowing for frequent exchanges *(22)*. CCPD has many advantages, including eliminating active dialysis during the day, reducing the number of exchanges, and possibly reducing rates of peritonitis. However, CCPD may be associated with a faster rate of first-episode peritonitis than CAPD (23). Other disadvantages include cost, machine dependency, and lack of portability. Simpler cyclers will make CCPD an increasingly popular technique. CCPD became more prevalent than CAPD in 2001 and, as of 2007, is approaching twice the prevalence of CAPD (1).

DEFINITIONS

There are a number of infections associated with peritoneal dialysis. By definition, *peritonitis* signifies inflammation of the peritoneal membranes as a result of infection or other insult. For clinical purposes, the definition proposed by Vas *(22)*, consisting of any two of the following three criteria, is often used to establish a diagnosis of peritonitis: cloudy peritoneal effluent containing more than 100 neutrophils/mm^3, abdominal pain or tenderness, and microorganisms in the peritoneal fluid.

Exit-site infections are usually characterized by the presence of pain, erythema, tenderness, or induration of the

catheter site often accompanied by purulent discharge. Infection, when present, is commonly limited to the area between the cutaneous surface (exit site) and the superficial Dacron cuff embedded in the subcutaneous tissue near the skin.

With *tunnel infections,* in which the area between the two Dacron cuffs is commonly referred to as the *tunnel* (the other cuff is embedded deep in the abdominal wall near the peritoneum), signs of infection include induration, tenderness, or redness of the overlying tissues with or without overt abscess formation.

EPIDEMIOLOGY AND RISK FACTORS ASSOCIATED WITH INFECTION

Regardless of the method of dialysis, infection, especially peritonitis, remains a serious threat to the patient. The incidence of peritonitis associated with an acute dialysis is high, approaching 0.5% to 4% *(24)*. The incidence of peritonitis in patients receiving chronic dialytic therapy varies from center to center and depends on the method of chronic dialysis. However, no study has actually randomized patients with chronic renal failure to receive treatment by the three different methods of chronic dialytic therapy.

Over the years, the incidence of peritonitis associated with CAPD has continued to decrease from early observations of six episodes per patient year reported in the late 1970s *(25,26)* to 0.35 episodes per patient year documented by 2004 (27). The initially precipitous drop in infections was largely attributable to enhanced center experience and training *(26)*, substituting plastic dialysis bags for glass bottles, reducing the number of connect–disconnect times *(4)*, incorporating titanium connectors to connect tubing to catheters *(28)*, and developing other methods to reduce touch contamination during bag exchanges *(28–30)*. Currently, the peritonitis rate is down to an average of one infection per 25 patient months of dialysis (31).

Clearly, the risk of developing peritonitis on CAPD increases with time. The period of greatest risk is the first few months of therapy. By the end of 6 months of treatment, the probability of developing at least one episode of peritonitis is at least 30% *(32)*. This risk increases to 50% by the end of 1 year of treatment, 70% by 2 years, and approaches 80% by 3 years of uninterrupted therapy *(26)*. More than half of all episodes of peritonitis occur in only 25% of all patients on CAPD. Twenty percent of patients develop three or more infections each year, whereas others remain free of infection for 3 or more years *(10,33,34)*.

Several factors place a patient at increased risk for infection, especially peritonitis. These factors have been best studied in patients receiving CAPD. Although age or gender *(35)* does not appear to be important risk factors [rates may be higher in young children who perform their own therapy as opposed to children who obtain assistance from another family member *(36)*], underlying disease states may be important. For example, diabetic patients have been found to have higher rates of both peritonitis and exit-site infections *(37)*. Lack of compliance with asepsis, lapses in technique, low patient motivation, depression, lack of social support, fewer years of education, and lower socioeconomic status all have been found to be contributing factors to infection (38). Both African Americans *(39)* and Native Americans *(40)* are at increased risk. The type of catheter design and operator do not appreciably influence rates of peritonitis *(41)*. Antibiotic prophylaxis at time of catheter placement may decrease infection risk *(42,43)*. Vancomycin use in this setting appears superior to cephalosporin use in prevention of early peritonitis *(42)*. However, routine use of vancomycin is discouraged for fear of VRE development (15). Downward direction of the exit site also lowers rates of peritonitis *(44)*. Data have demonstrated that catheters containing both a superficial and a deep Dacron cuff (double-cuffed catheters) were associated with significantly lower rates of peritonitis than single-cuffed catheters *(41)* and may be associated with longer catheter survival and fewer exit-site complications *(45)*. However, another study found that single-cuffed catheters were not inferior if the single cuff was placed in the deep position *(46)*. Studies have also confirmed that both the type and the method of connection used between the dialysis bag and the indwelling peritoneal catheter can influence rates of peritonitis. Patients using connection devices permitting flush before fill systems such as Y-sets *(30)* or using disconnect systems that sterilize the connection, such as UV radiation *(47)*, had rates of peritonitis significantly lower than those of patients using standard spike connectors *(29)*. Manual spiking of dialysis bags is a discouraged procedure (48). Finally, patients who were prescribed intraperitoneal medications and added these medications themselves had higher rates of peritonitis *(29)*.

Intermittent peritoneal dialysis appears to result in lower rates of peritonitis when compared with CAPD. Perhaps much of this reduction can be attributed to the need for less frequent manipulations. In fact, patients on CIPD perform only 156 to 208 connect–disconnect procedures per year, as opposed to the more than 1,400 required for CAPD. Likewise, patients on CCPD appear to become infected at rates between those described for CIPD and for CAPD *(18)*; these patients perform approximately 700 connect–disconnect procedures annually.

Exit-site or tunnel infections occur more commonly in individuals with concomitant peritonitis. Studies have also demonstrated that nasal carriers of *Staphylococcus aureus* are at increased risk for infection *(49–54)*. Persistent carriage of *S. aureus* at the catheter exit site or the anterior nares is associated with a threefold increase of CAPD infections than compared with intermittent carriers (55). Another study found that frequent and comprehensive washing (ablution) combined with intranasal mupirocin significantly decreased *S. aureus* carriage and CAPD-related *S. aureus* peritonitis *(56)*. Diabetics may also be at increased risk for infection, although this observation may be confounded by the observation of high carriage rates of *S. aureus* in these patients *(57)*. The overall risk of an exit-site or tunnel infection in a patient receiving CAPD approaches 0.2 to 0.7 episodes per patient year *(51,58)*. Half of patients on CAPD do not develop exit-site infections within 2 years of catheter placement.

Epidemics of peritonitis in patients receiving chronic dialysis have been observed, especially in patients receiving CIPD via machines that use RO to sterilize water that then mixes with a dialysate concentrate *(17,59,60)*. Outbreaks

have also occurred as a result of delivering contaminated dialysate to the patient, either directly *(61,62)* or indirectly by use of water baths to heat the dialysate before infusion *(63–65)*. Contaminated disinfectants used to clean exit sites and tubing ports have also resulted in outbreaks of infection *(66)*.

PATHOGENESIS

Routes of Infection

The four major pathways resulting in peritonitis in patients on dialysis are schematically represented in Figure 64-2. These include intraluminal transmission of microorganisms (microorganisms gaining entry through the infusion system); periluminal infections (infection of the catheter site with resultant local infection and, at times, spread into the peritoneum); transmural infections (peritonitis as a result of intestinal injury, perforation, or transmigration of microorganisms); and hematogenous spread, usually from a site of infection elsewhere. Exit-site or tunnel infections almost always result from a periluminal infection, although peritonitis can cause infection at the deep Dacron cuff of the silastic catheter with resultant tunnel infection or abscess formation.

Few studies have examined the most common means by which peritonitis develops in patients receiving acute dialytic therapy. Clearly, infection of the catheter site with resultant spread into the peritoneum is a major route of infection. Unlike the situation with chronic dialysis, the cannula is usually inserted directly into the peritoneum after a stab wound is made. A protective tunnel with stabilization by Dacron cuffs is not usually made for short-term acute dialysis. Another important means by which peritonitis may develop in these patients is inadvertent perforation of the bowel during blind catheter placement or as a result of perforation from migration of the rigid catheter during dialysis with injury to the bowel wall. Microorganisms can also be introduced in the lumen during bag or tubing changes.

Contrast this scenario with what is observed in patients on chronic forms of peritoneal dialysis. It appears from inferential and intervention studies that the most important route of infection in these patients is intraluminal. Intraluminal contamination can occur during the numerous connect–disconnect manipulations by means of loose-fitting connectors or malfunctioning clamps, through defects in the plastic tubing or bags, or from the dialysis fluid itself. First, peritonitis occurs at least twice as often as exit-site infections in patients on chronic dialysis (27), suggesting that microorganisms are instilled into the peritoneal cavity. Second, the most common microorganisms causing peritonitis are coagulase-negative staphylococci rather than *S. aureus,* a microorganism found more frequently as a cause of periluminal infections *(67)*. Third, studies have found that a major cause of peritonitis in patients on chronic dialysis is poor technique or observed breaks in technique resulting in intraluminal contamination *(68)*. Fourth, CIPD or CCPD, methods associated with fewer manipulations, have consistently been associated with fewer infections *(18)*. Finally, incorporating devices or procedures to reduce touch contamination have resulted in fewer infections *(29,30)*.

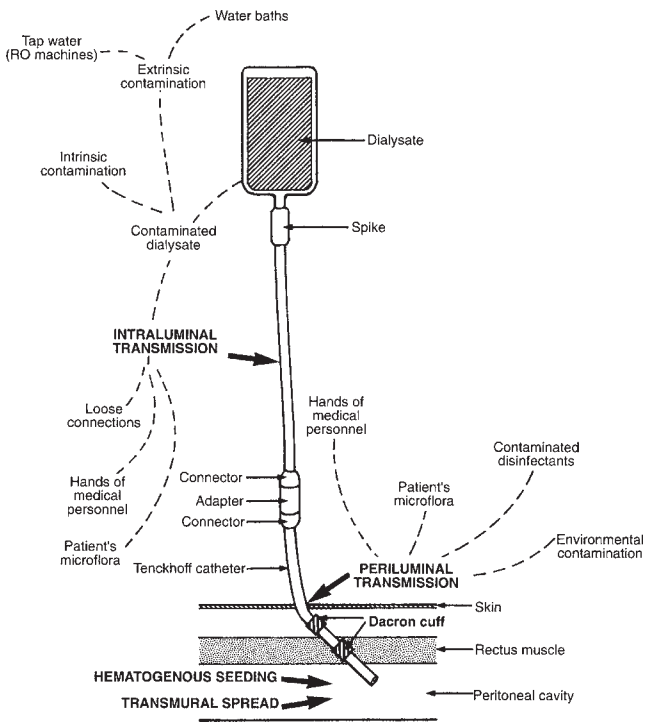

FIGURE 64-2 Sources of peritonitis and exit-site and tunnel infections in dialysis patients.

Contaminated Dialysate

Intrinsic contamination of dialysate has been reported infrequently and may result in infective peritonitis *(61)* or a sterile peritonitis resulting from delivery of endotoxin *(62)*. In-use or extrinsic contamination may occur during bag exchanges. Fortunately, commercially available dialysate does not support the growth of staphylococci, the most common pathogen responsible for infection, although some gram-negative microorganisms proliferate readily if introduced *(69,70)*. Water-adapted microorganisms such as *Mycobacterium chelonae*–like microorganisms and *Pseudomonas* species have caused outbreaks of peritonitis in patients on CIPD *(17,60)*. Microorganisms such as *M. chelonae*–like organisms not only can live in chlorinated water but also may survive exposure to high concentrations of disinfectants such as formaldehyde *(71)*.

Infection of the catheter site is the second most common cause of peritonitis and the leading cause of exit-site infections in patients on chronic peritoneal dialysis. The implanted catheter never forms a complete sealed junction with the skin; thus, microorganisms are present within the exit site and can result in infection. Although the superficial embedded Dacron cuff is a reasonable barrier, limiting the migration of microorganisms deeper into the abdominal wall or to the peritoneum, its efficacy is clearly not 100% *(72)*. Up to 17% of patients who develop an exit-site infection also have peritonitis *(67)*. *S. aureus* carriers are at high risk for developing an exit-site infection *(50–54,57)* as are diabetics *(73)*.

Transmural infections occur as a result of abdominal perforation or injury, inflammation of the serosal surfaces,

or transmural migration *(74)*. Rates of peritonitis resulting from intestinal microorganisms are higher in patients with preexisting diverticular disease *(75)*. Infection of the peritoneum or exit site by the hematogenous route is uncommon.

Host Defense Mechanisms

For peritonitis to develop, the patient's host defenses must not be able to contain, destroy, and remove the invading pathogens. Peritoneal fluid normally contains up to 200 cells/mm^3, of which more than 80% are mononuclear cells predominately macrophages *(76–78)*. These cells represent the primary cellular barrier against infection *(79)*; patients prone to infection may have fewer macrophages available to combat infection *(80)*. Many microorganisms causing peritonitis require opsonization by heat-stable substances, such as immunoglobulin G (IgG) and other specific antibodies, or heat-labile components, including complement for efficient removal. Deficiency in IgG or C3 may also predispose patients to infection, as would neutropenia *(81)*.

It is well known that the delivery of dialysate into the peritoneal cavity has a direct adverse effect on host defense mechanisms because of the effects of the low pH and hyperosmolarity of the dialysate. Both acidity and hyperosmolarity reduce the ability of macrophages and polymorphonuclear leukocytes to phagocytize and kill microorganisms *(82–84)*. Also, the presence of extra liters of fluid in the peritoneal cavity during dialysis results in a marked dilutional effect on both cellular and humoral protective factors, resulting in fewer leukocytes per milliliter and a relative opsonic deficiency *(81,85)*.

Obviously, an indwelling peritoneal catheter has adverse effects on the host. A conduit between the outside environment and the peritoneum now exists. The catheter may act as a foreign body, initiating inflammatory changes that predispose to infection, and can serve as a substrate on which colonization may be established. Although silastic catheters appear to be less thrombogenic than polyurethane catheters *(86)*, all catheters eventually become coated with a fibrin sheath *(87)*. Microorganisms can become embedded in this sheath or in the biofilm produced by many microorganisms, resulting in proliferation with resultant infection. This protective environment may be responsible for the difficulty in eradicating infection by seemingly appropriate antibiotics or for relapses of infection *(88)*.

Finally, patients with end-stage renal failure often have defects in cellular immune functions and are more susceptible to infection in general *(89–91)*.

TABLE 64-1

Prevalence of Microorganisms Isolated from Patients with Peritonitis and Catheter (Exit-Site and Tunnel) Infections

		Catheter
Microorganisms	***Peritonitis (%)***	***Infections (%)***
Gram-positive aerobic bacteria		
Coagulase-negative staphylococci	40–65	15–20
S. aureus	10–25	25–35
Streptococcal species	8–15	2–5
Enterococci	3–7	2–5
Corynebacterium or *Bacillus* species	1–4	2–5
Gram-negative aerobic bacteria		
Escherichia coli	7–12	5–10
Klebsiella species	2–4	2–5
Other Enterobacteriaceae	1–7	1–5
Pseudomonas species	5–9	10–15
Miscellaneous	1–5	1–5
Multiple microorganisms	2–6	25–35
Anaerobes	<5	<1
Fungi	4–8	4–6
Miscellaneous	2–5	3–5

(Data from references *22,33,34,51,67,73,92*.)

ETIOLOGIC AGENTS

Causative Microorganisms of Peritonitis

Although numerous microorganisms have been isolated from infected patients on peritoneal dialysis, most of these microorganisms are skin commensals such as coagulase-negative staphylococci (Table 64-1) *(22,33,34,51,67,73,92)*. At least two thirds of all episodes are caused by gram-positive microorganisms; *Staphylococcus epidermidis* is isolated most frequently. The second most common microorganism is *S. aureus,* followed by various streptococcal species. Gram-negative bacteria account for 20% to 30% of all episodes, with *E. coli* and other members of the family Enterobacteriaceae most prevalent. Fewer than 10% of episodes of peritonitis are due to *Pseudomonas aeruginosa* or related microorganisms. Anaerobes are uncommon. When anaerobes are present, the possibility of peritonitis from bowel perforation increases, especially if polymicrobic peritonitis is found.

Peritonitis resulting from fungal microorganisms has been reported to occur in as many as 8% of episodes. The most commonly isolated fungus is *Candida albicans,* followed by other *Candida* species *(93,94)*. Less commonly isolated microorganisms include *Mycobacterium* species and related pathogens. Viral microorganisms and parasites are exceedingly uncommon causes of peritonitis in patients on peritoneal dialysis.

Aseptic peritonitis is a well-described entity. Although the frequency of culture-negative peritonitis has decreased with improved culture techniques (95), 10% of episodes of peritonitis yield no growth of pathogens on culture. Clearly, some of these episodes represent failure to isolate an infecting microorganism because of the lack of sensitivity of culture techniques *(96)*. Others may be due to a foreign body reaction to the implanted catheter *(97)*, chemical peritonitis *(17,98)*, or delivery of endotoxin into the peritoneum *(61)*. Culture-negative peritonitis rates >20% should prompt a program's review of culture methods (48).

Causative Microorganisms of Exit-Site or Tunnel Infections

The microbiology of exit-site or tunnel infections differs somewhat from that observed in patients with peritonitis (Table 64-1). Mixed infections, rare in dialysis-associated peritonitis, may be found in up to 30% of these catheter infections *(67)*. The most commonly isolated pathogen is *S. aureus,* accounting for 25% to 35% of all episodes, followed by *S. epidermidis* in 10% to 20% of cases. *Pseudomonas* species are also more frequently recovered from device-related infections than from peritoneal fluid in patients with peritonitis.

Piraino et al. *(67)* found that 17% of all catheter infections occurred simultaneously with or were followed shortly thereafter by an episode of peritonitis resulting from the same microorganism, supporting the conclusion that exit-site infections can result in peritonitis. Peritonitis and exit-site infections caused by *S. aureus* and *P. aeruginosa* require catheter removal more often than when these same infections are caused by *S. epidermidis* (38). Others have found high rates of treatment failure when infection was due to fungi *(93,94,99)*. Piraino et al. (38,*67*) also found that peritonitis episodes resulting from *S. epidermidis* infrequently had associated exit-site infections, whereas peritonitis caused by *S. aureus* or *Pseudomonas* species were frequently associated with a catheter infection.

Comments on Specific Pathogens

Coagulase-Negative Staphylococci Eighty percent of coagulase-negative staphylococci belong to the species *S. epidermidis (100,101)*; coagulase-negative staphylococci are an important component of the cutaneous flora. Although adherence factors and slime production are thought to be important in pathogenesis of infection, studies have not confirmed this hypothesis. Strains capable of producing slime were not more frequently isolated from episodes of peritonitis (95); in one study, peritonitis-causing strains lacking adherence and slime productivity were more frequently associated with complications *(102)*. Infections resulting from *S. epidermidis* tend to be milder and more responsive to therapy than infections resulting from *S. aureus*. These infections are generally felt to be a consequence of touch contamination (see also Chapters 30 and 31).

Staphylococcus aureus Several studies have found that nasal carriers of *S. aureus* are at higher risk for exit-site infections and peritonitis than noncarriers *(49–54,103)*. Epidemiologic typing has confirmed a high concordance between strains of *S. aureus* isolated from infections and those isolated from the nares *(54,103,104)*. More recently, strains of staphylococci with reduced susceptibilities to glycopeptide antibiotics including vancomycin have been described *(105–107)*, as well as isolates possessing absolute resistance *(108,109)* (see also Chapters 28 and 29). *S. aureus* peritonitis may be a consequence of touch contamination but is more often associated with catheter infection.

Enterococci Although an infrequent cause of initial peritonitis in patients on peritoneal dialysis, enterococci, including vancomycin-resistant strains, have been found in increasing frequency, especially among patients with heavy exposure to antimicrobics. Guidelines for preventing the emergence and spread of vancomycin-resistant enterococci have been published *(110)* (see also Chapter 33).

Enterobacteriaceae Although the precise origin of these microorganisms as a source of exit-site infections and peritonitis is not known, hand and cutaneous carriage seems more plausible than transmural migration. Ill patients and those with chronic medical problems often are colonized with these microorganisms *(111–113)*. Also, dialysate readily supports the growth of microorganisms such as *E. coli*, as opposed to staphylococcal species; a high index of suspicion for contamination by these microorganisms should be maintained *(69,70)*.

Pseudomonas Species These microorganisms also colonize the skin of chronically debilitated patients *(111–113)*. Their repeated isolation should also prompt investigation of products, including disinfectants, that might be contaminated *(66,114)* or exposure to water sources, including pool water or even potable water *(115)*.

Fungi The source of most yeast is the patient's skin, mucous membranes, or the bowel; less comes from the environment. Fungal peritonitis is rarely caused by exit-site infections but rather by touch contamination from individuals colonized by yeast (116). Established predisposing factors include recently treated bacterial peritonitis, use of broad-spectrum antibiotics, and healthcare-associated acquisition *(94)*. Infections usually respond poorly to therapy without removal of the peritoneal catheter. Filamentous fungal infections usually arise from environmental contamination. Of these, *Fusarium* species is most common *(117)*.

Mycobacteria Environmental contamination, especially from water, predisposes to mycobacterial infections resulting from *M. chelonae* and related microorganisms *(118)*. Several outbreaks have been reported in patients receiving intermittent peritoneal dialysis by automated machines *(17)*.

Miscellaneous Microorganisms Infections resulting from other human flora (e.g., *Haemophilus* species, *Neisseria* species, *Branhamella* species, and *Gardnerella* species) have been reported, as have infections caused by diverse microorganisms, including *Campylobacter* species, *Pasteurella* species, *Listeria* species, and vibrios. Even episodes of peritonitis caused by *Prototheca wickerhamii* have been reported *(119)*.

DIAGNOSTIC CONSIDERATIONS

Clinical Manifestations of Peritonitis and Exit-Site Infections

Most patients who develop peritoneal dialysis–associated peritonitis usually have some complaints of abdominal pain and notice a change in their dialysis effluent from a clear to somewhat cloudy fluid. Onset may be abrupt or relatively indolent depending on the bacterial load and nature of the infecting pathogen. For example, patients who develop peritonitis from *S. aureus* or *P. aeruginosa*

TABLE 64-2

Symptoms and Signs Associated with Dialysis-Associated Peritonitis

Clinical Manifestations	*Percentage of Patients (Range)*
Symptoms	
Abdominal pain	73–95
Nausea, vomiting	25–35
Chills	18–23
Diarrhea	6–9
Signs	
Cloudy effluent	86–98
Abdominal tenderness	
Fever (=38°C)	24–34
Drainage problems	10–15

(Data from references *10,67,121–123.*)

have a more aggressive course than patients who have *S. epidermidis* peritonitis *(64,67,73,120)*. Obviously, if peritonitis occurs as a result of bowel perforation, patients usually develop signs of an acute abdomen.

Table 64-2 lists the common manifestations of dialysis-associated peritonitis *(10,67,121–123)*. Of particular importance is the relative infrequency of constitutional manifestations. In general, less than one third of infected patients have fever. However, patients can develop acute illness rapidly. Incubation periods range from a few hours to several days.

Exit-site or tunnel infections usually present with pain accompanied by serous or seropurulent drainage. Unless peritonitis is also present, systemic signs or symptoms occur rarely.

Examination of the Peritoneal Fluid

More than 90% of patients with peritonitis have cloudy effluent because of the elevated number of peritoneal leukocytes. Normally, the peritoneal fluid contains <60 white blood cells/mm^3; most are mononuclear cells. Infection rapidly results in an increase in the number of white blood cells in the peritoneal fluid and a shift from mononuclear cells to polymorphonuclear leukocytes *(76–78,124)*.

Most patients develop cell counts ranging from a few hundred to several thousand *(20,124,125)*; more than 50% of the cellular component is composed of polymorphonuclear leukocytes *(126)*. Polymorphonuclear leukocyte counts >100/mm^3 in the peritoneal fluid correlate strongly with infection. Occasionally, in some infections, a mononuclear cellular response is found, such as with tuberculous peritonitis. However, most microorganisms associated with dialysis-induced infection result in neutrophilia.

Peritoneal neutrophilia can also be seen in noninfectious inflammatory conditions affecting the peritoneum, including peritonitis caused by chemical irritants or endotoxin, an intraperitoneal bleed, serositis resulting from systemic vasculitis, or primary gastrointestinal disease. Occasionally, peritoneal eosinophilia is observed. Its presence suggests a foreign body (catheter) reaction or an allergy to a catheter component or other product. It is generally a self-limiting process *(127)*.

Gram Staining of Peritoneal Fluid or Drainage from Exit Sites

For cases of suspected peritonitis, preparation of a gram-stained smear (or other special stains for acid-fast or fungal microorganisms, as appropriate) of the sediment from a centrifuged sample of effluent is important. If the stain is positive, more specific therapy can be instituted, and purely empiric therapy can be avoided. Unfortunately, studies have found a positive Gram stain in only 9% to 35% of cases of peritonitis *(128)*. If purulent drainage is present from an exit-site infection, the Gram stain may prove quite useful in guiding initial therapy.

Culture Methods

Peritoneal dialysate effluent should be cultured as soon as possible in any patient with suspected peritonitis. If this is not feasible, the bag should be stored in a refrigerator and transported to the laboratory within 6 hours.

The optimal method for culturing peritoneal effluent is a matter of considerable controversy. Because the inoculum is usually quite low *(20,129)*, large-volume sampling has resulted in a higher yield. Effluent should generally be concentrated by centrifugation or filtration or inoculated into an enrichment medium *(20,22)*. Use of filters, however, is technically demanding and may result in contamination *(130)*. von Graevenitz and Amsterdam's review (95) of the various microbiologic techniques available is excellent. These authors reviewed studies published before 1987 and found significant problems in comparing various culture methods because of problems in study design and the use of inadequate volumes for direct culturing. They concluded that a minimum of 10 mL of effluent should be cultured, using an enrichment broth with antiphagocytic and lytic properties.

More recently, additional studies have demonstrated that, in addition to concentrating specimens, direct sampling of dialysate into an isolator tube with subsequent inoculation or direct inoculation into semiautomated blood culture systems such as Bactec bottles has been associated with high yields *(131–133)*. An Ad Hoc Advisory Committee on Peritonitis Management (chaired by W.F. Keane, M.D.) recently released a consensus on techniques for sampling and culturing peritoneal dialysis effluent and exit sites (134). Their recommendations are as follows:

1. Peritoneal dialysate effluent should be analyzed as promptly as possible after peritonitis is suspected.
2. An aliquot of 10 to 50 mL should be centrifuged, and the sediment should be examined by Gram stain.
3. Specimens should be cultured by using either concentration methods such as centrifugation (resuspension in nutrient broth or sterile saline with subsequent inoculation of blood and MacConkey agar plates; if a perforated viscus is suspected, anaerobic cultures can also be done; lytic substances such as Triton X can be added to the effluent before centrifugation and may increase the yield of positive cultures) or Millipore filtration. A semiautomated blood culture system for culturing peritoneal dialysis effluents appears to be suitable as well.

4. Using media with antiphagocytic substances and antibiotic binding resins may also result in higher yield.
5. A Calgi swab should be used to culture purulent exudate obtained from an exit site.

COURSE AND PROGNOSIS

Although most patients are not acutely ill, some patients initially develop high-grade toxicity with onset of infection. Blood cultures occasionally are positive. Peritoneal infection also results in impaired ultrafiltration, increased glucose absorption, and tremendous protein losses *(135)*. Infection can result in pulmonary complications resulting from bowel distention with displacement of the diaphragm and pulmonary edema from inadequate volume removal. The inflammatory reaction itself produces a fibrinogen-rich exudate with fibrin clot formation and impaired drainage. Repeated episodes can cause scarring with loss of the peritoneal membrane for further ultrafiltration.

Most cases of peritonitis respond promptly to appropriate antimicrobic therapy. However, as discussed previously, certain microorganisms tend to be more difficult to treat or do not respond well to antimicrobial therapy unless the implanted catheter is removed *(67,93,94,99)*. Patients who relapse after seemingly appropriate therapy also usually require catheter replacement. However, this can often be done as a simultaneous procedure often obviating the need for "bridge" hemodialysis (38).

Most exit-site infections can be managed conservatively. However, the presence of a tunnel abscess almost always necessitates replacement of the implanted catheter, which can often be done as well by a simultaneous procedure (38).

PREVENTION AND CONTROL

Despite major advances since the acceptance of chronic peritoneal dialysis as a method of chronic dialytic therapy, infection and catheter-related complications continue to cause significant morbidity. Table 64-3 summarizes important recommendations for prevention.

It is strongly suggested that each center monitor all peritoneal dialysis–associated infections by type, cause, microorganism, etc. as part of its quality assurance programs. The recent 2005 ISPD Recommendations offer several monitoring methodologies for this purpose (48).

Prevention largely depends on three factors: proper selection and training of patients, strict adherence to aseptic techniques in all aspects of dialysis, and use of intervention strategies for special at-risk populations.

Patient Selection and Training

Few medical conditions make chronic peritoneal dialysis the method of choice for chronic dialytic therapy. Its ease of performance, ability to be done in the home setting, lower cost when compared with hemodialysis, and, as in the case of CAPD, machine independence have led to greater patient acceptance. Rates of complications are reduced in the highly motivated patient who has received thorough training with continued supervision *(136,137)*. Although peritoneal dialysis training nurses experience would be expected to lower infection rates, one study showed the opposite effect, at least for gram-positive infections *(138)*. This suggests that more "active learning" and continuing trainer education may be more reliable than lengthier experience times. Periodic patient retraining, use of infection control programs, and continuous infection review can aid in lowering infection rates (139).

TABLE 64-3

Prevention of Infection in Patients on Chronic Peritoneal Dialysis

- Select well-motivated patients and thoroughly instruct them in sterile techniques.
- Place the implantable silicone catheter using sterile technique. Double-cuffed catheters may be preferred.
- Anchor the catheter site firmly.
- Wash hands before all manipulations and avoid touch contamination of tubing connections.
- Consider special catheter connectors such as Y-sets using the "flush before fill" concept, patient-assist devices, or connecting devices using ultraviolet sterilization.
- Reduce manipulations to a minimum.
- Perform daily site care with at least soap and water (possibly chlorhexidine) and inspect site for signs of early infection.
- Consider antibiotic prophylaxis (topical, such as mupirocin vs. systemic) only in very limited circumstances (e.g., staphylococcal carriers with frequent exit-site infections).
- If using an automated machine using reverse osmosis to "sterilize" tap water, clean, and disinfect it regularly.
- Treat other sites of infection early to reduce chances of hematogenous or transmural spread to the peritoneum.
- Optimize host defenses by good nutrition and care of other medical problems.

Type of Catheter and Insertion Techniques

Although studies have not established that the precise type of catheter inserted has definitely affected rates of infection, Silastic catheters containing both a superficial and a deep Dacron cuff may lower rates of infection when compared with single-cuffed catheters *(45,46)*. Because silicone can be degraded by iodine or povidone-iodine over time and does not resist biofilm formation (134), newer catheter materials are needed. Bonding of antimicrobic agents to indwelling devices may reduce risks for device-associated infections *(140)*. Studies have not shown definitive advantages for any single method of placement (blind vs. surgical vs. peritoneoscopic insertion) or for placement performed in an operating room suite as opposed to elsewhere; strict attention to asepsis is always important (15,*46*,139). Downward direction of the catheter exit has been suggested (139). A recent Cochrane review also failed to find any catheter-related intervention that had any impact on peritoneal dialysis–associated peritonitis or exit-site infection (141). Antimicrobial prophylaxis appears to be warranted immediately before surgical placement

of the catheter (*42*,139,*142*). Likewise, preoperative skin cleansing with chlorhexidine-alcohol appears to be more protective against infection than povidone-iodine for surgical-site antisepsis (143).

Asepsis during Peritoneal Dialysis

Most episodes or peritonitis are due to inadvertent contamination of the dialysis fluid or peritoneal catheter during exchanges (intraluminal contamination). Strict adherence to aseptic practices is essential and can reduce infection rates *(68,144)*. Good hand washing practices using an alcoholic gel rub or antimicrobial soap *(145)*, performing dialysis in a clean and safe environment, and inspecting all supplies for defects before use are important. Numerous connectors and connecting devices have been developed to reduce the possibility of accidental contamination during bag exchanges. These include such items as the titanium adapter *(28,146)*, use of added tubing to permit flush before fill as the Y-connector *(30)*, mechanical patient assist devices *(146)*, connecting devices with in-line bacteriologic filters *(130)*, and devices designed to clean the connections with disinfectants *(147,148)*, UV radiation *(47)*, or heat *(149)*. Studies on the efficacy of these devices have produced contradictory results but definitely show added costs. It does appear that both the UV and the Y-connectors have promise; a study of 3,366 CAPD patients who started dialysis at home for the first time between January 1, 1989, and June 30, 1989, demonstrated a relative risk of first peritonitis significantly lower for the Y-set (relative risk: 0.6; $p < .01$) and UV set (relative risk: 0.75; $p < .01$) when compared with the standard spike connecting set *(29)*. The difference in relative risk between the Y- and the UV sets was also statistically significant ($p < .01$). The benefits of the Y-systems on reducing rates of peritonitis was confirmed in another recent study with rates of one episode per 40 months, compared with one episode per 16 months for other systems *(150)*. In Europe, Y-sets containing disinfectants have resulted in fewer episodes of peritonitis when compared with standard connection systems. However, because of fear of accidental chemical peritonitis during use, these modified systems are not popular in the United States. More recently, Y-sets, in which both the dialysis solution and the drain bags were preattached, appear to have reduced peritonitis rates further *(151)*. A recent randomized control trial review showed that the only catheter-related intervention that was effective at preventing peritonitis was use of twin bag and Y set disconnect systems (152). Of two common twin bag systems, Ultrabag and Andy-Disc, the Ultrabag System has trended toward a lower peritonitis risk (153). The use of standard spike systems is strongly discouraged.

Systems that permit fewer connections and disconnections have also been associated with reduced rates of peritonitis. Some patients can tolerate three exchanges per day rather than four. Use of the CCPD machine reduces manipulations to twice daily with lower rates of peritonitis *(18)*. Automated intermittent peritoneal dialysis permits even fewer interruptions but may be associated with outbreaks when used at centers or with endemic disease because of problems with disinfection and sterilization *(17,59,60)*. Formal recommendations for the care of these machines have been published *(154)*.

Use of disinfectants can also reduce rates of peritonitis. With the popular twin bag system came disposable peritoneal dialysis tubing that does not require disinfection. However, disinfectants are still used to maintain sterility of transfer set tips and peritoneal dialysis catheters. Either povidone-iodine or sodium hypochlorite (each with pros and cons) can be used. This topic has been reviewed recently *(155)*.

Site Care and Special Considerations

Daily inspection and care of the exit site is also important, although some controversy exists as to whether such care should include daily showering with soap or additional use of antiseptics on the exit site. One study suggested that rates of exit-site infection can be reduced by using a protective nonocclusive dressing and povidone-iodine cleansing *(44,51)*; others have not confirmed this observation (134), whereas another small study suggested chlorhexidine to be superior to povidone-iodine *(156)* for site care. An excellent summary of exit-site practices has recently been updated (15). However, optimal site care procedures are largely undetermined secondary to lack of controlled studies. Infection must be detected and treated early to reduce progression to a tunnel abscess or peritonitis.

S. aureus carriers are anywhere from two- to sixfold at higher risk for peritonitis than noncarriers *(157)*. *S. aureus* nasal carriers seem to have benefited from attempts to eliminate carriage by use of various antimicrobic prophylactic agents in some, but not all, studies *(49,52)*. Agents used have included rifampin, trimethoprim-sulfamethoxazole, intranasal bacitracin or mupirocin, or topical mupirocin applied to the exit site *(57,158)*. A multicenter study involving 267 staphylococcal carriers suggested that monthly application of intranasal mupirocin for 5 days results in a reduction of exit-site infections due to *S. aureus* *(159)*. A meta-analysis involving 14 studies and a total of 1,450 patients showed that topical mupirocin decreased rates of peritonitis and exit-site infections by *S. aureus* by 70% (160). However, a recent Cochrane review did not show an overall decrease in peritonitis (only exit-site infections) (161), and this was corroborated earlier in another study *(162)*. Widespread usage of mupirocin applied topically to the nares or exit site may result in significant development of resistance *(163)*, may cause catheter rupture *(164)*, and may not be cost-effective *(165)*. However, another study documented low mupirocin resistance rates even after 7 years of exit-site use *(166)*. Unfortunately, more serious infections such as tunnel infections and peritonitis resulting from *S. aureus* were also unaffected by this regimen. However, the epidemiology of infections in staphylococcal carriers is not completely understood, and many chronic carriers do not develop exit-site infections. It might be prudent to restrict such intervention to proven carriers with repeated infections. The device should best be removed after successful renal transplantation (within 4–6 weeks after surgery). The use of mupirocin appears to decrease *S. aureus* peritoneal dialysis infections but does not decrease pseudomonas or other gram-negative infections. Use of topical gentamicin at the exit site was shown to decrease gram-negative infections (including pseudomonas) at the exit site and gram-negative peritonitis. It may also be as effective as mupirocin at preventing

S. aureus infections at least in one randomized, double-blind study (116). Whether or not regular showering with chlorhexidine at home will reduce exit-site infections or peritonitis, especially due to gram-positive microorganisms including coagulase-negative staphylococci and *S. aureus* is uncertain. If studies demonstrate benefit, as suggested in recent papers in other settings, rates of infection due to gram-positives may fall further (167,168).

Antibiotic Prophylaxis to Reduce Episodes of Peritonitis

Preoperative intravenous antimicrobial prophylaxis appears to reduce early rates of peritonitis but does not alter rates of exit-site or tunnel infections (161,*162*) nor does it result in a reduction of peritonitis in the long term *(169,170)*. An uncontrolled and nonrandomized study suggested that oral prophylaxis with nystatin administered at the time of bacterial peritonitis may reduce subsequent episodes of fungal peritonitis *(171)*. More recent studies also suggested that oral nystatin reduced antibiotic-related fungal peritonitis *(171,172)*. A recent Cochrane review also corroborated this finding (161) but found no conclusive evidence to support use of topical disinfectant, oral prophylactic antibiotics, connection device germicidal chambers, or staphylococcal vaccines.

FUTURE CONSIDERATIONS

Improved catheter materials designed to minimize foreign body reactions, adherence of microorganisms, and biofilm formation; improved techniques of catheter placement and site sealing; newer delivery systems resulting in fewer episodes of contamination; and improved methods of skin cleansing are needed. Enhancing both local and systemic host defense systems may also lead to lower rates of infections in patients on chronic peritoneal dialysis therapy. Trials of a *S. aureus* conjugate vaccine in patients receiving hemodialysis appear promising in preventing systemic infection resulting from *S. aureus (173)*, and investigations using modified hyperimmune globulin to *S. aureus* are also being investigated for patients with recurrent staphylococcal infections.

CHAPTER 65

Infections that Complicate the Insertion of Prosthetic Devices

Ilker Uçkay, Daniel P. Lew, and Didier Pittet

The insertion of implants and medical devices is now a common procedure that benefits patients, often in a lifesaving way, who are suffering from a variety of exogenous-acquired (trauma, endocarditis, rheumatic fever, hydrocephalus) or degenerative diseases (arthrosis or arthrosclerosis). A fundamental feature of foreign bodies is their exquisite susceptibility to infection. The inoculum of bacteria necessary to induce such postsurgical infections is extremely low when compared with surgery in the absence of a foreign body *(1,2)*. In addition, bacteria that are often nonpathogenic and normally present as skin commensals (i.e., coagulase-negative staphylococci or *Propionibacterium* species) are able to cause infections under these conditions *(2)*.

The impact of such infections is profound, because they often result in tissue destruction, serious dysfunction of the prosthetic device, and sometimes systemic dissemination of the pathogen. These infections are very difficult to cure with antimicrobial agents alone and most often necessitate the removal of the device or surgical debridement. In this chapter, we take as paradigms the four most frequent surgical implants: orthopedic implants, vascular devices, cerebrospinal shunts, and breast implants. By analogy, the knowledge of infections associated with these four foreign bodies includes the current knowledge for most surgical implant infections. In the first part, we provide insights into their general pathogenesis, incidence (Table 65-1), microbiology, and prevention. In the second part, we discuss individual aspects of the different implants including clinical presentation, pathogenesis, microbiology, and prevention.

PATHOPHYSIOLOGY

To understand the difficulties underlying foreign body infections, it is necessary to characterize four different problems: (i) biofilms, (ii) local neutrophil dysfunction, (iii) small colony variants (SCV) of staphylococci, and (iv) multiresistant staphylococci.

Biofilms

The biofilm concept is extensively discussed in Chapter 31 and only the most important aspects are summarized here. Fundamental differences exist between surface-adherent bacteria and bacteria present in the fluid (planktonic) phase. It has been suggested that biofilm-enclosed microorganisms escape antibiotic killing because the extracellular material prevents diffusion and bacterial uptake of antimicrobial agents *(2,3)* (Fig. 65-1). Moreover, microorganisms attached to foreign material and exposed to bactericidal concentrations of antibiotics develop tolerance (i.e., the bacteria become resistant to the lethal effect of the antibiotic) *(2,3)*. In an *in vitro* model of surface-adherent *Staphylococcus aureus* growing onto polymethylmethacrylate, it was possible to demonstrate a decreased susceptibility to antimicrobial agents within 4 hours after adherence *(3)*.

Altered Host Defense in the Vicinity of Foreign Material: Neutrophil Dysfunction

Data from a study investigating neutrophils from animals with experimental foreign body infection revealed that cells recovered from the vicinity of the implant produced only a weak respiratory burst and had poor bactericidal activity compared with those collected from the blood of the same animals. This deficiency was due to prior activation of the neutrophils by the foreign material. This phagocytic defect may explain the high susceptibility of foreign bod-

TABLE 65-1

Frequency of Foreign Body Infections

Device	*Infection Incidence*[a]
Cardiovascular Implants	
Prosthetic heart valves	~4%
Pacemakers	1–3%
Cardioverter-defibrillators	~4%
Left ventricular assist devices	10–30%
Vascular grafts	~1.5%
Neurosurgical Shunts	
Cerebrospinal fluid shunts	1–10%
Orthopedic Implants	
Primary hip arthroplasties	<1.5%
Primary knee arthroplasties	<1.5%
Primary shoulder arthroplasties	~4%
Fracture implants (plates, nails)	3–4%
External fixation PINs	2–11%

[a]Adapted from reference *(27)*.

ies to infection *(4)*. A foreign body reduces the inoculum of *S. aureus* required to induce infection from more than 100,000 to as few as 100 colony-forming units *(5)*. Additionally, the extracellular slime substance produced by adherent staphylococci has potent immunomodulatory properties *(6)*. Several neutrophil functions appear to be affected. Chemotactic responsiveness is diminished and degranulation of specific granule content is increased. Finally, total joint prostheses may shed ultrahigh molecular weight polyethylene particles, thus impairing the phagocytic abilities of the neutrophil *(7)*.

Staphylococcal Small Colony Variants

Staphylococci are responsible for most infections associated with implants *(8)*. Staphylococcal SCV phenotypes are often found in foreign body infections *(9,10)*. They constitute a subpopulation of bacteria and have atypical colony morphology and unusual biochemical characteristics, thus making them a challenge for clinical microbiologists to identify. Clinically, SCV persist in mammalian cells and are less susceptible to antibiotics, especially aminoglycosides, than their wild-type counterparts and are a cause of recurrent infections (*3*,11,*12*). SCV of *S. epidermidis*, a phenomenon well known in *S. aureus (9,10)*, also exist and can emerge during glycopeptide therapy *(13)*.

Multiresistant Staphylococci

Since implants are particularly prone to infections due to staphylococci, resistance to current antibiotics among these pathogens adds to the heavy burden of disease. The ever-increasing incidence of implant infections due to methicillin-resistant *S. aureus* (MRSA) *(14)* and methicillin-resistant *S. epidermidis* (MRSE) *(15,16)* is a serious challenge. MRSE is already the most commonly encountered variant of *S. epidermidis* in many healthcare institutions *(16,17)*. With coagulase-negative staphylococci, polyclonal implant infections may occur, and this may be one of the explanations for treatment failure as laboratories do not always perform antibiotic susceptibility testing for all isolates *(2)*. So far, it remains unknown when patients become colonized with MRSE upon hospital admission, but it is probable that it occurs very fast. In a Swedish study, most patients on an orthopedic ward were colonized with MRSE at day 14 of admission *(18)*.

MRSA is usually resistant to many clinically important non–beta-lactam drugs, such as fluoroquinolones and clindamycin that have excellent bone and joint penetration *(19)*. Vancomycin, which is mostly used to treat MRSA infections, has slow bactericidal activity. In this setting, treatment of these infections can be problematic, particularly in the presence of multiple drug intolerance or allergy.

MRSA-related orthopedic implant infections (even with hospital-acquired MRSA) yield a high risk of treatment failure, independent of the clonal microbiological properties and genetic characterization of the isolates. In a recent study including different orthopedic implant material, treatment failure was reported as 35% *(20)*. Failure was nine times more frequent in patients with prosthetic joint infections due to hospital-acquired MRSA than in patients with methicillin-susceptible *S. aureus* (MSSA) infection (21). However, this remains a controversial issue, and while some reports do not attribute an increased treatment failure *(22)*, others report higher failures in resistant staphylococcal infection *(23)*. Of note, known MRSA skin colonization poorly predicts the pathogen of underlying implant infection due to *Staphylococcus* species *(24)*.

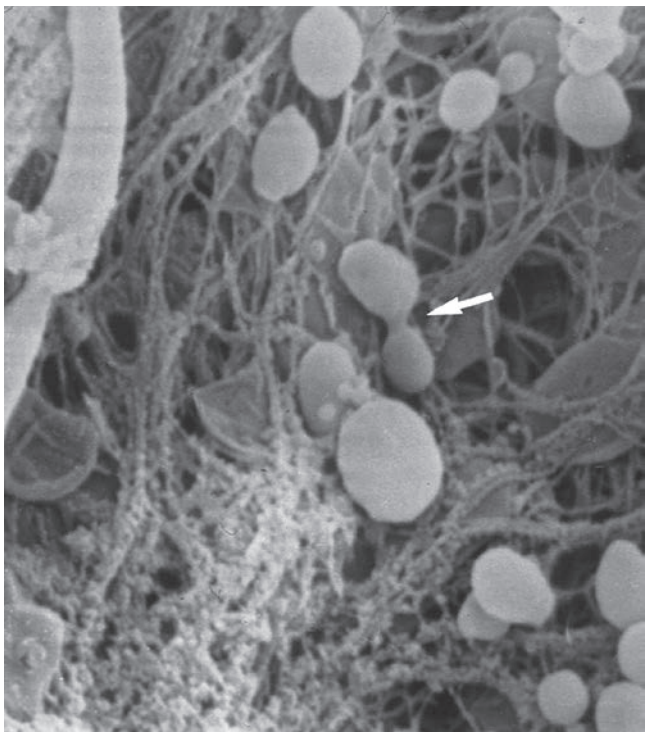

FIGURE 65-1 Biofilm in prosthetic infection. Scanning electron micrograph from infected total hip prosthesis. Cocci-shaped bacteria are shown, partly surrounded by extensive biofilm, amorphous material, and fibrinous elements. In the middle (*arrow*), the bacterium is dividing. *Staphylococcus epidermidis* was isolated (*2*).

ORIGIN AND MICROBIOLOGY OF PROSTHETIC INFECTIONS

Surgical site infections (SSI) are discussed in detail in Chapter 21 and only key salient points are provided here. Prostheses become infected by three different routes: (i) through the introduction of microorganisms during the operative procedure *(25);* (ii) by hematogenous seeding *(26)* or (iii) by lymphatic spread in the case of adjacent erysipelas. Most SSIs are believed to be acquired during surgery *(25)*, and this is supported by the success of prevention measures targeted on activities inside the operating room and a few reports demonstrating matching strains of pathogens from the surgeon's fingers and postoperative infection *(27)*. At present, the proportion of SSI really acquired in the operating room versus postoperatively on the ward remains unknown. Similarly, within the subgroup of SSI acquired during surgery, the proportion attributable to the patient himself or herself versus that transmitted by the surgical staff or the operating room environment is also unknown *(27)*. Freshly implanted biomaterial is probably more susceptible to infection. In addition, any factor or

event that delays surgical site healing increases the risk of infection, and ischemic necrosis, infected hematomas, and suture abscesses are common preceding events for joint sepsis *(28)*.

Apart from the setting of cardiac implants, hematogenous seeding probably occurs rarely compared to inoculation during surgery and early postoperative care. The estimated incidence of hematogenous infection among all arthroplasty infections ranges from a low 5.6% *(29)* to 9% to 10% *(27,30)*. However, in absolute terms, the incidence is quite low. Ainscow et al. *(31)* detected only three cases of prosthetic joint infections among 1,112 prostheses (2.7 per 1,000) that developed a hematogenous infection. In their prospective arthroplasty cohort, the authors of this chapter detected only seven hematogenous infections among 6,100 arthroplasties (1.1 per 1,000) performed during 1996 to 2008. Arthroplasty patients hospitalized for severe remote infections developed only one hematogenous arthroplasty infection compared with 88 remote infections *(27)*. Any bacteremia can induce an implant infection by hematogenous seeding *(27)*, although there appears to be a higher risk for prosthetic joint infection in the setting of *S. aureus* bacteremia *(32–34)*. The skin is reported to be the most frequent source of infection *(25)* followed by the genitourinary, respiratory, and gastrointestinal tracts *(27)*. However, this ranking is not fixed and depending on the setting, a gastrointestinal origin can be predominant *(27)*.

Staphylococci (*S. aureus* and coagulase-negative staphylococci) account for at least 60% of all implant infections (*8*,*35*,36) (Table 65-2). Aerobic gram-negative bacteria *(37)*, streptococci, enterococci, and anaerobes cause infection in <25% of cases. Culture-negative arthroplasty infection may occur in 15% of cases *(38)*. Polymicrobial infection is commonly seen as a complication of poor postoperative wound healing *(39)*. Certain comorbidities increase the risk of infection with specific microorganisms. For instance, patients with rheumatoid arthritis are at increased risk for *S. aureus* infection *(40)*, and *Propionibacterium acnes* is more commonly encountered in patients with an infected total shoulder arthroplasty *(41,42)*.

PREVENTION OF PROSTHETIC INFECTIONS

Prevention remains the cornerstone of infection control. It is efficacious and certainly more cost-effective than any form of therapy. SSI and preventive measures in general are discussed in detail in Chapter 21. In this section, we highlight special issues regarding the prevention of surgical prostheses infections.

Well-established, modifiable risk factors for SSI are reported in the literature. These include preoperative hair shaving instead of clipping (43), intraoperative hypothermia *(44)* or hyperglycemia *(45)*, lack of compliance with hand hygiene and surgical antisepsis (46), and suboptimal timing of perioperative antibiotic prophylaxis *(47)*. However, it is probable that no single measure is superior to others in preventing SSI of exogenous origin. This highlights the need for a multimodal approach involving active postdischarge surveillance and measures at every step of patient care: from the operating room to nonnegligent postoperative care *(27)*. An active surveillance program is important for the detection of implant infections *(27)* and should comprise a minimum length of 1-year follow-up *(48)*. Programs without active postdischarge surveillance readily miss half of all prosthetic infections *(27)*. Multicenter or supranational intervention programs based on guidelines, "bundles," or safety checklists are likely to be beneficial on a global scale *(27)*.

Antimicrobial Prophylaxis

The benefit of the administration of preoperative antimicrobial agents is largely undisputed. In orthopedic implant surgery, prophylaxis helps to reduce infection rates from 4% to 8% without antibiotics to 1% to 3% according to several trials performed in the 1970s to 1980s *(27)*. Administration of prophylactic antibiotic agents follows some rules. (a) A single intravenous dose of first- or second-generation cephalosporins is sufficient for most types of surgery *(47–51)*, and an additional benefit of antibiotics in irrigation fluid *(47)* has not been proven. (b) Timing is of

utmost importance (*47*,52,*53*) and prophylaxis should be entirely administered within 1 hour before incision. (c) One dose is sufficient. For operating procedures longer than 4 hours or with significant blood loss, redosing might be justified (*47*,52). (d) When a tourniquet is used, the entire dose should be administered prior to its inflation *(54)*.

A single dose of vancomycin (1 g) is the prophylactic antibiotic of choice for all procedures requiring prophylaxis in patients colonized with MRSA *(48,55)*. Concerning MRSE, a switch to glycopeptide prophylaxis for implant surgery patients is sometimes suggested in the literature. A review of four randomized trials comparing prophylactic teicoplanin versus prophylactic cephalosporin in settings with a high MRSE prevalence identified the same infection rates in both groups (56). This has been confirmed also in a meta-analysis of seven randomized trials for cardiac surgery *(57)*, even though single trials in favor of a general switch to vancomycin prophylaxis in cardiac surgery exist *(58)*. A recent systematic review and economic model of switching from nonglycopeptide to glycopeptide antibiotic prophylaxis for surgery in endemic MRSA settings failed to show increased efficacy in preventing SSI due to methicillin-resistant strains *(59)*. Even for MRSA, there is insufficient evidence to determine whether there is a threshold prevalence to justify a switch to general glycopeptide prophylaxis *(59)*.

Antibiotic prophylaxis before a dental intervention in implant patients is contested, apart from those with artificial cardiac valves (*60*,61), cardioverter-defibrillators, and left ventricular assist devices. This topic is further expanded upon in the corresponding subchapter.

Other Prevention Measures

MRSA has the capacity to colonize patients' skin for several months *(62)* if not years. These infections represent a failure in quality of care, are costly, and may ultimately compromise patient safety. Prevention is of the utmost importance and the introduction of universal MRSA screening upon hospital admission is seriously debated for this patient population (63,*64*). However, the results of several outstanding prospective trials in recent years are inconclusive. While some before–after studies *(65–67)* report a benefit, other randomized, crossover design trials (63,*68*) failed to show a reduction in infection rates (or at least in SSI rates due to MRSA). The debate is not closed. The screening for MSSA nasal colonization and consequent decolonization is equally debated *(27)*. Very recently, a multicenter, double-blind, prospective trial assessing *S. aureus* carriage at admission by PCR and subsequent nasal and total body decolonization during 5 days showed a significant reduction of hospital-acquired *S. aureus*. The authors concluded that the number of hospital-acquired surgical site *S. aureus* infections can be reduced by this strategy. However, results for SSI due to non–*S. aureus* were not reported *(69)*.

Vaccines provide an attractive conceptual alternative to preventing bacterial infections. A preliminary study with an antistaphylococcal vaccine in hemodialysis patients failed to reduce sepsis due to *S. aureus* in the first year following vaccination (relative risk reduction: 26%; $p = .23$) *(70)*, but further research is necessary to explore this possibility.

Aggressive treatment of infection present elsewhere in the body is required before any implant replacement, and all patients need to be informed about this potential complication. Infections should be treated without any delay to allow surgery to be performed. Asymptomatic bacteriuria is probably no risk for subsequent implant infection *(26,71)*.

Many hospitals in resource-rich countries are equipped with relatively expensive vertical or horizontal laminar airflow systems in operating rooms that reduce the bacterial burden in the air *(72,73)*. However, in 2008, a retrospective analysis of the German national nosocomial infection surveillance system showed no benefit of ventilation with laminar airflow and suggested that it was even associated with a significantly higher risk for severe SSI after hip prosthesis *(74)*. Of note, this study has some flaws, such as a lack of data on individual antibiotic prophylaxis, obesity, normothermia, etc., and these findings need confirmation in large-scale studies *(75)*.

INFECTED ORTHOPEDIC PROSTHESES

Orthopedic surgery encompasses most implant-associated surgery. Joint replacement has become one of the most common prosthetic surgical procedures over the past decades because of its success in restoring function to disabled arthritic individuals (*76*,77). The overall number of prostheses is rising steadily due to the increasing number of replacements in an aging population. Thus, the number of arthroplasty infections will equally continue to increase, and it is projected that approximately four million hip and knee arthroplasties will be performed annually in the United States alone by the year 2030 *(78)*. Second to loosening, infection is the most common complication of arthroplasty surgery.

Presentation of Arthroplasty Infections

There is no standard definition of what constitutes an arthroplasty infection and thus, interpretation of the literature related to the treatment of these infections is difficult (77,*79*). Arthroplasty infection is obvious when multiple cultures from specimens surrounding the prosthesis yield identical microorganisms, when purulence and microorganism are detected surrounding the prosthesis, or when a sinus tract that communicates with the prosthetic device is present. To enhance specificity of diagnosis, five or six periprosthetic intraoperative samples should be obtained for aerobic and anaerobic culture (77,*80*). Submitting a smaller number of specimens leads to a decrease in sensitivity of the submitted cultures. When possible, withholding antimicrobial therapy for at least 2 weeks prior to collecting the specimens increases the yield of recovering a microorganism (77,*80*).

The absence of an obvious mechanical reason for a painful prosthesis in the first few years following implantation, a history of prior wound healing problems, or superficial or deep infection, should raise the suspicion of arthroplasty infection. The pattern of clinical presentation is determined largely by the nature of the infecting microorganism (i.e., the symptoms may be more prominent in *S. aureus* infections and less with coagulase-negative staphylococci). Constant joint pain suggests infection, whereas mechanical loosening commonly causes pain only with motion and weight bearing *(76)*.

Epidemiology of Arthroplasty Infections

Improved infection control practices and the standardization of antimicrobial prophylaxis have decreased the incidence of infection over the last 30 years *(76)*. Currently, the infection rate for hip and knee surgery is generally <1.5%, but it may be higher for other joints *(27)* (Table 65-1). Infections have been categorized by the postoperative period in which they occur *(81,82)*. Acute infection is defined as identified within 12 weeks of surgery (up to 40% of total infections). Subacute infection occurs within 2 years of operation (up to 45% of infections). In this setting, the patient usually develops articular pain after several months of symptom-free ambulation. Late infection (15% of infections) develops after 2 years of pain-free mobility and may be hematogenous in origin. However, this classification is artificial and flawed: for example, hematogenous infections can produce a fulminant presentation resembling early infection despite their late onset. Moreover, the absence of positive blood cultures does not exclude an occult bacteremia. In practice, blood cultures are not regularly obtained if patients do not have chills or fever, signs frequently absent in the elderly population undergoing joint replacement surgery *(26)*.

Prevention of Orthopedic Implant Infections

There is a wide range of risk factors for arthroplasty and other orthopedic implant infections, such as incorrect antibiotic prophylaxis (*47*,*48*,*50*,77), obesity, long operating times *(26)* revision arthroplasty *(83)*, or immunosuppression *(84)*. These are usually the same for every SSI, but arthroplasty-specific issues are also to be considered. Antibiotic-containing cement can be used both for prophylactic *(85)* and therapeutic indications (86,*87*). The choice of antibiotics is limited to those that are water soluble and thermostable as the polymerization of cement is an exothermic reaction that generates a substantial amount of heat (86). The most commonly used agents are tobramycin (e.g., 4.8 g of tobramycin per 40 g of cement), gentamicin, vancomycin (2 g per 40 g of cement), and cephalosporins to a lesser extent (86). Higher antibiotic doses substantially weaken the consistency of the cement. Implantation in sheep showed an antibiotic concentration in the bone cortex four times the minimal inhibitory concentration (MIC) 6 months after implantation. Human pharmacokinetics during total hip replacement showed concentrations 20 times the MIC in drainage fluids *(85)*, and local levels of antibiotics remained effective up to 4 months following surgery *(88)*. Many trials assess the use of antibiotic-loaded cements with systemic perioperative antibiotic prophylaxis. McQueen et al. *(89)* performed a prospective, randomized trial including 295 arthroplasties of the hip and knee. The cement group received 1.5 g of cefuroxime in 40 g of cement powder and the parenteral antibiotic group received 1.5 g of cefuroxime intravenously at the induction of anesthesia and two additional doses of 750 mg at 6 and 12 hours later. The observed frequency of deep surgical site infection was 0.7% in the cement group and 1.3% in the parenteral antibiotic group. Espehaug et al. *(90)* reviewed 10,905 primary cemented total hip replacements and concluded that systemic antibiotics combined with antibiotic-containing bone cement led to a lower number of infections. In another analysis of the same arthroplasty register, antibiotic-containing cement reduced infection frequency from 0.7% (with 24 hour intravenous prophylaxis) to 0.4% (24 hour intravenous treatment plus antibiotic-containing cement) *(91)*. The use of antibiotic-impregnated cement is usually only one of a series of determinant variables in clinical studies, and a lowering of the infection rate is often difficult to attribute to its use alone. It is also worth noting that tobramycin and gentamicin, the most widely used compounds, are not the ideal agents to prevent staphylococcal infections and may lead to local development of *S. aureus* SCVs *(9,10,76)*.

Antibiotic Prophylaxis before Dental Procedures The prevention of hematogenous infections in prosthetic joint infections with regard to dental procedures is not evidence-based (61) for several reasons: (a) the usual prosthetic joint infection pathogens are not of oral origin; (b) even if administered, systemic antibiotics do not completely suppress occult bacteremia occurring during dental intervention; (c) humans may have up to 12 daily episodes of occult bacteremia of dental origin. Routine antibiotic prophylaxis should be clearly distinguished from antibiotic treatment required in the case of established oral cavity infection (61). A computer simulation model *(92)* assessed the risks and efficacy of no prophylaxis, oral penicillin prophylaxis, and oral cephalexin prophylaxis among dental patients at risk for prosthetic joint infection. The analysis suggested a lower risk of infection than the risk of death-associated anaphylactic reaction to an antibiotic. Recently, a prospective cohort study conducted at the Mayo Clinic failed to show any protective effect of prophylactic antibiotics prior to dental procedures for subsequent hip or knee prostheses infections *(93)*.

In conclusion, we discourage the use of prophylactic antimicrobial agents before a dental intervention for patients with joint prostheses. Instead, patients with orthopedic prostheses should be carefully instructed about the risk of infection and carry this information with them at all times. However, any minor infections should be treated aggressively. Finally, a constant optimal oral and dental hygiene is more important in terms of prevention and should be routinely recommended (61).

INFECTIONS OF CARDIOVASCULAR SURGICAL IMPLANTS

Prosthetic Heart Valve Endocarditis

In a series assessing 5,671 recipients of prosthetic heart valves, 220 patients developed prosthetic valve endocarditis (PVE). Estimates of cumulative risks varied from 1.5% to 4.1% at 12 months and from 3.2% to 5.7% at 60 months *(94)*. Agnihotri et al. *(95)* reviewed risk factors in 2,433 patients who underwent valve replacement; endocarditis occurred in 3.7%. Both studies defined a higher risk period during the initial 12 months after surgery and a lower risk period thereafter. Although no difference has been reported between patients with mitral or aortic prostheses, a difference appears to emerge among mechanical valve recipients as compared with patients with bioprostheses. Calderwood et al. *(96)* found an enhanced risk for PVE among recipients

of multiple prostheses compared with recipients of a single valve. Ivert et al. *(97)* noted an increased risk of PVE with a longer cardiopulmonary bypass time.

Pathogenesis Specific to Prosthetic Valve Endocarditis: Early Versus Late Infection Early infection occurs within 12 months after surgery and most authors consider these as healthcare-associated and acquired during surgery. The bacteriology of late PVE suggests that these infections have been acquired outside the hospital. Incidental infections (e.g., urinary tract infections and furunculosis) and trauma to mucosal surfaces (e.g., genitourinary tract or pneumonia) may be identified as predisposing events for 50% of patients with late-onset PVE. The recovery of fastidious gram-negative bacilli (*Haemophilus* species, *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella kingae*, so-called HACEK) months and often years after surgery suggests that late-onset PVE is primarily acquired through incidental nonnosocomial infection and bacteremia.

In the past, fungi have not only accounted for significant numbers of early cases, but were also associated with high fatality rates. *Candida* species are the most common fungi causing PVE. Patients with PVE caused by *Legionella* species, mycobacteria, and fungi other than *Candida* species commonly present with negative blood cultures when routine techniques are used. Similarly, for *Coxiella burnetii* (the etiologic agent for Q fever), *Bartonella, Brucella* species, or *Treponema whippelii*, blood cultures are usually negative.

Clinical Features of Prosthetic Valve Endocarditis With the exception of more frequent signs of valve dysfunction and myocardial invasion, the clinical features of PVE are similar to those of native valve endocarditis. Most patients present with new murmurs, congestive heart failure, and septic embolism, for example, cerebrovascular complications. A small proportion of patients present with acute fulminant disease with severe hypotension or septic shock associated with infection resulting from *S. aureus* or *S. pyogenes*.

Prevention Placebo-controlled trials demonstrated a significant reduction in SSI by antibiotic prophylaxis *(50)*. Based on a literature review, Kaiser *(50)* recommends cefazolin (1 g intravenously). For patients unable to tolerate beta-lactam antibiotics, vancomycin (1 g intravenously) is suggested. In hospitals with a high prevalence of MRSA or MRSE, general cardiac surgical prophylaxis with vancomycin is appealing, but has not shown to be superior to prophylaxis with a cephalosporin *(60)*.

Patients must also be protected against late-onset PVE. Existing problems likely to give rise to transient bacteremia in the future (e.g., existing dental and gingival disease) should be addressed before an elective valve replacement is performed. For dental interventions, the regimen in the guidelines of the American Heart Association should be followed whenever possible *(60)* as the presence of prosthetic valves is a recognized indication for antibiotic prophylaxis before this type of intervention (Table 65-3). Peroral amoxicillin is the preferred choice, because it is well absorbed in the gastrointestinal tract and provides high and sustained serum concentration, although a substantial part of the *Streptococcus viridans* group may be resistant to it *(98)*. For patients with (pseudo)allergy to penicillins, the use of oral cephalosporins, clindamycin, or macrolides is recommended, although again, a minority of oral streptococci might be resistant to clindamycin *(99)*. Cephalosporin use should be avoided for patients with a history of anaphylaxis to penicillins due to possible cross-reactions.

The official recommendations for an intrabuccal procedure partly apply to bronchoscopies for which prophylaxis might be warranted when involving incision of the mucosa *(60)*. For invasive procedures related to the urogenital or gastrointestinal tract, antibiotic prophylaxis can be applied, thereby covering enterococci that are practically the sole pathogens known to provoke endocarditis. Again, no published data demonstrate a conclusive link between the gastrointestinal or urogenital tract procedures and the development of endocarditis and, to our knowledge, there are no studies demonstrating that the administration of antibiotic prophylaxis really prevents endocarditis in these settings *(60)*.

Prosthetic cardiac valve sewing rings impregnated with antimicrobial agents showed promising results *in vitro* but were marketed without definitive outcome-based randomized studies in humans *(100)*.

Infections Associated with Pacemakers and Cardioverter-Defibrillators

The estimated number of functioning pacemakers worldwide was more than three million in 2006, and approximately 200,000 for cardioverter-defibrillators *(101)*. The risk for pacemaker and cardioverter-defibrillator infections with antibiotic prophylaxis upon insertion is low. According to a recent prospective randomized trial in Brazil, this risk is 0.63% compared to the placebo arm of 3.28% *(102)*. The incidence of age- and gender-standardized pacemaker infections is estimated as 550 cases/million pacemaker recipients per year *(103)* or 1.9 infections per 1,000 pacemaker years (104).

As for other implant infections, gram-positive pathogens (staphylococci, followed by streptococci and enterococci) predominate over *Klebsiella* and other species (*103*,104). Apart from a lack of antibiotic prophylaxis, known risk factors in multivariate analysis are postoperative hematoma *(102)*, advanced age, diabetes mellitus *(103)*, and bacteremia of remote origin (*101*,104). In a large retrospective, population-based cohort study among 1,524 patients with pacemakers or cardioverter devices, Uslan et al. (104) found 45% to 54% infections with remote bacteremia due to *S. aureus* versus 12% in case of remote gram-negative bacteremia. The stratified risk was higher for patients with defibrillators compared to those with pacemakers. Early bacteremia (defined as <1 year after insertion) is more likely to reflect subsequent pacemaker infection *(105)*. Endothelization of implanted leads could be a key factor in the prevention of late infection and is usually complete within 1 to 3 months of insertion *(101)*. Prompt treatment of remote infections, by analogy to the antibiotic prophylaxis of endocarditis before dental procedures *(60)*, and general issues regarding SSI are the cornerstones of prevention (see also Chapter 61).

Infections Associated with Left Ventricular Assist Devices

Cardiac transplantation is a potentially lifesaving intervention for terminal heart failure. Ventricular assist devices provide temporary support until myocardial recovery

TABLE 65-3

Antibiotic Prophylaxis for Patients with Mechanical Heart Valves before Dental Procedures

		Regimen: Single Dose 30–60 min Before Procedure	
Situation	***Agent***	***Adults***	***Children***
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin	2 g IM or IV	50 mg/kg IM or IV
	OR		
	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillins or ampicillin—oral	Cephalexin[a,b]	2 g	50 mg/kg
	OR		
	Clindamycin	600 mg	20 mg/kg
	OR		
	Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone[b]	1 g IM or IV	50 mg/kg IM or IV
	OR		
	Clindamycin	600 mg IM or IV	20 mg/kg IM or IV

These recommendations are valid also for cardioverter-defibrillator and ventricular-assist devices.
[a]Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.
[b]Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.
IM, intramuscular; IV, intravenous.

occurs or a donor heart becomes available. They reduce the risk of death and improve quality of life *(100)*. One part of the device is inside the patient's blood system and the other part is connected outside with a permanent highway for bacteria to colonize and ultimately infect through connecting drivelines. The incidence of infection is extremely high and ranges between 18% and 59% *(106–108)*, even if rates might be decreasing in recent years *(106)*. Infection generally enhances the mortality risk in this patient population to 33% *(109)* and is frequently more prevalent than other complications such as thromboembolism (30%), bleeding (30%), hemolysis (10%), neurologic events (25–30%), tamponade (25%), or right ventricular failure (20–30%) *(106,107)*. In general, driveline infection is the most common *(106)* and half of all infections include multiple sites. The risk for sepsis peaks generally between 20 and 30 days postoperatively. After 90 days, the incidence is around 5% *(110)*.

As for other implants, staphylococci predominate among infecting microorganisms, but gram-negative pathogens (e.g., *Pseudomonas* sp.) or fungi are also encountered, especially in the case of selection by previous antibiotic treatment. Fungemia has the highest hazard ratio for death, followed by gram-negative and then gram-positive bacteremia *(106)*.

Prevention of Infections Associated with Ventricular Assist Devices The prevention of ventricular assist device infections is similar to other SSI in general. There are no specific randomized trials in this particular field. Numerous strategies have been used *(111)*, but their efficacy is difficult to assess in the absence of data resulting from clinical trials *(108)*. Tunneling of the driveline contralateral to the pump pocket is recommended to increase the length of the subcutaneous course, thus potentially delaying ascension of the pathogens to the pump pocket *(108,112)*. The exit sites of the driveline should be kept mechanically stable and dressing changes should be performed on a daily basis. Indications for antibiotic prophylaxis are the same as those recommended for patients with an artificial heart valve *(60,108)*. A prolonged antibiotic prophylaxis or a preemptive antibiotic treatment upon positive swab cultures of driveline exit sites is not evidence-based and should be avoided.

Infections Associated with Vascular Grafts

Infections of vascular prostheses are associated with substantial morbidity and mortality *(113)*. The incidence of graft infections ranges from <1% to more than 6%; however, it varies markedly depending on the anatomic site of the prosthesis. The highest incidence has been observed in grafts crossing the inguinal area.

Pathogenesis and Risk Factors As for many other implant-related infections, most arterial prosthetic infections are thought to arise from contamination at the time of implantation. Only a few late-onset infections appear to be due to hematogenous spread from other body sites. The high incidence of graft infections in the groin may be due to the superficial location of the graft that favors cutaneous contamination and SSI occurring at this site, which may secondarily contaminate the prosthesis. Independent risk factors for infection include surgery on lower extremities, delayed surgery, diabetes mellitus, past history of vascular surgery, and short-course antimicrobial prophylaxis *(114)*.

Microbial Etiology Staphylococci are the most common microorganisms isolated from vascular prosthetic infections *(113)* followed by *E. coli* (13.4%), *Streptococcus* species (8.5%), *Pseudomonas* species (6.1%), *Klebsiella* species (5.4%), *Proteus* species (4.8%), and coagulase-negative staphylococci (3.6%). As for other implants, the prevalence of MRSA infections in these patients is increasing. Infection of aortic grafts with MRSA appears to be fatal and lower graft infection is associated with high limb loss *(115)*.

Prevention Infection prevention is no different from general SSI prevention. Potential sites of bacteremic seeding (urinary tract infection, dental abscess, etc.) and local infections of ischemic extremities should be eradicated before placement of a bypass graft. Because of their vascular location, these prostheses are more exposed to bacteremia. Paradoxically, the incidence of graft infections induced by bacteremia is quite low. Data are inadequate to determine the necessity for antimicrobial prophylaxis in patients with arterial prostheses undergoing dental and surgical procedures. Prevention is, thus, analogous to the prophylaxis recommended to prevent infective endocarditis in patients with prosthetic heart valves, particularly during the first postoperative months when experimental data indicate that the graft is most susceptible to bacteremic seeding. If prophylaxis is chosen, the regimens suggested by the American Heart Association are applicable *(60)*.

INFECTIONS OF CENTRAL NERVOUS SYSTEM SHUNTS

Incidence and Risk Factors

Neurosurgeons increasingly use prosthetic devices within the central nervous system for a variety of clinical indications, such as hydrocephalus or continuous monitoring of intracranial pressure in posttraumatic patients. Shunt infection is a serious complication causing persisting intellectual, cognitive, and neurological deficits *(116)* and may even be life threatening. The costs of managing these complications have been estimated as high as US$ 30,000 per patient *(117)*. The incidence of infection varies greatly (between 0.3% and 13%) *(116)* depending on the nature of the intracerebral device. Risk factors are elderly patients *(102,103)*, infants and premature births *(116–120)*, immunosuppression, intracranial pressure of ≥ 20 mm Hg, impaired consciousness, ventricular catheterization for ≥5 days, duration of shunt use, duration of surgery, hematomas *(119)*, and overcrowding of operating rooms *(116)*. However, the highest risk by multivariate analysis is associated with the presence of a former shunt infection (odds ratio, 5.0: 95% confidence interval, 1.6–16) *(116)*. As a general conclusion, reported risk factors for infections are no different from those for other implant-related infections.

Microbial Etiology and Clinical Presentation

Leading pathogens of shunt infections are staphylococci and MRSE (or coagulase-negative staphylococci in general) with *Propionibacterium* species reported to be more prevalent than *S. aureus (116,120)*. The most common presentation of shunt infection is nonspecific, consisting of fever, nausea, altered sensorium, vomiting, malaise, or signs of increased intracranial pressure. The latter suggests malfunction. In most cases, these symptoms appear within a few weeks to months after insertion. Obvious SSI may be evident in the immediate postoperative period. Classic signs of meningeal irritation are present in roughly one-third of shunt infections. Inflammatory exudates may lead to inoculation of cerebrospinal fluid, resulting in the formation of a peritoneal cyst. These cysts are often palpable in infants and can be visualized by radiological imaging. At times, patients infected with microorganisms representative of normal skin flora, such as coagulase-negative staphylococci and *Propionibacterium* species, may pursue an extremely indolent clinical course and exhibit only intermittent low-grade fever and malaise with little or no change in spinal fluid cell count, glucose, or protein.

Prevention

As for other types of infections associated with foreign materials, there has been a marked decrease in the incidence of infections associated with the insertion of indwelling central nervous system prosthetic devices, partly because of the use of antibiotic prophylaxis and improvements in technique and materials. In 2005, Choksey and Malik reported only one shunt infection among a total of 176 procedures performed in 126 patients with hydrocephalus due to strictly adhering to the following surgical principles: asepsis; appropriate and timely antimicrobial prophylaxis; and avoidance of hematomas *(121)*. To our knowledge, no one has yet reported a better result with shunt-related surgery over a prolonged period *(27)*.

Several placebo-controlled studies justify the use of perioperative antibiotic prophylaxis during implantation. Langley et al. (122) conducted a meta-analysis to determine the value of antimicrobial prophylaxis in shunt placement. Twelve randomized controlled studies were selected representing 1,359 patients. Combining the results of the 12 trials showed that prophylaxis was associated with a significant reduction in subsequent infection (Mantel-Haenszel weighted risk ratio = 0.52), corresponding to a 48% risk reduction. This was confirmed in a Cochrane meta-analysis involving 17 trials with a total of 2,134 participants *(123)*. Again, the use of systemic antibiotic prophylaxis for the first 24 hour postoperatively decreased shunt infections by half, although the benefit beyond 24 hour remained uncertain.

An unresolved issue is the ideal dosing of antibiotics for the prevention of intracranial or ventricular infections.

While enhanced doses for the treatment of these infections are commonly accepted among infectious disease physicians, antibiotics are administered often at the same dose as for example, arthroplasty surgery. At least in cases of hydrocephalus, shunted patients might require higher than usual doses of vancomycin *(124)*.

Continuous prophylactic antibiotics are widely used for patients with external ventricular drains (EVDs) despite the lack of evidence. Alleyne et al. *(125)* reported the results of a retrospective cohort study in two groups of patients who received cefuroxime (1.5 g/8 hour) for the entire duration of EVD, that is, an average of 9.2 days compared with cefuroxime given periprocedural only (maximum three doses). The overall rate of ventriculitis (3.9%) was similar in the two groups. Because long-term use of antimicrobials may select for resistant microorganisms (126), we recommend periprocedural antibiotics only.

The use of ventricular catheters impregnated with antimicrobial agents failed to show any benefit in terms of intra- or extracranial infections in a recent prospective randomized trial from Hong Kong *(127)*. This lack of benefit was confirmed in a retrospective Cochrane meta-analysis *(123)* and in a prospective observational study *(116)*.

INFECTION IN BREAST IMPLANTS

Mammary implants are used in breast augmentation and reconstruction after mastectomy. Approximately 50,000 procedures are performed annually in the United States alone *(128)*. They may be placed above the muscle and under the gland (subglandular) or under the muscle (submuscular) (129) and consist often of silicone gel contained within a silicone rubber envelope (Fig. 65-2).

Incidence

In a worldwide survey of complications among 10,941 patients undergoing breast augmentation, infections were observed in 2.5% of all procedures (incidence, 1.7% and 0.8% for acute and late infections, respectively) *(130)*. Other large epidemiologic retrospective cohort studies with long-term follow-up confirmed similar incidences ranging from 1.7% to 2.5% (129,*131*,*132*). The incidence of postsurgical implant infections correlates with the complexity of the surgical condition. Acute postsurgical infection has been encountered in 0% to 4% of cases *(130,133)*. Most infections occur during the first month after implantation, but neither the type of implant nor the surgical procedure appear to have a significant influence on the timing of infection *(133)*. Late infection usually results from a secondary bacteremia, infection at another site, or an invasive procedure *(130,133)*.

Risk Factors

Risk factors for breast implant-associated infection have not been carefully assessed in prospective studies and almost all studies are retrospective. The risk factors for breast implant infections are similar to other implants or SSI in general. Olsen et al. *(134)* retrospectively assessed 325 patients and revealed the following variables as independent risk factors in multivariate analysis: suboptimal antibiotic prophylaxis, blood transfusion, smoking, a high American Society of Anesthesiologists score, underlying cancer, and high glycemia during surgery. In particular, breast reconstruction after mastectomy and radiotherapy for cancer is associated with a higher risk for infection and other complications after surgery (129,*134*). Other possible predisposing factors include skin-penetrating accidents, nipple piercing *(135)*, pyoderma gangrenosum, preceding infectious processes, breast trauma, breast skin irritation *(133)*, and reconstruction. Infection was less likely in a two-stage procedure in another series *(136)*. One hypothesis is that there is no time for host defense mechanisms to cleanse the tissue of bacteria before the insertion of the prosthesis in immediate reconstruction. With delayed reconstruction, there has been time for bacteria to have been removed from the tissue.

Microbiology of the Breast

The human breast is not a sterile anatomic structure. Multiple breast ducts provide a passage from the skin surface to deep within the breast tissue. Coagulase-negative staphylococci were isolated from 53% of specimens in

women undergoing breast surgery *(137)*. Microorganisms were lactobacilli (9%), *Bacillus* species (5%), and alpha-hemolytic streptococci (3%). Anaerobic microorganisms were mostly *P. acnes*. Cultures of material milked from the nipples before breast augmentation grows mainly *S. epidermidis* (67%), but also *B. subtilis* (24%) and diphtheroids (see also Table 65-4.)

Capsular Contracture and Locally Instilled Antibiotic Prophylaxis

Capsular contracture is the most common and frustrating complication in women who have undergone breast implantation (*128*,129). Contracture of the scar around a soft deformable implant will lead to a hard spherical mass; this type of envelope is referred to as a capsule. Factors thought to be associated with capsular contracture include infection *(128)*, hematoma, silicone bleed, and individual predisposition for hypertrophic scarring. Implant filler material (silicone, saline), placement (submuscular, subglandular, subcutaneous), and surface texture might also affect the risk of capsular contracture *(138)*.

Cultures performed at the time of surgical capsulotomy are often positive, predominantly growing *S. epidermidis* and *P. acnes (128,139)*. Based on this finding, Burckhardt et al. *(139)* used local antibiotics leading to a decreased incidence of capsular contracture. The practice of breast pocket irrigation with various antimicrobial solutions and povidone-iodine is supported by some data and extensive clinical practice among most plastic surgeons (129,*140*,*141*). However, in 2000, the U.S. Food and Drug Administration prohibited the use of povidone-iodine for breast implant surgery (129) as it may be associated with deflation of saline-filled prostheses in a small proportion of patients. Similarly, minocycline and rifampin-impregnated, saline-filled silicone implants were less likely to be colonized and cause *S. aureus* infection than unimpregnated implants when inserted subcutaneously in a rabbit model *(142)*. Further studies are required on the clinical effectiveness and the potential for resistance development before widespread use can be recommended.

Systemic Prophylactic Antibiotics

The need for prophylaxis in breast surgery is controversial. Although most experts do not recommend prophylaxis routinely for breast procedures, they do recommend prophylaxis in cases of implant placement. Systemic antibiotic prophylaxis at the time of surgery was associated with a significant reduction of the infection rate (0.42% vs. 0.87%) in a large study of 39,455 patients undergoing breast augmentation (129). Some authors advocate antibiotic prophylaxis prior to any dental procedure in patients with breast implants, but there is no scientific evidence to support this recommendation.

CONCLUSIONS

The increasing need for prosthetic materials and indwelling medical devices has markedly improved both materials used and surgical implantation techniques. Overall, three major strategies have been developed to prevent infectious complications: a sterile environment; better operating procedures; and the appropriate use of prophylactic antibacterial agents. Only the latter lends itself to a well-controlled, randomized, double-blind clinical trial. Thus, many improvements in the setting of medical device complications seem to reflect improved medical or surgical practice without proof based on randomized studies. Sterile environment and the different quality of surgical procedures can hardly be randomized.

So far, systemic antibiotic prophylaxis has proven efficacy for prosthetic heart valve replacement, and orthopedic and vascular prostheses. To extrapolate from these results to other procedures, several factors have to be taken into account. These encompass timing of administration, dosage, pharmacokinetics and tissue penetration, and type of infecting microorganism. With these simple concepts, new clinical and experimental studies can be conceived regarding prosthetic infections.

Changes in surface characteristics, such as surface charge and adhesive properties for host proteins and/or bacteria, may be another means to decrease infection rates. Incorporation of antibacterial substances, such as silver,

must be explored further. Clearly, this will continue to be an area for high priority not only for the field of infectious diseases and infection control, but also for biotechnology.

CHAPTER 66

Healthcare-Associated Infections Related to Respiratory Therapy

Keith S. Kaye, Dror Marchaim, David J. Weber, and William A. Rutala

The most representative data on the incidence of healthcare-associated infections have been provided by the Centers for Disease Control and Prevention (CDC) via the National Healthcare Safety Network (NHSN, formerly NNIS) system. According to the NHSN system data, healthcare-associated pneumonia (HAP) is the third leading cause of device-related healthcare-associated infection (HAI) and second leading cause of HAI overall, accounting for approximately 16% of all HAIs and 24% to 27% of all infections acquired in medical intensive care and coronary care units (1,*2–4*,5). The frequency (episodes per 100 hospitalizations) of HAP is 0.2 to 0.94, the lower rates being reported from small private hospitals and the higher rates from large academic hospitals *(2,6)*. The pooled mean rate of ventilator-related HAP (per 1,000 days ventilated) in intensive care units (ICU) range from 1.3 (medical pediatric ICU) to 5.5 (burn ICU) (7). The frequency of HAP is reportedly higher in selected patient populations, ranging from 0.66 to 1.47 in the elderly (*8*,9), 1.7 to 7.2 among newborn ICU patients *(6,10)*, and 2.0 to 21.6 among adult ICU residents (*11–14,*15,*16*). A point prevalence study of ICUs in 17 Western European countries revealed that 20.6% of all patients had an ICU-acquired infection; pneumonia accounted for 46.9% and lower respiratory tract infections other than pneumonia accounted for 17.8% of all ICU-acquired infections *(17)*. A more recent point prevalence study conducted in May 2007 included 14,414 patients in 1,265 ICUs from 75 countries revealed that 51% of patients were infected and that among infected patients 64% had a respiratory tract infection (18).

More than 50% of the antibiotics prescribed in ICUs are for the treatment of HAP, and over 90% of HAPs in ICUs are ventilator-associated pneumonias (VAPs) (5). HAP increases hospital stay by an average of 7 to 9 days per patient and has been reported to produce an excess cost of more than $40,000 per patient (5). The crude mortality rate for HAP may be as high as 30% to 70%, and the HAP-related attributable mortality is estimated to range from 33% to 50% (5,*19*). It is often difficult to define the exact incidence of HAP and VAP, because there are frequently overlaps with other lower respiratory tract infections, such as tracheobronchitis, especially in mechanically ventilated patients (5).

Multiple risk factors for HAP have been identified by univariate analysis: abdominal or thoracic surgery *(14,20,21)*, advanced age *(14,21)*, altered mental status (*8*,9,15,*21*), prior episodes of large-volume aspiration (*8*,9,*12*,*20*,*22*), H_2 blocker therapy (9,*22*,*23*), steroid therapy *(22)*, ICU residence (9,*20*), nasogastric intubation (*8*,9,*14*,*20*), previous antibiotic use (9,*20*,*24*,*25*), rapidly or ultimately fatal disease *(12,14)*, trauma (15,*16*), neurologic disease *(16)*, underlying chronic lung disease *(20)*, and intubation with mechanical ventilation (9,*12*,15,*20*). The risk factors for ICU-acquired pneumonia have been reviewed *(26,27)*. Most (9,*12*,*20*,*22*,*28*) but not all *(14)* multivariable analyses have shown that mechanical ventilation is a major risk factor for HAP, with odds ratios ranging from 1.3 to 12.1 (for positive studies). The exact incidence of pneumonia is considered 6- to 20-fold greater than in nonventilated patients (5). Few investigators have included variables related to type of respiratory care procedures in their multivariable risk factor analyses. Joshi et al. *(14)* found a 2.95-fold increased risk of HAP associated with recent bronchoscopy in ICU patients. Reintubations are additional risk factors for VAP (5).

This chapter focuses on healthcare-associated infections associated with respiratory therapy. The epidemiology of HAP in general has been reviewed by others (see Chapter 22). Several reviews have focused on the prevention of HAP, especially VAP (5,29,*30*,31,*32*).

PATHOGENESIS OF HEALTHCARE-ASSOCIATED PNEUMONIA AND ROLE OF RESPIRATORY CARE EQUIPMENT

HAP may occur by four major routes: (a) aspiration of oropharyngeal flora; (b) inhalation of infectious aerosols; (c) contiguous spread adjacent site; and (d) hematogenous spread from a distant focus of infection. Colonization of the oropharynx and gastrointestinal tract by pathogenic gram-positive and gram-negative bacilli, followed by aspiration in the setting of impaired host defenses, is the major cause of HAP. Exposure to invasive respiratory devices and equipment is important in the pathogenesis of HAP and VAP (5).

Contaminated respiratory care equipment may lead to HAP by two routes. First, respiratory care equipment may serve as a reservoir for microorganisms, especially

gram-negative bacilli. Fluid-containing devices such as nebulizers and humidifiers may become heavily contaminated by bacteria capable of multiplying in water. Pathogens may then be spread to the patient by hospital personnel or by aerosolization into room air. Second, contaminated equipment may lead to direct airway inoculation of microorganisms if it is directly linked to a ventilatory system or if contaminated medications are instilled by aerosolization. The role of inhalation and respiratory care equipment in HAP has been reviewed several times in the era of medical/surgical intensive care (15,*26*,*27*,29,*32–35*,36,*37–44*,45–*47*). Multiple reports exist in the scientific literature regarding outbreaks associated with the use of equipment introduced into the respiratory system, ranging from tongue depressors to bronchoscopes *(48)*.

Fluid-containing respiratory devices are the major environment-associated reservoirs for HAP; however, most or all phases of respiratory support have been linked to healthcare-associated respiratory infections or suggested as potential environmental reservoirs. These include mechanical ventilation bags (MVBs), ventilators, aerosolized medications, bronchoscopy, suction catheters, suction regulators devices, and respiratory support personnel. Evidence suggests that alterations in infection control practices during the 1960s decreased the number of cases of HAP from environmental sources *(49)*.

INFECTIONS ASSOCIATED WITH INTUBATION AND MECHANICAL VENTILATION

Pathophysiology of Infection

Intubation for respiratory support increases the patient's risk of HAP. Nasotracheal or orotracheal intubation predisposes patients to bacterial colonization and HAP by the following pathophysiologic alterations (5,*50–52*): (a) it causes sinusitis and trauma to the nasopharynx (nasotracheal tube); (b) it impairs swallowing of secretions; (c) it acts as a reservoir for bacterial proliferation; (d) it increases bacterial adherence and colonization of airways; (e) it requires the presence of a foreign body that traumatizes the oropharyngeal epithelium; (f) it causes ischemia secondary to cuff pressure; (g) it impairs ciliary clearance and cough; (h) it can cause leakage of secretions around the cuff; and (i) it requires suctioning to remove secretions. Mechanical ventilation also exposes the patient to fluid-filled devices, such as in-line nebulizers and humidifiers, which are used to provide humidification or medications.

Incidence of Respiratory Infections

Multiple studies have demonstrated that mechanical ventilation is a major predisposing factor for HAP (5,*22*,*26*,*28*,*53–61*). Direct comparisons of the various studies require caution because of important differences in study design, including patient population, period of study, criteria for entry into the study, and diagnostic criteria for pneumonia. However, the following generalizations can be made: between 15% and 40% of patients who undergo mechanical ventilation for more than 48 hours develop HAP, and the case-fatality rate is exceedingly high.

INFECTIONS ASSOCIATED WITH COMPONENTS OF MECHANICAL VENTILATION

Ventilators

The internal machinery of mechanical ventilators is not considered an important source of bacterial contamination of inhaled air *(62)*. In the 1960s, the use of a high-efficiency bacterial filter interposed between the machinery and the main breathing circuit was advocated to eliminate contaminants from the driving gas and to prevent retrograde contamination of the machine by patients *(63)*. The filters were shown, however, to alter the function of the ventilators by impeding high gas flows. Later studies have not shown that a filter placed between the inspiratory phase circuit and the patient prevents infection *(64,65)*.

Placement of a filter or condensate trap on the expiratory limb of the mechanical-ventilator circuit may help prevent cross-contamination of the ventilated patient's immediate environment *(66)*, but the importance of such filters in preventing HAP has not been demonstrated (29,*67*).

Periodic sterilization or high-level disinfection of the internal ventilator machinery is unnecessary; however, ventilator circuits should be sterilized or subjected to high-level disinfection between patient uses (68). Failure to properly clean and sterilize ventilator circuits between patients has led to outbreaks with *Pseudomonas aeruginosa (69)*, *Bacillus cereus (70)*, and *Acinetobacter* species *(71)*. The failure to properly disinfect ventilator temperature probes between patients has led to outbreaks of *Burkholderia cepacia* pneumonia *(72)*.

Nebulizer Equipment

Nebulizers have been a significant source of HAP. Nebulizers with large-volume (>500 mL) reservoirs, including those used in intermittent positive-pressure breathing (IPPB) machines and ultrasonic or spinning-disk room-air "humidifiers," pose the greatest risk of pneumonia to patients, probably because of the total amount of aerosol they generate (73). Other types of nebulizers include small-volume nebulizers for administration of medications, most commonly bronchodilators. Such small-volume nebulizers may be placed in the inspiratory circuit of mechanical ventilators or handheld.

Nebulizers used in association with mechanical ventilators may be inserted into the inspiratory phase tubing of the mechanical ventilator circuit for the administration of medications or used to provide humidification of air. In-line medication nebulizers may become contaminated by reflux of tubing condensate *(74)* or use of contaminated solutions *(75)*. Contaminated nebulizers may then lead to HAP via direct instillation of pathogenic bacteria into the lung *(76,77)*. Botman and de Krieger *(78)* demonstrated that small-volume nebulizers frequently become colonized with pathogenic bacteria, and that nebulizers are associated with an increased risk of respiratory colonization of patients. The risk of pneumonia is related to the production of contaminated bacterial droplets <4 μm in diameter *(50)*. Particles larger than 10 μm are trapped in the nasopharynx or trachea, whereas particles smaller

than 4 μm may be delivered into the patient's terminal bronchioles and alveoli. Craven et al. *(50)* emphasized that the risk of pneumonia is related to the size and number of the aerosol particles, the concentration of pathogenic bacteria, and whether aerosol particles are delivered directly into the endotracheal tube or into the oropharynx. The temperature of the reservoir fluid is also critically important, because most healthcare-associated pathogens cannot survive for long periods in distilled water or saline at temperatures above 50°C. Decreases in the frequency of nebulizer contamination were shown to relate to decreases in the occurrence of necrotizing pneumonia *(49)*.

In addition to the previously mentioned mechanisms of contamination, in-line, fine-particle nebulizers used to humidify air mixed with oxygen from a wall oxygen outlet may become contaminated when ambient air contains bacteria *(79)*.

Contaminated nebulizers have been responsible for several outbreaks. Four cases of *Legionella pneumophila* pneumonia resulted when contaminated tap water was used in jet nebulizers to humidify oxygen administered by face mask *(80)*. Failure to disinfect nebulizers between patients led to an outbreak of *Serratia marcescens* pneumonia *(75)*. Use of contaminated ultrasonic nebulizers in IPPB machines has led to infections with *S. marcescens (81,82)* and *P. aeruginosa (83)*. Use of contaminated inhaled budesonide with sulbutamol through nebulizers led to seven cases of *B. cepacia* bacteremia in a pediatric ICU *(77)*. In 2005, six pediatric cases of *Ralstonia* spp. infections were related to the use of a particular brand of oxygen delivery device *(84)*.

Mechanical Ventilation with Humidification

Humidification of inspiratory air is an important aspect of ventilator management. Humidification may be achieved by bubble-through humidifiers, which produce minimal aerosols, or wick humidifiers, which produce no aerosols *(85)*. Bubble-through humidifiers are usually heated to temperatures that reduce or eliminate bacterial pathogens *(86)*. For these reasons, current humidification practices are not believed to pose a significant risk of pneumonia to ventilated patients (73). However, one study that purposely used contaminated water found that although colony counts in bubble-through humidifiers decreased with time, viable microorganisms remained throughout the study *(86)*. Further, when bubble-through humidifiers were heated, both condensate and effluent gas rapidly became contaminated. Additional studies are required of actual ventilators in use to assess the importance of humidification as a risk factor for HAP *(87)*. It is currently recommended that sterile water be used to fill these humidifiers (29) because tap or distilled water may harbor relatively heat-resistant pathogens *(80,85,88–91)*.

A potential risk factor for pneumonia in patients using mechanical ventilation with humidification is the condensate that forms in the inspiratory-phase tubing of the ventilator circuit. This condensate forms as a result of the difference in the temperatures of the inspiratory-phase gas and ambient air. Condensate formation is increased if the tubing is unheated compared to the use of heated bubble-through humidifiers. Both the ventilator tubing and condensate rapidly become colonized by gram-negative and gram-positive bacteria during use. The colonizing pathogens originate from the patient, and thus, the highest levels of bacteria are closest to the endotracheal tube, with lower levels near the humidifier reservoir. Craven et al. *(88)* demonstrated that 33% of inspiratory circuits became colonized by oropharyngeal flora from the patient within 2 hours of use, and 80% were colonized within 24 hours of use. They hypothesized that spillage of this contaminated fluid into the patient's respiratory tract, as might occur during procedures such as patient suctioning or transportation for clinical studies, might lead to HAP. Contaminated condensate can also serve as a reservoir for respiratory pathogens, which can be transmitted person to person via the hands of medical personnel if staff members fail to wash their hands following ventilator manipulation.

The frequency of ventilator tubing changes and its relationship to the incidence of HAP has been investigated by several research groups (Table 66-1). In a landmark study, Craven et al. *(99)* reported that ventilator tubing could be safely changed every 48 hours as opposed to the then-recommended 24-hour changes. After many years and multiple investigations (Table 66-1), current data indicate that breathing circuits, including all its variable components, should not be changed on a routine basis, and individual components should be replaced only when they malfunction or become visibly contaminated (68,*100*).

Filling the in-line humidifier with contaminated water has led to an outbreak of *Pseudomonas fluorescens* infections *(101)*. The reuse of inadequately disinfected ventilator circuits has led to outbreaks with *Acinetobacter* species *(71,102)* and *Pseudomonas* species *(103)*. Reusable ventilator tubing should be thoroughly cleaned and dried after patient use and then sterilized with ethylene oxide gas, subjected to high-level disinfection with a Food and Drug Administration (FDA)-cleared chemical sterilant, or pasteurized (see Chapters 80 and 81). Only sterile water should be used in humidifiers and nebulizers.

Condensate formation can be eliminated by the use of a heat-moisture exchanger (HME) or a hygroscopic condenser humidifier (also known as an "artificial nose") *(104,105)*. The HME eliminates the need for a humidifier by recycling heat and moisture exhaled by the patient. Because a humidifier is not used, no condensate forms in the inspiratory tubing of the ventilator circuit. Thus, bacterial colonization of the tubing is avoided. Some authorities still advocate to routinely change the HME every 5 to 7 days or as clinically indicated *(100)*. Potential problems with HMEs include increased dead space and resistance to breathing, and leakage around the endotracheal tube with drying of sputum and blockage of the tracheobronchial tree *(106)*. Several investigators have reported on the use of an HME *(107–118)*. Prospective studies demonstrate that changing HMEs every 48 to 72 hours rather than every 24 hours did not affect their efficacy or the incidence of HAP *(115,119–121)*. In addition, randomized studies found no difference in the infection rates of patients assigned to a hydrophobic HME or a hygroscopic HME *(113,118,119,122,123)*. Multiple randomized trials have compared the rates of VAP in patients in whom an in-line HME was used compared to patients managed with a conventional heated-wire humidifier

(109,112–114,116,117,124). The rates of pneumonia were lower with use of the HME (range of relative risks (RRs), 0.35–0.85); one study reached statistical significance *(117)*. Use of the HME was speculated to be cost-effective and reduces the rate of late-onset, ventilator-related HAP *(117,125)*, but recent guidelines state that despite the fact that HME reduces colonization, the role of HME in VAP prevention is not clear and remains questionable (5,*100*,*126*).

Manual Ventilation Bags

Manual ventilation bags are used for urgent ventilation, during routine suctioning of the intubated patient, during transport of the intubated patient, and to ventilate patients during chest physiotherapy. The exterior surface and connecting port of manual ventilation bags are routinely contaminated during use. Secretions left in the bag may be aerosolized and/or sprayed into the lower respiratory tract of patients. Further, the exterior surface may serve as a reservoir for pathogens transmitted person to person on the hands of healthcare personnel. Contaminated manual ventilation bags have been linked to epidemics of HAP and VAP related to specific microorganisms *(102,127–129)*. Thompson et al. *(130)* demonstrated that, in patients with gram-negative bacteria in their sputum, 71% of the manual ventilation bag valves and 29% of the air samples taken from the exhalation valve assemblies were culture positive for the same microorganisms. Weber et al. *(131)* cultured the interior and exterior surfaces of manual ventilation bags used on 14 ICU patients whose respiratory tracts were colonized or infected. Overall, 51 simultaneous cultures of manual ventilation bag components resulted in the following findings: (a) the manual ventilation bag exterior surface was culture positive 100% of the time; (b) the manual ventilation bag exhalation port was culture positive 96% of the time; and (c) the manual ventilation bag interior surfaces were culture positive only 12% of the time. In three instances (6%), the manual ventilation bag port became colonized with a pathogen prior to its appearance in the patient's respiratory tract, suggesting that the manual ventilation bag was the source for the colonizing pathogen.

Contaminated manual ventilation bags may serve as a source for healthcare-associated infection by colonizing the hands of medical personnel who then may cross-transmit such pathogens directly to other patients or to respiratory or other medical equipment, and by introducing pathogens into patients. The following guidelines have been suggested

for the prevention of healthcare-associated respiratory tract infections associated with manual ventilation bags *(131)*. First, all medical personnel should wash their hands before and immediately after any contact with patients or potentially contaminated equipment such as manual ventilation bags. Second, manual ventilation bags should be sterilized or subjected to high-level disinfection between patients (68). Third, the manual ventilation bag should be cleaned of visible secretions daily and then disinfected with alcohol (68). Both the exterior surface and the manual ventilation bag exhalation valve should be disinfected. The interior surface does not need to be disinfected during routine use. When reprocessed in an appropriate area of the ICU or in central processing, if tenacious sputum cannot be removed from the exhalation port, the port should be disassembled, cleaned, and sterilized or subjected to high-level disinfection.

Prevention of Healthcare-Associated Pneumonia

Several authors have summarized measures that may reduce the incidence of VAP (5,29,*30*,31,45,73,*100*,*132–135*,136,*137–139*,140,*141–150*,151,*152*). These measures include (a) preference to the orotracheal (as opposed to nasotracheal) route when intubation is necessary; (b) use of aseptic technique for respiratory tract manipulation; (c) use of mouth washes with oral antiseptics for intubated patients (e.g., chlorhexidine); (d) proper disinfection and maintenance of respiratory equipment; (e) use of a new ventilator circuit each time a new patient is placed on a ventilator, but no routine change of circuits for a single patient unless visibly soiled or mechanically malfunctioning; (f) new HME for each patient, and change of HME as clinically indicated (some still recommend routine changes every 5 to 7 days *(100)*); (g) hand hygiene before and after contact with mucous membranes or contaminated equipment, whether or not gloves are worn; (h) elevation of the head of the bed to 45 degrees (when it is not possible to elevate this high, then attempts should be made to raise the head of the bed as much as possible *(100)*); (i) continuous subglottic suctioning, particularly in patients expected to be mechanically ventilated for >72 hours *(100)*; and (j) noninvasive ventilation to avoid risks associated with endotracheal intubation and mechanical ventilation *(153)*. Additional measures include (a) identification and elimination of environmental reservoirs for pathogens; (b) use of barrier precautions for colonized and infected patients; (c) extubation and removal of nasogastric tubes as soon as clinically possible; (d) avoidance of oversedation and paralytics; (e) use of proper endotracheal suctioning techniques; (f) maintaining adequate endotracheal cuff pressures; and (g) control of antibiotic use. Table 66-2 summarizes the current and the past CDC guidelines relevant to this chapter for the prevention of HAP.

More recent guidelines, from various professional societies, (*100*,151,*152*) address issues and data related to VAP prevention that were not fully covered in the 2004 CDC guidelines (29). These are as follows: (a) subglottic drainage of secretions. Although this was mentioned in CDC's 2004 guidelines as being helpful in preventing VAP *(154)*, more recent guidelines have more strongly supported the use of subglottic suctioning (5,*100*,151,*152*). (b) Silver-coated endotracheal tubes. In a large prospective study, involving 54 institutions and 2003 patients, the use of silver-coated endotracheal tubes reduced the incidence of VAP by 36%, though no differences in mortality, length of ICU stay, and duration of mechanical ventilation were noted (140). (c) Polyurethane cuffed endotracheal tubes. So far, this device, which is designed to prevent leakage and aspiration of subglottic secretions around the endotracheal cuff, has only been tested in a pilot study design and only in postoperative cardiac surgery patients *(155)*. (d) Selective oral decontamination (SOD) and selective digestive decontamination (SDD). One randomized trial *(156)* demonstrated a favorable impact of SOD and SDD on mortality of mechanically ventilated patients; and one meta-analysis *(157)* reported a reduction in VAP rates associated with SOD and SDD, but reported conflicting results regarding reduction in overall mortality. Emergence of antimicrobial resistance is a concern pertaining to this practice. (e) Oral care with chlorhexidine. Most guidelines recommend routine care with antiseptics (most commonly chlorhexidine), despite publication of few negative trials *(158–160)*. (f) Daily assessment of readiness to wean and following weaning protocols reduces VAP prevalence and improves patient outcomes (151,*161*). (g) Stress ulcer prophylaxis. The bulk of recent data (although mostly retrospective) suggest that avoiding use of antacids, when possible, might reduce risk for VAP (151,*162*,*163*). (h) Implementing VAP prevention bundles are cost-effective and are associated with reduced incidence of VAP (*133*,151,*164–166*).

Studies evaluating airway management of mechanically ventilated patients have been reviewed *(167)*. The following conclusions are justified by the current scientific literature. First, ventilator circuits should not be routinely changed (68,*100*). Second, the type of endotracheal suction system does not appear to influence the rate of VAP, but results from various studies have conflicted. Two trials comparing open and closed suctioning systems showed no significant difference; range of RRs, 0.84 to 0.91 *(168,169)*; but in a later study, use of a closed suctioning system was associated with a significantly decreased risk for VAP (adjusted RR 0.29, $p = .05$) *(170)*. Additional studies are needed to determine the impact of closed suctioning on reduction of risk for VAP. Recent Canadian guidelines recommended the use of closed system over open ones *(100)*. Third, lower rates of VAP and decreased hospital costs may correspond with the avoidance of heated humidifiers and use of HMEs *(114,167)*. Fourth, as mentioned previously, the use of endotracheal tubes that allow continuous aspiration of subglottic secretions has been associated with a reduced risk of pneumonia (5,*100*,*152*). Lower rates of pneumonia with use of kinetic versus conventional beds have been demonstrated in several studies, but significant reductions have not been demonstrated consistently *(100,152)*. In addition, complicating factors relating to patient discomfort and problems maintaining IV access occurred in several of the studies and may limit the use of kinetic beds. For this reason, routine use of kinetic beds has not been recommended by the CDC (29). Finally, noninvasive positive-pressure ventilation can be used in certain patient populations as an alternative to endotracheal intubation and mechanical ventilation *(153)*

Recommendations for the Prevention of Healthcare-Associated Pneumonia Involving Respiratory Care Equipment

Prevention Strategy	*CDC 1994 (73)*	*Kollef 1999 (31)*	*CDC 2002 (29)*
Decontaminate hands with soap and water if hands are visibly soiled or contaminated with blood or body fluids, or with a waterless antiseptic agent after contact with mucous membranes, respiratory secretions, or objects contaminated with respiratory secretions, whether or not gloves are worn	IA	B	IA
Thoroughly clean all equipment and devices to be sterilized	—	—	IA
Whenever possible, use steam sterilization or high-level disinfection by wet heat pasteurization for reprocessing semicritical equipment or devices	IB	—	IA
When rinsing is necessary after chemical disinfection of semicritical equipment or devices used on the respiratory tract, use sterile or pasteurized water if feasible. If not feasible, rinse with isopropyl alcohol or use a drying cabinet	IB	—	IB
Do not routinely sterilize or disinfect the internal machinery of mechanical ventilators	**IA**	—	IB
Do not change routinely, on the basis of duration of use, the ventilatory circuit that is in use on an individual patient. Change the circuit when it is visibly soiled or mechanically malfunctioning	Change ≥48 h, IA	A	IA
Sterilize reusable breathing circuits and bubbling wick humidifiers, or subject them to high-level disinfection between uses on different patients	IB	—	IB
Periodically drain and discard any condensate that collects in the tubing of a mechanical ventilator, taking precautions not to allow condensate to drain toward the patient.	IB	C	IA
Placement of a filter at the distal end of the expiratory-phase tubing of the breathing circuit to collect condensate	U	—	U
Do not place bacterial filters between the humidifier reservoir and the inspiratory-phase tubing of the breaking circuit of a mechanical ventilator	IB	—	II
Use sterile or pasteurized water to fill bubbling humidifiers	II	—	IB
Preferential use of a closed, continuous-feed humidification system	U	—	U
Use a HME to prevent pneumonia in a patient receiving mechanical ventilation	U	A	U
Change an HME that is in use on a patient when it malfunctions mechanically or becomes visibly soiled	IB	—	IB
Do not change routinely more frequently than every 48 h, an HME that is in use on a patient	No routine change, IB	—	IB
Daily change of HME	—	A	—
Do not change routinely (in the absence of gross contamination or malfunction) the breathing circuit attached to an HME while it is in use on a patient	IB	—	II
Follow manufacturers' instructions for use and maintenance of wall oxygen humidifiers unless data show that modifying the instructions poses no threat to the patient and is cost-effective	IB	—	IB
Between patients, change the tubing, including any nasal prongs or mask, used to deliver oxygen from a wall outlet	IB	—	IB
Use only sterile or pasteurized fluid for nebulization and dispense the fluid into the nebulizer aseptically	IA	—	IA
Do not routinely sterilize or disinfect the internal machinery of anesthesia equipment	IA	—	IB
Do not routinely sterilize or disinfect the internal machinery of pulmonary-function testing machines between uses on different patients	II	—	II
Unless there is a filter between the mouthpiece and tubing of pulmonary-function testing equipment, sterilize or subject to high-level disinfection or pasteurization reusable mouthpieces and tubing or connectors between uses on different patients	IB	—	IB
Do not use large-volume room-air humidifiers that create aerosols unless they can be sterilized or subjected to high-level disinfection at least daily and filled with sterile or pasteurized water	IA	—	IB
Use of either the multiuse closed-system suction catheter or the single-use open-suction catheter	U	—	U

(*Continued*)

TABLE 66-2

Recommendations for the Prevention of Healthcare-Associated Pneumonia Involving Respiratory Care Equipment (*Continued*)

Prevention Strategy	*CDC 1994 (73)*	*Kollef 1999 (31)*	*CDC 2002 (29)*
If the open-system suction is employed, use a sterile single-use catheter	II	—	II
Use only sterile or pasteurized fluid to remove secretions from the suction catheter if the catheter is to be used for reentry into the patient's lower respiratory tract	IB	—	IB
Remove devices such as endotracheal tubes from patients as the clinical indications are resolved	IB	C	IB
When feasible and no medical contraindications, use noninvasive positive-pressure ventilation delivered continuously by facial or nasal mask, instead of performing endotracheal intubation, in patients with hypoxemia or acute respiratory failure	—	C	II
Use an endotracheal tube with a dorsal lumen about the endotracheal cuff to allow drainage (by continuous suctioning) of tracheal secretions that accumulate in the patient's subglottic area	U	A	IB
If there is no medical contraindication, elevate at an angle of 30–45° the head of the a patient at high risk of aspiration pneumonia	IB	B	IB
Routine use of "kinetic" beds or continuous lateral rotational therapy for prevention of healthcare-associated pneumonia in critically ill and/or immobilized patients	—	—	U

CDC Classification: IA, strongly recommended for all hospitals and strongly supported by well-designed experimental or epidemiologic studies; IB, strongly recommended for all hospitals and viewed as effective by experts in the field and a consensus of HICPAC based on strong rationale and suggestive evidence, even though definitive studies may not have been done; II, suggested for implementation in many hospitals – recommendations may be supported by suggestive clinical or epidemiologic studies, a strong theoretical rationale, or definitive studies applicable to some but not all hospitals; U (unresolved issue), practices for which insufficient evidence regarding efficacy exists.
Kollef Classification: A, supported by at least two randomized, controlled investigations; B, supported by at least one randomized, controlled investigation; C, supported by nonrandomized, concurrent-cohort investigations, historical-cohort investigations, or case series; D, supported by randomized, controlled investigations of other healthcare-associated infections; U, undetermined or net yet studied in clinical investigations.

and has been shown to significantly decrease the risk for pneumonia in a randomized trial (RR, 0.13) *(171)*.

INFECTIONS ASSOCIATED WITH OTHER RESPIRATORY CARE PROCEDURES

Bronchoscopy

Infection Risks Flexible fiberoptic bronchoscopy is widely used as a diagnostic and therapeutic modality to procure pulmonary specimens for microbial identification via special stains and cultures to obtain specimens for cytologic and histopathologic examination, to aid in intubation, to provide pulmonary toilet, and to remove foreign bodies *(172–174)*. Overall, flexible bronchoscopy has proven to be an invaluable and safe diagnostic procedure *(174)*. A mail survey of more than 24,000 bronchoscopies by Credle et al. *(175)* revealed a rate of major complications of 0.08% and only two cases of pneumonia. A later survey by Suratt et al. *(176)* that included information on approximately 48,000 bronchoscopies did not mention infections complications. A prospective study of 100 patients undergoing flexible bronchoscopy detected temperatures >101°F and/or a new or more extensive pulmonary infiltrate on chest radiography in 16 patients *(177)*. These findings resolved without antimicrobial therapy in all but one patient, and bacteremia was not demonstrated in any patient. However, in a similar study involving 43 consecutive bronchoscopies, Kane et al. *(178)* reported no instances of postprocedure fever or bacteremia. A survey of 51 European centers that performed a total of 7,446 pediatric bronchoscopies reported the following incidence of fever (not defined): rigid bronchoscopy <5% of cases—22 centers, 5% to 10% of cases—four centers, and more than 10% of cases—one center; fiberoptic bronchoscopy <5% of cases—30 centers, 5% to 10% of cases—five centers, and more than 10% of cases—three centers *(179)*. The significance of the fever was not analyzed. A recent review of complications of bronchoscopy did not even report infections or fevers as notable complications *(174)*.

Mechanism of Healthcare-Associated Infections Bronchoscopes routinely become contaminated with a patient's respiratory flora during use. Because many hospitalized patients are colonized with gram-negative bacilli, contamination with these microorganisms is likely. Bronchoscopes may also become contaminated with environmental flora via airborne spread, rinses with nonsterile tap water, contact with contaminated transport cases, healthcare workers' hands, or use of nonsterile brushes. The major environmental agents of concern are bacteria that survive in water (e.g., *Pseudomonas,* nontuberculous mycobacteria). Mycobacteria are of particular concern, because they are relatively resistant to disinfectants. In the setting of impaired host defenses, use of contaminated bronchoscopes may lead to

colonization or infection of the patient. Use of contaminated scopes may also result in pseudoepidemics in which cultures obtained at the time of bronchoscopy represent colonization of the scope as opposed to colonization or infection of the patient. Although the patient is not infected, such false-positive cultures may have serious consequences, leading to inappropriate therapy of the patient with the risk of drug toxicity and/or an inappropriate diagnosis, which may lead to failure to consider other explanations of the patient's original symptoms and signs (see also Chapter 9).

Healthcare-Associated Outbreaks Healthcare-associated outbreaks due to flexible bronchoscopy have been reviewed *(180,181)* (Table 66-3). Contaminated equipment has resulted in cross-transmission leading to infection and pseudoepidemics *(183–217,219,222–224,226,228–236,238,240,242–244)* (see also Chapter 9). These outbreaks highlight the critical importance of proper cleaning and disinfection. Problems uncovered by these outbreaks include failure to properly remove debris from scope channels by brushing *(188,205,211)*, use of inadequate disinfectants *(188,193,184,192,210)*, use of contaminated tap water *(200,192,206,210,232)*, and failure to dismantle all equipment *(185,199,198)*. Detection of outbreaks *(209,210,216–218,220222,226,228,229,)* and determination of the environmental reservoir *(209,210,222,226)* have been aided by molecular typing of outbreak pathogens. Several specific issues in proper cleaning and disinfection of bronchoscopes warrant further elaboration. First, all scope components (e.g., suction valves) must be dismantled and appropriately cleaned and disinfected (68). Second, terminal rinses to remove residual glutaraldehyde must be done with sterile water. Third, damaged scopes leading to protected foci for microorganisms may lead to cross-transmission despite use of adequate cleaning and disinfectants *(194,229,230)*. Finally, properly cleaned bronchoscopes must be sterilized with ethylene oxide or peracetic acid, or disinfected with an appropriate high-level disinfectant such as 2% glutaraldehyde or 0.55% orthophthalaldehyde. Outbreaks have occurred when the disinfectant used was 70% alcohol *(184)*, povidone-iodine *(188)*, alcohol plus povidone-iodine *(193)*, cetrimide plus chlorhexidine *(192)*, or 0.13% glutaraldehyde-phenate *(210)*. Further, the disinfectant must be in contact with all surfaces for the correct exposure time and at the appropriate temperature *(194,201,203)*. Exposure times for glutaraldehyde of <20 minutes do not reliably inactivate mycobacteria. Preventing healthcare-associated transmission of microorganisms by bronchoscopy requires meticulous attention to hand washing and proper cleaning and disinfection of the bronchoscopes. Appropriate care must also be taken by bronchoscopy personnel not to contact pathogens from the patient via airborne transmission (see also Chapters 38, 39, and 80).

Guidelines for Disinfection of Bronchoscopes General guidelines for the disinfection of medical equipment are available (68) (see also Chapter 62). Bronchoscopes should be sterilized or high-level disinfected between patients; however, because of the pressures of time, most scopes are subjected to high-level disinfection. By definition, high-level disinfection will inactivate all microbes with the exception of high numbers of bacterial spores. The microorganisms most resistant to inactivation are bacterial endospores and mycobacteria. Diluted glutaraldehyde preparations (<2%) do not reliably inactivate mycobacteria with a 20-minute exposure time *(245)*. Of concern, many hospitals employ either inadequate exposure times or inappropriate disinfectants *(246)*. US guidelines differ from those practiced in other parts of the world, and current practice in the United States should be based on the most recent US guidelines (68).

Spirometry

Spirometry is a basic function test that allows the measurement of forced vital capacity and time-related indicators of dynamic pulmonary function *(247)*. Data obtained from the forced expiration maneuver can be used to generate flow–volume and volume–time curves. Such measures are widely used in diagnosing pulmonary disorders, evaluating the risks associated with intra-abdominal surgery, and assessing the response to bronchodilators. Much attention has been paid in the past to standardizing spirometry equipment and methods *(248)*. Several outbreaks have been linked to the use of contaminated spirometers *(249,250)*. Contaminated spirometers have been linked to cross-transmission of *Stenotrophomonas maltophilia (172)*, *Haemophilus influenzae (251)*, and *Acinetobacter* species *(249)*. Hazaleus et al. *(250)* reported transmission of *Mycobacterium tuberculosis* infection to 1 of 22 patients who underwent pulmonary-function testing using a dry-seal spirometer within 12 days of its use for a patient with active pulmonary tuberculosis. Few studies have carefully evaluated the potential of spirometers as vehicles for cross-transmission of microorganisms. Rutala et al. *(252)* prospectively examined the extent of microbial contamination of two commonly marketed dry-rolling spirometers following use for patients with a heavily colonized or infected respiratory tract. The investigation revealed that the mouthpieces became contaminated with the patients' oral flora and with the associated respiratory pathogen; 14% of tubing samples after patient testing contained the respiratory pathogen. All other equipment samples (e.g., interior surface of the machine) were negative for the respiratory pathogen. These data suggest that changing the mouthpieces and tubing between patients will eliminate the possibility of cross-transmission, and that it is unnecessary to routinely clean the interior surfaces of the machine. Burgos et al. *(253)* found frequent colonization of the proximal tubing, distal tubing, water, and water-bell of a water-sealed spirometer; however, no transmission of potentially pathogenic microorganisms from equipment to patients or vice versa was demonstrated.

Room Humidifiers

Cool-mist humidifiers have been linked to healthcare-associated epidemics of sepsis or pneumonia caused by *Acinetobacter* species *(254,255)*, *P. aeruginosa (256)*, and *Legionella pneumophila (80,257)*. Experiments using tap water contaminated with *L. pneumophila* have demonstrated that cool-mist humidifiers can readily generate aerosols of *Legionella* that disseminate throughout a two-bed patient room *(258)*. Nonaerosol humidifiers used

to humidify wall oxygen may also support the growth of *P. aeruginosa (259)* and have been linked to respiratory infections with this pathogen *(260,261)*.

Inhaled Medication

Direct instillation of aerosolized contaminated medications is a well-established, although unusual, cause of lower respiratory tract infection *(77)*. Both colonization and pneumonia caused by *Klebsiella pneumoniae* resulted from the use of a contaminated stock bottle containing a bronchodilator *(262)*. Use of contaminated inhaled budesonide with sulbutamol led to seven cases of *B. cepacia* bacteremia in a pediatric intensive care unit (ICU) *(77)*.Contamination of saline vials used in respiratory care equipment has led to multiple outbreaks *(81,263–265)*. Use of contaminated multidose saline vials for IPPB treatments was reported to lead to both pneumonia and sepsis with *S. marcescens (81)*. Intrinsic contamination of single-dose vials of tracheal irrigant solution has led to multiple outbreaks of pulmonary colonization with *Ralstonia pickettii (263,265,266)*. Following one of these outbreaks, experiments revealed that *R. pickettii* is capable of proliferating in 0.9% sodium chloride solution and that *R. pickettii* is not fully retained by a 0.2-μm cartridge filter *(267)*. Manipulation of disposable saline squeeze vials for use during suctioning frequently leads to contamination of the vial contents with coagulase-negative staphylococci, *Staphylococcus aureus,* streptococci, and enterococci *(268)*. In several cases, the contaminating pathogen was isolated from the nurse's hands, suggesting that contamination occurred during opening of the vial. Despite its frequency, whether such contamination leads to lower respiratory tract infection has not been evaluated. Of note, symptoms resembling neonatal sepsis have resulted from inadvertent administration of inhaled epinephrine *(269)*.

In 2000, the FDA released a regulatory rule regarding the sterility requirements for production of aqueous-based drug products to be distributed and used for oral inhalation *(270)*.

Aspiration of Contaminated Medications

An outbreak of neonatal listeriosis was traced to bathing of infants with mineral oil from a multidose container that was contaminated by *Listeria monocytogenes (271)*. Aspiration of the contaminated oil presumably led to clinical infection and sepsis. Aspiration of commercial charcoal has reportedly led to colonization and, possibly, infection with *Aspergillus niger, Paecilomyces variotti,* and *Penicillium* species *(272)*. The authors noted that commercial charcoal is not a sterile preparation, and its use may lead to colonization in immunocompromised patients.

Ingestion of Contaminated Foods or Medications

Ingestion of contaminated ice led to the development of HAP due to *Legionella pneumophila* in a long-term ventilated patient *(273)*. Ice machines may serve as the reservoir for healthcare-associated pathogens, and appropriate management, including periodic cleaning, is indicated *(241,273—277)*.

The addition of food dye contaminated with *P. aeruginosa* to nasogastric tube feedings to monitor for possible aspiration led to a cluster of infections in ventilated patients *(278)*. The outbreak was terminated by replacing the multidose bottles with single-use vials.

An investigation of nursing home outbreaks of respiratory infection caused by *Legionella sainthelensi* identified history of a stroke and eating pureed food as risk factors for infection *(279)*. The association of these variables with swallowing disorders suggests that aspiration of contaminated potable water was the cause of *Legionella* infection.

Contaminated mouthwash led to a large pseudo-outbreak of *B. cepacia* from respiratory tract specimens of intubated patients at two hospitals *(280–282)*. Swabbing with the mouthwash was used for routine oral care for all case patients. *B. cepacia* was grown from unopened bottles of the mouthwash, and the pseudo-outbreak ended after use of the mouthwash was discontinued.

Hospital Personnel with Dermatitis

Healthcare-associated infections have occasionally been linked to colonized or infected respiratory therapists. An epidemic of healthcare-associated respiratory tract infections due to *A. calcoaceticus* was linked to a respiratory therapist with chronic dermatitis who had persistent hand colonization and who contaminated sterile respiratory care equipment *(283)*. Healthcare-associated hepatitis B was reported to have been acquired from a therapist with exudative dermatitis during placement of intra-arterial catheters *(284)*. Careful hand hygiene (water and a disinfectant or waterless alcohol-based product) and the use of sterile gloves should minimize transmission of infection during invasive procedures *(285)*. Healthcare workers with weeping or exudative dermatitis should refrain from direct patient care or handling of patient care equipment until the dermatitis has resolved (see also Chapter 93).

Suctioning Apparatus

The collection of body fluids using suction is accomplished by portable pumps or wall vacuum lines. Suction is most commonly used to clear the upper respiratory tract (pharynx and trachea) of secretions in sedated or intubated patients. Suction collection units can lead to healthcare-associated infections either by producing aerosols containing potential bacterial pathogens or by serving as an environmental reservoir *(286)*. Transmission to patients can occur through contamination of the hands of healthcare personnel during manipulation of the suction unit or through retrograde spread to the patient undergoing suction.

The use of older or improperly designed suction units has resulted in aerosolization of potential microbial pathogens, most commonly aerobic gram-negative bacilli or *S. aureus (287–289)*. Contaminated suction units that generate aerosols have led to outbreaks caused by *Klebsiella aerogenes (290)*, *P. aeruginosa (291)*, and *Salmonella montevideo (292)*. Contaminated suction units, along with other environmental reservoirs, have been linked to neonatal infections caused by *P. mirabilis (293)* and *P. aeruginosa (291,294,295)*, and to adult infections caused by *K. aerogenes (290)* and *P. aeruginosa (296–298)*.

Prevention of healthcare-associated infections caused by spread of the contaminated secretions contained in suction units requires use of units designed to prevent aerosolization of body fluids or overflow, disinfection between

patient uses, disposal of fluids in a non–patient-care area, and hand washing after handling (29,68).

Tracheal suctioning has occasionally led directly to healthcare-associated infections. Withdrawal of the suction catheter across the patient's face has reportedly led to serious healthcare-associated eye infections, most frequently due to *P. aeruginosa (299)*. Van Dyke and Spector *(300)* reported transmission of herpes simplex virus type I from a physician with herpes labialis to an infant during suctioning for meconium aspiration *(300)*. Standard guidelines should be used by hospital personnel performing tracheal suctioning to minimize the risk of healthcare-associated infection (Table 66-2).

Several studies have compared "open" and "closed" methods for suctioning patients *(168–170)*. Some did not detect a difference in the incidence of HAP. "Closed" suctioning was associated with fewer arrhythmias and less desaturation in one study *(169)* but with an increased rate of colonization in a second study *(168)*. However, in a different study, open suctioning was associated with a 3.5-fold increase in VAP *(170)*. The current data do not favor either mode of suctioning as superior in regard to prevention of pneumonia, though some experts state clearly that a "closed" method is superior in terms of VAP prevention *(100)*.

Several studies have compared the incidence of pneumonia in patients when endotracheal tubes that allowed continuous aspiration of subglottic secretions versus standard endotracheal tubes were used *(154,301–303)*. The vast majority of studies demonstrated that the use of continuous aspiration of subglottic secretions reduced the rate of pneumonia (RRs, 0.22–0.61), but not all studies had reached statistical significance *(154,303)*. Continuous aspiration of subglottic secretions appears to be an effective method to prevent VAP, and it is currently incorporated into multiple VAP prevention guidelines (5,*100*,151).

Suction regulator devices are used to intermittently drain gastric secretions in ventilated patients. In a recent study, it was demonstrated that these devices can become colonized rapidly (median duration of 1 hour) by pathogens such as *P. aeruginosa* and *S. aureus*, and that both sides of the canister, that is, patient side and wall side, can rapidly become colonized *(304)*. In a simulated model, bacteria were able to move throughout the tubing systems, and were isolated in both the apparatus connected to the unit wall and the experimental "mock" stomach *(304)*.

SUMMARY

Respiratory tract infections and infections associated with respiratory devices are well-established complications of modern medicine. Numerous devices have been associated with both endemic infection and outbreaks in ICU settings. In the past decade, multiple guidelines from leading medical societies have been published. The guidelines have helped to incorporate the most updated scientific knowledge and technology into process "bundles" to facilitate efforts by clinicians and administrators to prevent respiratory tract infections. Evidence-based processes have been incorporated into the clinical setting as well into the process of high-level disinfection and sterilization of respiratory equipment. Adherence to basic clinical concepts, such as rigorous adherence to hand hygiene and infection control practices and guidelines, and minimizing the duration of mechanical ventilation are instrumental in minimizing the infectious risks associated with respiratory therapy.

CHAPTER 67

Healthcare-Associated Infections Following Transfusion of Blood and Blood Products

Charles J. Schleupner and Eyad Cheikh

The transfusion of blood and blood products exposes recipient patients to both noninfectious and infectious adverse events (1). Approximately 15 million units of blood are collected and processed into 29 million products annually, with an average of 2.7 units administered per recipient (2). In a recent review of noninfectious early and late adverse events after transfusion, mortality rate estimates are one per million to 8 million transfused components, much lower than prior estimates (0.0001–0.00001%; 3). Infections account for 8% to 17% of these deaths. The remainder of deaths are related to early or late, frequently immunologic, reactions, or to errors of processing or administration. The nonfatal adverse effects range from minor inconveniences to life-threatening emergencies; they may occur immediately during or within hours of the transfusion (early events) or may be delayed for weeks, months, or years (late events). The physician should always consider the risk of such ill occurrences in the decision to transfuse. The public desires absolute safety in a product regardless of cost *(4,5)*; accordingly, there has been a marked increase of safety of transfused blood in the United States over the last 20 years (6,*7–12*). This chapter reviews the potential infections transmitted by blood and blood products (Table 67-1) and their prevention.

NONINFECTIOUS COMPLICATIONS

Noninfectious complications of blood transfusion have emerged as the most common cause of fatal transfusion reactions and have become the focus of hemovigilance by the National Healthcare Safety Network (NHSN; *13*). The noninfectious complications of blood transfusion include acute transfusion reactions (within 24 hours) and delayed reactions (>24 hours after transfusion; 1,3,*13*). *Acute reactions* include acute hemolytic reactions, which may be immunologically or nonimmunologically mediated and account for the majority of deaths, and nonhemolytic reactions, which are usually febrile or allergic in nature and account for 19% to 25% of deaths resulting from transfusion (1,*13*). Other nonhemolytic reactions include volume overload, transfusion-related acute lung injury (TRALI), sepsis from bacterial contamination (*vide infra*), air embolus, hypertension associated with coadministration of an angiotensin-converting enzyme inhibitor, hypocalcemia, and hypothermia (1,3,*13*). Delayed reactions include hemolysis due to anamnestic antibody responses, alloimmunization to red blood cell (RBC) or human leukocyte (HLA) antigens, posttransfusion purpura, hemosiderosis, graft-versus-host disease (GVHD) in severely immunosuppressed hosts, and processing errors (1,3,*13*). Some of these noninfectious complications are obviated by routine measures. Most are not life threatening and can be medically managed when they occur. Macroaggregate leukocyte filters during transfusion may reduce some of these reactions *(9,14)*. Leukocyte reduction (LR) before storage with third-generation filters is very important for reducing transfusion reactions associated with the presence of cytokines generated by leukocytes in the plasma phase of stored donor units *(15,15a,16)*. Since implementation in Canada and European countries, LR has resulted in decreased transfusion-associated mortality, fever, transfusion-related immunomodulation (TRIM), and decreases in the incidence of TRALI and its associated mortality *(17–21)*. LR in the United States has resulted in similar benefits (3,*13*). Prestorage LR was advocated by the American Red Cross (ARC) in the summer of 1995 and by the summer of 2000, 95% of ARC donor centers had implemented this policy. In 2010, over 95% of ARC centers continue to use prestorage LR; many but not all non-ARC donation centers in the United States are doing likewise (personal communication, ARC).

INFECTIOUS COMPLICATIONS

It was not until the early 20th century that transfusion was made feasible for nonterminally ill patients. The new methods included anticoagulation techniques, classification of blood type isoagglutinins *(22)*, and storage of donor blood. Previously, only direct donor-to-recipient transfusions were reluctantly and rarely performed because of the high frequency of often severe complications *(23)*. With the advent of this technology, the infectious complications of blood transfusion became recognized. By World War I, potential donors with malaria, syphilis, and fever were excluded *(24)*. The increased number of transfusions during World War II led to the recognition of posttransfusion hepatitis (PTH) *(25)*. However, even before this description, the American Red Cross Donor Service had deferred all potential blood donors with a history of jaundice within 6 months *(26)*.

TABLE 67-1

Infectious Complications of Transfusion of Blood or Blood Products

I. Transfusion-related immunosuppression with secondary infection
  a. Postsurgical patients
  b. Patients with burns affecting more than 10% of body surface area
II. Infections potentially transmitted by transfusion:
  a. Hepatitis
    1. HAV, HEV
    2. HBV
    3. HCV
    4. HDV
    5. HGV (GBV-C)
    6. CMV
    7. EBV, HHV-8
  b. Other viral infections
    1. HIV-1 and HIV-2
    2. HTLV-I and HTLV-II
    3. Other non-A, non-B, non-C agent(s) (TT virus, SEN virus)
    4. West Nile virus, Colorado tick fever virus
    5. Erythrovirus B-19
    6. Vaccinia virus
    7. Yellow fever virus, dengue virus, chikungunya virus
    8. Xenotrophic murine leukemia virus–related virus (XMRV)
  c. Prion disease
  d. Protozoal diseases
    1. Malaria
    2. Babesiosis
    3. Trypanosomiasis
    4. Toxoplasmosis
    5. Leishmaniasis
  e. Spirochetal infections
    1. Syphilis
    2. Lyme disease
    3. Relapsing fever
  f. Bacterial infections
    1. Brucellosis
    2. Salmonellosis
    3. Yersinosis
    4. Gram-positive or gram-negative contaminants
  g. Parasitic infestations (loiasis, other filaria)
  h. Rickettsioses

CMV, cytomegalovirus; EBV, Epstein-Barr virus; GBV-A, B, GB viruses A and B, respectively; HAV, HBV, HCV, HDV, HEV, HGV, hepatitis A, B, C, D, E, G viruses, respectively; HIV-1, HIV-2, human immunodeficiency virus types 1 and 2, respectively; HTLV-I, HTLV-II, human T-cell leukemia virus types I and II, respectively.

The organized collection of blood and blood products for civilian use began in 1947. Hepatitis B virus (HBV) was defined serologically by 1972; its partial control has led to our understanding of other causes of PTH, including hepatitis C virus (HCV), hepatitis delta virus (HDV), hepatitis G virus (HGV), other non-A, non-B, non-C hepatitis viral agents, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and, rarely, hepatitis A virus (HAV) and hepatitis E virus (HEV) *(8,10,27–33)*. The epidemic of human immunodeficiency virus type 1 (HIV-1) infections led to its recognition in the early 1980s as transmissible by blood and blood products *(34)*. Other infectious agents transmitted by blood and blood products include protozoa, filaria, spirochetes, other viruses, and bacteria (1,*8–10,27–31*).

The remainder of this section reviews each of these pathogens and the prevention of their transmission by blood transfusion after a brief discussion of the recently recognized phenomenon that blood transfusion may cause immunosuppression and thereby predispose the recipient to infections. Table 67-2 summarizes the most recent donor selection criteria of the American Association of Blood Banks (AABB) for the protection of recipients of donor blood (35).

Infections after Noncontaminated Blood Transfusion

Several authors have reviewed the observations that blood transfusions may result in suppression of the recipient's immune defenses (TRIM), leading to secondary infections *(36–39)*, in addition to an association of transfusion with recurrence of malignancy and increased (renal) allograft survival *(14,38,40–42)*. Using multivariable analysis, Tartter *(43)* and others *(44–47)* have presented data associating blood transfusion with infection after various types of surgery. Subsequently, reports have made similar associations after surgery for trauma *(48–53)*, Crohn's disease *(54)*, gastrointestinal bleeding *(55)*, open fractures of an extremity *(56)*, and coronary artery bypass surgery *(57,58)*, and with healthcare-associated infections in critical care patients *(59,60)*. Recent studies have shown that RBC transfusions have also been associated with infections, in addition to pulmonary dysfunction, TRALI, and enhanced mortality in critical care *(61)*. Increased rates of infection after noncontaminated blood transfusion have also been documented in humans with burns affecting more than 10% of their bodies *(62)*; initial studies in an animal burn model indicated similar findings *(63,64)*. However, reports after elective surgery have failed to document such an association *(65,66)*, and others have questioned the relationship of transfusion to TRIM and infection in critically ill patients *(67)*.

The proposed mechanism accounting for these observations is immunosuppression induced by the transfusion; Waymack and Alexander *(68)* noted a higher incidence of tumor recurrence and reduced survival among oncologic surgery patients who received perioperative blood transfusions. Waymack et al. *(69,70)* suggested that the mechanism of this immunosuppression may be alteration of macrophage arachidonic acid metabolism, given elevations of prostaglandin E and a decrease of interleukin-2 (IL-2) production documented in animal models after allogeneic transfusion *(69–71)*. Lenhard et al. *(72)* reported decreased lymphocyte antigen responsiveness in transfused patients with chronic renal failure before renal transplantation; Lenhard et al. *(73)* also documented increased circulating blood monocytes with augmented prostaglandin E production in transfused patients with chronic renal failure. An analogy with the immunosuppression of pregnancy resulting from a blunted IL-2 response and upregulation of interleukin-4

(IL-4) and interleukin-10 (IL-10) has been summarized *(40)*. These altered cytokine kinetics may lead to enhanced Th2 and depressed Th1 responses. Other authors have suggested optional mechanisms, including antigen-induced anergy and immune tolerance, and the effects of transfused cytokines *(38,40–42,74,75)*. These reported immunologic abnormalities in transfusion recipients have not been linked with potentially transfused agents (e.g., CMV). Given that the transfusion of RBC units after 14 days' storage is more often associated with pneumonia in trauma patients

TABLE 67-2

American Association of Blood Banks Criteria for Protection of Recipients of Donor Blood (2009)

1. Appearance of good health in donor, including lack of major organ disease, malignancy or bleeding tendency.
   a. Oral temperature of donor ≤37.5°C (99.5°F); age 16 y or older, hemoglobin/hematocrit ≥12.5 gm/dL/>38%
   b. Permanent exclusion for stigmata of injectable drug use or for use of a needle, even once, for nonprescription drug administration
   c. Deferral for active alcoholism
   d. Medication deferral: finasteride, isotretinoin (1 mo), dutasteride (6 mo), acitretin (3 y), etretinate (permanent), aspirin, piroxicam (48 h), clopidogrel, ticlopidine (14 d), and warfarin (1 wk).
   e. Deferral if pregnant within last 6 wk.
2. Deferral of donor for 2 wk after live attenuated bacterial or viral vaccine receipt (measles, mumps, oral polio, oral typhoid, yellow fever), except for 4 wk after rubella or varicella zoster vaccine and for 1 y after rabies vaccine given for a rabies prone animal bite.
3. Donor deferral for 12 mo after HBIG
4. Donor deferral if during the previous 12 mo the donor was given blood or potentially infected blood products (components, human tissue or plasma-derived clotting factor concentrates).
5. Permanent donor deferral:
   a. If history of hepatitis after age 11 y,
   b. If HBsAg (confirmed) or anti-HBc positive (positive at two different donations),
   c. If anti-HCV, HTLV-I/II, or HIV-1/2 seropositive,
   d. If in a high-risk group for HIV-1/2 infection, including having sex with a person from Africa,
   e. If prior donation led to hepatitis, HTLV-I/II, or HIV-1/2 infection in recipient
   f. A history of babesiosis or Chagas' disease,
   g. Donors with a family history of Creutzfeldt-Jakob disease, donor after receipt of human pituitary growth hormone or dura-mater grafts, and donor at risk for variant Creutzfeldt-Jakob disease (e.g., receipt of bovine insulin made in United Kingdom, having spent more than 3 mo in United Kingdom between 1980 and 1996, having lived in Europe for ≥5 y, or having received blood transfusion in the United Kingdom. or France between 1980 and the present),
   h. Having made payment for sex or having received any payment for sex, or, if the blood donor is a male, having ever had sex with another male.
6. Donor deferral for 12 mo after:
   a. Unsterile body piercing or application of a tattoo or permanent make-up unless performed aseptically in state-regulated facility,
   b. Mucous membrane exposure to blood or skin penetration by an instrument contaminated with blood or a body fluid,
   c. Sexual exposure to a person with symptomatic viral hepatitis or confirmed positive test for HBsAg or HVC antibody,
   d. Sexual contact with a person infected with or at high risk for HIV-1 infection,
   e. Incarceration for >72 h in a correctional institution,
   f. History of syphilis or gonorrhea, reactive screening test or confirmatory test for syphilis, or completion of therapy for syphilis or gonorrhea,
   g. After return from an area endemic for leishmaniasis.
7. Donor deferral due to malaria (plasma donations excepted):
   a. 3-y deferral for those after recovery from malaria or for persons who lived in a malaria endemic area for ≥5 y,
   b. 12-mo deferral for travelers after return from a malaria endemic area if free of symptoms suggestive of malaria,
   c. 3-y deferral for immigrants after departure from malaria endemic areas if asymptomatic,
   d. 12-mo deferral of residents from countries that are malaria free but who have traveled to an area where malaria is endemic (acceptance as donor if symptom free).
8. Donor deferral until 14 d after recovery from suspected or documented West Nile virus (WNV) infection, or until 28 d from onset of illness (suspect or known to be WNV)
9. Donor deferral after smallpox vaccination without complications for 21 d or until scab has fallen off, whichever is longer; donor deferral after smallpox vaccination with complication until 14 d after resolution of complication
10. Donor is provided opportunity in confidence to declare collected blood unsuitable for transfusion by call-back system.

Anti-HBc, antibody to hepatitis B core antigen; HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus; HIV-1/2, human immunodeficiency virus types I and II, HTLV-I/II, human T-cell leukemia virus types I and II.
(From Price TH, ed. *Standards for blood banks and transfusion services*, 26th ed. Bethesda, MD: American Association of Blood Banks, 2009.)

(76,77), the transfusion of cytokines leading to TRIM is even more plausible because cytokine levels increase with duration of storage without LR *(75)*.

Current data clearly suggest that transfusion is a modulator of the immune system, although an independent role for transfusion as an immune suppressant is not yet definitive *(37,40–42)*. However, in one prospective randomized trial of postoperative infection *(74)*, as well as other reports *(39,59,60)*, a dose-dependent relationship of transfusion to infection risk and immune suppression has been supported.

Several methods are available for avoiding the potential immunosuppressive effects of transfusion associated with surgery and trauma. Improved surgical techniques with attention to hemostasis may avoid much of the need for transfusion. Furthermore, there is minimal scientific justification for the current hemoglobin level (10 g/dL) at which transfusion is advocated *(78,79)*. The decreased blood viscosity associated with reduced hemoglobin concentrations of anemia may increase cardiac output and partially compensate for decreased oxygen delivery to tissues *(79,80)*. Acceptance of reduced indications for transfusion according to hemoglobin concentration and the use of autologous blood for transfusion (self-donated preoperatively or intraoperatively recovered blood) will also reduce the immunosuppressive effects of transfusion *(79)*. Furthermore, restrictive transfusion strategies in critical care and patients with acute coronary syndromes have reduced TRALI and mortality *(81–84)*. Hebert et al. have reported noteworthy benefits from a restrictive transfusion strategy (hemoglobin was maintained from 7–9 g/dL) in critical care patients at 25 Canadian hospitals; observed reductions were seen in ICU and hospital mortality, organ dysfunction, and length of ICU and hospital stay *(85)*. Restrictive transfusion criteria are now being advocated for various types of surgery, after trauma, and in critical care and are advocated by the Society of Critical Care Medicine in its latest guidelines (*82*,*86*,*87*,*88*,*89*,*90*,91). In the past, prior to near-universal prestorage LR, other preventive techniques have included the use of leukocyte-reduced blood products, such as frozen deglycerolized RBCs or RBCs after treatment with second-generation micropore or third-generation absorption blood filters, and the use of blood alternatives (e.g., hemoglobin solutions depleted of erythrocyte stroma, chemically modified hemoglobin solutions, and artificial RBCs or neohemocytes) *(14,92–97)*. These leukocyte-reduction techniques also prevent many febrile transfusion reactions *(97)*. The stimulation of the patient's bone marrow with erythropoietin to produce RBCs is another method to avoid transfusion and has been effective in dialysis patients, despite side effects *(98)*.

The concepts of immunomodulation and increased infection risk after allogeneic blood transfusion have been unified mechanistically through the appreciation of cytokine release by leukocytes during blood storage *(16,41,42,44,75)*. A number of studies have demonstrated that leukocyte-depletion of transfused RBCs may have favorable effects on infection rates, morbidity, and/or mortality *(75,99–102)*. These studies further support the role of cytokines, in a variety of clinical settings, derived from leukocytes as a cause of described ill effects of transfusion. Additionally, while LR of RBCs is not universally accepted *(103,104)*, LR programs have reduced infection risks post operationally and after trauma *(75,105–109)*. Much of the confusion about the benefit of LR of all donor units stemmed from the lack of understanding of the need for prestorage LR to avoid cytokine accumulation during storage (110). The ARC has implemented LR prestorage for all donor units since 2000.

Infections after Transfusions Contaminated with Pathogens

Febrile reactions, defined as a temperature rise of 1°C (2°F) or more, may be associated with 1% to 2% of all RBC transfusions (3,*13*,*97*). In addition to an infective cause, either ongoing in the recipient or rarely resulting from bacterial contamination of the transfused blood product (see later discussion), fever may also follow a hemolytic transfusion reaction or may be associated with cytokines or antibodies in the transfused blood products, or antibodies in the recipient against leukocyte or platelet antigens *(16,97)*. Such febrile, nonhemolytic transfusion reactions may present as acute noncardiogenic pulmonary edema resulting from either reactive lipid products or antileukocyte antibodies or in association with the platelet refractory state (failure of the platelet count to rise after transfusion because of rapid antibody-mediated clearance). These febrile reactions are most commonly seen in multiply transfused, alloimmunized recipients, in multiparous female recipients of transfused blood or blood products, or after transfusion of blood or blood products from multiparous female donors. These reactions can be avoided by using leukocyte-reduced blood products (3,*9*,*16*,*21*,*42*,*97*). Febrile antiplatelet reactions may resolve with LR, but the platelet refractory state is seldom benefited.

Another febrile reaction related to transfusion of immunoincompetent and, rarely, normal hosts is a delayed reaction occurring 1 to 2 weeks after transfusion with the presentation of fever and erythroderma *(111,112)*. This often fatal transfusion-associated GVHD is not infectious, is usually not confused with a febrile transfusion reaction, and is obviated by irradiation of cellular blood products for at-risk patients (3) and by universal LR *(21)*.

The most frequent serious transfusion complication is the transmission of infection, of which hepatitis and, more recently, HIV-1 are the most important. Parenteral transmission of hepatitis was not recognized until 1883 when an outbreak occurred among recipients of a smallpox vaccine of human origin *(113)*. In 1938 and again in 1942, a yellow fever (YF) vaccine stabilized with human serum was reported to have caused jaundice among recipients *(114,115)*; a virus was presumed to have contaminated the human serum. Subsequently, epidemiologic studies and human volunteer experiments defined two forms of viral hepatitis: hepatitis A or infectious hepatitis, believed to be transmitted only orally (short incubation period of 15–50 days), and hepatitis B or serum hepatitis, associated with parenteral exposure (long incubation period of 50–180 days; *116*). Although it was known that both forms of hepatitis could be transmitted parenterally by blood and that hepatitis A could be acquired orally from various body fluids, physicians identified the form of hepatitis by exposure history until 1965 when Blumberg et al. *(117,118)* serendipitously associated Australia antigen with the surface

antigen of hepatitis B. The development of serologic assays for hepatitis B and subsequently for hepatitis A opened the door to our evolving understanding of the other agents of PTH (*119–121*; Table 67-3).

Hepatitis A Much of the epidemiologic information contrasting hepatitis A and hepatitis B resulted from human volunteer studies performed in the 1940s *(116)* and at the Willowbrook State School in New York between 1956 and the late 1960s *(122,123)*. These and other studies defined the differences of incubation periods and antigenicity, the presence of HAV in feces, and the lack of chronic carriage of HAV *(116,122–124)*. HAV was first visualized in stool using immune electron microscopy in 1973 *(125)*; this finding ultimately led to methods for detection of serum antibody to HAV. The periods of viremia, clinical illness, and aspartate aminotransferase elevation have been related (Fig. 67-1); the transience of the immunoglobulin M (IgM) antibody response, followed by a persisting immunoglobulin G (IgG) response, has also been defined by both radioimmunoassays (RIAs) and enzyme immunoassays (EIAs) *(126–129)*. Although IgM antibody usually disappears within 3 to 6 months after infection, it may persist for more than 300 days in 10% to 15% of patients *(130)*.

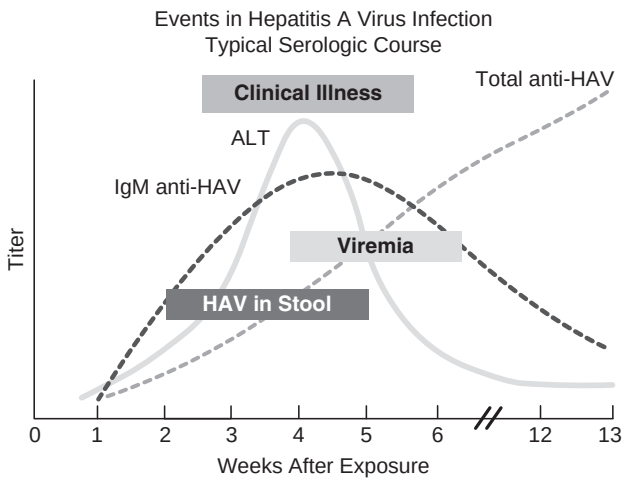

FIGURE 67-1 The clinical, virologic, and serologic course of acute hepatitis A virus infection. (Redrawn from *http://www.cdc.gov/hepatitis/Resources/Professionals/Training/Serology/gr_hav.htm*)

Because of the lack of an HAV carrier state and the brevity of HAV viremia (usually 2 weeks or less, with onset of viremia 7–10 days before onset of clinical symptoms, Fig. 69-1), frequent episodes of PTH A are unlikely *(9,26,120,121,131,132)*. With few exceptions, this has been the case *(133–141)*. Usually, PTH A occurs as a sporadic case report after blood donation during the incubation period of the illness *(139–141)*. Unfortunately, several outbreaks have been due to single contaminated units of blood being transfused to multiple infants, resulting in nursery outbreaks with secondary and tertiary cases *(134,136,137,139)*. One outbreak occurred among cancer patients treated with IL-2 and lymphokine-activated killer lymphocytes apparently resulting from contaminated serum in the lymphocyte culture medium *(138)*; another outbreak has occurred among patients with hemophilia given clotting factor concentrates inadequately treated to inactivate HAV *(142)*. These few reported outbreaks might have been prevented by serologic testing for antibody against HAV; however, the 50% seroprevalence rate for HAV IgG antibody among Americans by age 50, the possible persistence of IgM antibodies for 3 to 6 months after infection despite lack of infectivity, the frequency of symptoms during the viremic phase of the illness *(123)*, and the rarity of fatal illness resulting from HAV are strong arguments against the economic or the medical merit of routine testing of donor blood for HAV antibody *(9,27,132,143)*. The estimated current residual risk of acquiring HAV from a unit of transfused blood is estimated at 0.0001% (*9*,144). The prompt administration of immune serum globulin (ISG) prophylaxis would be appropriate for a recipient of blood found after transfusion to contain HAV *(27)*. The elimination of febrile symptomatic patients as blood donors generally prevents HAV transmission. Frequent recipients of clotting factor concentrates are candidates for receipt of HAV vaccine *(30,142)*.

Hepatitis B Blumberg et al.'s classic seroepidemiologic studies of diverse populations led to the discovery of a

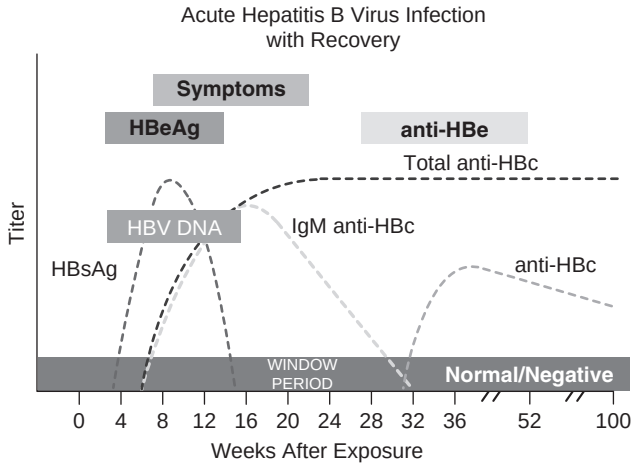

FIGURE 67-2 The clinical and serologic course of hepatitis B infection. (Redrawn from *http://www.cdc.gov/hepatitis/Resources/Professionals/Training/Serology/gr_hbv_acute.htm*)

unique antigen in Australian aborigines and recipients of multiple transfusions, which was called "Australia antigen" *(117,118,145,146)*. The terminology subsequently evolved from hepatitis-associated antigen to hepatitis B antigen and finally to hepatitis B surface antigen (HBsAg) when it was associated with the surface lipoprotein of HBV *(147,148)*. HBsAg can be found in serum of patients developing acute hepatitis B for 30 to 60 days before illness and may persist for variable periods after clinical recovery (Fig. 67-2). Persistence for longer than 6 months is defined as the chronic carrier state. Antibody against HBsAg (anti-HBs) develops as HBsAg disappears and accounts for long-term immunity *(149)*.

Hepatitis B core antigen, reflecting active viral replication, transiently appears in the blood during acute infection, only to be replaced by its antibody (anti-HBc) *(150)*. Anti-HBc appears during acute infection as an IgM antibody and is replaced in up to 80% of patients by a persistent IgG antibody during convalescence *(151)* (Fig. 67-2).

Hepatitis B e antigen (HBeAg) is a soluble product of HBV infection found transiently in serum during acute hepatitis B and in the serum of patients with chronic hepatitis *(152–154)* (Fig. 67-2). The presence of HBeAg correlates with the presence of HBV virions in serum. Antibody to HBeAg is more commonly found in chronic asymptomatic carriers of HBsAg *(153,154)*. The presence of HBeAg is associated with increased risk of maternal-fetal HBV transmission and transmission via accidental needle stick *(155–157)*.

Transmission of HBV occurs through percutaneous or transmucosal inoculation of HBV in blood or infectious body fluids (primarily semen and breast milk). Inoculation may occur by contaminated needles, during sexual contact, at birth, or during transfusion. Continuous household or institutional contact with an infected person may presumably transmit infection via unapparent exposures.

Acute hepatitis B causes a chronic viral carrier state in 6% to 10% of infected adults and 90% of infected newborns with or without chronic hepatitis (25% of carriers). The most serious sequelae in chronic carriers of HBsAg are cirrhosis and hepatocellular carcinoma. It is estimated that approximately 800,000 to 1.4 million chronic HBsAg carriers live in the United States as of 2007 *(158)*. These individuals serve as a potential reservoir within the pool of blood donors. High-risk groups for chronic carriage of HBV are shown in Table 67-4.

TABLE 67-4

High-Risk Groups for Acquiring Hepatitis B Infection

Group	*Seroprevalence[a] (%)*
Parenteral drug users	60–80
Heterosexual men and women and homosexual men with multiple partners	20–80
Household contacts and sexual partners of chronic HBV carriers	30–60
Infants born to HBV-infected women	40–95
Patients and staff in institutions for the developmentally disabled	35–40
Hemodialysis patients	20–80
Healthcare and public safety workers with frequent exposure to blood	≤10[b]
Persons born in areas endemic for HBV	70–85
Alaskan natives	40–70
Prison inmates	10–80

[a]Any serologic assay positive.
[b]Prior to immunization of these groups.
HBV, hepatitis B virus.

Before the development of assays for HBsAg, it was believed that HBV accounted for most cases of PTH. When use of the first-generation immunodiffusion assays for HBsAg was initiated voluntarily on donor blood in 1969 and became mandatory in 1972 (Table 67-5), it was anticipated that PTH would be virtually eliminated. Although there were marked reductions in the frequency of PTH (30–55%) and mortality related to transfusion, the problem persisted. Hepatitis B may still account for up to 10% of cases of PTH *(9,159,160)*. Recently published risk estimates for PTH resulting from HBV are 1 infected unit per 220,000 donor units (0.00045%; 144,161); among first-time blood donations, 19.14 units are positive for HBsAg per million units donated *(162)*.

The transmission of HBV via transfusion has been reduced to present levels because of the screening of all blood donors for HBsAg with more sensitive assays. Counterimmunoelectrophoresis was introduced in 1972 to 1973, and sensitivity for HBsAg detection was further increased by currently available RIAs, reversed passive hemagglutination, chemiluminescence immunoassays, and EIAs *(159,160,163–166)*. With the successive introduction of second-generation counterimmunoelectrophoresis and current third-generation tests for HBsAg (Table 67-5), Alter et al. *(167–169)* documented the parallel reduction of PTH resulting from HBV. This reduction was likely augmented because of current ARC donor selection and deferral procedures and the elimination of paid donors in favor of all-volunteer donors *(9,10,159,160,167–170)*. HBeAg has been found more frequently in paid blood donors (15%) compared with volunteer donors (5%; *171*). Further

[a]Most large centers are now using a nonreponemal EIA or a treponemal test, (automated MHA-TP, FTA-Abs, TPI, or TPHA).
[b]Required by Food and Drug Administration (FDA).
[c]With significant HTLV-II cross-reactivity.
[d]Requirement deleted June 20, 1995.
[e]Requirement now deleted.
[f]FDA approved.
[g]NAT, nucleic acid testing (polymerase chain reaction—PCR, or transcription-mediated amplification—TMA); 6–16 minipool or single donor testing currently utilized.
[h]Bacterial detection—culture or alternative detection method (CO_2 production, O_2 consumption, fluorescent labeling, pH > 6.4).
ALT, alanine amino transferase; anti-HBc, antibody to hepatitis B core antigen; anti-HCV, antibody to hepatitis C virus; ChLIA, chemiluminescence immunoassay; CIE, counter immunoelectrophoresis; EIA, enzyme immunoassay; HBsAg, hepatitis B surface antigen; HIV-1/2, human immunodeficiency virus types 1 and 2; HTLV-I/II, human T-cell leukemia virus types I and II; RIA, radioimmunoassay.

reduction of PTH due to HBV may also result from the fact that asymptomatic HBsAg carriers continue to be removed from the donor pool through repeat donor testing *(27,172)*. Figure 67-3 presents the current algorithm for screening donor blood for HBV.

The residual frequency of PTH resulting from HBV is apparently due to the fact that HBsAg is circulating at undetectable levels for current screening assays; some of these donor units can be eliminated by screening for anti-HBc *(173–178)*. Such donor unit screening was initiated in 1986 (Table 67-5) as a surrogate test for non-A, non-B PTH but is believed to have contributed further to the reduction of HBV-related PTH. It is estimated that because of the institution of surrogate screens for non-A, non-B PTH (anti-HBc and alanine aminotransferase [ALT], the latter no longer performed), the incidence of HBV-associated PTH has further decreased by up to 84% to current levels (144,*179*). However, this reduction may also have been affected somewhat at that time (and currently; 35) by more stringent donor population screening to prevent transfusion-related HIV-1 transmission *(159)*, because the incidence of PTH was already further dropping before the initiation of anti-HBc screening *(180)*. Regardless, the risk of HBV-related PTH has currently dropped at least to 0.00045% per transfusion recipient *(8,146,159)*. However, further reduction may require more sensitive assays, because 4% to 12% of HBV-DNA carriers are identified by nucleic acid testing (NAT) and are seronegative for HBsAg, HBcAb, and other HBV serologic markers *(30,181)*. Such NAT positive but HBV serologically negative donor units may not transmit HBV infection *(181)*. HBV mutations or genotypes may contribute to falsely negative HBsAg serologic tests *(8,30,182)*.

In addition to the marked reduction of PTH caused by HBV resulting from HBsAg and anti-HBc testing of each donor unit of blood, the development of the NAT for whole blood (to assay for HBV DNA in plasma of donors without HBsAg) has the potential to decrease the already low rate of PTH resulting from HBV *(183,184)*. It is projected that an additional 81 HBV infected units of blood would be detected annually among the 12 million screened units *(8)*, thereby potentially reducing the risk of HBV transmission due to transfusion by 42% to 0.00045% per unit (*8*,*9*,144,*172*). NAT screening for HBV was introduced for all US blood donor

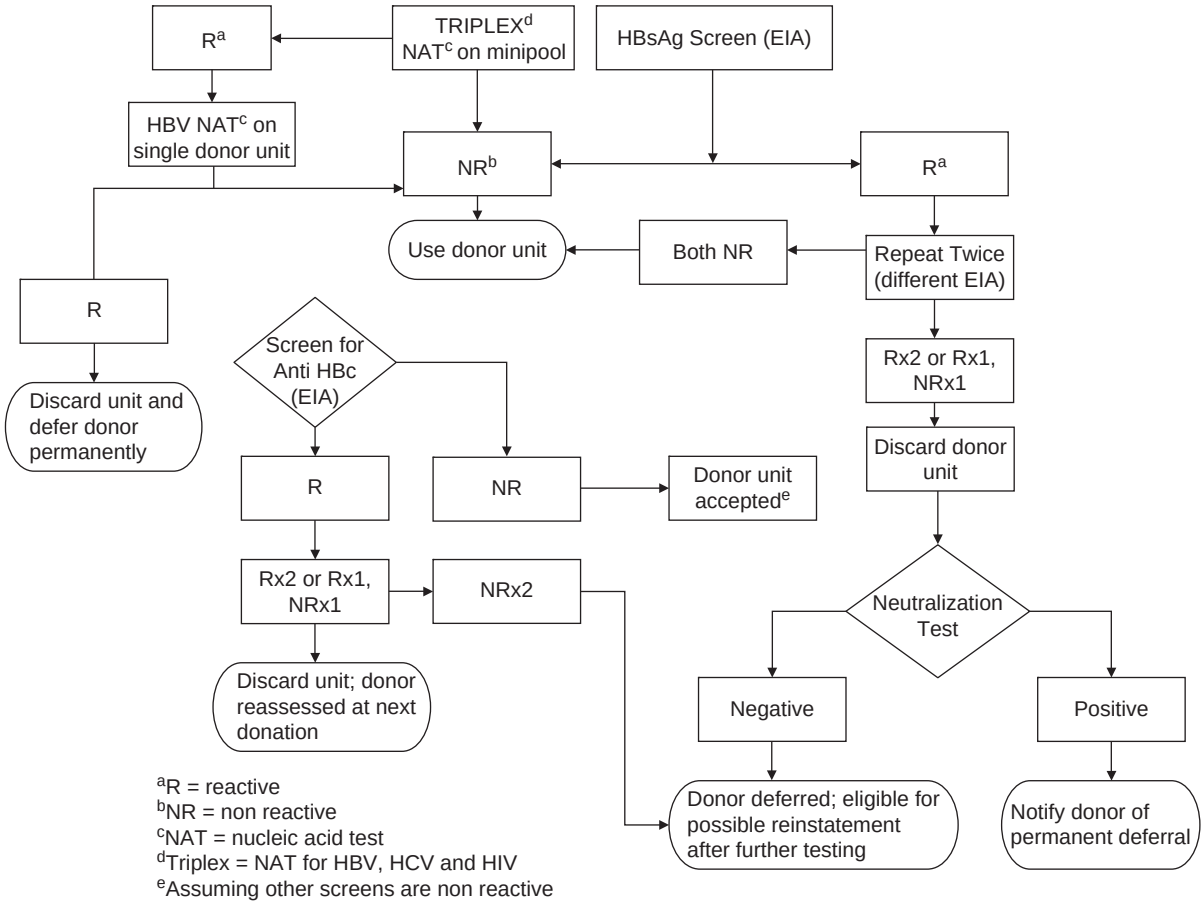

FIGURE 67-3 Algorithm for screening of donor blood for hepatitis B.

units between 2006 and 2010 as a triplex screen with HCV and HIV-1 (Table 67-5). The clinical benefit of NAT for HBV remains controversial (185). The addition of NAT for HBV, while expected to avoid 9 to 37 HBV transfusion–transmitted infections annually, adds an additional $39 to $130 million dollars per year to donor unit screening costs *(186)*.

If it were established within 1 to 2 weeks of receipt that a patient had been administered a unit of HBV-contaminated blood, there are no data that the use of HBV vaccine or hepatitis B immune globulin would be of value. In this unusual situation, one could argue for the use of both preparations, as after accidental parenteral exposure, in an attempt to modify the anticipated illness. When it can be anticipated that a person is going to receive multiple future transfusions (e.g., a hemophiliac), HBV vaccine should be administered as early in life as possible. However, the mainstays of prevention of PTH B for most patients are deferral of high-risk donors and serologic testing and NAT of donor units. Given the recommendations of the Immunization Practices Advisory Committee for universal childhood HBV vaccination, the risk of PTH resulting from HBV should become even smaller *(187)*. Before NAT for HBV, the risk of transmission of HBV via transfusion had remained stable in the United States *(9,10,172)*. This stability and the lack of an increasing relative risk of HBV transmission probably reflect an effect of universal childhood immunization, in addition to continued refinement of donor deferral criteria and use of antigen and antibody testing and possibly NAT.

Delta Hepatitis Delta agent hepatitis was initially described in 1977 by Rizzetto et al. *(188)* in Turin, Italy, and was reviewed by Hoofnagle in 1989 *(189)*. Although endemic to southern Italy, this virus has a worldwide but geographically variable distribution, including the Middle East and parts of Africa and South America. In nonendemic areas, such as the United States and Western Europe, the delta virus is found primarily in injectable drug users and multiply transfused patients, including hemophiliacs *(190)*. HDV is a defective RNA virus that replicates only in the presence of HBV with circulating HBsAg *(189)*. It is composed of an inner low-molecular-weight RNA genome associated with the internal delta antigen protein and coated with HBsAg as the surface protein *(191)*.

HDV infection occurs in only two settings: as a simultaneous coinfection with acute HBsAg-positive hepatitis B or as a superinfection superimposed on the chronic HBsAg carrier state *(189–191)*. During coinfection, although the ensuing hepatitis may be severe, biphasic, and protracted with a 2% to 20% mortality rate, most patients recover as hepatitis B resolves and fewer than 5% of patients develop chronic hepatitis *(190,192)*. The mortality rate resulting from coinfection of HDV with HBV contrasts with the <1% mortality rate associated with hepatitis B alone *(189)*. Illness associated with HDV is defined by a resurgence of the ALT serum levels after an initial decline, concomitant with the appearance of a transient anti-HDV–IgM response and followed by the development of low titer anti-HDV–IgG *(189,192)*. These

antibody responses may be detected by commercially available RIAs and EIAs *(193,194)*.

In contrast to acute coinfection, when HDV infection is superimposed on the chronic HBsAg carrier state, most patients (70%) develop chronic hepatitis with continued presence of HBsAg and HDV in the serum *(192)*. Sixty percent to seventy percent of patients with chronic delta hepatitis develop cirrhosis, and most of these die from liver disease *(195)*. Chronic HDV infection is documented by the persistence of anti-HDV–IgM in high titer *(192)*. HDV antigen may also be detected in the liver.

Because HDV is usually parenterally spread, its frequency in PTH associated with HBV (HBsAg positive) has been evaluated; 3.5% of 262 patients with PTH resulting from HBV were positive for anti-HDV *(196)*. Of these patients, 2.5% of those with self-limited disease were anti-HDV positive, whereas 14.5% of those with fatal hepatitis were infected with HDV. These data raise serious concerns for transfusion recipients; however, screening for HBsAg and NAT in each donor unit provides a high degree of protection for HBsAg-negative blood donor recipients *(196)*. HDV antibody screening is not needed. However, the HBsAg-positive prospective transfusion recipient is at some risk, especially if multiply transfused. In addition to the usual HBsAg screen of donor blood, blood-derivative recipients who are HBsAg carriers should be given products from single or minipool plasma sources *(196)*. Furthermore, all donors whose ALT is known to be elevated should be eliminated as blood sources for HBsAg-positive recipients.

Hepatitis C and Non-A, Non-B Hepatitis After the introduction of testing of all donor blood for HBsAg, it quickly became apparent that not all PTH was due to HBV *(27,120,121)*. Hepatitis A was also quickly excluded as a potential cause of the residual PTH *(120,131)*, as were CMV and EBV *(120,197,198)*. It was concluded that another virus (or viruses) accounted for most of PTH cases in the United States, initially designated "non-A, non-B or type C PTH" *(199,200)*. Much of the epidemiologic description of non-A, non-B hepatitis is now applicable to HCV, which caused most cases of non-A, non-B PTH *(201–204)*.

HCV is believed to be the most common cause of nonalcoholic liver disease in the United States. The prevalence of HCV in the US population is approximately 1.8%; 73% of patients with chronic infection have genotype 1, with the remaining predominately genotypes 2 and 3 *(205)*. The risk factors for infection somewhat parallel those of HBV. Among well-defined factors, transfusion (5–10%) and injectable drug use (60%) have accounted for most infections; transfusion is a virtually eliminated risk today (1,*8–12*,*172*,*202*,*205–207*). The risk of transfusion-related HCV infection declined between 1981 and 1988 from 17% to 6% before antibody screening *(208)*. Antibody to HCV is found in up to 85% of injectable drug users *(209,210)*. Other high-risk groups include prisoners, patients with transfusion-dependent bleeding disorders, and hemodialysis patients *(207,209–212)*. Sexual, household, and perinatal transmission and receipt of intravenous immune globulin are less important risks for HCV *(207,209,213–215)*; sporadic cases without defined exposure have declined (from 40% to 50%) to 5% of new cases *(207,208,216)*. In the contemporary era of home intravenous infusion therapy,

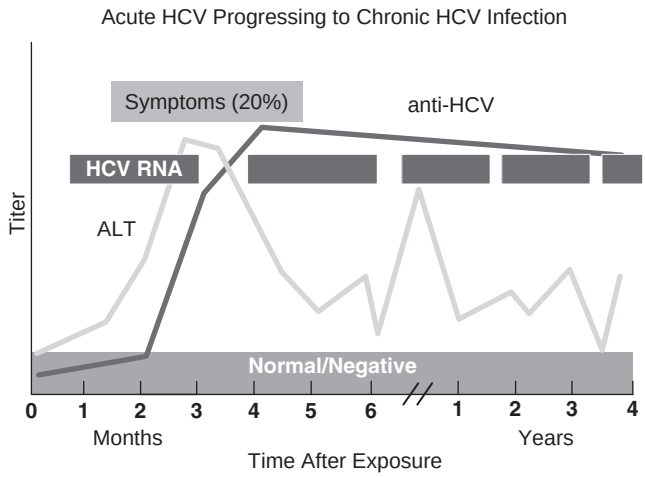

FIGURE 67-4 The clinical, biochemical, and serologic course of hepatitis C infection. (Redrawn from *http://www.cdc.gov/hepatitis/Resources/Professionals/Training/Serology/gr_hcv.htm*)

risks for HCV infection previously recognized in other sites have emerged in the household setting; a recent report suggests that transmission of HCV from an HCV-infected mother to her hemophiliac child may occur via accidental percutaneous (ungloved) needle stick during venipuncture for clotting factor infusion *(217)*. A family history of liver disease and prior history of blood transfusion, tattooing, sexual promiscuity, injectable drug use, intranasal cocaine use, and male ear piercing have been associated with anti-HCV positivity among blood donors *(218,219)*.

Approximately 75% of cases of HCV are subclinical, but, when symptomatic, hepatitis C is clinically and biochemically identical to other forms of hepatitis *(201,207)*. Figure 67-4 depicts the clinical, serologic, and biochemical course of HCV infection. Up to 85% of patients with hepatitis C develop chronic hepatitis *(31,201,220,221)*. Despite resolution of hepatitis after HCV infection, HCV RNA can often be detected by PCR, indicating HCV persistence in asymptomatic, biochemically normal patients (about 30% of chronic carriers; *207,220*). Symptoms or serum ALT level do not correlate with disease severity *(220,222)*. Most patients develop chronic active hepatitis with or without cirrhosis *(220–224)*. Cirrhosis may variably appear in 20% to 50% or more of patients *(201,207,224)*. Chronic hepatitis C has also been linked with hepatocellular carcinoma *(207,225–227)*. Patients seropositive for HCV antibody but with normal ALT values, no HCV RNA in serum, and normal hepatic histology, although uncommon, (up to 15% of those infected) probably have recovered from HCV infection *(221)*.

There are several studies assessing the outcome of PTH resulting from HCV. Seeff et al. *(228)* reported a study of long-term mortality after non-A, non-B PTH in 568 patients matched with two control groups, both of which comprised patients who had been transfused but had normal ALT values after transfusion. After an average of 18 years of follow-up, there was a small statistically significant increase in deaths resulting from liver disease in the patients with PTH (3.3% vs. 2.0% and 1.1% in the control groups). In a retrospective study, Tong et al. *(229)* defined that PTH resulting from HCV evolves into a progressive disease; chronic active hepatitis (23%), cirrhosis (51%), and hepatocellular

carcinoma (5.3%) are noteworthy sequelae. Goedert et al. *(230)* recently reported 137 hemophiliac patients with end-stage renal disease (ESRD) and HCV infection; ESRD was significantly associated with HIV-1, older age, HBV coinfection, and a low CD4 cell count. Another study has suggested a more benign outcome (45% viral clearance by PCR) in children infected via transfusion *(231)*.

Before the development of the current serologic tests to detect HCV, surrogate markers for non-A, non-B hepatitis were used as screening methods for donor blood. Initially, *ALT assays* were proposed to help reduce non-A, non-B PTH *(232–234)*. Up to 45% of donor units implicated in transmission of PTH have ALT elevations >60 IU/L *(179)*. Discarding units of blood positive for *anti-HBc* was subsequently shown to reduce posttransfusion non-A, non-B hepatitis (*177,178*; Fig. 67-5). Approximately 53% of blood donors implicated in PTH and positive for anti-HCV have anti-HBc *(179)*. The use of these assays instituted in 1986 and 1987, respectively, led to an approximately 30% to 40% reduction of PTH *(179)*. After 1985, blood transfusion as a source for acquiring HCV decreased to only 4% of new cases *(220)*.

Contemporary molecular biologic techniques led to the discovery of HCV. Nucleic acid extraction of infectious chimpanzee plasma led to the isolation of viral RNA, its transcription to DNA, and expression after insertion into a phage. Screening of several million DNA sequences for production of proteins that reacted with antibody in the serum of patients with non-A, non-B PTH led to the discovery of a polypeptide (C100-3) that was developed as an antibody-capture RIA for HCV *(204)*. This assay was quickly shown to detect 65% of donor blood capable of transmitting chronic PTH and 17% of acute PTH *(235)*. This commercially available antibody capture RIA was adapted also to an EIA, which has been shown to detect HCV as a cause of PTH *(236–238)*. Initial enthusiasm for this assay dampened because of the delayed seroconversion and, therefore, potential seronegativity of blood donors infected with HCV (despite the greater sensitivity of first-generation EIAs compared with RIA; *210*, *239–242*). The sensitivity of the EIA and RIA for preventing non-A, non-B PTH resulting from HCV was variably estimated at 60% to 85% *(206,239,243)*. First-generation assays for anti-HCV became positive up to a year after acute hepatitis C, and up to 20% of patients remained seronegative by these assays due to the insensitivity of the first-generation screening assays *(210,237,244)*. Regardless, contrasting the period when only surrogate tests for non-A, non-B PTH were used to the period after 1990 when the first-generation assays were implemented, Donahue et al. *(245)* demonstrated an 84% reduction of the risk of PTH resulting from HCV among transfused cardiac surgery patients (Table 67-6).

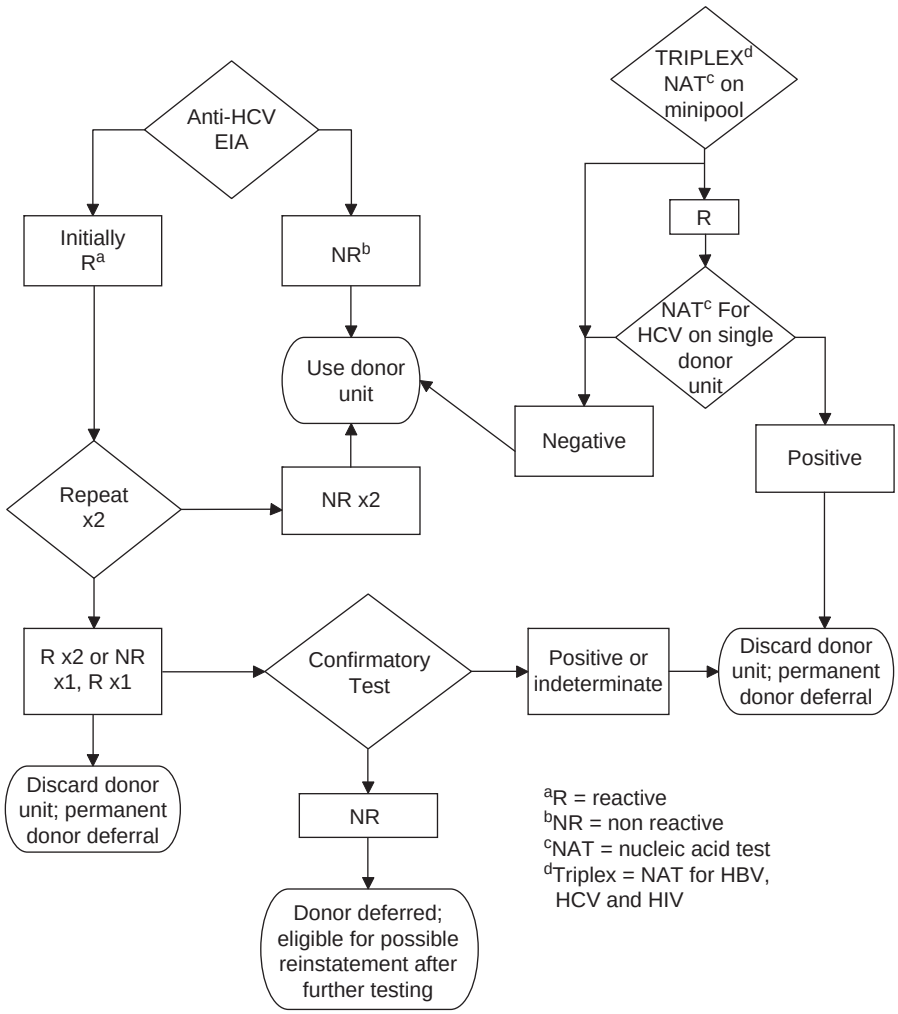

FIGURE 67-5 Algorithm for screening of donor blood for hepatitis C and hepatitis non-A, non-B, and non-C.

TABLE 67-6

Estimated Transmission Risk of Various Potentially Transfusion-Transmitted Infections, USA (Based on 2008 Data)

Agent	*Percentage of Risk*	*Risk Per Unit of Blood/ Blood Product Transfused*
Hepatitis B	0.04545	1:220,000
Hepatitis C	0.000056	1:1,800,000
HIV-1, HIV-2	0.000044	1:2,300,000
HTLV-I, II	0.000033	1:2,993,000
Cytomegalovirus(HHV-5)	—	Unknown, probably rare[a]
Epstein-Barr Virus (HHV-4)	—	Unknown, probably rare[a]
Human Herpes Virus 8(HHV-8)	—	Unknown, probably rare[a]
Hepatitis A	<0.0001	Unknown, probably <1:1,000,000
Hepatitis E	—	Rare case reports outside United States
GB viruses	—	Well documented–no disease risk
Parvovirus B-19	0.005–0.002	1:20,000–1:50,000 usually asym
Sen virus, Torgue Teno Virus	—	Well documented, no disease risk
West Nile Virus	Variable[b]	Rare (1:10,000–1:1,000 prior to NAT)
Bacteria[a]	0.0013	Platelets—1:75,000
0.0002	RBC—1:500,000	
Babesia sp.	≤0.0556	Unknown, up to 1:1,800 in endemic areas
Ehrlichia chaffeensis	Rare	
Anaplasma phagocytophilia	Rare	
Leishmania sp.	Unknown, described in endemic areas[a]	
Plasmodia sp.	0.000025	1:3 million to 4 million
Trypanasoma cruzi	0.01–0.004	1:5,400 to 1:25,000[d]

[a]Risk reduced by universal leukocyte-reduction of cellular blood products.
[b]Seasonally and geographically variable.
[c]Coagulase-negative Staphylococci, *Staphylococcus aureus*, *Streptococcus* sp., *Serratia liquefaciens*, *Yersinia enterocolitica*, *Acinetobacter* sp., *Enterobacter* sp., *E. coli*, *Pseudomonas* sp., *Providencia rettgeri*.[d]Geographically variable.
(From Feibig EW, Busch MP. Infectious disease screening. In: Roback JD, Coombs MR, Grossman BJ, et al., eds. *AABB technical manual*, 16th ed. Bethesda, MD: AABB, 2008:241–282.)

The ability to prevent PTH resulting from HCV was further improved by second-generation EIAs, which incorporated detection of antibodies to the core antigen (C22-3 protein) and the C200 antigen, which combines the epitopes included in the c33c and C100-3 proteins (coded by the NS-3 and the NS-4 regions of the RNA genome) *(30,206)*. Wang et al. *(246)* demonstrated 100% sensitivity of a second-generation EIA incorporating these three antigens, compared with 83% sensitivity of the first-generation assay; the newer assay also detected anti-HCV 6 weeks earlier than the single-antigen EIA. Using dot-blot assays, several groups demonstrated that antibodies to the c33c or core proteins (C22) consistently appeared before those to C100-3, from 4 to 13 weeks after transfusion *(247,248)*.

In addition to their sensitivity, another concern with the first-generation anti-HCV EIAs and RIAs was their positive predictive value. A positive EIA or RIA was confirmed by the more specific recombinant immunoblot assay (RIBA) in only 19% to 60% of cases *(243,249–252)*, with only one study showing 100% correlation of the screening EIA with RIBA *(239)*. Newer RIBA and matrix (a semiautomated immunoblot) assays each contain four recombinant antigens *(253)*. In keeping with Bayes' theorem, in high-risk populations, 70% to 100% of sera repeatedly reactive by second-generation EIAs were determined to be true positives by the RIBA or matrix assays, whereas fewer than 50% of repeatedly reactive second-generation EIAs are true positive in low-risk populations *(220,253)*.

Despite the limitations of first-generation EIAs, on May 2, 1990, an anti-HCV first-generation screening assay became mandatory on all donor blood (Table 67-5). Blood banks began using the second-generation EIA to screen for HCV antibody on April 6, 1992. Because of the previously discussed suboptimal sensitivity of these assays for HCV infection in a donor unit, the screening of donor blood for ALT level and anti-HBc was considered as important and was retained as required assays until June 20, 1995, when the requirement for ALT assays was rescinded (Table 67-5 and Fig. 67-5) (*29*,35,*206*,*243*,*249*,*250*,*254*).

Third-generation EIAs were initially tested in Europe and then approved by the FDA in May 1996 for use by blood donation centers. Similar to the second-generation assays, these third-generation assays incorporate recombinant antigens and include those described previously for the second-generation products, in addition to the protein product of the NS-5 region of the genome (RNA polymerase) *(30,255,256)*. These assays detect all genotypes and offer marginal improvement in reducing the seroconversion window (by 12 days) and the potential infectivity of a donor unit (15% reduction of an already low rate) *(30,255,256)*.

All HCV-antibody positive specimens by EIA are confirmed as positive by RIBA; a second-generation RIBA now incorporates the same recombinant antigens as the newer EIAs.

The risk of PTH was estimated to be <0.5% per patient transfused with the use of the third-generation EIA *(30,220,253)*. In addition to screening for HBsAg and antibody to HIV-1 and the adoption of a totally volunteer blood donor system with donor screening for HIV-1 infection risks, screening for ALT, anti-HBc, and especially anti-HCV had a major impact on the reduction of PTH. Donor questionnaire screening and donor unit serologic screening produced an overall low prevalence of anti-HCV positivity among volunteer blood donors (<0.5%) *(210,239,240,243,249,253)*. The frequency of anti-HCV positivity has been found to be higher among paid blood donors (10%; *257*), compared with volunteer groups (0.36%); anti-HCV positivity has been estimated to be 53.6 donor units positive for each million units collected *(162)*. Despite this low prevalence in volunteer donors, anti-HCV screening has demonstrated an impact (Table 67-6) because of the frequency of PTH (58–95%) after transfusion of anti-HCV reactive donor units and because of the ability of second- and third-generation EIAs for anti-HCV to detect 90% or more of donor units that transmit HCV *(206,210,237,239,241,243,253)*. The residual risk with the third-generation EIA was related to the possible 12- to 14-week window period after infection with HCV before the appearance of antibody *(258)*.

With these added screening tools, but before NAT, the risk of PTH had declined to <0.5% of transfused patients, a risk comparable with or less than the risk of hepatitis in nontransfused hospitalized patients *(202,206,253)*. Furthermore, 58% to 80% of the patients developing PTH in the past have developed persistent ALT elevations and 26% to 85% have chronic hepatitis; 90% of these patients are anti-HCV reactive *(179,188,198,215,219,231)*. Therefore, with current blood donor unit serologic screening, there is the potential not only to reduce PTH resulting from HCV by 90% or more but also to reduce chronic hepatitis resulting from HCV after transfusion by 80% to 90% *(235,253)*. On June 20, 1995, the prior requirement for ALT assays on all donor units was made optional because of rejection of many acceptable donors, especially males, because ALT assays are subject to interlaboratory variation and because the risk of PTH in groups receiving blood screened with or without ALT testing was equivalent *(254)*.

The use of NAT has further enhanced the ability to decrease the already low frequency of PTH resulting from defined HCV infection in donor blood *(207,259–262)*. PCR can detect HCV RNA within 59 days of infection *(8)*. With resolution of PTH resulting from HCV, HCV RNA detected by PCR has been shown to clear from blood as antibody levels decrease *(248)*. Before NAT for HCV, the risk of PTH resulting from HCV had been reduced to approximately 0.001% per unit of blood *(8,9)*. The addition of NAT in 1999 (initially as a duplex screen with HIV-1, and now a triplex screen also with HBV) has further reduced this risk to 0.00005%, an estimated 72% further risk reduction (*8*,*9*,144,*172*,*263*). Despite NAT, HCV can still be transmitted by anti-HCV- and NAT-negative blood products *(264)*. However, Dodd et al. *(172)* have documented the very low risk of HCV hepatitis after transfusion; they reported only 74 units of blood from more than 19 million drawn between March 1999 and February 2002 that were HCV antibody negative but HCV-RNA positive, for a rate of one positive unit per 267,700 units. This low rate has been confirmed by two more recent studies, one of which assessed 66 million donor units between 1999 and 2008 (185,265). In addition, the Centers for Disease Control and Prevention (CDC) has reported no transfusion-related HCV seroconversions among 11,171 hemophiliac patients between May 1998 and June 2002 and no transfusion-related cases during 2007 *(132,266)*. These improved safety data reflect an estimated decrement of the window period of infectivity of donor blood for HCV from 82 days with current antibody tests alone to 23 to 36 days by also incorporating NAT (8,267). NAT has been estimated to avert 56 to 59 HCV infections annually at a cost of several hundred million dollars annually *(186)*. PTH has become an uncommon event, reflecting the current safety of the blood supply.

Additional potential methods to prevent PTH resulting from HCV await development of a vaccine. Studies evaluating pretransfusion or post-transfusion administration of ISG have demonstrated conflicting results *(268–270)*. The variable efficacy probably reflects inconsistent anti-HCV content of preparations. ISG is not given in this setting *(207)*.

Other unsolved issues regarding non-A, non-B PTH remain. Only 91% of non-A, non-B PTH is associated with anti-HCV reactivity *(206,209,237)*. Although the incubation periods for anti-HCV–positive and anti-HCV–negative PTH are the same (6–12 weeks) *(244)*, anti-HCV–positive patients are more seriously ill and have twice the incidence of chronic hepatitis *(206,244)*. Other agents remain yet to be defined to account for the 9% of cases of PTH that are not due to HAV, HBV, or HCV *(8–10,172,244,271,272)*.

Hepatitis E Hepatitis E virus (HEV) is a single-stranded RNA virus in the Hepeviridae family. The epidemiology of HEV is similar to HAV in terms of fecal-oral transmission; HEV is more common in developing countries in tropical areas (144). The seroprevalence is <2% in the United States. Pigs, chickens, and other animals may be infected with HEV and serve as a source of human infection *(273)*. Illness is more severe than HAV infection, with 2% fatality (higher in pregnancy; 144). There are rare reports of transfusion-related infection, both in developing and developed countries *(33,274,275)*. Although HEV is a recently recognized pathogen, with our understanding of HEV yet evolving, as with HAV, there is not a need at this time to consider screening for HEV given its lack of chronic infection and likelihood of donor self-deferral during acute illness.

Hepatitis G Similar to the original work with HCV, in 1996 Linnen et al. *(276)* reported the cloning of HGV from the plasma of two patients, one with non-A, non-B hepatitis and the other asymptomatic with intermittent enzyme elevations. This group reported that HGV was genomically similar to another human virus isolate from a surgeon ill with hepatitis in the 1960s, termed "GB virus C." HGV is a member of the Flavivirus family, along with HCV and GB virus C. Using reverse transcriptase PCR technology, 2 of 12 patients with PTH were found positive for HGV RNA by Linnen et al. *(276)*, as were 5 of 38 patients with non-A to non-E community-acquired hepatitis. Four of the latter five patients remained HGV-RNA positive for 2 to 9 years

without evidence of chronic hepatitis. In addition, Linnen et al. reported 13 of 779 (1.7%) of volunteer blood donors with normal ALT values positive for HGV RNA, as were 11 of 709 donors (1.5%) with ALT elevations. These authors reported HGV to be globally distributed. More recent screening studies have confirmed these findings *(277)*.

Subsequent studies have confirmed this work and have found HGV in hemodialysis and postoperative patients, presumably transfusion associated *(278–280)*. Several authors have reported on the clinical disease associated with HGV, whether alone or in association with HCV; HGV is at worst a cause of mild acute hepatitis *(280,281)*, but frequently infection with HGV is asymptomatic without evidence of hepatitis *(280–282)*. HGV does not augment disease when accompanying HCV *(280–284)*. HGV was not associated with chronic hepatitis *(279,280,282)*. HGV is persistent in HIV-1 infected men and had variable effects on short- and long-term survival *(285)*. HGV is also prevalent in injectable drug users and hemophiliacs; HGV can be passed vertically mother to child and after heterosexual or homosexual contact with HGV-positive partners *(280)*. Its modes of transmission parallel HCV generally. Tanaka et al. *(283)* reported HGV responsiveness to interferon-α, but most patients relapsed.

Despite the prevalence of HGV in the volunteer blood donor population (1–4%), its role in PTH remains to be determined, because 75% of patients with transfusion-acquired HGV lack biochemical evidence of hepatitis *(280,281)*. Those with hepatitis have only mild elevations asynchronous with their HGV-RNA levels *(281)*. The relevance of HGV (and GB virus C) to PTH remains to be defined with broader seroepidemiologic, biochemical, and clinical studies. Currently, there appears to be no reason to test blood donors for HGV *(286,287)*.

Cytomegalovirus CMV is a member of the herpes virus family of DNA viruses (human herpes virus 5, HHV-5). Like other members of this group of viruses, latency is the rule after recovery from acute infection. Acquired CMV infection rarely presents as hepatitis, but may do so in adult patients *(288)*. Epidemiologically, CMV is acquired by human-to-human contact, congenitally or perinatally from mother to child by contact with cervical secretions, postnatally by an infant via breast milk, and in settings for the care of multiple children (e.g., in neonatal nurseries, in day care centers, and in the family setting) *(289)*. CMV is also transmitted by heterosexual or homosexual contact, by transfusion of donor blood, and by transplantation of donor organs *(289)*.

CMV infections are classified as primary (with seroconversion from negativity to positivity), reactivation of an endogenous infection, or reinfection with a new exogenous strain of CMV (in a seropositive host) *(288,289)*. The latter two forms of infection can be distinguished by using restriction enzyme DNA analysis, but this is not routinely practical *(290)*. Because there are no accurate data on the proportion of reactivation and reinfection for CMV post-transfusion infections, these two forms of infection are called "recurrent infections" *(288,289)*.

Depending on socioeconomic stratum and age, the seroprevalence of CMV ranges from 25% to 88% (144, *287–294*). In studies of CMV infection after transfusion in normal hosts before 1972, the incidence varied from 16% to 67% *(288)*. Most of these infections were asymptomatic. Risk factors for transmission included increasing number of units of blood transfused, use of fresh blood, and use of seropositive blood *(288)*. After 1972, transfusions became less common and involved little or no fresh whole blood, especially in cardiac surgery. Concomitant CMV post-transfusion infections have decreased to 1.2% to 17% *(288)*. In contrast to fresh whole blood, leukocytes containing CMV (monocytes and polymorphonuclear leukocytes) survive storage poorly at 2°C to 6°C *(288)*. This observation correlates with the observed reduction of CMV post-transfusion infection rates; studies have shown that 86% of patients infected with CMV after transfusion had received fresh whole blood, compared with 11% of uninfected patients *(295,296)*. Dworkin et al. *(297)* demonstrated a greater likelihood of isolation of CMV from donor blood during the first 5 days after collection, with infrequent isolation thereafter. In addition to fresh whole blood, granulocyte transfusions have been associated with an especially high risk of CMV infection in compromised hosts *(298–300)*. The difficulty with isolating CMV from donor leukocytes may be a reflection of the small number of leukocytes infected or the need for a posttransfusion host-versus-graft reaction to reactivate the virus *(288)*.

The reduction in overall CMV-related transfusion infections since 1972 also suggests that only a subset of CMV-infected donors (most of whom are seropositive) can transmit infection via donated blood *(288,301)*. This observation is paralleled by the infrequency with which CMV can be isolated from donor blood *(288)*. The receipt of blood from a CMV-seropositive donor significantly correlates with the infrequent residual post-transfusion CMV infections observed since 1972 *(302)*; this has been very well defined in transfused neonates *(303)*. An increased frequency of transmission also correlates with receipt of blood from a donor positive for CMV-IgM antibody *(302,304)*. The pathogenesis and presentation of CMV infection after transfusion involves several factors: the volume of blood transfused, activation of leukocytes harboring CMV, and survival of donor cells in the recipient to allow CMV replication *(304)*.

CMV infection can be diagnosed by direct examination of tissues or exfoliated cells for intranuclear inclusions; however, this lacks sensitivity for active infection *(305,306)*. Isolation of CMV in cell culture from blood (leukocytes) is more sensitive and specific for active infection but labor intensive (1–4 weeks for positivity). The development of fluorescein-labeled monoclonal antibodies for "immediate-early" and "early" antigen detection permits the diagnosis of CMV infection in cell culture within 24 to 48 hours *(307–310)*. Such antibodies can also be used directly to stain biopsied tissue *(307,311,312)*. CMV DNA probes with hybridization and electron microscopy of tissues and leukocytes are limited to research applications generally and have been reported to have lower sensitivity *(288,294)*. "Nested" quantitative PCR has been applied to various body fluids, including cerebrospinal fluid and blood, for the diagnosis of active CMV infection in HIV-1 infected patients *(289)*. This has not been applied to the blood donor setting.

CMV-specific antibodies can be detected by a variety of techniques (complement fixation, indirect hemagglutination,

indirect immunofluorescence, anticomplement immunofluorescence, latex agglutination, RIA, and EIA) *(288,289)*. Several of these can be applied to the detection of CMV-IgM antibody, including RIA and EIA *(313)*.

CMV disease most frequently occurs in a seronegative individual after primary infection and usually manifests as mononucleosis; however, post-transfusion CMV infection is usually asymptomatic. Therefore, there is no need to provide CMV-seronegative blood or blood products to immunocompetent recipients *(288,304)*.

The groups at risk for serious post-transfusion CMV infection are seronegative pregnant women, seronegative premature infants, seronegative organ transplant recipients who received an organ from a seronegative donor, seronegative oncology patients receiving chemotherapy, and seronegative patients with HIV-1 infection *(289,314,315)*. Seronegative premature neonates (<1,200 g) receiving CMV-seropositive blood are at greater risk for pneumonia, hepatitis, hemolytic anemia, and thrombocytopenia *(304,316)*. Mortality may reach 40%. This subgroup warrants routine receipt of CMV-seronegative blood.

Transplant patients developing primary infection (via a transplanted organ or transfusion) develop more serious disease *(289,315)*. In renal transplantation, the seropositive kidney donor is the major source of CMV *(317,318)*; seronegative transplant recipients receiving kidneys from seronegative donors rarely become infected and have better graft survival than those receiving kidneys from seropositive donors *(319–321)*. It is prudent to provide seronegative recipients of seronegative renal transplants with CMV-seronegative blood *(288,289,304)*. The same comments apply to heart transplantation *(304,322)*. Better-controlled studies in solid-organ transplant patients are needed, however *(304)*. The data are less clear and less well defined for donor blood in the bone marrow transplantation setting; however, prophylactic granulocyte transfusions, if given during bone marrow transplantation, should be from CMV-seronegative donors if the recipient is seronegative because of the high frequency of symptomatic and fatal infections *(298–300,304,323)*. The use of CMV-seronegative or leukocyte-reduced cellular blood products is warranted in seronegative recipients of bone marrow transplants from CMV-seronegative donors *(14,304,314,315,323,324)*. Such practices have reduced the risk of transfusion-associated CMV infection in this setting (23–37%) to 1% to 4%.

Preiksaitis et al. *(325)* documented the low risk of transfusion-related CMV disease in CMV-seronegative children with malignancy because of their low frequency of exposure via transfusion and because of LR of transfused units. In oncology patients, currently available data do not support screening donor blood for CMV *(288)*. Leukocyte-reduced cellular blood products are indicated in patients with hematologic malignancies who are CMV-seronegative to prevent CMV-associated morbidity *(14,315,326)*. A similar argument can be made for the exceptional HIV-1–infected patient who is seronegative for CMV *(304,314,315)*. However, LR lowers but does not absolutely prevent CMV infection from donor blood; seronegative blood components are more efficacious (*327*,328,*329*).

When indicated and necessary, the screening of donor blood for CMV antibodies is problematic because of the high frequency of seropositivity in the population *(294,330)*. At least in the neonatal setting, screening only for evidence of acute or reactivated CMV infection (i.e., CMV IgM) in donor blood will increase the size of the donor pool while reducing post-transfusion disease *(288,331)*. It has been demonstrated that the risk of transmitting CMV is diminished by using leukocyte-reduced blood, either as frozen deglycerolized RBCs or leukocyte-filtered RBCs (*14*,*304*,*326*,*327*,328,*329*,*332–336*). Differential centrifugation of platelet units may also enhance their safety *(304)*. The use of CMV immune globulin may have some role for preventing CMV-related complications in premature neonates born to CMV-seropositive mothers and in bone marrow transplant recipients, but ganciclovir appears to be more effective in the latter setting and in patients with HIV-1 infection *(288,289,337–339)*. The effect of the attenuated CMV vaccine in preventing CMV complications of transfusion has been disappointing *(289)*.

Epstein-Barr Virus and Human Herpes Viruses 6 and 8 EBV (human herpes virus 4; HHV-4) is another member of the herpes virus family of DNA viruses that is prone to latency in B lymphocytes and pharyngeal epithelial cells. Transfusion-related EBV infection is rare, with only a few recognized cases in the literature despite a 90% seroprevalence among blood donors *(315,340–344)*. Seroconversion after transfusion is usually associated with mild or inapparent clinical illness *(341,344)*. However, Alfieri et al. *(345)* documented the development of B-cell lymphoproliferative disease in a liver transplant patient after transfusion of EBV-positive donor blood. Because of the seroprevalence of prior infection in the population, screening donor blood is not indicated. Leukocyte-reduced RBCs may prevent transmission from a seropositive donor even during acute infection; LR is prudent in compromised hosts, especially in the transplant setting *(315,344–346)*.

Although no precautions are yet indicated for human herpesvirus-6 (HHV-6) uninfected potential transfusion recipients (60–100% of adults are infected), further experience is needed before use of seronegative donor blood can be recommended for seronegative compromised hosts *(315,344)*. HHV-6 has limited recognized pathogenic potential in immunocompromised adults *(315)*.

Human herpes virus 8 (HHV-8) has been associated with Kaposi's sarcoma, primary-effusion lymphomas, and multicentric Castleman's disease *(347)*. HHV-8 remains latent in peripheral blood mononuclear cells *(348)*. Its seroprevalence is 0% to 3.5% of volunteer blood donors, but from 12% to 36% in homosexual males and injection drug users and >40% in African countries *(347,349,350)*. In a study of women who had a history of injection drug use or high-risk sexual behavior, HHV-8 seropositivity was associated with black race, Hispanics, lower level of education, and infection with syphilis, HBV, HCV, and HIV-1 *(350)*. Although there is the potential for transmission by transfusion, the low seroprevalence of HHV-8 in US volunteer blood donors makes transmission unlikely. However, HHV-8 seroprevalence in transfusion recipients is 21% higher than the donor population *(351)*; in a study of seroconverting transfusion recipients, risk was greater with PRBC stored ≤4 days *(352)*. There are no recognized consequences of transfusion-mediated infection at this time *(315,347)*. A recent editorial concluded that testing for

HHV-8 in volunteer donor units is not an option and that LR is likely to reduce risk of transmission; therefore, no action was deemed needed at present regarding HHV-8 *(353–355)*.

Human Immunodeficiency Virus Type 1 Within several years after the epidemic of the acquired immunodeficiency syndrome (AIDS) was recognized, its epidemiology was recognized to include transmission by sexual contact and by sharing blood-contaminated needles *(356–358)*. Avoiding sexual contact and needle sharing with homosexual males, individuals with multiple sexual partners, and individuals using injectable drugs became confirmed methods for avoiding infection with HIV-1, the cause of AIDS. Initially, the only mechanism for reducing what appeared to be transmission by transfusion was voluntary self-deferral of donors in high-risk groups, including sexual partners of members of the high-risk groups mentioned previously *(359)*. The directive to blood banks for voluntary blood donor deferral was issued on March 4, 1983 *(358)*. The first cases of transfusion-associated AIDS were reported in patients with hemophilia A *(360)*. Subsequent reports included infants and other adults without risk for AIDS other than transfusion *(359)*. The risk of transfusion was subsequently stressed to potential recipients by the recommendation for signed informed consent for nonemergent transfusions, issued on May 8, 1986.

Whole blood, blood cellular components, plasma, and clotting factors were implicated in transmission of HIV-1, but not immune globulin preparations and plasma-derived hepatitis B vaccine *(34,361)*. Ninety percent to hundred percent of patients transfused with blood contaminated with HIV-1 became infected *(8,362,363)*. Because blood donors with HIV-1 infection are usually asymptomatic, self-deferral by those in high-risk groups was important, in addition to assaying for antibody. The risk of HIV-1 infection was great for hemophiliacs before 1985; coupled with donor deferral and HIV-1 antibody testing, moist heat or solvent detergent treatment of clotting factors reduced this risk to a very low level for pooled plasma products *(364–368)*.

After the isolation of HIV-1 in 1983 to 1984 *(369–372)*, serologic tests for detection of antibodies to HIV-1 in patients with AIDS were described *(373–375)*. The assay techniques for these antibodies were quickly developed by private industry as an EIA, and blood centers within the United States initiated donor screening in March 1985 *(376)*. The blood supply was thereby rendered safer *(377)*. Despite the lack of specificity of an initially positive EIA, this screening EIA soon was also used as a diagnostic test, coupled with a confirmatory Western blot (WB).

Because of this evolving diagnostic function of the EIA, the CDC and the ARC established alternate test sites in April 1985 for anonymous testing to prevent high-risk individuals from using blood donor sites for diagnostic purposes *(378)*. Individuals recommended for testing gradually evolved to include, in addition to the high-risk groups mentioned previously, pregnant women at high risk for HIV-1 infection, attendees of sexually transmissible diseases clinics and drug abuse clinics, and recipients of transfusions between 1978 and 1985. During this time, the definition of high-risk behavior warranting HIV-1 antibody testing and deferral from donating blood was expanded to include a single homosexual encounter since 1977, sexual contact with a prostitute, and residence in sub-Saharan Africa (because of HIV-2 risk). These attempts at high-risk donor self-deferral were effective, except among injectable drug users *(379,380)*. This broadened definition of high-risk individuals was promulgated because of the window period after infection before antibody to HIV-1 was detected (see later discussion).

In June 1986, notification was mandated for recipients of units of blood or blood products transfused before March 1985 that were subsequently determined to be seropositive for HIV-1. This "lookback program" allowed earlier medical evaluation, management, and observation of the natural history of HIV-1 infection in patients with well-defined dates of exposure.

With the use of the EIA, WB, and an antigen-capture EIA *(375,381,382)*, the serology of HIV-1 infection was defined (Fig. 67-6). HIV-1 is composed of several structural (glyco) proteins that elicit antibodies *(375)*. The core protein of 24,000 molecular weight (p24) correlates with active viral replication, appears early after infection, and coincides generally with plasma HIV-1 RNA levels (Fig. 67-6); its disappearance correlates with development of anti-p24. The envelope glycoprotein of 160,000 molecular weight (gp 160) is composed of a transmembrane subunit

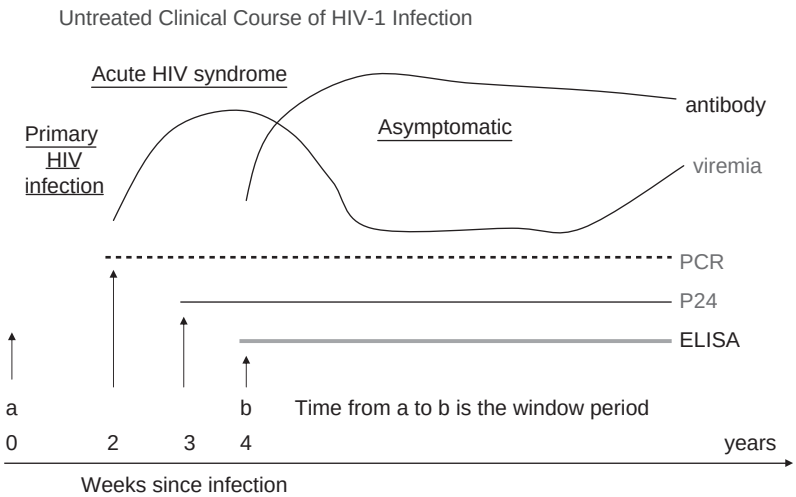

FIGURE 67-6 Chronology of human immunodeficiency virus type 1 infection defined by presence of core (p24) antigen, viral RNA by PCR and antibodies by ELISA. (*Source*: S Conway and John G. Bartlett, 2003; Courtesy of John G. Bartlett, Johns Hopkins University).

(gp 41) and an attachment subunit (gp 120); the host makes an antibody to each of these components. Internal polymerase gene products include the reverse transcriptase protein (p66, p51) and an endonuclease (p31); antibodies are made against each of these gene products. The first-generation EIA detected antibody to any of these proteins, because an impure virus lysate was used; however, the WB (and a radioimmunoprecipitation assay) allow differentiation of antibodies to each antigen *(375)*. Other confirmatory antibody assays used to demonstrate infection with HIV-1 are available, but further testing of blood beyond antibody assays necessitates tests for HIV-1 detection (p24 antigen capture EIA, viral culture, or NAT [proviral DNA or viral RNA]) *(375)*.

Because a lysate of human cells infected with HIV-1 was used as the antigen source for the first-generation EIA, antibodies to human cell antigens (and not viral antigens) in human serum caused false positivity of the EIA and resulted in its lack of specificity despite sensitivity; although the WB assay for antibodies used the same lysate, the viral (glyco) proteins were separated from each other and from contaminating human cell antigens electrophoretically, thereby allowing differentiation of antibodies and greater specificity *(378)*.

The sequence currently utilized for testing for HIV-1 in donor units is depicted in Figure 67-7. The criteria for a positive WB have been defined by the CDC as the presence of antibody to p24 and antibody to either gp 41 or gp 120/160 *(383)*. Using this sequence of testing (Fig. 67-7), estimates of the frequency of transfusion of donor blood infected with HIV-1 ranged from 3 to 26 per 1 million transfusions with early EIAs *(384–388)*. The most recent estimate using contemporary antibody assays approximates the lower frequency of 1 in 493,000 donor units (0.0002%) or less *(8)*. The entire antibody testing sequence, even with first-generation EIA and WB, had a positive predictive value of 81% to 100% with a 99% to 100% specificity *(389)*. Follow-up evaluations of blood donors with indeterminate WB patterns (Fig. 67-7)—the presence of one or more antibodies but not enough to meet the definition of positive—have shown that these donors or recipients of their blood never develop serologic evidence of infection *(390–394)*.

Because of the window period with EIAs for HIV-1 antibody (between infection of a patient and seroconversion), rare transmission of HIV-1 could occur by transfusion *(8,395,396)*. The window period was estimated at 42 to 45 days with the HIV-1 viral lysate EIAs and at 22 to 25 days with the contemporary HIV-1 recombinant protein supplemented EIAs (second- and third-generation EIAs) *(8,30,397,398)*. This window period may be further reduced to 6 to 16 days by assaying for p24 antigen or HIV-1 DNA in

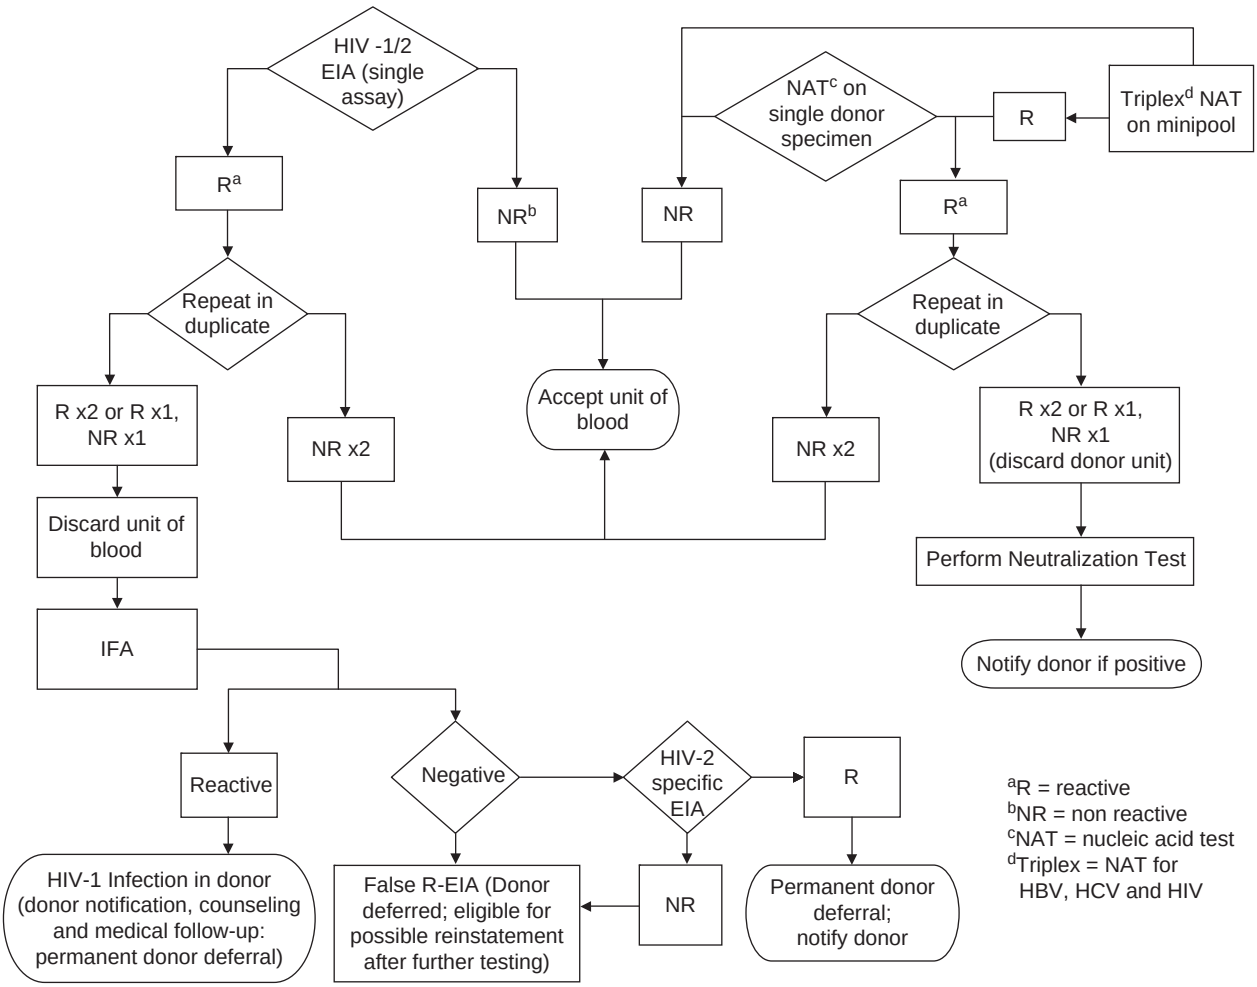

FIGURE 67-7 Algorithm for screening donor blood for human immunodeficiency virus type 1 and type 2 infections.

leukocytes by PCR *(8,30,398,399)*. Detection of HIV-1 RNA by PCR may reduce the window period after infection to 11 to 13 days *(8,30,398)*. Proposals to initiate p24 antigen testing on all blood and plasma donor units were not supported in the scientific community because of minimal estimated benefit (5–10 infected donor units detected per year in the United States) *(30,398–401)*. Despite this, in August 1995, the FDA recommended p24 antigen detection assays on all donor units *(402)*. The first p24 test was licensed in March 1996, at which time antigen screening of donor blood ensued *(30)* (Table 67-5). This assay is no longer used due to application of NAT.

In an attempt to make the blood supply additionally safe, in April 1999 NAT for HIV-1 was initiated on all donor blood in the United States *(403)*. PCR for both HIV-1 and HCV was initially combined and this duplex assay was applied to minipools of plasma from 16 donated units of blood for cost efficiency *(404–406)*; when positive by the combined assay, individual units that were part of the plasma minipool then undergo NAT for HIV-1 and HCV. It is estimated that the window period (preseroconversion) was shortened by PCR for HIV-1 by 14 to 15 days (the window for HCV is also shortened by 26 days) *(267)*. Dodd et al. *(172)* reported that from March 1999 through February 2002 more than 19 million units of blood were tested by NAT; five of these units were seronegative for HIV-1 but positive for HIV-1 RNA, for a rate of 1 per 3,962,000 units. These safety data reflect an estimated decrement of the window period of infectivity of donor blood for HIV-1 from 22 days with current antibody tests alone to 8 to 11 days by also incorporating NAT *(9,267)*. This rate is very close to that projected by Schreiber et al. *(8)* and in keeping with the fact that the risk of receiving an HIV-1 infected unit of blood today is so low that it is more easily estimated than measured *(8,172)*.

The prevalence of HIV-1 infection in donor units with antibody screening alone was very low (7.7–13 per 100,000 units; *407–409*). With antibody screening plus NAT, the current prevalence of HIV-1 infection in a volunteer donor unit is estimated to be 1.8 to 2.2 positive units per million donors (*162*,185). As a result of the current blood donor unit testing algorithm, including the third-generation EIA and PCR for RNA (the NAT for HIV-1 is now combined with HCV and HBV into a triplex NAT), the risk of receiving a unit of blood transmitting HIV-1 is estimated to be 0.00004% to 0.00005% (or 1 per 2,300,000 units transfused; *9,132*,144,*172*). Despite such sensitivity of this testing algorithm and very low risk, transmission of HIV-1 from an infected unit to two recipients has been reported in Singapore using identical screening assays *(410)*. The cost of NAT testing for HIV-1 is several hundred million dollars annually to avert 4 to 7 HIV-1 positive units being transfused *(186)*. Other transfusion risks now deserve more attention for their potential clinical benefit than further efforts at risk reduction for HIV-1.

The rarity of HIV-1 infection in seronegative blood donors has been confirmed by the use of HIV-1 culture, in addition to PCR, to detect HIV-1 infection in donor blood (*9,132*,144,*411*). In addition to all blood donors being screened for HIV-1 infection, all organ, tissue, and semen donors undergo self-deferral for high risk and are screened for antibody to HIV-1 *(367)*; transmission has occurred in this setting *(412)*. Because 40% of HIV-1–seropositive individuals also have anti-HBc, screening for this surrogate marker of HCV and for prior HBV infection has also contributed somewhat to the risk reduction for HIV-1 transmission when antibody tests alone were used as screening *(179)*. However, the continued value of the anti-HBc assay in this regard has been questioned *(413)*. Screening donated blood for syphilis also possibly contributed to further risk reduction for HIV-1.

In addition to self-deferral for those in high-risk groups and antibody screening, other attempts have been made to enhance the safety of blood for HIV-1 infection. EIAs and to some extent PCR tests for HIV-1 infection have been modified to include non-B subtypes (M subtype and group O) to broaden the scope and sensitivity of the assays *(414)*. LR may reduce but not eliminate the infectivity of donor blood *(415)*. Experimental studies of photoinactivation of HIV-1 in whole blood have been reported *(368,416)*. Immune globulin preparations are already safe because of Cohn fractionation, and clotting factor and plasma products have been made safe by the application of heat treatment with steam vapor and solvent–detergent treatment *(361,363,368)*. Additional chemical treatments of clotting factors have been suggested, in addition to the possible future use of monoclonal antibodies to inactivate HIV-1 *(363)*. Synthetic production of clotting factors by genetic engineering and the use of artificial blood may also become available (see later discussion).

Human Immunodeficiency Virus Type 2 HIV-2 is a retrovirus currently endemic in West Africa. Producing a similar illness, it has been reported in immigrants to the United States *(417–419)*. Despite the low prevalence of HIV-2 infection in the United States, screening of donor blood for antibodies to HIV-2 began in June 1992 using a combined HIV-1 and HIV-2 recombinant viral protein antigen preparation in an EIA *(420)*. The testing algorithm for HIV-2, if the combined HIV-1 and HIV-2 EIA is positive but assays for HIV-1 are negative, follows that outlined in Figure 67-7. If the serum specimen is repeatedly reactive by the combined HIV-1 and HIV-2 EIA, a WB for HIV-1 is performed; if this is negative or indeterminate, an HIV-2–specific EIA is performed, followed by an HIV-2–specific WB *(420)*. The first two cases of HIV-2 infection among blood donors have been reported *(421)*, but this is a rare event.

Human T-Cell Leukemia Virus Types I and II Human T-cell leukemia virus type I (HTLV-I) is a chronic latent retrovirus infection epidemiologically linked to the islands of southwestern Japan and the Caribbean, where 20% of adults and 2% to 5% of blacks are seropositive *(418,419)*. This virus is also endemic in the southeastern United States. HTLV-I infection is rare overall in the United States population, occurring in 9 to 80 of 100,000 blood donors *(407,417,422–424)*. In Italy, this infection has been found serologically in 290 of every 100,000 donors; this higher rate of infection is believed to reflect frequent infection among persons using injectable drugs in Italy *(425)*. Transmission occurs from mother to child primarily through breastfeeding; transmission also occurs by sexual contact, by contaminated needles, and by transfusion of whole blood, packed cells, and platelets (144,*418,419*). Although not totally safe, blood derivatives such as coagulation

factors seem to be free of transmission risk because of the intraleukocytic location of the virus *(418,419)*. From 30% to 63% of recipients of cellular blood products, 40% of platelet recipients, and 28% of recipients of RBC units from infected donors become infected; cell-free products may pose no risk *(423,426–428)*. Storage of units of RBCs for more than 14 days may eliminate the risk of transmission of HTLV-I and HTLV-II from an infected donor *(427)*. Antibodies have become detectable by 3 to 6 weeks after transfusion with units seropositive for anti-HTLV-I; IgM antibodies, detected early, became undetectable within a few months. Although the risk of transmission of HTLV-I infection by transfusion had been estimated at 0.024% per unit before HTLV-I EIA screening *(388,428)*, estimates of this risk after introduction of the EIA suggest a rate as low as 0.00015% to 0.002% before LR *(8,429)*. The combined HTLV-I and HTLV-II viral lysate and recombinant antigen EIAs have resulted in this lowered risk. Since implementation of LR, it is believed that the risk of receipt of an infected donor unit is now 1 per 2,993,000 units (Table 67-6) (0.00003%; 144).

Infection with HTLV-I has been linked with the development of human T-cell leukemia, which may be either a smoldering or a fulminant leukemia, associated with hypercalcemia, hepatosplenomegaly, lymphadenopathy, and skin lesions *(418)*. Circulating lymphocytes with indented nuclei are suggestive of the disease. After a latency of up to 20 years, the risk of developing this leukemia after HTLV-I infection is estimated at 1 in 80 *(418)*. HTLV-I infection has also been linked with tropical spastic paraparesis *(430)*.

HTLV-II is not linked definitively with any particular disease process but has been associated with atypical hairy cell leukemia and a chronic neurodegenerative disease *(418,419,428,431,432)*. Transmission of HTLV-II is epidemiologically linked with transfusion but primarily with injectable drug use in the United States *(407,433–435)*. Murphy et al. *(424)* have associated HTLV-II transmission, focused on the West Coast, with injectable drug use and secondary sexual transmission; seroprevalence among blood donors from 1991 to 1995 was 0.0223%.

Because of the 84% homology of the p24 core antigens of HTLV-I and HTLV-II, the EIA for HTLV-I may detect infection with HTLV-II *(429,434)*. Although the incidence of HTLV-II infection in the United States is low, in some areas HTLV-II is at least as common as HTLV-I *(424,427)*. A specific HTLV-II screening test for donor blood is currently not performed; a combined recombinant antigen HTLV-I and HTLV-II EIA serves this function *(428,434)*.

Serologic methods used to document HTLV-I and HTLV-II infection include EIA, immunofluorescence, WB, and radioimmunoprecipitation assay *(418,428,434)*. The EIA and the WB are similar to those performed for HIV-1, with similar gene products. The first-generation EIAs used HTLV-I viral lysates or recombinant gene products as antigens for antibody detection *(428)*; these assays had a high degree of crossreactivity for HTLV-II but failed to detect 9% to 45% of HTLV-II–positive blood specimens *(422,428,434)*. They were also prone to some false positivity for HTLV-I; however, surveys suggest a specificity of 98% and sensitivity of 96% to 99% for HTLV-I–infected donor units *(434)*. There was no crossreactivity of HTLV-I–positive specimens in the HIV-1 EIA *(418)*; however, 70% to 78% of HIV-1 EIA positive, WB indeterminate specimens reacted in the HTLV-I EIA *(418)*. On November 29, 1988, the FDA issued the initial directive for anti-HTLV-I testing of all blood donated for cellular products (but not for plasma). The algorithm for testing follows that for HIV-1 (Fig. 67-7).

Second-generation EIAs for HTLV-I and HTLV-II have combined the viral lysate or recombinant gene antigens with a recombinant transmembrane envelope antigen (rgp21e) that crossreacts between HTLV-I and HTLV-II *(428,436)*. Although this assay remains incompletely sensitive for HTLV-II, its specificity and sensitivity for HTLV-I antibodies was further improved *(428)*. Newer third-generation EIAs for HTLV-I and HTLV-II were introduced, combining both HTLV-I and HTLV-II recombinant antigens or viral lysates; these assays are variably more sensitive than second-generation assays *(428)*. In 1998, the combined third-generation HTLV-I and HTLV-II viral lysate or recombinant antigen EIA was implemented by blood centers (Table 67-5).

For repeatedly reactive anti-HTLV-I and HTLV-II EIA donor units, specimens are initially tested with a WB that can differentiate infection with HTLV-I or HTLV-II *(428)*. However, the WB is indeterminate in 38% to 75% of anti-HTLV-I and anti-HTLV-II reactive donor units *(428)*. Most of these indeterminate specimens are PCR negative, implying a high WB false positivity resulting from indeterminate reactions. A recently developed RIBA is more specific, resolving 66% of WB indeterminate reactions *(428)*. Therefore, the RIBA may be a more sensitive and specific confirmatory assay for HTLV-I and HTLV-II than WB, because it can detect antibodies to the viral envelope glycoprotein; WB is more sensitive for antibodies to core proteins, which are the frequent cause of false positivity *(425)*. However, other surveys report improved HTLV-I and HTLV-II WB specificity (>97%), but there are also continued problems with its sensitivity (<65%) *(434)*.

DNA PCR has been used to confirm HTLV-I and HTLV-II infection in lymphocytes of seropositive donors. Of patients with a positive HTLV-I and HTLV-II EIA, DNA PCR confirms infection with HTLV-II in 42% to 52% *(422)*. By DNA PCR, up to 15% of persons with a positive EIA may be uninfected with either virus *(422)*.

HTLV-I or HTLV-II infection has been found in 0.014% to 0.021% of all blood donors in the United States *(422)*. After institution of donor questionnaire screening and testing of all donor blood by the HTLV-I EIA, this rate dropped for HTLV-I and HTLV-II to about 0.0014% *(422,429)*. The risk of HTLV-II is about three times higher in first-time blood donors compared with HTLV-I *(10)*. There is considerable geographic variation in seroprevalence. Generally, higher seropositivity rates for blood donors for HTLV-II are seen on the West Coast and in women *(162,422,424)*. Rates are highest among African Americans, Hispanics, and Asians; among injectable drug users or their sexual contacts; among persons born in the Caribbean or Japan; and among persons with a history of blood transfusion. In addition to serologic screening, self-deferral of these high-risk groups (as for HIV-1) is an important adjunct. The risk of transmitting HTLV-I or HTLV-II is now estimated at 1 in 2,993,000 transfused units (0.0003%; 144). In addition, the overall risk for HTLV-II infection in blood donors has declined due to LR (144,*172*).

TT Virus and Sen Virus Torgue Teno virus (TTV) is named for the initials of the patient in whom it was initially

defined in 1997; this patient had hepatitis, thereby linking TTV possibly to non-A, non-B, non-C, non-D, non-E hepatitis *(437,438)*. TTV is a circular, single-stranded DNA virus with up to 16 genotypes, which was initially thought to be another agent of PTH *(437)*. TTV is present in 5% to 50% of volunteer blood donors in the United States but has a much greater seroprevalence in less well-developed areas of the globe, varying from 14% to 86% of populations (144,*437*). TTV is epidemiologically linked to multiply transfused patients and injectable drug users but probably also has a fecal–oral route of spread *(437)*. Although TTV is transmitted by transfusion and found in higher titer in liver than in serum, it is not associated with hepatitis or other liver disease, despite its apparent replication there *(437,439–442)*. Given these data, there is no reason to assess prospective donor units for the presence of TTV at this time.

SEN virus (SENV) was isolated from an injectable drug user and reported in 2000 *(443)*. SENV is a circular, single-stranded DNA virus with eight strains (A through H) and is related to TTV with a seroprevalence in blood donors of 1.8% to 13%; up to 70% of multiply transfused patients are seropositive *(443–445)*. SENV DNA becomes undetectable in serum within 6 months in 55% of patients after transfusion acquisition *(445)*. SENV-H is most common in the United States; 7% to 76% of patients with HCV and 20% to 60% of HBV infected patients are SENV seropositive *(444,445)*. However, the presence of SENV does not affect the severity of HCV or HBV infection, or the response to therapy for HCV, despite long-term persistence of SENV *(445)*. Other studies continue to find no etiological role of SENV in chronic hepatitis *(445a)*. Without a relationship to hepatitis or other disease, there is no reason to test donor units for SENV presently.

West Nile Virus Considerable discussion has developed in the last 5 to 10 years about emerging pathogens, especially as they relate to the safety of the blood supply (*354*,*355*,446,447). Included among these potential threats to the safety of transfused donor units are West Nile virus (WNV), parvovirus B-19, prion disease, malaria, Babesiosis, Tryponasomiasis, leishmoniasis, Dengue, and Chikungunya viruses, among other less likely transmissible agents (*354*,*355*,446,447). Much of such discussions center around the political (and unreasonable) demand for a "zero-risk" product, an unachievable goal *(354)*. Within this chapter a number of these realistically potential emerging pathogens will be covered.

WNV is an Old World Flavivirus, previously endemic in Africa, Asia, the Middle East, and southern Europe *(448)*. Since its initial recognition in 1937 in an ill woman in the West Nile region of Uganda, there were infrequent human outbreaks; notable exceptions have been an Israeli nursing home outbreak in 1957 and outbreaks in Romania (1996), Russia (1999), and Israel (1999, 2000) *(448,449)*. In late summer 1999, eight patients with encephalitis were initially recognized as a WNV outbreak in New York City; this led to the recognition of 59 patients hospitalized for WNV infection *(450)*. In subsequent years, WNV spread via its mosquito vector and/or its migratory bird definitive hosts (crows, ravens, blue jays) to at least 44 of 48 continental United States *(451)*. Humans and horses are dead-end hosts after the bite of an infected mosquito *(448)*. In the United States, there were 3,389 human cases during 2002 with 201 deaths. Four of every five patients are asymptomatic, and only 1 in 10 infected patients seek medical attention *(448)*. One in one hundred and fifty infected patients develops meningoencephalitis or a poliolike syndrome *(448,452)*.

Because of the presence of mild illness after infection, especially in young adults (the likely blood donor population), and because of an incubation period of 3 to 14 days *(448,449)*, the potential for transfusion transmission associated with viremia was evident. Viremia rarely lasts more than 2 weeks (at high levels) without antibody, though may persist for 2 months occasionally; viremia averages 6 days' duration *(354,453)*. During the WNV epidemic of 2002, at least six patients developed confirmed WNV infection via transfusions, with an additional 27 suspected occurrences *(454)*. During the epidemic in New York City in 1999, the risk that a blood donor would have WNV in the blood was estimated at 2 per 10,000 donors *(455)*. Because of these risks, the FDA initially released its guidance for assessing donor suitability and blood product safety regarding possible WNV infection in the donor on October 25, 2002 *(456)*. Self-reported symptoms were and continue to be of little value in predicting WNV infection in the donor *(457,458)*. Transfusion and donor-organ related transmission of WNV continued to occur *(459,460)*.

For these reasons, NAT for WNV RNA was initiated in all donor centers by July 14, 2003 (Table 67-5) *(453)*. Minipools of 6 or 16 specimens (MP-NAT) were assayed. If the MP-NAT were positive, specimens from individual donor units (ID-NAT) are tested. However, despite MP-NAT of donor units, transfusion-related WNV infections did occur, probably related to donor units with low-level viremia *(461–464)*. It had previously been noted that some donor units were only positive for WNV-RNA testing by ID-NAT and not by MP-NAT *(465)*. Due to this issue of false-negative MP-NAT for WNV, selected ID-NAT was implemented at many centers in 2004 and 2005 *(466)*. In 2008, the FDA issued guidance for each blood donation center to develop criteria for switching from MP-NAT to ID-NAT for WNV during periods of high WNV activity *(467,468)*. Some centers make such a switch when two MP-NAT are confirmed positive from donors living in the same postal zip code within a 7-day period, while others make this switch if only one MP-NAT is positive for WNV within their collection area *(468)*. With the sensitivity and positive predictive value of ID-NAT for WNV estimated at 92% to 99%, respectively, and with the current adjustments to screening techniques depending on WNV activity, the blood supply is quite safe from risk of WNV transmission by donor units (Table 67-6) *(468,469)*.

COLORADO TICK FEVER VIRUS, ERYTHROVIRUS B-19

Other potential viral causes of post-transfusion infection include Colorado tick fever virus (CTFV) and parvovirus, now Erythrovirus B19. The rarity of reports of transmission by transfusion and the usual association of illness in the potential blood donor with CTFV infection argue for no additional donor precautions at this time despite the development of a PCR assay for CTFV RNA in human serum *(344,470–472)*.

Erythrovirus B-19 is now divided into genotypes 1 to 3 *(473)*. After respiratory acquisition of infection, the immunocompetent patient (usually a child) develops viremia with or without symptoms 1 week after infection; by 3 weeks specific IgG immunoglobulin develops and viremia clears, usually by 6 months after infection *(473)*. However, persistence of viremia for 6 months or longer can be seen in normal hosts, usually without symptoms *(474,475)*.

Questions continue to be raised about the need for studies to define the risk of B19 transfusion-related infection, studies to improve detection techniques, and studies to refine inactivation techniques *(473,474,476)*. These concerns are raised because of continued but infrequently recognized episodes of transfusion-related infection *(477–480)* and one reported episode of B19 transmission by intravenous immune globulin *(481)*. B-19 DNA positivity rates are 37% to 67% for untreated plasma pools, 25% for albumin, 100% for factor VIII, and 20% for IV-Ig *(473)*. Ten percent of clotting factor concentrates are contaminated because of incomplete inactivation by dry heat, wet heat, or solvent/detergent treatments and may transmit infection *(476,482–486)*. Plasma pools usually have detectable B19 DNA after treatment *(473,487)*. The frequency of B19 DNA among blood donors is stated to be 1 in 20,000 to 50,000 donor units but may be higher (144,*354*,*473*,*487–489*). The frequency among Pittsburgh blood donors was reported to be 0.1% during June and July, the peak of the B19 season *(490)*; 2 of 11 recipients of B19 DNA positive blood developed clinically apparent infection. However, clinically consequential B19 posttransfusion infection is uncommon *(474,486,487,491)*. Given the problems with persistence of B-19 viremia, though often at lower levels with the presence of IgG, currently only plasma pools are tested for B-19 DNA *(474,487)*. If the pool has $<10^6$ IU/mL of B-19 DNA by NAT or $<10^4$ genome equivalents/mL, it is accepted; this technique has made plasma pools more safe with low or undetectable levels of B19 DNA *(492)*.

There is a report of adding high-titered IgG to plasma pools to neutralize residual B-19 *(493)*. Additional efforts to reduce or eliminate B-19 infectivity of blood donor units or plasma derivatives are focused on use of amotosalen or riboflavin treatment, followed by ultraviolet (UV) light exposure *(473,494)*; riboflavin treatment with UV light would be applicable to platelets, RBCs and plasma, while amotosalen has been applied to platelets.

Regarding the risk of RBC donor units at present for transmitting B-19, no adverse clinical outcomes have been demonstrated *(473,474,484,487,491)*. These observations are probably the result of the high frequency of B-19 IgG in the recipient population and likely low levels of B-19 DNA in donor units when present *(473,474)*. Use of NAT screens for DNA on donor blood does not seem warranted *(474)*.

VACCINIA VIRUS

Vaccinia virus is a double-stranded DNA virus, related to cowpox virus, which has been used to immunize humans against smallpox (caused by variola virus). Use of this vaccine on a routine basis had ceased in 1971 to 1972, and in 1977 the last case of smallpox was documented in Somalia *(495)*. Because of the terrorist threat to use biologic weapons, on December 13, 2002, a presidential decision was made to initiate a smallpox vaccination campaign for individuals likely to encounter the first patients after a bioterrorist exposure. During a secondary phase additional healthcare workers, emergency personnel, policemen, and firemen on a voluntary basis were to receive the vaccine.

After percutaneous inoculation, vaccinia virus multiplies locally causing in succession a papule, vesicle, and pustule, which ruptures, crusts, and heals with scab formation. Investigations using the New York City Board of Health strain of vaccinia had previously documented viremia during disseminated vaccinia infection *(496,497)*; there are reports from 1930 and 1953 of isolation of vaccinia virus from blood 3 to 10 days after immunization *(498)*. Accordingly, because of the potential for vaccinia viremia in a recent recipient of smallpox vaccine, the FDA issued a "Final Guidance" in December 2002 recommending blood donor deferral for 21 days after vaccine receipt or until the scab has separated if there are no complications to vaccination; this and deferral if complications develop are summarized in Table 67-2 *(498)*. However, recent observations have failed to detect viremia in the plasma or blood of vaccinees by cell culture *(499)*.

OTHER ARTHROPOD-BORNE VIRUSES WITH A TRANSFUSION RISK

YF virus is endemic in Central and South American and in sub-Saharan African countries. A live attenuated virus vaccine is available; the Red Cross asks recipients to defer donation of blood for 2 weeks after vaccine receipt (35). The report of collection of donor blood from US active duty military trainees 4 days after YF vaccine receipt resulted in an investigation *(500)*; six units of blood products were transfused into five recipients. While one of the recipients died of an unrelated cause, the four remaining recipients had serologic evidence of response to YF vaccine virus. This report verified the relevance of deferral of recent recipients of live virus vaccines.

Perhaps more relevant are reports of two other arthropod-borne viruses and their threat to transfusion medicine. Dengue hemorrhagic fever was recently transmitted from an asymptomatic blood donor to the donor unit recipient in Singapore *(501)*; given the continuous threat of importation of Dengue virus (DV) from the Caribbean into the United States and the presence of its vectors, such a threat to the US blood supply is very real but yet not a reality (*354*,*355*,446,*502*). Using transcription-mediated amplification, DV has been detected in blood donor units in Honduras, Brazil, Australia, and Puerto Rico *(502)* and has been recognized as a considerable risk in Singapore *(503)*.

Chikungunya virus (CHIKV) has recently caused outbreaks originating in Kenya with spread to islands in the Indian Ocean, parts of India, Southeast Asia, and Europe (Northeast Italy; *504*). This epidemic has been fostered by a single amino acid substitution due to a base mutation, leading to enhanced transmissibility by its previously secondary mosquito vector, *Aedes albopictus*, while retaining *Aedes aegypti* as a vector. Given the high levels of viremia associated with CHIKV, the propensity of *A. albopictus* for

twice daily feeding and given our "Global Village" due to the ease of world travel, spread of CHIKV seems inevitable (as evidenced by WNV; *355*,446,*504*,*505*). The transfusion transmission risks of CHIKV have already been realized in epidemic areas; during the CHIKV epidemic on Reunion Island in the Indian Ocean, the risk of transfusion transmission of CHIKV peaked at 1,500 units per 100,000 donor units *(506)*. A crisis was averted by interrupting blood donations on the island. On Reunion Island, photochemical inactivation of CHIKV was effective for platelets as a pathogen inactivation technique *(507)*. A similar risk of blood donor unit transmission was averted in Northeast Italy after CHIKV was introduced by a traveler, with 217 secondary cases due to spread by mosquitoes; donor collections were reduced to avoid contamination of the blood supply *(508)*. The presence of both *A. aegypti* and *A. albopictus* in the United States, especially in the Southeastern states, makes the United States especially susceptible to the introduction of CHIKV and its threat to transfusion medicine.

RECENTLY RECOGNIZED POSSIBLE VIRAL THREATS TO THE BLOOD SUPPLY

Xenotrophic murine leukemia virus–related virus (XMRV) is a gammaretrovirus initially recognized in the prostatic cancer tissue of men undergoing radical prostatectomy *(509)*; subsequent assessments of similar tissue specimens have failed to confirm this association *(510)*. In 2009, a report noted the presence of XMRV proviral DNA in mononuclear blood cells of 67% of patients with chronic fatigue syndrome (CFS), compared to 3.7% of controls *(511)*. Reports from the UK and the Netherlands have failed to confirm this association *(512–514)*. The seroprevalence of XMRV in US blood donors may be 0.1%, but little else is known at present about the transfusion and health risk of XMRV. However, the Canadian Blood Donor Services has already opted to exclude CFS patients from blood donation.

PRION DISEASE

Sporadic Creutzfeldt-Jakob disease (sCJD) is transmitted by a proteinaceous infectious particle (prion). After a 4- to 25-year latency, sCJD has been recognized as acquired by corneal and dura mater transplants from infected donors, through use of human pituitary-derived growth hormone, and through reuse of electroencephalographic electrodes. A group in the United Kingdom has reported the transmission of bovine spongiform encephalopathy (BSE) to sheep via transfusion of whole blood from a sheep with incubating BSE *(515,516)*. There are no data in humans to support transfusion of blood or blood products as a mechanism for transmission of sCJD (*354*,446,*517*). More than 100 recipients of blood from patients who later developed CJD are being followed, some for more than 27 years; none has developed sCJD during follow-up *(518)*.

There is a greater concern for transmission of variant CJD (vCJD) by blood products (*354*,446,*518*); it is postulated that variant vCJD protein might be transmitted more efficiently with a shorter incubation period. Surveillance and lookback studies have defined at least 184 patients with vCJD acquired through transfusion worldwide *(518–521)*. Uncertainty surrounds the means to assure that plasma products are rendered safe *(522,523)*. Attempts using LR only partially reduced infectivity for cellular products (42–72% reduction; *524,525*). Prion reduction filters, if the infectious unit is not red cell bound and in lower titer, have had limited success *(526–530)*. Substantial removal of vCJD protein has been achieved with washed RBCs *(531)*.

In 1987, the FDA required permanent deferral of potential blood donors treated with human pituitary-derived growth hormone; on August 8, 1995, permanent donor deferral was also required for recipients of dura mater grafts and for donors with a family history of CJD *(30)*. The twenty-sixth edition of the AABB guidelines also apply permanent deferral status to anyone at risk for vCJD (35) (Table 67-2). Donor deferral remains the backbone of prevention, with prudent utilization of blood and blood products *(527)*. There has been minimal loss of potential donors using these deferral criteria *(532)*.

MALARIA

Transfusion-related malaria is the most common transfusion-induced parasitic infection worldwide, especially in the tropics, but it is rare in the United States (*354*,*355*,446,*533*,*534*). The average annual rate has remained 0.25 cases per million units of blood collected through 1987 or about three cases per year *(354,533,534)*. Mungai et al. *(535)* reported 93 cases of transfusion-transmitted malaria between 1963 and 1999 in the United States; 35% were due to *Plasmodium falciparum* and 27% each were due to *Plasmodium vivax* and *Plasmodium malariae*. Due to delay in diagnosis, 10 of these 93 patients died (11%) and approximately 62% of these cases could have been prevented by appropriate application of donor guidelines. Since its eradication from the United States in the 1940s, *P. malariae* had been the most common form of malaria associated with transfusion in nonendemic areas because of its persistence; however, *P. falciparum* and *P. vivax* are now becoming more important because of immigration and air travel associated with tourism *(534,535)*. This is also the experience in Canada *(536)*. In the last decade, most infected donors were immigrants *(535)*. Recently, *P. knowlesi*, previously restricted to monkeys, has infected humans (446); whether or not this evolution will affect the epidemiology of malaria is unclear.

Malaria has been transmitted by transfusion of whole blood, fresh plasma, and platelets *(533,534)*. The incubation period after transfusion is from 1 to 4 weeks. Diagnosis in the transfused patient often is delayed because of lack of a history of travel to an endemic area. Increased morbidity and occasional mortality result. Malaria has also been transmitted by renal transplantation *(534)*. Healthcare-associated transmission by needle stick and a multidose vial have been described *(534)*. The current guidelines recommended by the AABB (Table 67-2) should enhance prevention of this transfusion-related illness but do not obviate risk in all circumstances *(537,538)*. The current risk of transfusion of a unit of blood in the United States from a donor with malaria is estimated at one for every 3 to 4 million units (Table 67-6) *(354,368)*. Some European

Countries and Australia perform an antibody test on deferred potential donors (EIA); if negative, the donor is reinstated (*355*,446,*539*).

Previous options to donor deferral (which is deemed wasteful of potential donors in current format) include microscopic exam of blood smear, EIA for IgG in nonendemic countries, and providing antimalarials to transfusion recipients in endemic areas (540). Direct smear of donated blood for parasites is insensitive for detection *(535)*. Serologic screening with indirect fluorescent antibody, indirect hemagglutination or EIA is one of the most sensitive methods available for diagnosing plasmodial infection, but its disadvantages as a screening test include cost, seronegativity during early parasitemia, and exclusion of immune donors after adequate treatment (*534*,540,*541*,*542*,*543*). Detection of circulating antigens and nucleic acids (e.g., by PCR) is a very sensitive technique that may become useful (540,*544*,*545*). A combination of antigen and antibody detection can enhance sensitivity for plasmodial infection to 88% *(542,546)*. Due to the effects of donor deferral upon donor unit supply and the need to recapture such deferrees *(547,548)*, a number of suggested changes to the current reliance on donor deferral in the United States have been recently suggested, including decreasing the deferral duration to 3 months for travel to Mexico, universal use of LR filters (to which *P. faciparum* RBC adhere), and use of pathogen inactivation for RBC units *(549–552)*. No doubt there will be modifications forthcoming to current malaria prevention guidelines.

BABESIOSIS

Babesia microti is a zoonotic protozoal parasite of RBCs first reported in 1966 and transmitted to humans by tick bite and occasionally by transfusion (*354*,*553*,*554*,*555*,556). Babesiosis is second only to malaria as a reported transfusion-transmitted protozoal infection *(554)*. Most infections in endemic areas (primarily the Northeast, California, northern Midwest, and Northwest) are asymptomatic or subclinical, unless in a splenectomized host, when infection may be fatal *(553)*. Seroprevalence ranges from 0.3% in Connecticut residents to 9.5% of patients with confirmed Lyme disease (556). Serosurveys of blood donors in the Northeast have shown seropositivity rates of 0.9% to 4.3% without a clinical history consistent with infection, and parasitemia occurs in 50% or more of seropositive patients (*368*,556,*557*,*558*). Because of the subclinical nature of acute infection, with parasitemia, the possibility of transfusion-related illness is expected, especially during May through September, when the primary vector, the nymphal tick, feeds. The estimated annual incidence of transfusion-associated babesiosis is one to two cases per million units transfused *(554)*, but this estimate is likely low due to underreporting (556); many such cases may be unrecognized. In Connecticut, the risk from one unit of PRBC may be as high as 0.17% (144,556). There is a 1.1% seroprevalence among blood donors in Connecticut *(557)*.

Transmission by packed RBCs, frozen-thawed blood, and platelets (because of free parasites in plasma) from asymptomatic donors has been well documented *(534,555, 559–563)*. The parasite may survive for up to 35 days at 4°C liquid storage *(563)*. The incubation period in posttransfusion babesiosis is 6 to 9 weeks, which is somewhat longer than for tick-borne disease (1–3 weeks; 556). The longer incubation period after transfusion is surprising, because up to 30% of RBCs may be parasitized in the infected normal host *(564)*. Clinical disease in transfusion recipients is unusual, however *(554)*. Interestingly, recent reports reflect either better reporting due to hemovigilance or increasing mortality over the last decade (nine deaths between 2005 and 2007; *565,566*).

Prevention of transfusion-related babesiosis relies on recognizing acute illness in a potential blood donor, deferring individuals from highly endemic areas from donating blood during May through September, avoiding donors with fever within the 2 months before donation, and eliminating potential donors with a history of tick bite *(553,554)*. A history of babesiosis is cause for permanent donor deferral (35) (Table 67-2). Serologic screens using indirect fluorescent antibody are not practical and are insensitive early in disease *(553,554)*. PCR is not yet available. Inactivation techniques applied to donor blood with promising results have included gamma irradiation, combined psoralens with UV light, and photosensitization with pheophorbide *(417)*. Pathogen reduction techniques have been advocated in endemic areas *(567)*. As deer herds increase in endemic areas, transmission by tick bite will increase, thereby enhancing the likelihood of an infected blood donor. Physicians must remain aware of babesiosis as a potential transfusion-related illness in an endemic area.

TRYPANOSOMIASIS

African trypanosomiasis (or sleeping sickness) is rarely transmitted by transfusion, because infected patients are usually symptomatic when parasitemic and thereby unsuitable blood donors; unusual asymptomatic parasitemic patients have accounted for rare transfusion-related disease *(534,563)*.

In contrast, blood transfusion is the second most common means for transmission of American trypanosomiasis, or Chagas' disease, in the endemic countries of Central or South America *(568,569)*. This was first recognized in 1952 *(534,563). Trypanosoma cruzi,* the etiologic agent, is naturally transmitted by various species of hematophagous triatomine insects (or reduviid bugs). Both mammals and humans are infected. The signs and symptoms of acute infection are so mild that they are unnoticed by the host or at least not attributed to *T. cruzi*. Untreated, such hosts remain infected for life, and parasitemia may be detected years after infection in up to 50% of patients *(368,534,563,569)*. Up to 20% to 40% of infected patients may develop cardiac or gastrointestinal symptoms after years or decades.

In Central and South America, 18 to 20 million people may have been infected in the past, but this number has fallen to 7.6 million by 2006 due to eradication efforts in Latin America *(569)*. However, Chagas' disease remains the most common transfusion-transmitted infection in endemic

areas *(368,568–570)*. Because of recent immigration to the United States from these areas, especially from Mexico, it is estimated that 100,000 persons in the United States are infected with *T. cruzi (569,571)*. The seroprevalence of *T. cruzi* antibodies in the US blood donor population ranges from 0.004% to 0.01% (1 in 25,000 to 1 in 5,400 donor units; *569,572*). The potential for infection of the US blood supply has been recognized, but concerns have been heightened by several reports of acute symptomatic infection in immunocompromised hosts *(534,573–575)*. Whole blood, packed RBCs, and platelets have a higher risk of infection than plasma; the parasite can survive storage at 4°C for 18 to 21 days and can survive freezing *(563)*. There have been seven reported episodes of transfusion acquired tryponasomiasis in the United States *(569)*. Transmission by renal transplantation has also been documented *(534,563)*. Although the likelihood of transmission by blood from an infected donor may range from 13% to 49%, most post transfusion infections are asymptomatic in immunocompetent hosts *(568,576)*. Those reports of more serious illness typical for compromised hosts raise concern about more widespread transfusion-related infection. Seropositivity rates in Los Angeles County have been reported to be 2.4% to 4% *(577,578)*. A report of questionnaire results of blood donors in 18 California donor centers identified risk factors for Chagas' disease in 1 of every 340 donors (living in endemic area for more than 1 year, living in dwellings with mud walls or thatched roofs, transfusion in endemic area, or history of Chagas' disease; *578*). With an up to 4% serologic positivity rate in a similar population, an infection rate of 1 in 8,500 donors can be estimated in this donor population *(578)*. Other serosurveys demonstrated infection in populations in Texas and New Mexico *(578)*. A Southwest Region American Red Cross serosurvey demonstrated 3 reactive units among 100,089 tested *(572)*.

Prevention in the United States is problematic. LR is not effective *(579)*. Detection of parasitemia is unlikely during chronic infection. Serologic testing with complement fixation, indirect hemagglutination, EIA, and the direct agglutination or recombinant immunoassays are used in areas of high endemicity; a lysate-based EIA for *T. cruzi* has been found to have 97.7% to 100% sensitivity and 99.9% to 100% specificity in the United States *(580–582)*. Despite low infection rates of blood donors in the United States, an EIA for *T. cruzi* was licensed on December 13, 2006, and universal blood donor screening was begun on January 29, 2007 (Table 67-5) *(582)*. As suggested by the AABB, deferral of donors with a history of Chagas' disease continues (Table 67-5) (35,*568*). A transfusion history in an area endemic for Chagas' disease should also be included as a deferral criterion *(578)*. Heightened awareness by health professionals about the potential transmission of *T. cruzi* by blood transfusion is also warranted, especially where Latin American immigrants have concentrated, such as Los Angeles, Chicago, New York City, Washington, DC, Miami, and possibly Texas and New Mexico *(541,563,568,572,578)*. If begun for other diseases (e.g., Babesiosis), efforts at pathogen inactivation with riboflavin, amotosalen, or thiopyrylium followed by UV light have been successful against *T. cruzi (583–585)*. Treatment of donor blood with gentian violet or crystal violet has also been described and used with good results *(568)*.

TOXOPLASMOSIS

Toxoplasmosis is a common infection of mammals and humans, usually acquired orally or congenitally and possibly by aerosol. The etiologic microorganism *Toxoplasma gondii* may survive at 4°C for up to 50 days *(563)*. Transmission by a transplanted organ (heart, kidney, bone marrow) has been documented *(534,541,563)*. Because asymptomatic prolonged parasitemia is uncommon, transmission by transfused blood is possible but has been documented only rarely *(586,587)*. Recent reports from Turkey, India, and Mexico have documented a 2.3% to 3.6% prevalence of IgM by EIA in blood donors from each country *(588–590)*; in Mexico, 78% of donors positive for IgM by EIA were positive for toxoplasma DNA by PCR *(588)*. Though declining from 1999 to 2004, the seroprevalence of toxoplasma IgG antibody by EIA in the United States is 10.8% among 6- to 49-year-old persons *(591)*. Given the infrequency of transfusion transmission and declining seroprevalence in the United States, routine screening of blood donors seems unwarranted *(368)*. Prevention of transmission by donor serologic screening or by use of prophylactic pyrimethamine in the transplant recipient in selected settings has been described *(534,541)*.

LEISHMANIASIS

Leishmania species have worldwide distribution in humans and mammals; the microorganism is transmitted by sandflies (or by *Phlebotomus* species in India). *Leishmania* microorganisms parasitize leukocytes and the organs containing tissue monocytes/macrophages; when found in blood, the microorganism is within leukocytes. Asymptomatic parasitemia is common with visceral leishmaniasis and such patients could be candidate blood donors. Transfusion transmitted infection is rare, with only a few reported cases, most recently in endemic areas of Greece and India *(534,563,592–594)*. None has occurred in the United States *(541,563)*. Among 21 EIA-positive asymptomatic volunteer blood donors in Rio de Janeiro, 5 were positive by NAT for DNA of *Leishmania donovani (595)*. PCR is actually more sensitive than antibody assays for diagnosis *(596)*.

In the United States, the immigrant or the traveler with infection would possibly be deferred because of signs of acute or chronic infection. No preventive measures are usually warranted except those for donor deferrals outlined in Table 67-2 *(368)*. However, military operations in the Middle East during 1991 resulted in a few cases of viscerotropic *Leishmania tropica* infection among returning military personnel. For this reason, the AABB, with the military, recommended deferral of military and civilian blood donors until January 1, 1993, if they had recently been in this area. Similar deferrals apply to those returning from subsequent conflicts in endemic areas (35). However, donors of plasma for further processing were not and need not be deferred. However, LR prestorage as practiced by American Red Cross Centers and many other blood collection agencies in the best recourse to prevent transfusion-transmitted leishmoniasis *(597,598)*. If implemented in the future, photochemical inactivation (with amotosalen, riboflavin, or thiopyrylium) also is effective on promastigotes in various preparations *(599–601)*.

SYPHILIS

Treponema pallidum is usually transmitted sexually or congenitally; less commonly, infection occurs by kissing, direct inoculation or, in the remote past, by transfusion *(602,603)*. Infection with *T. pallidum* induces a disseminated vasculitis with spirochetemia and secondary cutaneous, cardiovascular, neurologic, and other organ system effects. Transmission via transfused blood was recognized as early as 1915 *(602,603)*. Most infectious donors were in the primary or secondary stages of disease. However, many transfusion-related cases were probably unrecognized. Transfusion-related syphilis has not been recognized since 1966 *(604)*. The reasons for the lack of transfusion-transmitted syphilis include (i) serologic screening of all donor blood, (ii) the low incidence of syphilis in blood donors, (iii) an all volunteer blood donor pool, (iv) deferral of high-risk individuals, (v) the impact of refrigeration on spirochete survival, and (vi) the frequent administration of antibiotics to transfusion recipients *(605)*.

Although *T. pallidum* can survive in stored blood at 4°C for up to 4 days, its survival at clinically relevant concentrations may be only 2 days. During storage of blood at 4°C that was highly contaminated experimentally with *T. pallidum,* blood remained infectious for up to 5 days *(606)*. Platelets, which are stored at 22°C, may also transmit syphilis *(606)*.

Today, donated blood is routinely screened for syphilis in the United States, with a nontreponemal EIA or, most recently, an automated microhemagglutination-*T. pallidum*; the nontreponemal tests generally have lower sensitivity and specificity than treponemal tests *(602,605)*. It is argued that donor blood should continue to be screened for syphilis for multiple reasons: (i) the incidence of syphilis is increasing; (ii) there is an increasing demand for fresh blood components, obviating the inactivation of *T. pallidum* with storage for 72 hours at 4°C; (iii) screening identifies donors at high risk for other sexually transmissible diseases (e.g., HIV-1 infection; *606a*); (iv) the cost of screening is low; (v) screening remains legally required by the FDA, despite a decision by the AABB in 1985 to drop its requirement for syphilis screening; and (vi) screening identifies patients in need of therapy *(602,605,607)*. Other preventive measures for deferring donors who might be infected with *T. pallidum* are defined in Table 67-2.

Despite these arguments for continued screening, a strong case has been defined by Schmidt *(603)* to discontinue such screenings. Several recent publications add support to this opinion; Orton et al. *(608)* reported that between 1998 and 1999, among 169 sera that were FTA-ABS positive, none was positive for *T. pallidum* DNA and/or RNA. Therefore, even among units of blood screened as seropositive for *T. pallidum,* none is likely to be infectious. A recent publication also documented the lack of surrogate value of syphilis screening for other transfusion-transmissible infections *(609)*. An accompanying editorial comments that most positive screening tests for syphilis are biological false positives; those true positives are in donors with remote, treated infection *(610)*. Policy evolution in this regard awaits further study, given the desire for a zero-risk blood supply (446,*605*,*610*).

LYME DISEASE

Lyme disease is a tick-borne borreliosis caused by *Borrelia burgdorferi*. Like syphilis, Lyme disease results from vasculitis with associated spirochetemia. Its serologic diagnosis has become more reliable but remains somewhat cumbersome to differentiate active versus treated disease *(611)*. Although knowledge of the pathogenesis of Lyme disease supports the potential of transmission by transfusion, no case has yet been reported *(551,612)*. The microorganism has been shown to survive in stored blood experimentally for up to 60 days at 4°C, in fresh frozen plasma at <18°C for 45 days, and in platelet concentrates for 6 days at 20°C to 24°C *(612–614)*. At this time, serologic screening of donor blood is not needed nor are additional historical questions for the donor *(368)*. Noteworthy is a report documenting the lack of seroconversion among nine recipients of antibody-positive donor blood *(615)*. In addition, Perdrizet et al. *(561)* have reported a renal transplant patient who acquired babesiosis from a unit of blood donated by a patient who also developed Lyme disease 2 days after blood donation; the transfusion recipient remained free of Lyme disease *(561)*.

RELAPSING FEVER

Relapsing fever is another form of borreliosis transmitted by a louse or a tick; the former serves as a vector from human to human, whereas the latter serves as a vector from the mammalian reservoir to humans. *Borrelia recurrentis* and the *Borrelia* species of the tick-borne form of the disease can apparently survive in citrated blood, because there are rare case reports of infection by transfusion *(616,617)*. These are unusual events, and no donor-related preventive screening is appropriate.

BACTERIAL INFECTIONS

Transfusion reactions resulting from bacterial contamination of RBC units are usually due to one of two sources: contamination during collection and processing or a bacteremia undetected in the donor at the time of collection *(9,368,618–625)*. It is difficult to distinguish these two potential mechanisms in a given circumstance. The risk of such an event after RBC transfusion is estimated to be one per 5 million donor units *(626)*. Most contaminants of units of RBCs have been gram-negative microorganisms with low pathogenicity, including *Serratia*, *Pseudomonas* species, and *Klebsiella* sp., suggesting processing contamination *(627)*. The relatively few gram-positive isolates are most likely skin flora that contaminated the blood at the time of collection. One recent epidemic of *Serratia marcescens* bacteremia was traced to contamination of blood collection bags during manufacture *(628)*. A recommendation was made for production of blood packs with sterile exterior surfaces.

One report documented that during transfusion of contaminated RBC units, adverse reactions developed in 38 of 76 patients, including fever (80%), chills (53%), hypotension

(37%), and nausea with vomiting (26%) *(618)*. There was a 35% mortality rate overall. In the remainder of the patients, reactions developed from 15 minutes to 17 days after the transfusion *(618,619)*.

A subset of the gram-negative rods contaminating transfused RBCs or blood products in reviews *(618–623)* and other reports *(629–637)* most likely reflected disease in the donor. The report of two thalassemic patients with transfusion-acquired brucellosis and a later report reflect the potential for chronic asymptomatic *Brucella* species bacteremia with acquisition by transfusion *(629,637)*.

Most striking, however, are reports of *Yersinia enterocolitica* acquired via transfused RBCs *(619,621,622,631–636,638). Yersinia* species account for up to 80% of episodes of sepsis syndromes secondary to transfusions with RBCs from a donor infected with a bacterium *(621)*. Up to 60% of donor recipients may die with this syndrome *(621,622)*. This scenario reflects the recognized potential for this microorganism to persist in the intestinal mucosa and lymphoid tissue after acute illness resolves, followed by occult bacteremia *(639)*. Furthermore, storage conditions for RBCs are almost ideal for supporting growth *(621)*. This microorganism can grow at 4°C in blood and survives intracellularly in leukocytes; in addition, during storage, some hemolysis occurs, releasing hemoglobulin and iron; the latter is a growth factor for the microorganism. After an initial drop in bacterial counts following blood collection (obviating sensitivity of culture at the time of collection), bacterial counts surge within leukocytes during storage *(635)*. This has prompted recommendations for decreased storage times from 42 to 25 days, among others *(622,635)*. This microorganism also becomes resistant to complement-mediated lysis at temperatures below 20°C, especially when plasma has been removed *(640)*. Prestorage LR of RBC units after initial storage at 20°C for 3 to 8 hours does reduce but not totally eliminate the risk of transfusion of *Yersinia* (and coagulase-negative staphylococci) contaminated units of blood *(622,641,642)*.

Bartonella bacilliformis, a gram-negative bacillus, is an intraerythrocytic parasite endemic to the highlands of the western Andes in Peru, Ecuador, and Colombia, where it is transmitted by sandflies. Bacteremia is detected in 5% of apparently healthy persons in these areas. Transfusion-related infection might occur if a carrier immigrated to the United States *(563)*.

There are approximately 9 million platelet unit concentrates administered each year *(643)*. Platelet units, especially random donor pools compared with single-donor apheresis products, have emerged as the major problem with regard to bacterial contamination, because they are stored at room temperature for up to 5 days before use *(30,620,623–626,643–645,*646*,647)*. The incidence of a serious transfusion-associated sepsis episode is 1 in 15,000 to 1 in 100,000 for platelets, 10-fold higher than for RBCs *(623,625,626,643)*. Among transfusion-related fatalities reported to the FDA between 1986 and 1991, platelet transfusions accounted for 21 of 29 bacterially mediated deaths *(30,648)*. The eight remaining deaths were due to transfused RBC units. Today, platelets account for up to 77% of transfusion-related deaths *(643)*. It has been estimated that up to 10% of platelet pools used for transfusion are contaminated with bacteria *(649)*, but the risk of bacterial contamination of platelet pools is currently estimated at 1:1,000 to 1:3,000 units *(625)*. Bacterial contamination has been documented by culture in 0.06% to 0.28% of pooled platelet concentrate transfusions and in 0.005% to 0.03% of single-donor apheresis platelet transfusions *(30,648)*. Mechanisms of contamination are similar to those for RBC (*vide supra*). Most contaminants are skin flora such as *Bacillus* species and coagulase-negative staphylococci, but gram-negative microorganisms may also play a role *(619,620,648,650)*. The use of pH and glucose measurements on stored platelet concentrates to detect bacterial contamination immediately before transfusion has been variably successful *(651,652)*. Automated microbiologic culturing of platelet concentrates is established as a technique for reduction of the risk with random donor pools *(653,654)*.

Given the potential problem of bacterial contamination of platelet concentrates and to a lesser extent single donor apheresis platelet units, as well as blood and blood products with associated morbidity and mortality, suggested revisions for handling of donor blood were promulgated. Platelet storage time is limited to 5 days. Efforts for the prevention of contamination during collection and processing were re-emphasized *(618–620,623,*646*,647)*. On March 1, 2004, the AABB announced a new standard requiring platelet units to be tested within 24 hours of collection for bacterial contamination (Table 67-5) *(643)*; optional detection methods included glucose or PH (>6.4) monitoring and culture (three systems approved; *643*). Each is susceptible to false-negative results *(643)*. Enhanced physician awareness of the potential for bacterial contamination of transfused products is needed; should a reaction with or without fever occur, the platelet concentrate being transfused and the recipient's blood should be cultured *(618–620,643)*. Staining the residual material in the bag might give a more immediate answer as to the cause. The CDC has suggested testing RBCs stored for 25 days or more for bacteria before administration *(633)*. This can be accomplished with microscopy using various stains, with culture, with nucleic acid hybridization or PCR, and with a detection of endotoxin *(620–623)*. However, reactions to bacterial contaminants in transfused products are probably more common than reporting would reflect *(618,623)*.

The residual risk of sepsis after implementation of testing for bacterial contamination following platelet transfusions is now estimated to be one in 74,804, and the residual risk of fatality is estimated at 1 in 498,711 (Table 67-6) *(*646*)*. Regarding the use of platelet transfusions in thrombocytopenic patients, recent data suggest that the reduced platelet threshold before transfusion should be lowered to 10,000/mm^3 *(655–658)*. A reduction of the number of platelet-related episodes of sepsis and mortality may thereby be further achieved.

PARASITIC INFESTATIONS

Several tissue nematodes pose a remote potential transfusion hazard because of chronic asymptomatic microfilaremia; these include the microfilariae *Brugia malayi, Loa loa, Wuchereria bancrofti, Mansonella ozzardi,* and

Mansonella perstans (534,541,563). Transfused microfilaria are unable to complete their life cycle after intravenous inoculation; they are cleared rapidly in the recipient or may persist in the circulation for up to 2 years, usually without associated symptoms or only a mild febrile reaction *(541)*. The unlikelihood of such contamination of donor blood in the United States and the good outcome argue against a need to screen donors or donated blood *(541)*. However, in our "global village," the concern about filariasis after transfusion continues to be raised *(659)*.

RICKETTSIOSES

The rickettsia produce illness after insect vector inoculation (except for *Coxiella burnetii*) by producing a vasculitis. With microorganism replication in endothelial cells and the organs with tissue monocyte/macrophages, rickettsemia occurs during the incubation period and during acute illness. There are two remote reports of rickettsioses being transmitted by blood taken from donors during the incubation period of their illness; one was associated with Q fever in the recipient *(660)* and the other was associated with Rocky Mountain spotted fever *(661)*. *Ehrlichia chaffeensis* has survived experimental inoculation into refrigerated, stored RBCs for 11 days *(553)*. *Ehrlichia phagocytophilia* has been transmitted by blood transfusion in sheep and isolated from refrigerated stored blood from naturally infected patients for up to 2 weeks *(553)*. Eastlund et al. *(662)* reported a case of human granulocytic ehrlichiosis in a 75-year-old man after RBC transfusion. None of these rare occurrences with rickettsia or *Ehrlichia* sp. warrants donor screening other than that outlined in Table 67-2 *(553)*.

OTHER MECHANISMS FOR REDUCING TRANSFUSION RISKS

Additional attempts to reduce the risk of infection after transfusion have proceeded along several avenues other than serologic screening; these include physical or chemical treatment of blood or blood products for sterilization, the use of directed and autologous (instead of allogeneic) blood transfusion, intraoperative blood salvage and reinfusion, and the development of blood substitutes.

Factor VIII and IX concentrates are produced as lyophilized products after Cohn ethanol fractionation of plasma pools. These products unfortunately contained infectious hepatitis viruses and HIV-1 before 1984 when dry heat treatment of the lyophilized powder at 60°C for 24 hours was begun. However, although HIV-1 was inactivated, HBV and HCV remained viable. Subsequently adopted procedures, such as pressurized steam treatment of wetted lyophilized concentrates, pasteurization (liquid factor VIII and IX are heated at 60°C for 10 hours), and purification of these factors with monoclonal antibody affinity columns, have succeeded in rendering these products safe (1,*663,664*). The shortcoming of these procedures is reduction of factor yield.

The balance between pathogen reduction and retention of blood derivative activity is a difficult to achieve goal. Therefore, more promising methods using virucidal solvents or detergents are now used; also, further purified factor concentrates (by anionic exchange chromatography) to reduce alloantigen contaminants that might stimulate the immune system in an HIV-1–infected patient (thereby augmenting viral replication) are used *(368,665)*. Virus inactivation in fresh-frozen plasma has been accomplished by treatment with methylene blue, solvents and detergents, radiation, and heating *(664,666,667)*. Inactivation of pathogenic viruses has also been reported with amotosalen and UV light, as well as riboflavin followed by UV light (the latter can be applied to cellular products in addition to plasma and platelet units; *668,669*). Dilutional neutralization with antibody has also been reported *(669)*. While already implemented in Europe, published commentaries after US conferences have recommended adoption of the above two photoinactivation techniques for platelets and plasma, and riboflavin plus UV light for RBCs *(670–672)*.

Plasma protein fractions and albumin are also products of Cohn ethanol fractionation of plasma pools. After separation from plasma, they are subjected to pasteurization at 60°C for 10 hours; all infectious viral particles are inactivated, along with clotting factors (1).

In addition to photoinactivation of malaria parasites and other protozoa in blood, including leishmania and trypanosomes, as a physicochemical means of rendering blood noninfectious (see previous discussion), several authors have reported chemical inactivation of HIV-1 and other viruses in whole blood and plasma with aluminum phthalocyanine derivatives that left erythrocytes intact *(416,673,674)*. Such chemical sterilization of blood may offer hope for an even safer blood supply in the future. Photochemical inactivation procedures for virus and bacterial pathogens, including riboflavin, have been recently assessed for cellular blood products *(368,668–672, 675–677)*. Riboflavin is the only photoinactivator currently described, which is applicable to cellular products.

During the last decade, there has been a decline in the collection of allogeneic volunteer donor blood *(9,678)*. Fortunately, this has not compromised the national blood supply, because it was initially offset by autologous donations to some extent and a decline in the use of transfused blood and blood products *(9)*. After the definition of HIV-1 epidemiology, there was initial interest in the use of directed donations by friends, family, or another selected person for an individual recipient *(679)*. The disadvantages of such a policy were emphasized by many advisory bodies. These problems included the following: (i) a valid medical history is more uncertain when obtained from a solicited donor known to the recipient than from a volunteer donor; (ii) the anonymity of the donor is not preserved, leading to potential legal liability; (iii) such nonvoluntary donors have a higher risk of transmitting PTH *(679,680)*; (iv) such directed donors create an apparent double standard of transfusion medicine that may be, ironically, less safe; and (v) there are logistic problems with such a program *(679)*. Autologous donations are very limited today *(681,682)*; such donations were associated with a 12-fold increased risk of an adverse event and were not cost effective *(682)*.

Autologous blood donation (ABD) is immunologically perhaps the safest form of transfusion therapy, because it avoids isoimmunization and eliminates the risk of transmission of infectious agents except for contaminating bacteria *(683–685)*. Autologous transfusion can be one of

four types: (i) remote preoperative storage; (ii) immediate preoperative phlebotomy with acute normovolemic hemodilution; (iii) intraoperative recovery; and (iv) postoperative recovery (from drainage tubes with reinfusion). *Remote preoperative donation* and storage is the most commonly practiced type *(684–687)*. By 1992, 8.3% of all blood donated was for this purpose *(684)*. Up to 70% of patients can have their total transfusion needs satisfied by this technique *(687)*. However, although decreasing exposure to allogeneic blood, preoperative autologous donation may lead to increased transfusion of such donors *(688)*. Unfortunately, up to half of autologous units are discarded; they are not used for allogeneic transfusion and the practice is, therefore, wasteful *(684,685)*. Unexpectedly, the safety of autologous donor units is less (12 times the rate of reactions to allogeneic units) and their use has declined since the early 1990s *(9,682,684,685)*.

Immediate preoperative phlebotomy is a similar second option *(9,684,685)*. Potential problems related to such a practice are multiple. The safety of immediate preoperative autologous donations with normovolemic hemodilution has been raised, because patients are generally older with cardiovascular disease *(687)*. Curiously, severe donor reactions have been infrequent and use of allogeneic units is reduced with this practice *(684,685)*.

Overall, the need and extent of serologic testing for autologous donor units have been questioned; it seems prudent not to exempt such donor units and to discard them if they are found to be infected to protect healthcare workers and a potential accidental recipient other than the donor *(687)*. The potential autologous donor can be prohibited if the presence of an infectious agent precludes making donor units safe for handling. There are other logistical problems with such a program, and a residual risk of transfusion reactions exists (hemolysis, sepsis from bacterial contaminants, and pulmonary edema) *(684)*.

Two other forms of autologous transfusions, *intraoperative* and *postoperative salvage* of blood followed by autologous transfusion, have become safer because of methodologic improvements *(684,685,689)*. Concerns remain about such transfusions in patients with infection *(683,684,690)*; the presence of malignancy is generally a contraindication to autologous transfusion after intraoperative salvage *(683,684)*. Bacterial contamination, metabolic complications, and air embolism after use of perioperatively salvaged blood are recognized risks *(685,689)*. The success of perioperative prophylactic antibiotics has been reported recently *(691)*. There is also a question as to whether or not perioperative RBC salvage actually reduces allogeneic transfusion requirements *(684)*. These techniques have been used during vascular, cardiac, and abdominal trauma surgery, in addition to orthopedic procedures *(692–697)*. Normovolemic hemodilution has also been used in the setting of intraoperative salvage *(698)*.

More recent concerns about any form of ABD relate to its cost effectiveness *(682,699–704)*. The cost of a unit of allogeneic RBCs approximates $210 per unit (average) to the administration agency but costs may vary by region. In contrast, a unit after ABD costs approximately 50% more because of the labor-intensive donation process and costs of processing and storage *(704)*. In addition, 9% to 10% of ABD units are used, because they are available only for elective procedures. Few centers allow crossover of ABD units to the allogeneic donor pool of blood for safety reasons *(684,700)*; therefore, most ABD units are discarded. Despite low rates of use, ABD units are associated with higher transfusion rates than for allogeneic blood for the population served (transfusion criteria are not as stringently applied by surgeons) and thereby costs of administration accrue *(688)*. Despite utilization successfully, ABD has been judged not to be cost effective for total hip and knee replacement *(700)* and for coronary artery bypass surgery and transurethral prostate resection *(701,704)*. These findings have probably contributed to the reported decline of ABD *(9,682)*. Despite large cost disadvantages, some knowledgeable physicians still present an argument for continuing ABD because of the fewer noninfectious complications and the recipient's peace of mind *(705)*; however, Medicare and some private insurers will not cover ABD *(684,705,706)*.

The development of safe and effective blood substitutes has been disappointing despite the reduction of infection risk *(684)*. Perfluorocarbons have been ineffective for oxygen delivery and are toxic to leukocytes (1,*684*,*685*). RBC stroma-free hemoglobin solutions are used only in emergency situations because of their short half-life after transfusion (1,*94*). Furthermore, these products are associated with organ toxicity and hypertension *(707,708)*. Hemoglobin encapsulated in liposomes has a longer half-life, but there is concern about compromise of the organs with tissue monocytes/macrophages where it is cleared *(707,708)*. Polymerized hemoglobin was less toxic to organs but hypertensive reactions persisted *(707,708)*. During a multicenter trial for treatment of hemorrhage, use of human polymerized hemoglobin produced similar outcomes to allogeneic blood but adverse events were more frequent; in other analyses mortality was actually increased *(709,710)*.

Preoperative use of recombinant erythropoietin has resulted in reduced need for allogeneic transfusions *(685)*, but has been associated with an increased risk of thrombotic events *(711–713)*. Phlebotomy has been recently re-emphasized as an important cause of blood loss in hospitalized patients, especially in the critical care setting *(714–716)*. Despite recognition that a lower hemoglobin (7 g/dL) should serve as a target for transfusion and that transfusion quantity is directly related to hospital length of stay and mortality, overuse of phlebotomy is perpetuating transfusion ill effects.

Approximately 15 million units of blood are donated annually and 29 million products transfused in the United States, at an average cost of $210 per unit (or more to the patient or the insurance carrier) (2,*678*,*704*). Of this cost, approximately 37% is attributed to acquisition charges from blood donation centers, 13% to handling by the hospital blood bank, 43% to laboratory tests for cross matching, and 7% to blood administration charges *(704)*. In addition to these costs, only about one per 1 million to 8 million units transfused resulted in a serious or fatal infectious complication of transfusion, perhaps necessitating a more prolonged hospitalization or additional laboratory charges to the patient *(9,717)*. Because much of the present cost of a unit of transfused blood is related to screening for transmissible diseases (up to 20% of blood donation center charges), any further reduction of infection risk is

least expensively accomplished through prudent use of transfusions according to suggested guidelines *(9,79,685)*. Furthermore, transfusion related infections today pose less risks and are secondary to those following sometimes unpredictable (and unavoidable) noninfections transfusion reactions (3). It is estimated that 13% to 50% of transfusions are unneeded *(79)*. Most recent studies have documented the lack of benefit of overzealous transfusion thresholds. In intensive care patients, the use of a threshold of <7.0 g of hemoglobin was associated with a lower 30-day mortality compared with a 10-g threshold in multiple studies *(718)*. The exception to this policy appears possibly to be patients older than 55 years and those with cardiac disease *(719,720)*. However, in the patient group with cardiac disease undergoing interventions, unnecessary transfusions have also led to additional costs and potential morbidity *(718)*. The case for a moderate position has been summarized by Valeri et al. *(721)*.

A review of the management of a severely anemic patient who refused transfusion (a Jehovah's Witness) provides perspective for the management of many patients *(722)*. At this time, there is no functional substitute for blood when it is required. Clinicians must continue to strive to make an exceedingly low infection risk product even safer, while practicing cost-effective medicine by reducing reliance on overused blood products. Furthermore, given the results of the SHOT initiative indicating that most transfusion-related morbidity and mortality in Great Britain today is related to noninfectious complications of transfusion, as is true in the United States, one should give considerable attention in the United States to quality improvement initiatives to improve further the safety of utilization of blood products *(723)*.

CHAPTER 68

Healthcare-Associated Infections Related to Procedures Performed in Radiology

Bruce S. Ribner

The radiology department has traditionally been considered a low-risk environment for healthcare-associated infections. However, major advances in the field of radiology over the past few decades, with the introduction of isotope scanning, ultrasound, computed tomography, magnetic resonance imaging, and the development of interventional radiology, have increased the potential for the transmission of infectious pathogens to both patients and healthcare workers. Unfortunately, an appreciation for the occurrence of healthcare-associated infections associated with these radiologic procedures has not kept pace with this technology (*1*,2). Few radiology texts address healthcare-associated infections associated with radiologic procedures. In addition, most invasive radiologic procedures introduced over the past few decades have not been prospectively analyzed for measures that could decrease the occurrence of healthcare-associated infections resulting from them. This is due, in part, to the rather limited time during which the radiologist interacts with the patient, and the resulting difficulty in achieving the long-term follow-up required to identify healthcare-associated infections.

This chapter summarizes the infectious complications associated with radiologic procedures and the infection control practices that might decrease the occurrence of these infections. As conclusive data regarding the prevention of healthcare-associated infections are lacking for many of these procedures, reliance is placed largely on related procedures performed in other specialties of medicine in which interventions that reduce the healthcare-associated transmission of infectious pathogens have been identified.

INFECTION CONTROL POLICY

The radiology suite experiences a steady stream of a wide variety of patients each day. Patients referred from the ambulatory care and emergency areas are intermixed with inpatients requiring diagnostic procedures. All of these patients can contaminate the environment of the radiology service with infectious pathogens. Chin supports and chest racks used in obtaining chest radiographs *(3)*, radiography tables *(3)*, radiographic film markers *(4)*, barium enema equipment *(5)*, x-ray tubes *(6)*, and x-ray film and developing solutions *(7)* may all become contaminated with multiple microorganisms from patients. In addition, the ease with which *Clostridium difficile* contaminates the environment of the patient colonized with this microorganism *(8)* makes it likely that contamination of the radiology area with *C. difficile* occurs as well. This environmental contamination may result in the subsequent spread of pathogenic microorganisms from these objects to other patients. In addition to fomite transmission, potential pathogens may be spread to patients visiting the radiology area via the airborne route. Hopkins et al. *(9)* traced an outbreak of invasive aspergillosis in their hospital due to construction activity in the radiology suite. Patients visiting the radiology suite for diagnostic procedures were infected when there was inadequate containment of aspergillus spores generated during renovation. Similarly, investigations of hospital outbreaks of multidrug-resistant tuberculosis have revealed that most cases were acquired within the facilities via the airborne route. A major factor in most of these outbreaks was a delay in initiating the isolation of patients infected with pulmonary tuberculosis *(10)*. Many of these patients had made multiple visits to the radiology department, with no precautions taken to prevent the transmission of respiratory pathogens, making it likely that some transmission occurred within the radiology department.

Given the large numbers of both diagnosed and undiagnosed infected patients presenting to the radiology department, and the potential for these patients to contaminate both objects and the air with pathogenic microorganisms, the foundation of any program for the prevention of healthcare-associated infections in the radiology department must begin by establishing good infection control policies. Among other issues, these policies must address the effective disinfection of environmental surfaces likely to act as fomites. The cleaning of these surfaces must be performed with an Environmental Protection Agency (EPA)-registered germicide (see also Chapter 80) between all patients, with more rigorous cleaning protocols at periodic intervals (11) (see also Chapter 71). A material that can be either discarded or easily disinfected between patients should cover surfaces that may be difficult to disinfect, such as switches and control panels. Policies should ensure that all disposable items are discarded after a single patient use, as such items are not designed for reprocessing and reuse on multiple patients (11). Attention must also be given to the appropriate cleaning and disinfection of all reusable

equipment, with the level of disinfection determined by the intended use of the item (see also Chapter 80). Items that enter tissues or vascular spaces require sterilization. Items that contact mucous membranes or nonintact skin require high-level disinfection. Items that contact intact skin require only low-level disinfection.

The radiology department must also establish good communication with the clinical areas referring patients to the department so as to identify patients who may require Transmission-Based Precautions. Patients requiring Transmission-Based Precautions must have those precautions continued in the radiology department. When possible, patients on Transmission-Based Precautions should undergo their procedures late in the day when traffic in the department is light and more attention can be given to environmental cleaning. These patients should also spend the minimum time possible in the radiology department so as to limit the potential exposure of susceptible patients and staff.

Due to concern about the healthcare-associated transmission of tuberculosis in the radiology suite (see also Chapter 38), the Centers for Disease Control and Prevention (CDC) has published specific recommendations for precautions to be followed in radiology departments *(10)*. Patients with known or suspected tuberculosis should wear a properly fitted surgical mask when in the department. When possible, an area in the department should be specially ventilated for Airborne Infection Isolation Precautions. This requires a net negative air pressure in relation to surrounding areas, sufficient air changes to remove droplet nuclei between patients, and either direct exhausting of all air to the outside (preferred) or filtration of air through high-efficiency particulate air (HEPA) filters before it is recirculated. In facilities with a high incidence of tuberculosis, ventilation in waiting areas should also be designed and maintained to reduce the risk of tuberculosis transmission. This should include provisions for direct exhausting of all air to the outside (preferred) or HEPA filtration of all air before it is recirculated. A goal of 12 to 15 air changes per hour for such waiting areas has been established (12,*13*).

STANDARD PRECAUTIONS

The infection control measures discussed above protect employees and patients from the transmission of most potential pathogens. However, attention to the transmission of blood-borne pathogens in the workplace increased in the 1980s. Hepatitis B virus (HBV) and the human immunodeficiency virus (HIV) are the blood-borne pathogens that have attracted the most attention from healthcare workers and regulatory agencies *(14)*.

Personnel working in radiology departments historically have not been considered a group at high risk for infection with blood-borne pathogens *(14–17)*. However, radiology personnel are increasingly performing procedures that can result in exposure to blood and other potentially infectious materials (materials epidemiologically linked with the transmission of blood-borne pathogens) *(18)*. Because a high percentage of patients infected with HBV *(19)* or HIV *(20)* are unidentified during their encounter with the healthcare system, it is essential that all patients be approached as though they are infected with blood-borne pathogens. This concept of using Universal Precautions (see also Chapter 89) for blood and other potentially infectious materials of all patients was first suggested by the CDC in 1987 *(21)*. These precautions were subsequently mandated by the Occupational Safety and Health Administration for all healthcare workers *(14)*. In 1996, the CDC recommended replacement of Universal Precautions with Standard Precautions, a change aimed at focusing more attention on pathogens that are not primarily blood-borne (22). Reports have detailed how these precautions can be applied to the radiology department (*18*,22,*23–25*). In general, these recommendations mirror those for other areas of the hospital in which similar procedures are performed (Table 68-1).

SPECIFIC PROCEDURES

Radiographic Studies of the Gastrointestinal Tract

The spread of enteric pathogens during radiologic procedures of the gastrointestinal tract has been a matter of concern for a number of years. Meyers *(5)* and Steinbach et al. *(26)* demonstrated retrograde contamination

TABLE 68-1

Standard Precautions as Applied to Radiology

- Wash hands promptly and thoroughly after patient contact or contact with blood, body fluids, excretions, or secretions.
- All personnel who could be exposed to blood or other potentially infectious material must receive training on these risks and on ways to minimize these risks.
- Employees must be offered hepatitis B immunization free of charge within 10 d of being assigned to tasks that pose a risk of exposure to blood or other potentially infectious materials.
- Disposable sharps, such as needles and scalpels, must be discarded immediately after use into puncture-resistant containers located as close as practical to the point of use. Sharps should not be recapped, bent, or otherwise manipulated before being discarded.
- All personnel who are present at procedures that could involve contact with blood, body fluids, secretions, excretions, mucous membranes, or nonintact skin of patients must use appropriate barrier precautions. This may involve use of gloves, gowns, masks, goggles, or face shields, depending on the degree of potential exposure. Interventional radiologists may need to consider the length of the procedure when establishing gloving policies. Hansen et al. *(25)* found that 23% of the gloves worn for more than 2 h during interventional radiology procedures were perforated by the end of the procedure. Few of these perforations were noted by the wearer. Similar data from other studies could support double-glove policies or the routine changing of gloves during prolonged interventional procedures.

(Data from Centers for Disease Control and Prevention, American Dental Association, American Academy of Oral and Maxillofacial Radiology.)

of the apparatus used for administering barium during the performance of barium enemas. This equipment became heavily contaminated with fecal contents by the end of the procedure. Hervey *(27)* reported an outbreak of typhoid fever traced to an apparatus that resembles the equipment used to administer barium during a barium enema. In his investigation, as in those by Meyers and by Steinbach et al., it was noted that fecal contents could contaminate the apparatus and its tubing via retrograde flow during the procedure. Although the apparatus was cleaned between patients, sufficient microorganisms remained in the apparatus to infect patients on whom it was subsequently used. Similarly, Meyers and Richards *(28)* were able to demonstrate that six of seven patients who underwent barium enemas after contamination of the bag contents with poliovirus became infected with the polio virus, as documented by rises in serum neutralization antibodies to the virus. In a related report, 36 cases of amebiasis were traced to a contaminated colonic irrigation machine in an outpatient chiropractic clinic *(29)*. Although the irrigation equipment was cleaned after each patient use, cultures of the machine immediately after cleaning revealed heavy contamination with fecal coliforms. The ease with which *C. difficile* contaminates the environment of colonized and infected patients *(8)* makes it likely that this bacterium is also present where gastrointestinal procedures are performed.

Given this potential for the transmission of enteric pathogens, all equipment used in barium enema procedures either must be subjected to high-level disinfection or must be disposable. In fact, disposable kits have replaced reusable equipment in most facilities *(30,31)*.

Several investigators have documented bacteremia associated with radiologic studies of the gastrointestinal tract. In two large studies, 11% *(32)* and 23% *(33)* of patients undergoing barium enemas had bacteremia. In both reports, the bacteremia could be detected within 1 minute of the start of the procedure. This bacteremia was transient and could be documented only for 30 minutes. Radiologic findings and colonic pathology did not influence the likelihood of the occurrence of bacteremia. Bacteremia was most likely to occur during the maximal distention of the colon. In evaluating the patients in these studies, no adverse effects of the bacteremia could be documented. However, one episode of *Clostridium perfringens* sepsis has been reported in a patient with acute leukemia who underwent a barium enema *(34)*. Although the transient bacteremia associated with the barium enema is unlikely to adversely affect most patients, bacterial endocarditis after a barium enema has been reported in one patient *(35)*. This has, in turn, raised the question of antibiotic prophylaxis for the prevention of infective endocarditis (*36*,37). However, barium enemas have not been found to be a risk factor in studies evaluating the epidemiology of bacterial endocarditis. Although a definitive answer is probably not possible, the current consensus is to avoid the use of prophylactic antibiotics for patients undergoing barium enemas *(34)*.

Ultrasound Procedures in Radiology

Ultrasonography has become an increasingly popular mode of evaluating a wide range of tissues. It is estimated that the average ultrasound machine may be used on as many as 30 patients a day, giving this equipment the potential to serve as an important fomite for the transmission of pathogens between patients *(38)*. Although many of these procedures restrict the ultrasound probe to contact with intact skin, probes are also being utilized for procedures in which they come into contact with mucous membranes and normally sterile tissues, occasionally in the operating room. Several studies have documented heavy contamination of the ultrasound probe, especially after contact with a mucous membrane *(38–40)*.

The standard manufacturer's recommendation for disinfection of the ultrasound probe is to soak the probe in a dilute sodium hypochlorite solution or an EPA-registered germicide for the time specified by the germicide's manufacturer, frequently 20 minutes. Unfortunately, the multiple procedures scheduled for these probes frequently preclude such long soak times. In addition, the probes may be damaged by total immersion in these solutions due to leakage around the seals or deterioration of the acoustic lens or rubber seals *(38,41)*. In practice, routine cleaning of the probe followed by low-level disinfection with an alcohol wipe seems appropriate when procedures involve contact only with intact skin. For procedures where the probe comes into contact with mucous membranes or nonintact skin, thorough cleaning followed by high-level disinfection with an EPA-registered germicide is recommended (11,42). Because of the difficulty in achieving high-level disinfection, it is recommended that a new sheath, such as a condom, cover probes that will be in contact with mucous membranes or sterile tissues for each such procedure (11,42). In general, condoms have been shown to be less prone to leakage than commercial probe covers and have a sixfold enhanced acceptable quality level when compared to standard examination gloves.

Endoscopic Procedures in Radiology

Other subspecialists such as gastroenterologists, pulmonologists, and surgeons perform endoscopic procedures much more frequently than they are performed by radiologists. Often, endoscopy is not performed in the radiology suite but rather in patient care areas, in the operating room, or in other dedicated areas such as laboratories within the hospital or ambulatory center. To the extent that endoscopy is performed in areas outside of radiology, general infection control policies similar to those recommended for the radiology suite need to be implemented.

Endoscopic procedures of the pulmonary tract *(43–45)*, upper gastrointestinal tract *(35,45–47)*, lower gastrointestinal tract *(35,45)*, and biliary tract *(45,48)* have all been associated with healthcare-associated bacteremia and infections. *Salmonella* species and *Pseudomonas aeruginosa* are the most common pathogens isolated in infections after gastrointestinal endoscopy, whereas *Mycobacterium tuberculosis*, nontuberculous mycobacteria, and *P. aeruginosa* are the most common isolates in infections after bronchoscopy *(45)*. In general, *P. aeruginosa* and nontuberculous mycobacteria tend to come from environmental contamination of the equipment, whereas *Salmonella* and *M. tuberculosis* originate in patients previously studied with the endoscopes.

Risk factors for healthcare-associated infections after endoscopy tend to fall into two categories. The major patient risk factor that increases the likelihood of bacteremia and

infection following endoscopic gastrointestinal procedures is the inability to establish adequate drainage of the biliary tract after endoscopic retrograde cholangiopancreatography (ERCP) *(36,48–50)*. In a recent guideline *(51)*, it was suggested that antibiotic prophylaxis should be considered before an ERCP in patients with known or suspected biliary obstruction, in whom there is a possibility that complete drainage may not be achieved at the ERCP, such as in patients with a hilar stricture and primary sclerosing cholangitis. When biliary drainage is incomplete despite an ERCP, continuation of antibiotics after the procedure is recommended.

As in the case of the barium enema, the question of antibiotic prophylaxis for the prevention of infective endocarditis after ERCP has been raised *(35,36,50)*. However, in two recent guidelines (37,*51*), it was recommended that prophylactic antibiotics no longer be given to any patients undergoing gastrointestinal endoscopy for the prevention of endocarditis.

Failure to adequately disinfect the endoscope and associated equipment appears to be another major risk factor for bacteremia and sepsis associated with endoscopic procedures. Contaminated water bottles *(52)*, inappropriate disinfectants *(43)*, scope designs that make adequate disinfection of the endoscope difficult *(53)*, and inadequate quality control over cleaning procedures for the endoscopes *(54)* have all contributed to healthcare-associated infections. In 2003, a guideline was published for the reprocessing of flexible gastrointestinal endoscopes (55). A recent review (56) was unable to document any episodes of patient-to-patient transmission of pathogens when these guidelines were followed (for a detailed discussion on cleaning and disinfection of endoscopes, see also Chapter 62).

Myelography

Myelography is associated with an extremely low rate of healthcare-associated infections. Given the anatomic location of these infections, however, they can be catastrophic. Twenty-nine cases of meningitis after myelography have been reported *(57–60)*. Oropharyngeal streptococci have caused most of these infections. The presumed source of these bacteria has been the oropharynx of the individual performing the procedure. This has been attributed to the fact that those performing the myelography frequently do not wear masks. The low incidence of this infectious complication has impeded the implementation of more stringent infection control measures *(59)*. Nonetheless, the wearing of masks would appear to be a logical low-cost precaution for the prevention of this potentially lethal infection. At the October 2005 meeting of the Healthcare Infection Control Practices Advisory Committee (HICPAC), the committee voted unanimously to recommend that surgical face masks be worn during myelogram procedures and during placement of epidural catheters *(60)*.

Vascular Radiology

Vascular radiology covers a wide range of procedures performed both by radiologists and cardiologists. As such, these procedures may be carried out both in the radiology suite and in designated catheterization laboratories outside of the radiology suite (see also Chapter 61).

Simple angiography procedures generally have a very low rate of infectious complications. Although endocarditis after coronary angiography has been reported *(61)*, prospective studies have found low rates of bacteremia and infectious intravascular complications associated with angiography. Sande et al. *(62)* found that none of 106 patients undergoing cardiac catheterization had detectable bacteremia or postprocedural intravascular infections. Shawker et al. *(63)* were able to detect bacteremia in 4 of 100 patients undergoing angiography of various vessels. Three of the four episodes were caused by inadequate sterilization of the catheter before the procedure. None of these patients developed any infectious sequelae. Infections at the insertion site of the catheter also appear to be quite infrequent. Laslett and Sabin *(64)* found no evidence of insertion site infection in 504 percutaneous left-sided heart catheterizations. Leaman and Zelis *(65)* were able to collect data on 107,203 cardiac catheterization procedures through a survey of 250 facilities. Only 0.06% of catheterizations performed by percutaneous insertion were reported to lead to insertion site infections. Catheterizations performed by cut down had an insertion site infection rate of 0.62%. Although low, this was 10 times the rate of site infection that occurred after percutaneous insertions. In a recent analysis of patients undergoing diagnostic angiography and angioplasty, Biancari et al. *(66)* found that patients undergoing procedures where manual/mechanical compression was used after the procedure had a 0.2% groin infection rate, while the use of a vascular closure device was associated with a 0.6% groin infection rate—this difference was statistically significant.

In formulating infection control standards for simple angiography, it is generally agreed that the preparation of the insertion site should involve the same disinfection techniques as are used for other intravascular devices. Individuals performing the procedure should wash their hands with an antiseptic-containing hand washing agent before donning sterile gloves. Strict attention must be given to proper cleaning and sterilization of guidewires and catheters that are reused. For angiography performed via the percutaneous insertion technique, it would appear that the remaining elements of the environment may be less critical in preventing insertion site infections. Laslett and Sabin *(64)* and Leaman and Zelis *(65)* could demonstrate no benefit from the use of caps and masks by personnel performing the angiography in preventing site infections. Unfortunately, they did not address the issue of gowns for personnel involved in performing the procedure. Given the potential for inadvertent contact of the catheter with the body or arms of the personnel directly involved in the procedure, gowns for these individuals would seem appropriate, although there is no documentation that they are necessary. Leaman and Zelis's observations indicate that gowns do not appear to be necessary for ancillary personnel and observers.

The 10-fold increase in insertion site infections associated with angiography performed via the cutdown approach would argue for avoiding this technique whenever possible. When the cutdown approach was required, Leaman and Zelis *(65)* found that the use of masks, caps, and gowns for all personnel and observers significantly decreased the rate of site infections. They also demonstrated a significant correlation between the number of cutdown procedures performed by a laboratory per year and the rate

of insertion site infections. Laboratories performing more than 150 cutdown procedures per year had an insertion site infection rate of 0.49%. In contrast, laboratories performing fewer than 150 such procedures per year had an insertion site infection rate nearly three times greater (1.43%). This difference was statistically significant. This observation would argue for the importance of the learning curve in preventing healthcare-associated site infections associated with angiography. While the use of vascular closure devices leads to more rapid hemostasis, the associated complications may outweigh this advantage *(66)*.

Standard Precautions require the consideration of attire not only to protect the patient from infection but also to protect the healthcare worker from exposure to blood and other potentially infectious materials. Thus, although the wearing of masks, caps, and gowns by personnel may not have been documented to prevent infections in patients undergoing percutaneous angiography, the potential for blood exposure during these procedures requires the use of this attire to protect the healthcare worker from exposures (see Chapters 73 and 74). In addition, eye protection, such as goggles or face shields, is essential.

Interventional vascular radiology has moved substantially beyond simple angiography. Angioplasty, arthrectomy, the placement of intravascular stents, and embolotherapy are procedures that were introduced into the modern radiology suite and catheterization laboratory during the 1980s. Most of these procedures have been associated with low rates of healthcare-associated infection. Gardiner et al. *(67)* recorded no infectious complications in 453 transluminal angioplasties. However, Frazee and Flaherty *(68)* were able to identify 10 patients with septic endarteritis of the femoral artery after percutaneous transluminal coronary angioplasty. Zollikofer et al. *(69)* noted no healthcare-associated infections after the placement of intravascular arterial stents in 21 vessels, but Gordon et al. *(70)* documented an episode of renal artery arteritis after placement of a renal artery stent and were able to find reports of four other cases of iliac artery arteritis after stent placement. Both Frazee and Flaherty and Gordon et al. found that reuse of an indwelling catheter or sheath left in a groin for more than 24 hours, repeated procedures, local hematoma formation, and increased procedure time increased the risk of arteritis.

Percutaneous transcatheter embolization is defined as the intravascular deposition of particulate, liquid, or mechanical agents, or autologous blood clot to produce intentional vessel occlusion. *(71)*. This procedure has been associated with a high number of postprocedural infections in certain settings. Whereas Higashida et al. *(72)* detected no infectious complications after the balloon embolization of 215 intracranial neurovascular aneurysms, Hemingway *(73)* recorded seven deaths from sepsis among 410 embolization procedures involving a variety of arteries. All seven patients who died had embolization of hepatic lesions. Although the patients who died were all extremely ill at the time of the procedure, it is of note that all deaths occurred among the early cases performed by their group. A decrease in sepsis as a complication of embolization was observed as the group gained experience with the procedure and as prophylactic antibiotics were introduced into their protocol. Shibata et al. *(74)* reported on 358 patients with 455 liver tumors who underwent a total of 683 ablation procedures. Cholangitis and/or liver abscess occurred in 10 patients. Both cholangitis and liver abscess were noted in seven patients, cholangitis was noted in two, and liver abscess was noted in one. One patient died of septic shock associated with cholangitis.

Embolization of the spleen has also been associated with a high rate of infectious complications. Initial reports cited the almost universal occurrence of splenic abscesses and sepsis after splenic embolization *(75,76)*. After modification of this procedure, with a change to partial rather than total splenic embolization, the introduction of strict sterile technique, and the introduction of antibiotic prophylaxis, Spigos et al. *(77)* were able to perform splenic embolization on 13 patients without any postprocedural infectious complications. Since these modifications were introduced together, it is impossible to evaluate the efficacy of each intervention separately. Although not explicitly stated, the improvement in patient outcome occurred, as noted in Hemingway's series, as the author gained experience with the procedure.

Infection control guidelines in these newer forms of interventional vascular radiology should parallel those used for standard angiography. Strict attention to the disinfection of the insertion site and careful hand washing with an antiseptic-containing agent before donning sterile gloves are important. In angioplasty, arthrectomy, stent placement, and embolization of intracranial vessels, infectious risks appear to be small. However, adherence to Standard Precautions requires the use of masks, gowns, gloves, and goggles or face shields. The Society of Cardiovascular and Interventional Radiology has developed quality improvement guidelines for percutaneous transcatheter embolization *(71)*. Antibiotic prophylaxis is recommended for embolization of the spleen and for other body sites where bacterial contamination is likely, such as the colon, open trauma, and liver. In the embolization of hepatic and splenic vessels, the potential for severe infectious complications appears to be great. Pending more detailed studies, strict attention to sterile technique, the use of prophylactic antibiotics, and performance of the procedure by those with the most experience would seem to offer the greatest benefit in preventing healthcare-associated infections.

Nonvascular Interventional Radiology

Nonvascular interventional radiology has evolved since the 1970s to include percutaneous biopsies, diagnostic and therapeutic aspiration of fluid, treatment of strictures, and removal of stones. Of these, the image-guided percutaneous biopsy has become the most frequently performed interventional radiologic procedure *(78)*. Infections after such biopsies are uncommon. The Society of Interventional Radiology has set a performance standard for infectious complications of 1% for all biopsies and 3% for prostate biopsies *(79)*.

The ability to drain visceral abscesses and collections of fluid, often in lieu of a surgical procedure, has become an increasingly important radiologic intervention. As might be expected, these drainage procedures are associated with a higher rate of infectious complications than are percutaneous biopsies. vanSonnenberg et al. *(80)* summarized the outcomes of 250 percutaneous abscess and fluid

drainage procedures. Two patients experienced sepsis with hypotension, and five others had bacteremia with fever after the procedure. One patient had secondary infection of a noninfected lymphocele after percutaneous drainage. An additional six patients were noted to have infections at the catheter insertion site. Again, as in other interventional radiologic procedures, the authors emphasized that most infectious complications occurred early in the group's experience with the technique. It is also worth noting that although the infectious complication rate approached 6%, it was lower than the rate observed in an equivalent population undergoing surgical procedures to drain fluid collections *(81)*. The Society of Interventional Radiology has set a threshold of 1% to 2% for septic shock, 2% to 5% for bacteremia, and 1% for local superinfection associated with all abscess and fluid drainage procedures *(82)*.

Percutaneous transhepatic drainage of the biliary tract for acute relief of obstruction is an extension of the percutaneous drainage procedure. Drainage in most such patients is either palliative, when the obstruction is secondary to malignancy, or a preoperative measure to decrease the degree of patient illness when obstruction is secondary to cholelithiasis, stricture, or malignancy *(83–86)*. Most of these patients have evidence of cholangitis with multiple bacterial pathogens before the procedure, often with bacteremia. Given the degree of preexisting illness in many of these patients, it is not surprising that some series have reported high rates of infectious complications. Thus, Hamlin et al. *(84)* noted sepsis in 1% of the patients undergoing percutaneous transhepatic drainage. Kadir et al. *(83)* and Joseph et al. *(86)* noted sepsis in 27% and 33%, respectively, of the patients on whom they performed this procedure. Joseph et al. were able to decrease this rate by 50% through the administration of prophylactic antibiotics. Again, the surgical literature suggests that equivalent patients undergoing surgical decompression would experience sepsis over 50% of the time *(83)*.

Related procedures performed increasingly on the biliary tract include transhepatic cholangiography, placement of endoprostheses through a blocked duct, balloon dilation of strictures, and removal of stones. In general, the infectious complications associated with these procedures occur at approximately the same rate as those associated with percutaneous transhepatic drainage *(78,87,88)*. The Society of Interventional Radiology has set a performance standard that 2% of transhepatic cholangiograms should have an infectious complication *(89)*.

Percutaneous genitourinary procedures are most commonly performed to relieve obstruction secondary to neoplasms, stones, or strictures *(78)*. These procedures have fewer infectious complications than do the analogous procedures performed on the biliary tract. Yoder et al. *(90)* reported that 5 of 65 patients undergoing nephrostomy placement for pyonephrosis had septic complications, but none died. Similarly, Stables et al. *(91)* summarized the results of nephrostomy placement in 516 patients. Ten (2%) developed healthcare-associated infections, most commonly pyelonephritis or the exacerbation of pyonephrosis. There were no deaths, as compared with a 6% mortality rate in equivalent patients undergoing surgical drainage procedures. Cochran et al. *(92)* retrospectively reviewed 56 percutaneous nephrostomy procedures. Existence of struvite stones, abnormal urinalysis (not defined by authors), and positive urine cultures (criteria not given by authors) were believed to increase the likelihood of sepsis. Patients with one or more of these risk factors (the high-risk group) had a 50% chance of developing sepsis after percutaneous nephrostomy, as compared with a 14% likelihood of developing sepsis if none of these risk factors (low-risk group) were present. Antibiotic administration did not alter the rate of infection in the low-risk group but decreased the occurrence of sepsis by 80% in the high-risk group.

Although there are few prospective data evaluating interventions for the prevention of healthcare-associated infections after nonvascular interventional radiology *(87)*, a consensus appears to have emerged as to which infection control measures may help to reduce the rate of infectious complications associated with these procedures. With the exception of the percutaneous biopsy, many of these procedures are associated with a high rate of infectious complications with substantial morbidity and mortality. It is generally accepted that these procedures must be performed in an environment approaching that used for the equivalent surgical procedures. Strict adherence to sterile technique with the creation of a sterile field appears to be appropriate *(81)*. All personnel involved in the procedure should wear caps, masks, gowns, and gloves. The simplest procedure required to establish drainage and decompression should be performed with a minimum of manipulation and distention during the initial procedure *(81,91,93)*. Although prophylactic antibiotics have clearly been found to reduce the risk of healthcare-associated infections in a few studies, their exact role has not been determined (*87*,94). Antibiotic prophylaxis is unlikely to be of benefit in percutaneous biopsy procedures given the low rate of infectious complications associated with these procedures. Transhepatic and genitourinary procedures are followed by much higher rates of infectious complications, many of which will likely benefit from prophylactic antibiotics. Other drainage procedures are associated with much lower rates of infection. Further research is required to determine which, if any, of these procedures will benefit from prophylactic antibiotics. If prophylactic antibiotics are used, they should be administered no sooner than 1 hour before commencing the procedure. For most procedures, prophylactic antibiotics should not be continued after the procedure. However, for certain percutaneous drainage procedures, continuing antibiotics for 24 to 48 hours after the procedure may be appropriate *(87)*. Specific agents to be used depend on the body site involved and local susceptibility patterns.

As with vascular interventional procedures, experience is important; rates of healthcare-associated infections are reduced as groups gain experience *(80)*. As in vascular interventional radiology, all personnel must observe Standard Precautions.

Radiolabeled Imaging Studies

Radiolabeled imaging studies appear to be associated with a low rate of infectious complications. Proper attention to technique, as is required in all intravascular access procedures, is essential. In addition, because materials are removed from the patient, processed in another area, and then reinjected into the patient, strict protocols must be developed to prevent the contamination of the material to be reinjected. A

TABLE 68-2

Recommended Policies for Institutions or Clinics in Which Nuclear Medicine Procedures are Performed

- All healthcare providers should receive training on infection control procedures.
- Written infection control policies and procedures for nuclear medicine should be promulgated and disseminated. These should include procedures to follow in the event of a potential emergency, such as an administration error.
- All doses and syringes should be checked for identification and radioassayed before injection.
- All syringes should be labeled with appropriate identifying information, including the patient's name and the pharmaceutical. A unique identification number should also be used.
- Consideration should be given to the implementation of a system when administering biologic products that requires that two persons cross-check all labeling of product to be injected, the prescription, and patient identification.
- Contaminated and used syringes should be disposed of safely and appropriately.
- An administration error should be immediately reported to supervisory personnel. Patients involved should be managed according to policies established for blood exposures.

(From Centers for Disease Control. Patient exposures to HIV during nuclear medicine procedures. *MMWR* 1992;41:575–579, with permission.)

reminder of the care required in dealing with these materials is provided by the report of three patients who received intravenous injections of blood or other materials from patients infected with HIV while undergoing nuclear medicine procedures *(95)*. All three episodes occurred as a result of preventable administration errors. At the time of the report, two of three patients had developed infection with HIV. As a result of these errors, the CDC published recommendations to be followed when nuclear medicine procedures are performed *(95)*. These are summarized in Table 68-2.

Oral Radiology

The dental profession has a long tradition of concern for infection control issues (see also Chapter 54). Dentists were one of the first groups identified as being at high risk for occupational HBV infection *(96)*. In addition, dental personnel have been recognized as being potentially exposed to a wide variety of other pathogens, including *M. tuberculosis*, staphylococci, streptococci, cytomegalovirus, herpes simplex virus, HIV, and viral respiratory pathogens (97). The documented transmission of HBV *(98)*, staphylococci, streptococci *(6)*, and other infectious pathogens (97) to patients has further reinforced interest in infection control in dentistry. Further, dentistry remains one of only two professions in which transmission of HIV from a healthcare worker to patients has been documented *(99)*.

TABLE 68-3

Infection Control Guidelines for Dental Radiology

- Use standard precautions for all patients.
- Set out all necessary supplies and adjust patient chair and head position before beginning.
- The exposure switch and cone should be covered with paper backed by an impervious material, aluminum foil, or clear plastic wrap. These should be changed between patients. If covering is not possible, the switch and cone must be disinfected between patients.
- Operators should avoid touching environmental surfaces with contaminated gloves.
- All materials and instruments used during patient care should be kept on work surfaces that are covered. If this is not possible, work surfaces should be disinfected with an EPA-registered and ADA-accepted disinfectant between patients.
- Wear gloves when exposing radiographs and handling contaminated film packets. Use other PPE (e.g., protective eyewear, mask, and gown) as appropriate if spattering of blood or other body fluids is likely.
- Wash hands before and after wearing gloves.
- Use heat-tolerant or disposable intraoral devices whenever possible (e.g., film-holding and positioning devices).
- Barrier-protected film should be used whenever possible.
- Clean and heat-sterilize heat-tolerant devices between patients. At a minimum, high-level disinfect semi critical heat-sensitive devices, according to manufacturer's instructions.
- Dry film packet after film is exposed.
- If a protective film barrier is used, remove carefully to avoid contamination of the film.
- If a barrier is not used, gloves should be worn when the contaminated film packet is opened and the film allowed to fall out of the packet.
- Transport and handle exposed radiographs in an aseptic manner to prevent contamination of developing equipment.
- All darkroom surfaces that are contaminated by film packets must be disinfected regularly.
- Contaminated packets and gloves should be discarded before film processing.
- The following apply for digital radiography sensors:
  1. Use FDA-cleared barriers.
  2. Clean and heat-sterilize, or high-level disinfect, between patients, barrier-protected semicritical items. If the item cannot tolerate these procedures then, at a minimum, protect with an FDA-cleared barrier and clean and disinfect with an EPA-registered hospital disinfectant with intermediate-level (i.e., tuberculocidal claim) activity, between patients. Consult with the manufacturer for methods of disinfection and sterilization of digital radiology sensors and for protection of associated computer hardware.

(Data from Environmental Protection Agency; American Dental Association.)

Although many procedures within dentistry can lead to the transmission of infectious pathogens, dental radiology has been clearly associated with contamination of the office environment and transmission of microorganisms between

patients. The radiographic equipment, dental chair, headrest, adjacent horizontal surfaces *(100)*, radiographic film, film developer, and darkroom *(7)* may all become contaminated with oropharyngeal pathogens during the course of oral radiology. These pathogens, in turn, may be transmitted to healthcare workers or patients. Design features frequently contribute to this potential for the transmission of microorganisms. The control panel for radiology equipment in the dental operatory is frequently not designed for effective disinfection *(100)*, and it is difficult to aseptically remove the film from a film packet contaminated with oral secretions *(7)*.

In response to these concerns regarding the potential for spread of infectious pathogens between patients and between patients and healthcare workers in dentistry, the CDC (97) and several dental organizations (101,*102*,*103*) have published infection control guidelines for dental radiology (Table 68-3).

CHAPTER 69

Infection Control in Gene Therapy

Martin E. Evans, David J. Weber, and William A. Rutala

The first gene therapy protocol in the United States was begun in 1990 for the treatment of severe combined immunodeficiency *(1)*. Overall, gene transfer has been used most commonly to treat cancer, followed by monogenetic, infectious, cardiovascular, neurological, and ocular diseases (Table 69-1). Recent success has been reported in treating patients with severe combined immunodeficiency *(2)*, a fatal demyelinating disease of the central nervous system (*3*,4), and an inherited retinal disease causing congenital blindness *(5)*. As of 2009, 1,579 gene transfer protocols have been initiated worldwide (6). Of these, approximately 60% are in Phase I trials, 35% in Phase I/II or II trials, and the remainder in Phase III or IV trials. Only two gene therapy products have been marketed, and these are in China.

Clinical gene transfer trials reflect our developing understanding of the genetic basis of many diseases and rapid advances in molecular biology including the ability to produce vectors capable of transferring genetic material into somatic cells. However, the need for careful assessment of the potential benefits and risks of all gene therapy trials has been highlighted by the unexpected death of a young patient that was directly attributable to the gene transfer trial *(7)* and the development of leukemia in several patients who underwent retrovirus-mediated gene transfer to correct X-linked severe combined immunodeficiency syndrome (8,*9*).

Several live pathogenic viruses have been modified to transfer genes of interest. The ability of these vectors to infect patients (and potentially other unintended persons) raises considerations for infection control. This chapter provides an overview of gene transfer technology and regulatory requirements for research in the United States and discusses the infection control aspects of clinical trials using gene transfer.

Recommendations for infection control of gene therapy/transfer have been discussed in an editorial (10), consensus conference (11), and a review article (12).

BACKGROUND

Gene transfer is a term that can be applied to any clinical therapeutic procedure in which genes are intentionally introduced into human somatic cells *(13)*. Prior to considering gene transfer, several requirements must be fulfilled. First, the gene(s) in question must be identified, and the nature of the defect characterized. Genetic diseases can be defined by the aberrant, specific gene expression that differs from the disease-free state. This variance may be due to a gene product that is absent or deficient (e.g., the cystic fibrosis transmembrane regulator (CFTR) protein) *(14,15)*, one that is abnormally present (e.g., Epstein-Barr virus nuclear antigen-1 in Hodgkin's disease) *(16)*, or abnormal regulation or expression of normal cellular products (i.e., downregulation of human leukocyte antigens by adenovirus). Second, it is important to understand which tissues express the defect and how accessible they are to manipulation. For example, while hemophilia B is caused by inadequate production of factor IX by the liver, factor IX does not require precise metabolic regulation, and even small amounts of production of factor IX by any cell line can prevent disease manifestations. Thus, hemophilia B is potentially amenable to *ex vivo* manipulation of hematopoietic cells or fibroblasts *(17)*. The key technologies that have facilitated the utilization of gene transfer include new methods by which cellular genes can be isolated (cloned), manipulated (engineered), and transferred into human cells. To obtain a therapeutic effect, there are basically three options for somatic gene therapy: (a) replacement of defective or missing genes for the treatment of inherited diseases, (b) augmentation of normal gene function or introduction of additional genetic information that interferes with proliferative diseases, and (c) blocking disease triggering or supporting genes like oncogenes on the deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) level (Table 69-2). In brief, these three options could be thought of as gene replacement, gene addition, or gene correction *(18)*.

Human gene transfer is currently limited to manipulations affecting somatic, differentiated cells. Germline gene transfer, where reproductive cells are treated for the correction of a genetic disease being transferred to the patient's descendants, is not likely to become acceptable as a feasible strategy in the near future. Due to the potential risks and unpredictable results, germline gene transfer has never been authorized in humans.

There are two main approaches to gene transfer: *in vivo* gene transfer, in which genes are delivered directly to target cells in the body, and *ex vivo* gene transfer, in which

TABLE 69-1

Approved Gene Therapy Protocols Through 2009

Trial Division	*Subdivision*	*Number of Protocols (%)*
Country of origin	United States	989 (63%)
	Other	590 (37%)
Clinical phase	I	952 (60%)
	I/II	299 (19%)
	II	258 (16%)
	III	53 (3%)
	IV	2 (0.1%)
Diseases addressed	Cancer	1019 (65%)
	Monogenic diseases	125 (8%)
	Infectious diseases	127 (8%)
	Cardiovascular diseases	138 (9%)
	Neurological diseases	30 (2%)
	Ocular diseases	18 (1%)
Vector	Retrovirus	336 (21%)
	Adenovirus	387 (24%)
	Lipofection	109 (7%)
	Naked/plasmid DNA	287 (7%)
	Pox and vaccinia viruses	222 (14%)
	Adeno-associated virus	71 (4%)
	Herpes simplex virus	55 (3%)
	RNA transfer	23 (1%)
	Others/unknown	128 (8%)

target cells are genetically manipulated outside the body and then reimplanted *(13)*. To carry out gene transfer, the exogenous gene(s) is transferred in an expression cassette, including the promoter, which regulates expression of the new gene, often in the form of a complement DNA (cDNA), and stops signals to terminate translation *(19)*. The exogenous or therapeutic gene can be isolated from the genome of a human, another animal, a plant, a bacterium, or a virus and may code for any type of protein *(13)*. Depending on the choice of the regulatory element, which controls the expression of the therapeutic gene, gene expression can be high or low level, specific to certain cell types, or even continuously variable, and can respond to local environmental factors such as the partial pressure oxygen or the concentration of a drug *(13)*.

The expression cassette is transferred to target cells using a vector. The most commonly used vector systems include retroviruses, lentiviruses, adenovirus, adeno-associated virus, poxviruses such as vaccinia, and herpes simplex virus (Table 69-3). Each delivers the expression cassette via distinct mechanisms and each has unique advantages and disadvantages (Table 69-4). Although viral vectors have been most commonly used, nonviral vector systems are of increasing scientific interest. Nonviral vector systems include plasmid–liposome complexes, newer kinds of vectors that sheath DNA in nonlipid coats, and naked DNA *(20–22)*.

To date, the many obstacles to successful gene therapy/transfer have not been overcome. The ideal gene delivery vehicle would efficiently and specifically transfer the gene to target cells and subsequently obtain high, regulatable, and durable levels of gene expression *(19)*. In addition, an ideal vector should not evoke an immune response (unless designed to do so), should be nontoxic to the recipient and easily purified in high concentration, and there should be no risk of recombination or replication (unless desired). Current obstacles to successful gene therapy include low efficiency of gene transfer to the target cell, inadequate regulation of the therapeutic gene in the transduced cell, and maintaining long-term, stable gene expression at an appropriate level.

COMMONLY USED VECTORS

Adenoviruses

Adenoviruses are the most commonly used vectors for gene transfer (6). They are icosahedral, large, nonenveloped, double-stranded DNA viruses. Adenoviral vectors are widely used because of several advantages (Table 69-4) *(23–25)*. There are four adenovirus gene regions, designated E1 through E4, that encode proteins necessary for viral replication. Early gene transfer trials utilized vectors that were constructed by deleting portions of E1 and inserting the transgene. Although the goal of this method was to develop a replication incompetent vector, it was subsequently demonstrated that cytokines (e.g., interleukin-6) could supply the function of the E1 region and permit low-level vector replication. In addition, E1-deleted adenovirus could replicate in the

TABLE 69-2

Strategies for Use of Gene Transfer

Strategy	*Method*	*Example*
Supplementation	Transfer a functional gene into cells that have a defective gene	Cure severe immunodeficiency by replacing a defective adenosine deaminase gene with the normal gene by means of a retroviral vector
Immunotherapy	Deliver a gene that will elicit an immune response when the gene product is expressed	Infect with vaccinia containing prostate-specific antigen gene
Cancer therapy	Deliver a therapeutic gene into cancer cells	Infect cancer cells with adenovirus containing the gene for tumor necrosis factor
Chemoprotection	Transfer a gene for drug resistance into normal cells to protect them from chemotherapy	Transfer a multidrug resistance gene into normal bone marrow cells; transplant the cells and administer chemotherapy to kill unprotected tumor cells
Ablative therapy	Deliver a gene that will allow activation of a prodrug leading to cell death	Insert the herpes simplex virus thymidine kinase gene into tumor cells and administer ganciclovir
Antiviral therapy	Deliver a gene into infected cells that interferes with viral replication	Transfer the gene for hairpin ribozyme, which cleaves HIV-1 RNA, into HIV-infected cells
Marking	Insert a gene into cells to identify them when the gene is expressed	Infect harvested bone marrow cells with a retrovirus containing neomycin phosphotranferase gene; after transplantation, look for cells producing the enzyme as evidence for engraftment

(Adapted from Evans ME, Lesnaw JA. Infection control for gene therapy: a busy physician's primer. *Clin Infect Dis* 2002;35:597–605.)

presence of coinfection with other DNA viruses, such as papillomavirus or cytomegalovirus. For this reason, modern vectors have deletions in additional regions of E2, E3, and/or E4. Growth of adenovirus vectors in the HEK 293 packaging cell line has led to recombination between the vector and viral gene sequences present in the packaging cell line with the generation of replication-competent adenovirus. The use of alternative cell lines may minimize this problem *(26)*.

Retroviruses

Retroviruses (e.g., murine leukemia virus) and lentiviruses (e.g., HIV) are the second most commonly used vectors for gene transfer. When murine leukemia virus or other retroviral vectors are used for gene therapy, the genes required for retrovirus replication such as *gag, pol,* and/or *env* are deleted and the therapeutic gene is inserted in their place *(27–31)*. As a result of these deletions, the vector is unable to replicate. Lentiviruses are increasingly

TABLE 69-3

Vectors Used for Gene Therapy

Vector	*Genome Size (kbp)*	*Gene(s) Deleted or Inserted*	*Packaging Cell Line*
Adenoviruses	36–38	E1a, E2, E3, E4, or all genes leaving signal sequences	HEK 293
Murine retroviruses	7–11	*gag, pol*, and *env*	HEK 293
Lentiviruses	7–11	All except *gag*, *pol*, and *rev*; additional deletions in long terminal repeats to produce self-inactivating vectors	HEK 293
Adeno-associated viruses	4.7	*cap* and *rep*	HEK 293 with plasmid-bearing adenovirus helper functions
Vaccinia	130–380	No deletions; therapeutic gene inserted into silent regions of the genome or into nonessential genes (e.g., the thymidine kinase gene)	Not applicable
Herpesviruses	120–240	Immediate-early genes	
Plasmids and virus-like particles		Not applicable	Not applicable

TABLE 69-4

Advantages, Disadvantages, and Infection Control Concerns by Vector

Vector	*Advantages*	*Disadvantages*	*Infection Control Concerns*
Murine retroviruses	Little immune response; potential for stable integration into host chromosome; amphotropic viruses for a wide variety of tissues	Inefficient *ex vivo* transfer; genes insert randomly and therefore have risk of insertional mutagenesis; inactivated by complement; only infect actively dividing cells; size of transgene limited	Minimal hazard when they are incubated with host cells *ex vivo*; secondary infections via accidental inoculation unlikely
Lentiviruses	Little immune response; potential for stable integration into host chromosome (lifelong gene expression); can be administered *in vivo* because they are complement resistant	Insertional mutagenesis; limited to CD4+ cells unless pseudotyped with vesicular stomatitis or Ebola virus surface glycoprotein	Secondary infections via accidental inoculation possible
Adenoviruses	High titers can be grown; not integrated into host genome; large capacity for transgenes; infect dividing and nondividing cells; very stable virus; can be administered *in vivo*	Systemic infection possible; elicits an immune response that may limit repeated use; genes may function transiently	Stable in the environment; potential transmission via contaminated fomites, close personal contact, or droplets; relatively resistant to some disinfectants
Adeno-associated viruses	Integrates into host chromosome; infects dividing and nondividing cells, can be administered *in vivo*; does not elicit an immune response; requires helper virus for expression	Small capacity for transgenes; risk of insertional mutagenesis; association with male infertility; problems with expansion of production capacity	Prudent to use same precautions as for adenovirus
Vaccinia	Can accommodate large transgenes; can be lyophilized; does not integrate into host chromosome	Replication-competent vector with many adverse reactions; immune response may limit usefulness	Infection can be transmitted via contact or droplet routes; may cause severe disease in immunocompromised contacts or contacts with underlying skin disorders; vaccinators should receive vaccinia vaccine
Herpesviruses	Produced at high levels; targets nondividing nerve cells; can accommodate large transgene; latency	Latency	If cutaneous infection present, transmission may occur via direct contact
Plasmids and virus-like particles	Safe; gene expression can be regulated	Low gene transfer efficiency; unstable in most body tissues	None

(Adapted from Evans ME, Lesnaw JA. Infection control for gene therapy: a busy physician's primer. *Clin Infect Dis* 2002;35:597–605.)

used because they overcome some of the limitations of the murine leukemia virus vectors. Multiple gene deletions in the lentivirus vectors make it extremely unlikely that the vector could be reactivated. In addition, the vectors are engineered to be replication incompetent by deleting sequences in the terminal signal (i.e., long terminal repeats) that are essential for gene expression. Unlike murine leukemia viruses, these vectors are resistant to complement and can be infused directly into the circulation, where they infect quiescent or dividing cells expressing CD4 on their surface *(32)*.

Retroviruses are advantageous because they elicit little immune response and because they integrate into the host genome. They offer the potential for stable long-term gene expression. A major concern is that these viruses may induce insertional mutations and transform target cells into cancer cells *(33)*.

Adeno-Associated Viruses

Adeno-associated virus is a single-stranded DNA virus. The virus is usually found as a provirus integrated into chromosome 19 of the host cell genome, where it remains inert until

helper viruses supply the missing proteins or genes needed for replication. Helper viruses include herpesviruses, adenoviruses, or vaccinia virus. Replication-defective vectors can be constructed by removing all internal viral coding sequences of the wild-type strain and inserting the transgene. The use of adeno-associated viral vectors including their advantages and disadvantages has been reviewed elsewhere *(34,35)*.

Poxviruses

Vaccinia virus, the vaccine agent used in the eradication of smallpox, is being used as a gene therapy vector. Unlike other vectors, it has not been engineered to be replication incompetent. Instead, transgenes are inserted into silent regions of the vaccinia genome *(36)*.

Herpesviruses

Herpes simplex is an enveloped double-stranded DNA virus that infects sensory neural cells where it remains in a latent state. Replication-incompetent virus can be produced by mutations in the required immediate-early genes *(37)*. Transgenes can be inserted into these replication-incompetent vectors. The use of herpes virus vectors has been reviewed *(38,39)*.

INFECTION CONTROL

Key aspects of infection control include protection of researchers and healthcare workers administering the gene therapy vector and caring for subjects of gene therapy research, environmental and equipment disinfection, and laboratory safety. Institutional guidelines should be based on the vector used.

Protection of Healthcare Workers

Currently, there are no National Institutes of Health (NIH), Food and Drug Administration (FDA), or Centers for Disease Control and Prevention (CDC) infection control guidelines for minimizing the hazards to healthcare personnel caring for patients on gene transfer protocols or for preventing person-to-person transmission of gene transfer vectors. For protocols that are conducted at, or sponsored by, institutions that receive NIH funding for recombinant DNA research, the *NIH Guidelines for Research Involving Recombinant DNA Molecules* (http://oba.od.nih.gov/rdna/nih_guidelines_oba.html) requires that the submission of the gene transfer protocol to NIH include a description of the hazards of the proposed transfer to persons other than the patients being treated (40). Specifically, the investigator must describe the following:

1. On what basis are potential public health benefits or hazards postulated?
2. Is there a significant possibility that the added DNA will spread from the patient to other persons or the environment?
3. What precautions will be taken against such spread (e.g., patient sharing a room, healthcare workers, or family members)?
4. What measures will be undertaken to mitigate the risks, if any, to public health?
5. In light of possible risks to offspring, including vertical transmission, will birth control measures be recommended to patients? Are such concerns applicable to healthcare personnel?

However, *NIH Guidelines* do not discuss how to assess the level of risk, what level of risk is acceptable, or measures to minimize such risks.

The goal of the infection control policies should be to minimize the risk of transmission of the gene vector to healthcare providers and visitors. For protocols that involve removal of the target cell with *in vitro* alteration followed by reinfusion, environmental controls should be adequate to prevent hazardous exposure of healthcare personnel. For protocols that involve administration of vectors that could result in potentially transmittable diseases (e.g., vaccinia, adenovirus), use of appropriate personnel protective equipment as recommended in the isolation guidelines (41) of the CDC should be sufficient to protect healthcare workers (Table 69-5). Special precautions may be advised for use of certain vectors. For example, persons administering vaccinia-based products should be screened and, if no contraindications are present, immunized with vaccinia.

For directly administered gene vectors, prevention should focus on the known modes of transmission of the vector. Standard Precautions, as described by the CDC, should form the basis for rational infection control measures. At our current stage of knowledge, the use of Contact and Droplet Precautions (gloving and masking before entering the room) for vectors transmitted by the contact or droplet routes appears warranted. For vectors infused directly into the patient, Standard Precautions should be adequate.

All gene transfer protocols should include guidance on the management of healthcare workers accidentally exposed to a gene therapy vector.

Disinfection

Proper disinfection of work areas, instruments, and spills is critical to prevent person-to-person transmission of pathogens via contaminated hands. The environmental stability and susceptibility of microorganisms varies. Among gene transfer vectors, adenoviruses are likely to be the most environmentally stable. Healthcare-associated outbreaks have been reported with both poxviruses and adeno viruses. Although most transmission is likely via droplets, contaminated fomites have also played an important role. CDC guidelines for the disinfection of environmental surfaces and equipment should be scrupulously followed *(42)*. In general, an EPA-registered hospital disinfectant should be used for cleaning environmental surfaces. A 1:10 diluted preparation of household bleach (sodium hypochlorite) would be effective against all currently used vectors. Infection control personnel should consult with the manufacturer of the gene transfer vector for their recommendations on the most effective surface disinfectant. EPA-approved high-level disinfectants would be adequate for patient equipment. However, care must be taken (appropriate use of personal protective equipment [PPE]) during the cleaning steps to protect healthcare workers from accidental infection. When possible, initial decontamination followed by cleaning and then high-level disinfection should be undertaken.

Laboratory Safety

Gene transfer vectors may represent a laboratory hazard during their construction. The U.S. Public Health Service

TABLE 69-5

Recommended Biosafety Levels for Pharmacy and Transmission Precautions Used for Patients Undergoing Gene Therapy

has provided an excellent guideline for assuring the safe handling of microbes (41). Strict adherence to this guideline is recommended for all microbiological and biomedical laboratories (Table 69-5). The key principle of biosafety ensconced in the guidelines is "containment," a collection of engineering controls designed to allow the safe handling of infectious materials in the laboratory environment. *Primary containment*, the protection of personnel and the immediate laboratory environment from exposure to infectious agents, is provided by good microbiologic techniques and the use of appropriate safety equipment (e.g., biological safety cabinets, enclosed containers). Preexposure immunization may be available and recommended (e.g., vaccinia vaccine for personnel working with this agent as gene therapy vector). *Secondary containment*, the protection of the environment external to the laboratory from exposure to infectious material, is provided by a combination of facility design and operational practices (e.g., specialized ventilation systems to ensure directional airflow, controlled access zone).

The U.S. Public Health Guideline groups all microbes into four categories depending on several factors including pathogen virulence, modes of transmission, and availability of vaccine and treatment. The pathogen group then defines four levels of recommended biosafety levels (BSLs) that require increasingly elaborate primary and secondary containment:

- BSL-1 practices, safety equipment, and facility design and construction are appropriate for undergraduate and secondary educational training and teaching laboratories, for other laboratories in which work is done with defined and characterized strains of viable microorganisms not known to consistently cause disease in healthy adult humans (e.g., adeno-associated virus).
- BSL-2 practices, safety equipment, and facility design and construction are applicable to clinical, diagnostic, teaching, research, or production facilities in which work is done with the broad spectrum of indigenous moderate-risk agents that are present in the community and associated with human disease of varying severity (e.g., adenovirus). Primary hazards to personnel working with these agents relate to accidental percutaneous or mucous membrane exposures, or ingestion of contaminated materials.
- BSL-3 practices, safety equipment, and facility design and construction are applicable to clinical, diagnostic, teaching, research, or production facilities in which work is done with indigenous or exotic agents with a potential for respiratory transmission, and which may also cause serious and potentially lethal infection (e.g., lentiviruses). Primary hazards to personnel working with these agents relate to autoinoculation, ingestion, and exposure to infectious aerosols.
- BSL-4 practices, safety equipment, and facility design and construction are applicable for work with dangerous and exotic agents that pose a high individual risk of life-threatening disease, which may be transmitted via the aerosol route and for which there is no available vaccine or therapy (e.g., Ebola virus). Currently, no gene therapy vectors fall into this class. The primary hazards to personnel working with BSL-4 agents are respiratory exposure to infectious aerosols, mucous membranes or nonintact skin exposure to infectious droplets, and autoinoculation.

Management of Research Subjects

It would be ideal to either use or engineer live vectors that have a self-limited life span. In this case, research volunteers should be maintained on precautions until proven vector-free. Informed consent should include agreement to consent to isolation requirements. Prior agreement with state or local health departments can be sought to allow the use of a limited, legally enforced quarantine for patients who seek to leave the hospital and who may endanger the community. Quarantine measures should be individually reviewed by a biosafety

committee whenever instituted. Should volunteers exposed to live vectors decide to leave containment prior to the end of their quarantine period, they should be contacted by appropriate county or state health department personnel.

Adenoviruses

In persons with normal host defenses, adenoviruses cause minor illnesses such as conjunctivitis, respiratory tract disease, and gastroenteritis. In persons with abnormal host defenses, adenoviruses may cause serious illnesses including pneumonia, gastrointestinal hemorrhage, cystitis, and hepatic necrosis. The mortality rate has been reported to be as high as 60% among stem cell transplant patients and as high as 20% among renal or liver transplant patients with adenoviral infections. Currently, there is no effective prophylactic vaccine or therapy.

Initially, the use of adenoviral vectors generated two concerns. First, that the vector might recombine with wild-type virus and become replication competent. Second, that replication-competent adenovirus reactivants in the treatment inoculum might be shed by patients who had undergone gene transfer leading to transmission of infection to healthcare workers, visitors, family members, or other patients. For this reason, elaborate infection control measures were initially employed. However, published trials in which inocula $<10^{13}$ virus particles were used have not demonstrated either shedding or significant numbers of replication-competent recombinants. It is still not known if therapy with higher titers of virus would present a hazard.

Because of concerns that complementation by wild-type adenoviruses could lead to the development of replication-competent virus, it may be prudent to screen prospective gene transfer patients and healthcare workers for clinical signs of adenovirus infection. Subjects with possible active infection should be deferred from entering the trial; healthcare workers with possible infection should be reassigned to care for other patients. Pharmacy staff preparing adenoviral vectors should work in a level 2 biosafety cabinet and wear appropriate PPE (gloves, gowns). The vector should be transferred in a container clearly marked with a biohazard label. Air in syringes or tubing should be expressed in the pharmacy, not at the bedside.

Adenoviruses are extremely hardy and can survive on surfaces for an extended period of time. Surface disinfection should be performed after the subject has left his/her room. Only disposable equipment should be used, or equipment should be disinfected following patient use. Because of the theoretical risk of aerosol transmission if high-titer vector is provided, it would be reasonable to manage such patients on Droplet Precautions.

Retrovirus

Murine retroviral gene transfer is usually performed *ex vivo* in a laboratory under carefully controlled conditions. Since there is no evidence that wild-type murine retroviruses cause human disease, these vectors probably do not represent a risk even if directly inoculated into the bloodstream. Newer murine-based vectors that have been engineered to be complement resistant and lentiviral vectors are theoretically capable of causing human disease. However, replication-competent lentivirus vectors have not been reported and hence infection, while theoretically possible, is highly unlikely.

Standard Precautions as used to prevent HIV transmission should be effective in preventing transmission of retroviral vectors. Whenever possible, needleless devices should be used to minimize the likelihood of accidental percutaneous injury. There is no need to isolate patients, use dedicated equipment, restrict visitors, use special precautions for waste disposal, or require special handling of linens or eating utensils.

Adeno-Associated Virus

Only limited data are available on the frequency of vector shedding or reactivant shedding. Theoretically, adeno-associated virus vectors could be transmitted by the respiratory or fecal–oral route as is adenovirus. In the absence of specific guidelines, it seems reasonable to use the same guidelines for adeno-associated viral vectors as are recommended for adenoviral vectors.

Poxviruses

Vaccinia is administered most commonly by intradermal scarification or intradermal injection. The virus is likely to be shed from the immunization site until the lesion completely scabs and heals over. Administration of vaccinia vectors should be done using aseptic technique (gloves) in a private room. Because vaccinia vectors are not designed to be replication defective, the risk of cross-infection with this vector is greater than for other gene therapy vectors. The risk of contact transmission can be minimized by keeping the vaccination site covered with a semipermeable or gauze dressing. An occlusive dressing should not be used. Contaminated dressing should be managed and disposed of as regulated medical waste. All personnel working with vaccinia vectors should be screened and provided vaccinia immunization unless contraindicated. Personnel with a contraindication to vaccinia immunization should be prohibited from working with vaccinia vectors. Vaccinia vaccine should be provided only with informed consent. Vaccinated healthcare personnel should be managed as recommended by the CDC during the postvaccination period.

Vaccinated subjects may be managed using Standard Precautions. If they develop generalized vaccinia, progressive vaccinia, or eczema vaccinatum, they should be placed on Contact and Airborne Precautions. In some cases, use of vaccinia immune globulin may be indicated. There are no special recommendations for the handling of eating utensils. Potentially contaminated clothes and bed linens should be managed appropriately during transport and washed with either hot water followed by drying or washed with bleach.

Herpesviruses

Only limited information is available on the shedding of herpesvirus vectors. Transmission is possible with direct contact with lesions. However, the use of Standard Precautions should prevent transmission. Although, herpes simplex virus can survive on fomites for up to 4 hours, fomite-mediated transmission has not been reported.

REGULATION

The institutions with major regulatory responsibility over human gene therapy are the NIH and the FDA, which have overlapping jurisdiction in the United States. Within the NIH, the Office of Biotechnology Activities (OBA) is responsible for reviewing and coordinating all activities related to gene therapy (43). The Recombinant DNA Advisory Committee (RAC), administered by OBA, is a public advisory committee that advises the NIH Director on recombinant DNA research. Within the FDA, gene transfer oversight falls within the Center for Biologics Evaluation and Research (CBER) (44). Experiments involving the deliberate transfer of recombinant DNA or DNA- or RNA-derived recombinant DNA into human subjects (human gene transfer) cannot be initiated without review by both NIH/OBA and the FDA if the trial is conducted at, or sponsored by, an institution that receives any NIH funding for recombinant DNA research. For studies subject to NIH oversight, the local Institutional Biosafety Committee (IBC) must review these and other studies involving recombinant DNA and the IBC is responsible for insuring that the principal investigator carries out the requirements outlined in the *NIH Guidelines*. In addition, the local Institutional Review Board (IRB) must approve human studies.

PRODUCT PREPARATION AND MONITORING

Key regulatory and safety aspects of product preparation include (a) an adequate rationale for efficacy of therapy; (b) vector source materials, which should be characterized and documented thoroughly, and viral vectors or plasmids, which should be generated from cloned and characterized constructs and subjected to confirmatory identity tests; (c) a detailed understanding and description of the procedure for selection of the final gene construct, method of transfer of the gene construct into the host cell, and selection and characterization of the recombinant host cell clone including vector copy number and physical state of the final vector construct inside the host cell (i.e., integrated or extra chromosomal); (d) a master viral bank, which should be created when a virus, with or without a therapeutic gene, is used as a seed in the manufacture of a therapeutic vector; and (e) demonstration of lot-to-lot reproducibility.

Additional important factors in the preparation of material for human gene transfer include the following: (a) sterility of the final product must be maintained (e.g., freedom from bacteria, fungi, *Mycoplasma,* and adventitious viruses); (b) in the case of replication-defective or replication-selective vectors, master viral banks should be demonstrated to be free of replication-competent viruses, which may arise as a result of contamination or recombination during the generation of the master viral bank; (c) products made by cells and required for therapeutic activity should be shown to be biologically active, and this activity must be quantified and shown adequate to produce the desired effect *in vivo*; (d) for genetically altered *in vitro* cells, evidence should be available as to whether cells survive and continue to function *in vivo*; and (e) for directly administered vectors, a highly sensitive assay should be available for detecting infection with the vector. In addition to being highly sensitive, the assay should also be specific for detection of the genetically altered vector.

This last point has been a concern since the inception of the RAC in 1974 and is a critical issue in infection control. There are many viral-like sequences endogenous in mammalian genomes, and the possibility exists that a vector could recombine with endogenous sequences or with a coincident superinfecting virus. Consequently, vectors have been designed that would require multiple recombination events, each one unlikely to produce a replication-competent virus (45).

DEVELOPING AN INFECTION CONTROL POLICY

Infection control recommendations are based on the microbiology and epidemiology of the vector used in the gene therapy protocol. Infection control policies should be altered after scientific studies provide data to liberalize or alter the recommendations. Unfortunately, there are only limited data on which to base our current recommendation because data on transmissibility of vectors (e.g., shedding) and production of replication-competent vectors have often been considered proprietary. The development of infection control guidelines should gene therapy enter general medical use will be imprecise because data on which to base recommendations are limited by the small size of current trials, multitude of vectors in current use, highly selected patient populations,

TABLE 69-6

Components of an Infection Control Policy Regarding Gene Therapy

- Basis of infection control policy
  - Vector employed
  - Method of vector administration
  - Ability of vector to cause disease in the patient
  - Mode of transmission of the vector (i.e., contact, droplet, airborne)
  - Infectivity (i.e., transmissibility)
  - Ability of vector to cause disease in healthcare personnel
  - Potential for development of replication-competent vector
  - Environmental stability (i.e., survival)
  - Susceptibility to disinfectants
- Hospital care issues
  - Isolation precautions
  - Visitor guidelines
  - Restrictions on patient travel outside hospital room
  - Disinfection: surface, equipment
  - Restrictions on healthcare personnel allowed to care for patient
  - Laboratory risks: via percutaneous injury, via aerosolization
  - Monitoring: research subject, medical staff, environment, visitors

and handling of vectors by highly skilled researchers. Further, the limited number and small size of trials makes it impossible to assess the possibility of rare adverse events.

The issues to be assessed in developing infection control policies are described in Table 69-6. In general, patients should be placed on isolation precautions based on the vector, mode of transmission, and risk of transmission. All patients should be managed using Standard Precautions. Other CDC Precaution categories should be used as previously described. Measures should be in place to prevent sharps injuries.

Gene transfer vectors should be managed in the laboratory using NIH biosafety guidelines. Research personnel should be trained in the proper use of PPE. Vectors should be disposed of as regulated medical waste. Surface decontamination should be performed using EPA-registered hospital disinfectants unless the vector requires other agents to ensure inactivation. In general, the pharmacy should adhere to similar safety guidelines such as preparing vectors for administration in an appropriate biosafety cabinet and use of appropriate PPE.

The infection control policy should also address the screening and potential exclusion of personnel (e.g., workers with potential adenovirus infection), need for immunizations (e.g., vaccinia immunization), and management of personnel with accidental exposure to the vector (e.g., sharps injury).

Gene transfer studies have been conducted in the United States for more than 20 years. To date, such studies have not resulted in demonstrated illness or infection in healthcare personnel. Thus, healthcare personnel should be reassured that the recommendations described in this chapter can protect their safety.

CONCLUSIONS

Gene therapy is at the cutting edge of science. Appropriate infection control practices will need to be based on technologic advancements within the field of gene therapy, scientific assessment of the adequacy of current containment practices, and ongoing evaluation of risks to patients and healthcare personnel.

ACKNOWLEDGMENT

The authors wish to thank Jacqueline Corrigan-Curay, J.D., M.D., Acting Director, Office of Biotechnology Activities, National Institutes of Health, for her careful, thoughtful, and constructive review of this chapter.

SECTION IX

Prevention of Healthcare-Associated Infections Related to the Hospital Environment

CHAPTER 70

Central Sterile Supply

Lynne M. Sehulster

Reliable sterilization of surgical instruments, textiles, utensils, and innumerable other items essential to medical care is one of the oldest and most basic measures for the prevention of healthcare-associated infection (HAI), dating back to the studies of Louis Pasteur and Robert Koch over a century ago *(1)*. The central sterile supply (CSS) unit, or sterile processing department, is a specialized service area of virtually all hospitals and an increasing number of nonhospital healthcare settings (e.g., ambulatory surgical centers). This service area is responsible for collecting and receiving reusable patient-care items (e.g., instruments and devices) used during the provision of healthcare and for cleaning, reprocessing, and distributing these items back to appropriate patient-care areas in the healthcare facility (e.g., operating rooms [ORs], intensive care units). CSS units are often called upon to manage the receipt and distribution of sterile, single-use, disposable patient-care items and other consumables as well. Patient safety is the overriding objective for all aspects of CSS activities.

The delivery of safe products for use in patient care, however, depends not only on the efficacy of the microbial inactivation processes (e.g., sterilization, high-level disinfection) and a thorough understanding of these processes and instrument cleaning, but also on a well-designed facility, good infection prevention practices, effective quality control, and use of proven device management procedures before, during, and after device reprocessing *(2)*. The CSS unit should have in place policies and procedures governing all aspects of activity within the unit. Key elements in these documents include but are not limited to (a) engineering and facilities management requirements; (b) infection prevention; (c) quality assurance and process management; (d) occupational safety and health; (e) employee training and competency demonstration; and (f) traffic control *(3)*. Furthermore, the CSS unit should develop policies that address oversight of instrument reprocessing located elsewhere in the facility.

The findings and conclusions in this report are those of the author and do not necessarily represent the official position of the Centers for Disease Control and Prevention (CDC). Use of trade names and/or proprietary product names is for identification purposes only and does not constitute an endorsement by CDC or the U.S. Public Health Service.

GENERAL CSS UNIT DESIGN, ENVIRONMENT, AND INFRASTRUCTURE

CSS Unit Design, Configuration, Function

A CSS unit is divided generally into distinct areas based on unique functions (4,5). These areas should be partitioned into separate units whenever possible; separation of soiled and clean work areas is especially important to minimize spread of contamination. The receiving, decontamination, and cleaning area has work tables, sinks, and equipment to facilitate sorting, initial decontamination of, and thorough cleaning of devices and reusable items. Some washer–decontamination equipment units are designed with pass-through doors to allow items to move from the soiled area to a clean area in a single pass, thereby avoiding recontamination (4). The clean side of a CSS unit encompasses several functions. These include a preparation and packaging/tray

assembly, the sterilization area where the various sterilizers are located, an area for ethylene oxide (ETO) sterilization and aeration (if such a sterilizer is present), and a storage space for sterilized packs. If the hospital has a laundry on site, the surgical pack room where clean textiles are prepared for surgical packs to be sterilized may be located on the clean side as well (6). Other function-specific areas within the CSS unit include (a) a materiel management area (if assigned to the CSS unit) for incoming new, packaged manufactured supplies; (b) an equipment and cart holding area for sterilized packages awaiting distribution within the hospital; (c) an equipment storage area; (d) housekeeping and a housekeeping equipment storage room; (e) the personnel support area; and (f) the administrative area.

The design of a CSS unit takes into account the flow of the work load and the type of material distribution system. Distribution may be accomplished by automation (e.g., vertical or horizontal conveyor, pneumatic tube systems), powered delivery carts, or manual pickup and delivery. Hand washing facilities should be conveniently located throughout all areas within the CSS unit (4,5). Emergency eye wash stations and showers should be available in areas where chemicals are used (5). The layout of the CSS unit should allow for adequate space for personnel and equipment/cart movement. Clean areas should have adequate space for work tables and appropriate equipment and sterilization supplies support to facilitate the assembly of instrument trays and packages for sterilization. Equipment and cart areas should be readily accessible from the clean areas. CSS units may or may not serve as materiel management operations for the facility. If this function is assigned to CSS, the decasing/breakout area is used to accommodate the unpacking and distribution of manufactured clean supplies to locations elsewhere in the hospital. Alternatively, some of the purchased items may be sent to the preparation/assembly area to be packaged for sterilization. The material management area is usually located near the clean area but not in it (4,5). This helps to prevent introduction of environmental contamination often associated with packaging materials such as corrugated cardboard. The personnel support area provides space for toilet, shower, and locker facilities for employees. If the surgical pack room functions are assigned to the CSS unit, this is usually a room where clean textiles are inspected, repaired as needed, folded, and assembled into wrapped packs to be sterilized (6). If the hospital's laundry service, including surgical pack assembly, is provided by an outside contractor, the CSS unit must develop policies and procedures to have those packs delivered to the CSS unit for sterilization.

Climate Control and Ventilation Requirements

Adequate humidity, ventilation, and temperature control are important for prevention of environmental contamination of reprocessed items, provision of appropriate storage of sterile goods, and maintenance of a safe workplace. Temperatures in CSS areas vary, but it is common to find the temperature in general work areas, administrative areas, and personnel support areas set at 75°F (24°C). The main exception is for the cleaning/decontamination area where temperatures are in the range of 60°F to 68°F (15.6°C–20°C) as recommended by the Association for the Advancement of Medical Instrumentation (AAMI) (5). This provides an adequate comfort range for the workers who must wear substantial protective attire throughout the day. Humidity levels in CSS areas should be set generally in the range of 30% to 60% (4,5). The ventilation system should be designed so that air flows from clean areas into soiled areas and is exhausted to the outside or, if recirculated, passed through an appropriate bank of filters (e.g., a high-efficiency particulate air [HEPA] filter) for return to the system (4,5). Depending on which standards organization's benchmarks are used for reference, 4 to 10 air changes per hour (ACH) are specified for CSS ventilation, with a minimum of 6 to 10 ACH in the cleaning/decontamination area and a minimum of 10 ACH in the area where the sterilizer equipment is located (4,5). The areas under negative pressure (i.e., cleaning/decontamination, sterilizer loading area, and restrooms/housekeeping) are vented directly to the outside, whereas air from the other areas of CSS can be recirculated. Table 70-1 depicts the ventilation benchmarks set by two major standards resources.

The Joint Commission has updated the hospital accreditation standards for 2011 to reflect adoption of the Facility Guidelines Institute (FGI) *2010 Guidelines for Design and Construction of Health Care Facilities* (4,*7,8*). According to the Joint Commission, architects and design engineers for any new hospital construction or major renovation projects (including those in the CSS unit) initiated after January 1, 2011, need to use the 2010 edition of the FGI guidelines or look to relevant state rules and regulations pertaining to hospital construction.

Utilities Infrastructure

The availability and configuration of systems that provide steam, hot and cold water (or water of a temperature specified by reprocessing equipment manufacturers), distilled or demineralized water, compressed air, nitrogen, vacuum sources, electrical power, air exhaust, and drainage of sewage are important to consider when designing the CSS unit and installing equipment (*3*,4,5). The electrical system in the unit should allow for the safe and efficient operation of equipment and provide for adequate lighting. Availability of a source of uninterrupted power is recommended in the event of an emergency (5).

Moist heat sterilization methods (i.e., saturated steam under pressure) remain the primary choice for terminal reprocessing of heat-stable instruments and devices. The quality of the steam is critical to the efficient operation of these sterilizers, and there should be sufficient steam capacity engineered into the system to accommodate this demand. Hospital boiler systems may not be capable of providing steam of sufficient quality; self-contained packaged steam generators are another option. If a boiler is used, the equipment must be serviced and maintained by trained personnel. Additionally, the steam distribution system and piping should be insulated to prevent steam condensation to water while en route to the sterilizer *(9)*. Steam delivered to the steam sterilizers should be saturated steam with a steam quality between 97% and 100% (5,10). The purity of the steam should meet or exceed International Standards Organization (ISO) recommendations for limits on heavy metals, conductivity, pH, appearance, hardness, chlorine, phosphate, and evaporate residue (5,*11*).

KEY ELEMENTS OF INSTRUMENT AND DEVICE REPROCESSING

Effective sterilization of items depends not only on reliable operation of the gas, steam, or low-temperature sterilizers, but also on correct methods of cleaning, packaging, arrangement of items in the sterilizer, and storage of these items. Likewise, if it is appropriate for a device to receive high-level disinfection, the success of this process depends on thorough precleaning, adherence to disinfectant use conditions, followed by thorough rinsing and drying.

Cleaning and Decontamination

The essential first step to any terminal reprocessing strategy for reusable medical instruments and devices is the reduction of bioburden. Debris such as blood, mucus, oil, or other foreign matter interferes with the sterilization process by acting as a barrier to the sterilizing agent (5,*12*,13). Additionally, cleaning and decontamination of used instruments render those instruments safe for CSS unit staff to handle during further reprocessing *(14)*. Retained debris can also affect the functionality of a device at the point of use, resulting in additional patient safety concerns *(15)*.

A process definition of cleaning is the removal of all adherent visible soil from the surfaces, crevices, joints, and lumens of instruments. Decontamination is the physical or chemical process that renders a potentially contaminated, inanimate object safe for further handling (5,*15–18*). The techniques for instrument cleaning and decontamination are manual scrubbing with brushes, ultrasonic cleaning, and processing with a washer–sterilizer or washer–decontaminator *(15)*.

Initial Considerations Instruments in general should be kept moist prior to cleaning. Dried-on debris is more difficult to remove. Disinfection or sterilization cannot be accomplished if gross contamination is present on the instruments at the time when the final reprocessing steps are initiated (12,*15,16,18,19*). Instruments should be covered with a wet cloth and then contained for transport to the CSS unit. Soaking instruments in water or other fluid during transport is discouraged because of the risk of spills and the danger of injury to workers in lifting heavy basins or containers. Once in the CSS area, instruments contaminated with organic matter may be immersed in an enzyme detergent solution to enhance manual or mechanical cleaning effectiveness. Enzyme soaks keep debris suspended in solution, preventing its deposition and drying onto the surface of instruments. When employing this method, care should be taken to use the appropriate use-dilution, water temperature, and soak times as provided by the specific manufacturer of the enzyme detergent. Additionally, workers may get a false sense of security about the safety of handling the instruments immersed in a presoaking solution. These instruments are not yet safe to handle without personal protective equipment (PPE).

The use of an appropriate detergent avoids damage to instruments, prolongs their use life, and prevents the creation of crevices in which debris can collect *(20,21)*. One inadvertent result of the implementation of Standard Precautions has been the increasing use of disinfectant/detergent agents for presoaking or manually cleaning medical instruments. Agents that contain chlorinated compounds (e.g., bleach) or that are highly acidic or alkaline can damage the surface layer of stainless steel instruments, resulting in corrosion and weakening. It is important to use only those detergent and disinfectant products specifically labeled for instrument cleaning. Hard surface disinfectant/detergents registered by the U.S. Environmental Protection Agency (EPA) are generally intended for cleaning and disinfecting large environmental surfaces (e.g., floors, walls, and table tops) and are not appropriate for general use on instruments.

Manual Cleaning Manual cleaning of instruments at the sink is still done and may be necessary for powered equipment and some extremely delicate items or to apply direct water pressure to contaminated lumens. Cleaning agents commonly used in manual cleaning contain surfactants, and some mechanical cleaning action (i.e., scrubbing, brushing) is needed for the effective removal of organic matter. During the cleaning and decontamination process, personnel must wear appropriate protective apparel (e.g., fluid-impervious gown or apron with full sleeves, latex or vinyl gloves that resist puncture or tearing during the process, face shield or surgical mask and goggles, a hair covering, and impervious shoe covers) (22). Such items provide the worker with protection from wetness and exposure to body fluids and tissues *(23)*. Splatter or aerosols generated during hand scrubbing should be kept to a minimum through appropriate cleaning techniques (e.g., keeping brushes under water during scrubbing) (5).

Whenever possible, scrubbing the devices by hand should be avoided, because it increases the worker's contact with contaminated surfaces and involves the added danger of handling sharp and pointed objects, thereby increasing the risk of sustaining percutaneous injuries. Sharp instruments should not be cleaned by hand when they can be effectively washed in a machine. Furthermore, contaminated, reusable sharps must not be stored or reprocessed such that the worker would have to reach into a container to retrieve the item *(20)*. Alternatives that can help prevent these injuries include using forceps retrieval or a perforated tray so that the devices can be cleaned *in situ* (22).

Ultrasonic Cleaning Ultrasonic cleaning is a method that reduces the need for hand scrubbing. The ultrasonic washer cleans by cavitation, a process whereby sound waves produce vigorous microscopic implosions of tiny vapor bubbles on the surface of objects immersed in the cleaning chamber (5,13). This agitation causes a vacuum-scrubbing action, pulling out fine debris particles from manually inaccessible surfaces (e.g., box-lock joints and serrations). Ultrasonic cleaning is not suitable for all devices. Refrain from using ultrasonic technology on chrome-plated instruments; powered instruments; endoscope lenses; or items made of rubber, silicone, or plastic (24). Items should be rinsed to remove gross soil before being placed in the ultrasonic washer. When grossly soiled items are placed into the ultrasonic washer, the process is less effective because the debris absorbs the sound waves. The water needs to be changed more frequently as well to minimize the amount of tissue and gross soil, but also to minimize the buildup of gram-negative bacteria, biofilm,

and endotoxin. Ultrasonic technology produces aerosols that reflect the fluid contents of the chamber; operation of the ultrasonic cleaner unit without a chamber cover allows these aerosols to escape. Because of this, the ultrasonic washer should be located in the decontamination area of the CSS unit. The potential hazards to personnel from aerosolization of such contaminated fluids should be considered when planning CSS worker safety programs. Exposure to such fluids should be prevented by use of engineering controls, changes in work practices, or use of PPE. The unit's chamber should be disinfected, rinsed, and dried at the end of the day. The manufacturer's directions should be followed for optimal results (5,*17,18,20*,24,*25*).

Automated Reprocessing Systems Washer–sterilizers use one of two methods to wash chamber contents. The first is a flooding technique, in which the chamber partially fills with water to which detergent has been added and then is agitated by blowing steam into the chamber through the water. These units generally operate at 270°F (132°C). This is an inefficient cleaning method that should not be relied on when there are lumened or complex devices in the load. The second method is generally used in larger, tunnel-type units. In these, rotating spray arms create water jets that clean by impingement. In this second category, most machines reach a temperature of 285°F (141°C) *(17)*.

Washer–decontaminator or washer–disinfector machines easily remove excessive amounts of debris from instruments by using spraying water aimed to cover all parts of the load. The numerous water jets allow excellent cleaning even if instruments are grossly soiled. The agitation of the water is such that it cleans instruments thoroughly without tossing them about, thereby reducing the risk of damage to delicate items. The operating water temperature is generally around 140°F (60°C), below the level at which protein rapidly coagulates, making removal easier than at higher temperatures *(15,25)*. Appropriate soap and disinfectant should be used in accordance with the manufacturer's instructions *(17)*.

Automated cleaning/decontamination equipment must be loaded, operated, unloaded, and serviced in accordance with manufacturer instructions (22). Washer racks should never be overloaded, and the placement of loaded racks in the equipment chamber should allow sufficient clearance for the water jet arm to move freely. Instruments in the racks and trays should be open and disassembled if appropriate to allow maximum contact with water and cleaning agent. Routine service typically includes visual inspection for mineral deposits that should be removed.

It is important that these automated systems are cleaned and maintained regularly in accordance with the manufacturer's instructions to prevent the colonization of the equipment with bacteria (e.g., *Pseudomonas aeruginosa* or nontuberculous mycobacteria [NTM]). Outbreaks of HAIs and episodes of pseudoinfections related to endoscopy and bronchoscopy have been attributed to contaminated washer–disinfectors through molecular epidemiology and strain identification techniques *(26–29)*. Bacteria, particularly those microorganisms commonly found in tap water (e.g., *Pseudomonas* species), can become resident in poorly maintained equipment through the formation of biofilms that may help protect the bacteria from inactivation with liquid chemical germicides *(29–34)*. This phenomenon has led some to explore ways to enhance quality assurance of the process in the interest of patient safety. A recent issue of debate is the sampling of the automated endoscope reprocessing system (AER) rinse water to help verify that in-line bacteriologic filters are performing according to specifications *(33)*. This position, however, is still not widely embraced by the endoscopy community at present, although debate continues (13,*35*).

Automated cleaning/decontamination processing is not indicated for all instruments and devices. This processing is not appropriate for washing electrical devices, battery-operated devices, or pneumatic operated equipment and devices (22). Instruments and devices with such features must be cleaned manually. However, the use of automated cleaning/decontaminating systems offers some advantages over manual cleaning. The process is controllable and minimizes worker contact with contaminated items *(14,36)*. Automation can enhance the quality assurance for the cleaning portion of the overall instrument reprocessing strategy. A wide variety of mechanical washer–cleaners from a number of manufacturers is available, and new technology continues to be developed. New innovations that increase worker safety and protection are especially in demand *(37)*. No single approach to decontamination and cleaning is effective for all instruments and degrees of contamination. Risks and benefits are associated with each method, and it is the responsibility of the CSS unit director to become familiar with relevant standards, guidelines, and information from the medical literature to determine best practices for decontamination and cleaning.

Endoscope Reprocessing The cleaning and terminal reprocessing of flexible fiberoptic and video endoscopes and bronchoscopes are often performed by specially trained technicians in the care units where these instruments are used. Nevertheless, CSS managers should have some oversight of the policies and procedures in these satellite reprocessing areas. Briefly, endoscopes (categorized as semi-critical devices according to the Spaulding Classification) are cleaned and subjected to either sterilization or high-level disinfection (13,38). From a practical perspective, high-level disinfection is chosen because these devices are heat sensitive (thereby precluding use of steam sterilization), but also for effectiveness of this disinfection process and its reasonably rapid turnaround time *(39)*. At present, the only sterilization process available for endoscope reprocessing is that of ETO sterilization. However, this process may not be suitable or appropriate for makes and models of endoscopes, and the required aeration time is very long (e.g., ~18 hours), which makes this an impractical choice (13,*40–42*). Immersion in a liquid chemical sterilant is also an impractical method due to the lengthy contact time periods (e.g., 10 hours). The practical alternative (i.e., liquid chemical sterilization using peracetic acid as the active ingredient in a proprietary system [Steris System 1, S20 sterilant]) is not an option at present due to recent regulatory action by the U.S. Food and Drug Administration (FDA). FDA has determined that this equipment and its proprietary chemical agent are adulterated and misbranded products *(43)*. Consequently, this chemical sterilizing system has been withdrawn from the market (44).

Effective reprocessing of these instruments begins the moment they are removed from the patient (13,38). All surfaces of the endoscope or bronchoscope should be kept moist until cleaning and further reprocessing can be performed. Although endoscopes can be cleaned with manual scrubbing and disinfected using immersion into liquid sterilant (with a short contact time validated for disinfection) or high-level disinfectant, AERs for washing and disinfection are the predominant choice for the reprocessing of these instruments primarily for the effectiveness of the process, but also because of space limitations in the care unit. One critical point to remember is that all AERs on the market today require that the endoscope or bronchoscope be manually rinsed so that gross soil is removed before placing the instrument in the AER. Some units also require the use of special connection devices that may be specific to a type or model of instrument *(26)*. Use of appropriate connectors helps to ensure that the liquid chemical sterilant or high-level disinfectant can effectively reach the interior surfaces of the instrument's channels (13,*45*) Thorough rinsing with sterile water, or tap water if sterile water is unavailable, is necessary to remove disinfectant residues that could lead to adverse patient reactions (13,38). An alcohol rinse is used primarily as a drying agent to help eliminate any residual moisture in the lumen of the device. Reprocessed endoscopes should be hung vertically in a designated cabinet to drain and dry until next use (13,38). A reprocessed endoscope should never be stored until next use in its original case (with the original protective padding). This practice prevents the internal channels of the instrument from drying in a timely manner, but more importantly the padding in the case usually becomes wet, leading to a buildup of bacterial contamination of the padding that in turn will contaminate the endoscope (13,38).

Packaging

Materials used for hospital instrument wrapping and packaging should provide a cost-effective means of containment to maintain the sterility of the contents (5,22,46). An intact wrapper impervious to extraneous microbes, moisture, dust, and soil, and strong enough to resist punctures and tears during normal handling, theoretically should protect properly sterilized material indefinitely. However, such materials may also impede the passage of steam, ETO, or the sterilants in low-temperature sterilizing systems, thus interfering with the sterilization process. Therefore, compromises from this ideal must be made for items processed in healthcare facilities because of the limited choices available for terminal sterilization. Additionally, wrapping materials should (a) provide a seal of proven integrity, (b) be resistant to delamination when the pack is opened, (c) be free of pinholes, (d) allow suitable printing or labeling, (e) minimize the generation of nonviable particles, (f) provide evidence of tampering, and (g) produce minimal or no lint if fabric is used *(47–49)*.

Packaging materials should be compatible with the sterilization process. When the steam sterilization process is used, the materials should allow adequate air removal, steam penetration, and drying (5,46). When ETO sterilization is used, materials should allow adequate penetration and release of the gaseous sterilant and moisture, a function that is especially important during aeration. Packaging materials for use with hydrogen peroxide gas plasma sterilizers and ozone sterilizers should be made from materials that are compatible with those processes to allow effective sterilant penetration and will not interact with the contents of the pack (46). Manufacturers of sterilizer equipment should provide the user with some indication of which packaging materials are suitable for their units.

Packaging materials should also be inexpensive, impervious to bacteria, sealable before sterilization, and flexible enough to permit swift wrapping and unwrapping (46,*50,51*). Materials should be evaluated and selected according to their performance properties rather than according to whether they are woven, nonwoven, reusable, or disposable *(52)*.

Muslin (i.e., 140 thread count, 100% cotton fabric) was the standard for many years in packaging for healthcare facilities, and some healthcare facilities continue to use textile packaging. Other fabrics have been used for packaging, including duck cloth, twills, barrier cloth, and treated barrier fabrics (22). Textile packaging is generally a reusable product, but this means that the textile needs to be laundered and inspected for fabric integrity. Patching of reusable fabrics is acceptable as long as the patches are applied with adhesive and not sewn in place. The critical factor is the amount of nonoccluded surface left after patching and folding (6). It is also important that textile packaging be stored at room temperature and humidity for at least 2 hours before use. This approach minimizes moisture buildup in the textile, thereby preventing superheating of the pack contents during steam sterilization (22).

Before a textile wrapper can be marketed, the product must be cleared by the FDA for use as a sterilization wrapper. In addition, consideration should be given to requiring that the material pass the American Society for Testing and Materials (ASTM) standard test method for resistance of protective clothing materials to synthetic blood (53).

Durable containment for instruments and devices is another option. FDA-cleared rigid containers, instrument cases, instrument cassettes, and organizer trays are commonly used (46). Regardless of what type of packaging is used to prepare packs for sterilization, packs should not exceed 25 lb in weight (46). This includes both the contents of the pack and the wrapper or containment.

Policies and procedures for in-house packaging should be written, reviewed annually, and readily available within the institution (46,*47–52*,53,*54–58*).

Activities Associated with the Sterilization Processes

General Principles The first thing that must be considered before subjecting a cleaned, reusable device or patient-care item to a sterilizing process is whether or not the materials are compatible with that process. Saturated steam sterilization is the most commonly available processing method in healthcare facilities, and it should be used whenever the device or instrument can tolerate moist heat because of the inherent reliability and robustness of the process and its low cost relative to other methods. However, heat-sensitive materials are being incorporated increasingly into modern medical devices and patient-care items. A number of modern, low-temperature sterilizing

systems provide alternatives for the sterilization of heat-sensitive materials. When making the decision to purchase a low-temperature sterilizing system/equipment, it's important to have a clear sense of what types of instruments and medical devices will be reprocessed in this equipment and to carefully consider the manufacturer's equipment information and advisories for use. Some device materials may be incompatible with some of these newer processes, and such interactions may physically degrade the item, destroy its material, or leave toxic residuals on or in the treated item *(58,59)*.

Currently, the FDA-cleared sterilization processes/technologies used in CSS units are: (a) saturated steam under pressure (steam sterilization); (b) ETO sterilization; (c) hydrogen peroxide gas plasma sterilization; (d) dry heat ovens; and (e) ozone sterilization. A detailed description of each of these processes can be found in Chapter 81 in this text.

It is important to remember, however, that all sterilizing systems have inherent limitations and that no single system can be used effectively for all instruments and devices *(60)*. A common problem with any sterilizing system is the ability of the sterilizing agent (e.g., steam, gas, gas plasma) to diffuse throughout the chamber and the load so that the agent makes contact with all surfaces (both exterior and interior) of the items undergoing sterilization. In steam autoclaves, trapped air, either in the chamber or within an instrument or container, can prevent effective penetration of the steam to all surfaces in the load. Instrument design (e.g., a long, narrow lumen) can pose significant challenges both for effectiveness of the cleaning procedures and sterilant diffusion. Load configuration and density must be carefully controlled to allow air removal, sterilant penetration, and drying in steam sterilization cycles. This is especially critical if the sterilizer relies on gravity displacement to remove air (5,22). For steam sterilizers that have mechanisms to assist in air removal (e.g., dynamic-air removal using pulsing steam or vacuum conditioning phases), the configuration and density issues are not as great, but drying may still be a problem if the sterilizer is overloaded (5,22). The performance of low-temperature systems, including ETO and gas plasma, is particularly affected by the presence of residual organic matter, salt, and moisture *(61)*.

Loading the Sterilizer Chamber: Key Considerations

All articles to be sterilized should be arranged so that all surfaces are directly exposed to the sterilizing agent for the prescribed time and at the prescribed temperature and humidity as appropriate. All hinged instruments should be open and/or unlocked. Reliable sterilization depends on both the sterilant's contact with all surfaces of the item and the duration of that contact. All articles should be aligned on sterilization carriers or in the sterilizer so as not to interfere with air removal and introduction of sterilant. Instrument sets should be placed in perforated wire mesh bottom trays or in instrument container systems (5,22). They should not be tilted on edge, as this results in the concentration of metal mass at the bottom of the tray. This arrangement interferes with drying *(15)*. Wrapped trays should not be stacked, as instrument damage can result. Rigid, reusable, sterilization container systems may be horizontally stacked if the container design permits adequate penetration of the sterilant. The container manufacturer's written instructions on this point should be followed.

When items are nested in one package, they should be separated by absorbent towels or other moisture-absorbent material. This enhances the passage of steam to all surfaces during sterilization and facilitates drying by preventing the pooling of condensate. Nested items should be positioned in the same direction so that (a) air pockets are not created, (b) condensate can drain out, and (c) sterilant can circulate freely *(62)*.

Sterilization Cycle Parameters Sterilizer equipment manufacturers are required to develop validated sterilization cycle parameters in order to obtain FDA clearance of said equipment. Depending on the sterilizing technology, the parameters may include but are not limited to time, temperature, humidity, pressure, concentration of the sterilant, aeration time, dry time. Standard cycles are typically used to sterilize the majority of surgical instruments and devices that are fairly simple in design and materials (e.g., heat-stable metal, manual instruments). Table 70-2 depicts sterilization cycle parameters for routine loads for steam sterilizers as compiled by AAMI (5). Sterilizer manufacturers will typically program these standard cycles into the equipment.

More recently, manufacturers of complex instruments (e.g., instruments with complex design, increased weight, powered instruments) are indicating in their reprocessing instructions that extended sterilization cycles (i.e., longer contact time with the sterilant, increased dry time) are necessary for the successful terminal reprocessing of these instruments (63). It is important to consider both the sterilizer equipment operating instructions and the instrument reprocessing instructions to determine the appropriate cycle parameters. When there are differences between these two instructions, the instrument instructions should take priority *(64)*. Invariably, this means that extended cycle instruments cannot be autoclaved with standard cycle instruments in the same load (63). Furthermore, not all extended cycle instruments have the same validated cycle requirements. The result of this is that it may be necessary to process a few instruments at a time rather than in a full load (63). In addition to sterilizer operating instructions, CSS units should ensure that there are written reprocessing instructions for all instruments, but it's especially important for all extended cycle instruments *(64)*.

Performance records for all sterilizers should be maintained for each cycle, including load contents and retained for the period indicated by the individual healthcare facility and/or the state's statute of limitations. Records for implantable devices should allow for tracking from the sterilizer to the point of use. These records may be used as documentation for product recall and quality assurance (5,10,22). All packages should have internal and external chemical indicators appropriate for the sterilizing system used (i.e., steam or low-temperature systems using ETO, gas plasma, or ozone).

Methods to Monitor the Sterilization Process Monitoring the sterilization process is an important quality assessment procedure for infection control and patient safety. The three forms of monitoring are (a) physical monitoring (observing and recording the parameters of

TABLE 70-2

Minimum Parameters for Steam Sterilization Cycles Used in Healthcare Facilities

Cycle Times for Gravity-Displacement Steam Sterilization Cycles

Item	*Exposure Time at 121°C (250°F) (min)*	*Exposure Time at 132°C (270°F) (min)*	*Exposure Time at 135°C (275°F) (min)*	*Drying Times (min)*
Wrapped instruments	30	15		15–30
			10	30
Textile packs	30	25		15
			10	30
Wrapped utensils	30	15		15–30
			10	30
Unwrapped nonporous items (e.g., instruments)		3	3	0–1
Unwrapped nonporous and porous items in a mixed load		10	10	0–1

Cycle Times for Dynamic-Air Removal Steam Sterilization Cycles

Item	*Exposure Time at 132°C (270°F) (min)*	*Exposure Time at 135°C (275°F) (min)*	*Drying Times (min)*
Wrapped instruments	4		20–30
		3	16
Textile packs	4		5–20
		3	3
Wrapped utensils	4		20
		3	16
Unwrapped nonporous items (e.g., instruments)	3	3	NA[a]
Unwrapped nonporous and porous items in a mixed load	4	3	NA

Check the instructions for your sterilizer to ascertain the manufacturer's cycle specifications.

sterilizer functioning, such as time, temperature, pressure, or gas concentration); (b) chemical monitoring (color- or physical-change indicators that detect exposure to sterilizing agents or conditions); and (c) biologic monitoring (spore testing, the most important check on sterilizer function). Additional information about sterilization process monitoring can be found in Chapter 81.

Physical Monitoring Physical data (e.g., physical parameters information for time, temperature) are usually the first indications of whether or not the sterilization process is consistent with manufacturer recommended cycle parameters. For each sterilization cycle, the mechanical readings should be checked on the printout at the conclusion of the cycle. Sterilizers without such printouts (either in digital or chart form) are not appropriate for modern acute care facilities and other healthcare venues and should be phased out of use as soon as economically feasible. Any deviation from the expected normal readings of the various parameters (e.g., time or temperature) should alert the operator to potential problems (5,22).

For steam sterilizers that use a vacuum assist to remove air at the beginning of the cycle (dynamic-air removal steam sterilizers), a Bowie-Dick–type test should be run daily at the beginning of the day to ensure that this key operation in the system is working properly (5,22). If this test indicates that air is not effectively removed from the sterilizer chamber, the sterilizer needs to be taken out of service for maintenance/repair. Prior to the sterilizer being returned to service, a repeat Bowie-Dick test is run on the sterilizer to confirm that the air removal problem has been corrected.

Chemical Indicators Chemical indicators are devices to provide information relative to the achievement of one or several of the conditions necessary to destroy microorganisms by a sterilization process. Some chemical indicators can indicate that a device has been exposed to a sterilization process (e.g., a throughput or process indicator), while others may provide more detailed information on the exposure conditions endured by the device. They can be useful for (a) monitoring product flow, to make sure that unprocessed product is not mistaken for that which has been sterilized; (b) ensuring the use of proper packing and sterilizer load configurations; and (c) ensuring the proper functioning of the processing equipment (5,22,*65*).

Chemical indicators are intended for use in conjunction with other process monitoring systems. The AAMI and the International Organization for Standardization (ISO) have designated six classes of chemical indicators available in the United States (5,22,*66*,67,68,*69*,70). These classes are (a) Class 1—process or throughput indicators, typically affixed to the external surface of the pack or rigid containment; (b) Class 2—specific test indicators, of which the air removal indicator (Bowie-Dick tests) is the prototype; (c) Class 3—single parameter indicators, designed to react to one aspect of the sterilization process (e.g., temperature); (d) Class 4—multiparametric indicators, designed to react to two or more parameters of the sterilization process; (e) Class 5—integrating indicators that are designed to react to all of the critical parameters over a specified range of sterilization cycles; and (f) Class 6—emulating indicators that are designed to react to all of the critical variables of specified sterilization cycles, with stated values having been generated from the critical values of the specified sterilization process (5,22,*66*,67,68,*69*,70). Class 3, 4, 5, and 6 indicators are all designed to be inserted into a pack to demonstrate that the target parameter(s) of the sterilization process has been achieved. When a Class 5 integrator chemical indicator is used according to manufacturer instructions, it can provide very accurate information about the sterilization process. Class 6 chemical indicators (emulating indicators) must be specific for each sterilization cycle and sterilization technology. Consequently, the CSS unit must have a different Class 6 emulating chemical indicator for each sterilizer time/temperature combination used (5,22). As the availability of Class 5 and Class 6 chemical indicators is a recent event in the US healthcare market, readers should consult AAMI standards for more detailed information regarding use of these devices (5,*66*,67,68,*69*,70). When used properly, the performance of the Class 5 and Class 6 chemical indicators has been correlated to the performance of a biological indicator (BI), but it should be emphasized that these chemical indicators are not intended to replace or be used to the exclusion of a BI. Class 1 to 6 chemical indicators are available to monitor steam sterilization processes. Class 1, 3 to 6 chemical indicators can be used with dry heat sterilizers and ETO sterilizers. Consult the sterilizer manufacturers for ozone and hydrogen peroxide gas plasma sterilizers for their recommendations regarding selection of appropriate chemical indicators.

Biological Indicators In the early 20th century, microbiologists and clinicians began to seek further assurances of sterility of reprocessed items beyond monitoring the physical variables, and suspensions of bacterial spores came into use as a biologic means of monitoring steam sterilization. The earliest culture control used was garden soil to which had been added a number of sporulating cultures of known resistant laboratory strains. In the late 1950s, commercially manufactured BIs began to be used in US hospitals *(1,71)*. These consisted of standardized preparations of *Geobacillus stearothermophilus* (formerly known as *Bacillus stearothermophilus*) spores with defined heat-kill characteristics.

BIs are defined in the AAMI standard as a calibration of microorganisms in or on a carrier put up in a package that maintains the integrity of the inoculated carrier while allowing exposure to the sterilant, is convenient to the user, and serves to demonstrate whether the conditions were adequate to achieve sterilization (5,*65*). BIs are standardized bacterial spore populations known to be resistant to the particular sterilant and physical methods of sterilization to be monitored. Thus, no single BI can be used reliably to monitor all of the various physical methods of sterilization. There are three basic types of BIs: (a) paper strips inoculated with bacterial spores; (b) self-contained BIs, in which the spores are enclosed in a carrier; and (c) enzyme-based BIs *(72)*. Of these, only the enzyme-based BIs are capable of providing rapid readout of results, generally in a matter of hours, as opposed to the 48 hours incubation required for determining growth. There are two types of enzyme-based indicators. One such product contains only the enzyme itself and is regarded by the FDA as a chemical indicator (either Class 4 or 5, depending on data submitted to the FDA). Another type relies on the reaction of an enzyme that is actually in the spore coat of a microorganism known to be resistant to the method of sterilization. This second type can be used either as an early readout indicator when only the enzyme reaction is assessed or as a typical BI if the spores are actually incubated in growth media.

At present, the Joint Commission, AAMI, and the Association of periOperative Registered Nurses (AORN) recommend using *G. stearothermophilus* spores for steam sterilizers, ozone sterilizers, and hydrogen peroxide gas plasma sterilizers; and *Bacillus atrophaeus* (formerly known as *Bacillus subtilis* var. *niger*) spores for ETO sterilizers and dry heat ovens (*8*,73,*74,75*). The Centers for Disease Control and Prevention (CDC) concurs with the use of gram-positive bacterial spores for BIs (13). Manufacturers of low-temperature sterilizer equipment should provide the user with information on the proper selection of an indicator system for use with their equipment. All hospital steam autoclaves should be monitored at least weekly with BIs, although many CSS units are monitoring their equipment daily. The Joint Commission, AORN, and AAMI also recommend monitoring every load sterilized by ETO. Each load containing implantable objects should be monitored with a spore test. The Joint Commission, AORN, and CDC further recommend that sterilizer loads containing implantable devices or intravascular devices should not be released until the spore test has been reported as negative. It is recognized, however, that in an emergency situation it may not be possible to quarantine implantable items for the 48 hours necessary for BI incubation (culture assay), especially if the assay of the indicator is dependent on growth of survivors. Rapid BIs (e.g., enzyme-based indicators) may alleviate this situation. The enzyme-based indicator measures a spore-specific enzyme, α-D-glucosidase, which is inactivated proportionally with the inactivation of the spore population. The assay of this enzyme-based indicator can be accomplished in a matter of minutes, and it has been shown that this BI is equivalent in sensitivity to the more conventional BIs (13,*76*). The availability of this type of BI may encourage more healthcare facilities to incorporate this quality assurance process into their services. A questionnaire survey of US hospitals in the late 1980s showed that 30% of 120 hospitals used a spore test with all loads containing implants. Furthermore, few hospitals using spore tests in the late 1980s quarantined the items until results were available *(77)*. The AAMI has recently endorsed the routine

release of all steam-sterilized loads, including implantable devices, based on the results of the enzyme readout only for the enzyme/spore combination BI *(74)*.

The BI pack should be placed in the area of the sterilizer that will present the most challenge to all sterilization parameters. For steam sterilizers, the BI should be placed at the front on the bottom and near the door in a routinely loaded sterilizer. For ETO sterilization, the BI should be in the center of the load. Each manufacturer of a sterilizer should provide instructions on test pack placement for that sterilizer, since these may differ based on design and cycle considerations.

BIs are designed such that the inoculum size should reflect the expected degree of contamination plus a margin of safety. Currently, commercially available BIs fall in the range of 10^4 to 10^6 spores for *G. stearothermophilus* and at 10^6 spores for *B. atrophaeus*. Additionally, the resistance of these cultivated spores is generally higher than that found in native species of the same type. Because the BIs have 10^4 to 10^6 spores per unit (which is far in excess of the expected bioburden remaining on thoroughly cleaned instruments and patient-care items), and the resistance is considered to be greater than the microorganisms on the healthcare items undergoing sterilization, the probability of nonsterility of the items in the load is considered to be <1 in 1,000,000 after a 12-log reduction of the BI *(78)*. This provides for a sterility assurance level of 10^{-6}.

Since their development, commercial BIs have shown significant variability *(79,80)*, but manufacturers in the industry have reduced this variability, increasing the reliability of their product. Still, problems with sporadically false-positive BIs continue to occur *(81,82)*. There are several factors that may influence the occurrence of a false-positive BI, many of which relate to human error. Use of a self-contained BI can minimize handling and the inadvertent introduction of contamination. If a BI is used without spore strip containment, the extra handling and open transfer for assay may produce false-positive BIs more often *(83)*. At present, use of a bare spore strip is not a general practice.

A single positive test does not necessarily indicate sterilizer failure (13). If available, a presumptive identification of the growing microorganism should be performed. This can be done by Gram stain and microscopic examination to ascertain that the microorganism is of the *Bacillus* species (i.e., gram-positive rods). While this is occurring, equipment failure should be ruled out. Immediate service should be requested to detect any sterilizer malfunction. If a sterilizer malfunction is identified, the equipment should be taken out of service and all items processed in that load should be recalled, cleaned, and reprocessed (13). Once a sterilizer is repaired, it is necessary to challenge the unit to confirm proper operation. This approach is also used when it becomes necessary to switch steam sterilizers over to an auxiliary supply of steam. The unit should be operated until two consecutive runs return negative BI results before the unit is returned fully to service. Ordinarily, this will mean that steam sterilizers may be down for several hours after repair, whereas ETO sterilizers and gas plasma units may be off-line for at least 7 days *(83)*. It is important to recognize that the use of a BI does not guarantee sterility but rather provides an additional mechanism for monitoring the sterilizer cycle beyond the graphic temperature–pressure record and chemical indicators. A negative BI test offers further assurance that the sterilizer variables and exposure time were what was intended. It can be inferred that there is a very high probability that all viable microorganisms remaining on the cleaned items contained in the load were killed *(1,84–86)*.

Indicators are validated for standard, programmed cycles. Therefore, the cycle parameters specified on the indicator should be matched to the cycle used for the load. Extended cycles should be monitored with a BI validated for the specific extended cycle and a Class 5 integrating indicator placed in the least accessible location in the tray or load *(64)*.

Storage

The sterile storage area should be adjacent to the sterilizing area, preferably in a separate, enclosed, limited-access, and well-ventilated area to provide protection against dust, moisture, and temperature and humidity extremes (4,5). The maintenance of optimal environmental conditions in the storage area minimizes the potential for contamination of sterile supplies. There should be a minimum of 4 to 10 total ACH, and the relative humidity should be <70% (4,5). The area should also be free of insects and other vermin that seek the warmth of reprocessed packages for habitat.

Sterile materials should be stored at least 8 to 10 in. from the floor, at least 18 in. from the ceiling, and at least 2 in. from outside walls (5,6). The items should be positioned so that packaging is not crushed, bent, compressed, or punctured, all of which will compromise the sterility of the contents. The contents of any sterilized package should be considered contaminated if the packaging is damaged. All wrapped sterilized packages should be handled and stored in a manner that minimizes stress and pressure *(54)*. Storage of supplies on floors, windowsills, and areas other than designated shelving counters or carts should be avoided (5,10). Open shelves, cupboards, or drawers are acceptable, but articles stored in drawers may need special protection against physical damage *(57)*. Some hospitals have utilized movable shelves to maximize storage capacity when space is limited *(87)*.

Every package that has been sterilized within the facility should be imprinted or labeled with a load control number that indicates the sterilizer used, the cycle or load number, the date of sterilization, and an expiration date. The term *shelf life*, as used with respect to a sterilized product, is defined as the period during which sterility can be maintained. Shelf life considerations create more misconceptions, confusion, and misleading information than any other facet of the preparation and use of sterilized products *(47–50,54)*. There are reports in the technical literature describing the length of time sterile goods can be stored and still be considered sterile, with safe storage times reported to range from as short as 1 week to indefinitely (13,*50*). To add to the confusion, some reports discuss neither the wrapping material used nor conditions for storage in relation to the safe storage periods *(54,88)*. Some studies suggested that safe storage times ranged from 2 days to 9 months depending on the wrapper/storage combination. The problem related to most studies is that the conclusions became a standard for all hospitals regardless of the barrier properties of the wrappers used or the hospital's

control over the environmental factors that really affect shelf life. No trend toward increased probability of contamination over time was observed for any pack type studied. The studies were not ready to call any storage time safe or unsafe. They observed, however, that storage periods up to 50 weeks did not increase the probability of contamination regardless of the wrapping material used (nonbarrier woven, barrier nonwoven, or polypropylene peel pouches), storage location, or dust cover use (13,*47,48,62*).

Loss of sterility of package contents is considered event-related, not time-related, and depends in part on the type of packaging used *(89)*. Event-related factors include (a) frequency and method of handling; (b) storage area conditions such as location, space, open/closed shelving, temperature, humidity; and (c) the presence of dust, insects, flooding, and vermin (46). Sterility of package contents is considered compromised if packages become wet or are dropped on the floor, or if the packaging is torn, punctured, or otherwise comes apart (22).

Shelf life and expiration dating policies must be decided by each individual healthcare facility. Because of the differences in both packaging materials used and facilities for storage, it is impossible to recommend shelf times that would be universally applicable for sterile items.

Material Management and Inventory of Sterile Supplies

Inventory control means that the correct quantity and quality of supplies is readily available to meet demands. A stock rotation policy and procedure should be developed for all areas of the facility in which sterile supplies are stored. Supplies should be placed on shelves so that expiration dates are readily visible. Correct stock rotation minimizes waste by reducing the number of sterile items that will have to be reprocessed or discarded. This approach helps to ensure that devices that may no longer be sterile are not inadvertently used (46).

More and more material managers within CSS units are automating inventory control through the use of bar coding and radiofrequency technology *(90)*. Each of these approaches to automated inventory control offers innovative ways of tracking trends in usage, availability, product identification, recalls, etc. One inventory system may not be suitable for all purposes. For example, the integrity of information in bar coding can be compromised if the bar code is defaced in some fashion. Radiofrequency identification is accomplished via the affixing to an item a battery-powered tag that emits a radiofrequency, which in turn is detected with a scanner/reader device. Reports have indicated that this tag often becomes damaged when subjected to sterilization processes *(90)*. Nevertheless, use of automated inventory control has improved CSS unit efficiency in managing supplies moving in and out of the unit.

More recently, automated inventory control is being applied to reusable medical devices. This automation not only tracks the shipping, receipt of, and use life of devices, but also there is increasing interest in using this technology to follow the clinical uses of devices and even record the device information into the patient's medical record *(90)*. Although there are no formal studies as yet to examine the use of automated device tracking, there are a few observational reports in which hospital staff indicate that the use of a device tracking system has helped to manage device recalls or to trace device use to specific patients, thereby providing important epidemiologic information during adverse patient event investigations *(91,92)*.

On September 27, 2007, Public Law 110-85 was signed by President George W. Bush. Section 226 of this law amended the Federal Food, Drug, and Cosmetic Act by requiring the establishment of a "unique device identifier" (UDI) system. FDA is at present developing rules to carry out the intent of this law. Research groups who have explored the implications of utilizing a UDI system have reported to the FDA a number of situations for which a UDI may prove to be a beneficial tool to hospitals. These include: (a) recall of devices (e.g., disposable, reusable, implanted, reprocessed); (b) recall of capital equipment; (c) detection of magnetic resonance imaging–incompatible devices; (d) tracking and documenting device use (including tracking those devices associated with an adverse event, or tracking repairs); (e) identifying devices associated with medical errors; and (f) identifying and reducing device counterfeiting (93).

Distribution of Sterile Goods

Packs transported to ORs and other areas within the healthcare facility should be provided with an additional outer dust-protection cover that can be removed before the pack is taken into the clean zone. This can be applied either to the individual packages or to the total cart. The transporting vehicle should be reserved for CSS unit use (5,*55*).

Maintenance

Preventive maintenance of all sterilizers should be performed according to individual policy on a scheduled basis by qualified personnel, using the sterilizer manufacturer's service manual as a reference (24). Sterilizers should be inspected and cleaned daily or at intervals recommended by the manufacturer to prevent the accumulation of residue that may transfer to packaging in the chamber. The time–temperature charting devices and temperature–pressure gauges should be calibrated after any repair affecting sterilizer performance and at least every 6 months or at the interval recommended by the sterilizer manufacturer (5,24).

Reuse of Single-Use Medical Devices and Patient-Care Items

Over the past 20 years or so, there has been a growing interest in reuse of instruments and items clearly labeled and marketed as single-use only. Many of these devices appear to sustain little obvious wear and tear after their one-time use on the patient, and it is tempting to consider cleaning and reprocessing these devices. However, there are a number of factors that should be considered when evaluating whether or not a single-use device can be reused safely (e.g., difficulties in cleaning, presence of long narrow lumens, chemical coatings, integrity and compatibility of materials, and continued performance of the instrument according to specifications) *(94)*.

Most of the reprocessing of single-use medical devices in the United States is now being done by commercial companies commonly known as "third-party reprocessors." These companies decontaminate, clean, inspect/test, package, and sterilize the single-use devices (SUDs) and return them to the healthcare facility client. The FDA

has regulations governing the reuse of SUDs as is presently occurring in US hospitals (95,*96–100*). Although there are little available data on specific incidents of harm caused to patients because of the reuse of these devices, the government has concluded that the potential risks are such that reprocessing entities should be regulated in the same way as original medical device manufacturers. The FDA now considers hospitals that reprocess devices labeled for single use as manufacturers as well. FDA, therefore, expects hospitals to meet either the requirements of the industrial standards for device reprocessing or have an equally rigorous scientific rationale for sterilization procedures used in reprocessing *(101)*. The regulations do not apply to office-based practices, independent ambulatory surgery centers, or clinics at this time. Additionally, the question has been raised as to whether the regulations exclude SUDs that are opened from packaging but not used. To quote the agency's answer to this inquiry: "The FDA's guidance document 'Enforcement Priorities for SUDs Reprocessed by Third Parties and Hospitals' (dated August 14, 2000), defined *opened-but-unused* SUDs as single-use, disposable devices whose sterility has been breached or compromised, or whose sterile package was opened but not been used on a patient, that is, they have not been in contact with blood or bodily fluids." (Appendix B, page 40.) In Section "C. Scope" of the guidance document, it states that the enforcement priorities do not apply to *opened-but-unused* SUDs. This means that at this time, FDA is not requiring third-party or hospital reprocessors of SUDs to submit PMAs (premarket approval applications) or 510(k)s (premarket notification submissions) for *open-but-unused* SUDs. However, FDA's existing policy for *opened-but-unused* SUDs that are reprocessed by third parties remains unchanged: *opened-but-unused* SUDs reprocessed by commercial reprocessors are subject to the Quality System Regulation (QSR)" *(99)*.

Reprocessors must comply with all of the pre- and post-market regulations governing medical device manufacturing, including the need for premarket clearance if required for that specific device, registration and listing as a manufacturer, mandatory reporting of adverse events, medical device tracking (if required for a specific device), corrections and removals, labeling, and compliance with the QSR *(102)*. The FDA maintains a very helpful Web site on reuse issues and regulation *(100)*.

Contract, Off-Site Reprocessing Services

Healthcare facilities are under constant demand to reduce expenditures wherever possible while not compromising the quality of patient care. This discussion often comes up when it is time to replace outdated and old equipment *(103)*. Some healthcare facilities have opted to outsource their reusable instrument reprocessing service to a contractor, based largely on economic assessment. Many off-site contractors provide the instruments, devices, linens, and other durable goods in addition to the reprocessing service. This means that the healthcare facility can reduce its instrument inventory and largely eliminate an in-house service that has potential occupational risks for injury and infection. The disadvantages to utilizing such a service include the possible elimination of the facility infrastructure that would normally support instrument reprocessing, and the lack of "favorite" instruments from the physician/surgeon's perspective (unless arrangements to retain these instruments are built into the contract) *(104)*. Healthcare facilities are often expected to remove gross soil from the instruments before the contractor comes for instrument pickup. Contractors then fully clean and reprocess the instruments accordingly, and transport them back to the facility in a manner that prevents the reprocessed instruments from becoming contaminated prior to use. The frequency of pickup and delivery is dictated by the work volume of the facility. The company should provide CSS staff with full documentation of its operation, including the details of quality assurance and infection control. CSS staff should be confident that all aspects of the terminal reprocessing services provided by an outsourcer would be equal to or better than those provided in-house. Contract services also provide backup instrument reprocessing services on an as-needed basis, such as during emergency shutdown of a hospital's CSS or during construction and renovation of CSS areas *(104)*.

PATIENT SAFETY: ADVERSE OUTCOMES LINKED TO DEFICIENT CSS PROCESSES AND MATERIALS

Although CSS units have a long history of providing quality service to the patients in the hospitals, there are occasions when infections, injuries, and other adverse outcomes associated with CSS processes or materials affect patients and the quality of their medical care.

Strategies for Managing Errors in Reprocessing

Adherence to reprocessing standards and best practices is the basis for consistent quality service in the CSS unit. Briefly, sterilization and high-level disinfection are processes that effectively prevent transmission of potentially infectious material from one patient to the next. However, occasionally, healthcare facilities are made aware of adverse events during the delivery of patient care that may jeopardize patient safety, increasing the potential risk of infection transmission. In some instances, these events may be traced back to some deficiency in device reprocessing. There may be several contributing factors that need investigation: (a) human error (incorrect settings on reprocessing equipment or failure to follow established disinfection procedures); (b) equipment or product failure; or a (c) systemic or organizational failure (using incorrect connectors or reusing contaminated needles and syringes) *(105,106)*. CSS unit supervisors should establish policies and procedures to address human errors and equipment failures in their unit and partner with facility infection preventionists and epidemiologists to determine the root cause of the deficiency and assess the potential for infection transmission to patients. Within the CSS unit, equipment failures/malfunctions should be identified as quickly as possible so the equipment can be taken out of service, repaired or replaced as appropriate, and full function restored. Any unused instruments from affected sterilizer batches should be recalled, cleaned again, and reprocessed (22,*105*). The margin for allowable error implicit in modern

sterilization procedures is sufficiently large for those based on physical methods of microbial inactivation, such that there is minimal risk that items in a load will fail to achieve sterility in the event of a potential sterilizer malfunction, especially if the microbial bioburden on reprocessed items has been reduced before sterilization by proper cleaning. As a consequence, HAI, particularly bacterial infection, traced to mechanical failure of sterilization equipment has been infrequent *(1)* (see also Chapter 81). Nevertheless, it is important for CSS unit supervisors to provide reprocessing assessment information to the healthcare facility's efforts to determine the risk of transmission to patients that may or may not lead to patient notification.

Some adverse events have been attributed to failure to follow best practices when performing high-level disinfection on complex devices (i.e., endoscopes) *(105)*. Other events may be linked to poor infection prevention practices during the delivery of patient care (i.e., reuse of needles and syringes, or using previously contaminated needles and syringes with multidose vials) *(106)*. In these situations, the infection control breach is evaluated to determine the likelihood of pathogen transmission. This information, coupled with affected patient population factors and time line of events, is weighed in the decision whether or not to notify patients for medical assessment and follow-up *(106)*. If a reusable device is involved in a potential adverse event for a patient, the CSS unit supervisor can anticipate that he/she will be called upon to help assess the problem and assist with response strategy development.

Examples of Adverse Events Associated with Device Reprocessing Deficiencies

Several aspects of the instrument reprocessing strategy, however, can be associated with adverse outcomes for patients if recommended practices are not followed. In 1961, three cases of surgical site infection caused by *Clostridium perfringens* were reported as a result of inadequate cleaning of instruments and sterilizer failure *(107)*. Transmission from the index case to the other patients was linked to residual contamination on the surgical instruments. Another episode traced to sterilizer failure in a hospital resulted in six cases of *P. aeruginosa* meningitis or intra-abdominal abscesses *(108)*. Possible failure of flash sterilization processing of implantable neurosurgical devices was epidemiologically implicated in this outbreak. Bacteremias and fungemias have been associated with improperly sterilized pressure transducer domes *(109)*. Improperly sterilized surgical equipment was linked to an outbreak of postsurgical nasal cellulitis in which *Mycobacterium chelonae* was recovered from patients undergoing surgical rhinoplasty *(110)*. Improper packing of surgical linens/drapes prior to autoclaving was associated with an outbreak of polymicrobial ventriculitis in a surgical intensive care unit *(111)*. Tight packaging of the linens prevented the sterilant from penetrating throughout the pack. Additionally, the hospital failed to run routine process indicators (i.e., Bowie-Dick testing, BIs). Another episode resulting in transmission of NTM was linked to deficiencies in disinfection or sterilization practices in the OR and major defects in the autoclave located in the OR *(112)*. Inadequate sterilization and rinsing surgical instruments with tap water, coupled with minimal training in instrument reprocessing strategies, were implicated in an outbreak of *M. chelonae* abscesses after liposuction in a physician's office–based practice *(113)*. These latter two outbreaks illustrate the problems that may occur with instrument reprocessing activities that are based elsewhere in the healthcare facility. Lack of experience with proper instrument reprocessing and attendant quality assurance can be problematic, especially if the workers and the processes in these areas do not have any oversight from infection control or CSS unit personnel.

Proper maintenance of the equipment in CSS is very important in the prevention of healthcare-associated adverse outcomes for patients. One outbreak of diffuse lamellar keratitis (DLK) was attributed to endotoxin exposure from sterilized instruments *(114)*. Biofilms of gram-negative bacteria built up in the sterilizer's water reservoir, presumably diminishing the quality of the steam and thereby resulting in the transfer of endotoxin to the instruments. Biofilm control measures were implemented and a significant reduction in the development of DLK was observed.

Materials compatibility with sterilants has been a problem with the development of new options for sterilization. Therefore, it is important to review fully the advantages and limitations of new sterilization technologies so that it is clearly understood which items and materials can be safely reprocessed. An outbreak of corneal decomposition among patients receiving elective intraocular surgery was associated with residual copper and zinc in lumened, copper, and brass surgical instruments sterilized with the Plazlyte system (AbTox, Mundelein, IL), a sterilizer that is no longer marketed in the United States *(115)*. The contact of the instruments' metals with the sterilant in this system produced toxic by-products that resulted in ocular damage, with some of the cases experiencing irreversible conditions.

Reuse of single-use medical devices has also been debated in the context of potential infectious risks to patients or risk of injury should the reprocessed device malfunction. The medical literature has been mixed on this issue. Some *in vitro* studies lend support to the practice of reusing these items *(116–118)*, whereas others point to definite problems encountered with cleaning and with materials integrity or compatibility *(119–124)*. There is potential for injury, infection, or other adverse outcome to occur. In a Brazilian hospital, several patients undergoing cardiac catheterization with reprocessed catheters experienced pyrogenic reactions. The catheters were sterilized by ETO after being cleaned several times in a CSS unit. Analysis of the water used to reprocess catheters revealed elevated endotoxin levels; endotoxin was also detected in the reprocessed catheters *(125)*.

OCCUPATIONAL RISKS FOR CSS UNIT WORKERS

Occupationally Acquired Infections

CSS workers encounter blood, tissues, body substances, and devices contaminated with these proteinaceous materials on a daily basis. According to Standard Precautions, blood and body substances from all patients should be considered infectious, and used instruments and items

should be considered potentially infective and therefore handled with extraordinary care *(126)*. There is a recognized risk of exposure to blood-borne pathogens (i.e., human immunodeficiency virus, hepatitis B virus, and hepatitis C virus) for CSS unit personnel during the reprocessing of contaminated, reusable medical devices. CSS workers, therefore, are considered appropriate candidates for hepatitis B vaccination and should be offered the vaccine accordingly *(23,127,128)*. Additionally, these workers should be trained on the importance of promptly reporting occupational exposures to blood and body fluids *(23)*. Workers should be encouraged to report to employee health any occupationally acquired cut, puncture wound, or splash to the eyes and mucous membranes so that postexposure evaluation can be initiated and prophylaxis be administered as appropriate.

Although it is accepted that the work activities in a CSS unit can potentially expose the workforce to blood-borne pathogens, there is limited occupational event surveillance information with which to evaluate the extent of the injury problem in this part of the hospital. Cuts from sharp instruments and needle sticks from hollow-bore needles have been reported by CSS unit personnel *(126,129)*. In two reports from the United Kingdom during the late 1980s and early 1990s, the injury prevalence rates annually per 100 staff ranged from 17 to 83 injuries per 100 staff *(130,131)*. In one of these reports, however, it is evident that the actual number of injuries (two injuries) among a small workforce in the CSS unit represents only a very small proportion of the total number of needlesticks occurring in that hospital that year (2 of 64, or 3.4%) *(130)*. In contrast, the nursing staff sustained 29 needlesticks that year, or more than 45.3% of the total number of needlesticks *(130)*. In the past two decades, the healthcare industry has embraced technological improvements in PPE (e.g., fluid-impervious protective attire, gloves to prevent cuts to the hands) and CSS unit equipment to enhance worker safety. More recently, as states in the United States become more engaged in healthcare safety surveillance reporting, CSS unit–specific occupational event data may emerge. Texas, for instance, has conducted statewide surveillance for contaminated sharps incidents from 2001 to 2008 (2008 being the most recent year for data analysis). Reported injuries among CSS unit workers during those years ranged from 0.0% to 0.6% of the total number of sharps incidents reported among the participating healthcare venues during the year *(132)*.

CSS personnel performing decontamination should wear PPE appropriate for the task. For example, an impervious gown and shoe covers, heavy gloves, and eye goggles or face shields would be appropriate for the CSS unit staff that work in the decontamination and/or cleaning area(s). This work area houses the manual device cleaning activities that may produce aerosols and spray mists. Furthermore, automated equipment (e.g., washer–decontaminators, washer–sterilizers, and ultrasonic cleaners) may produce a spray from the fluids contained within, and this should be considered when one is planning programs for protection of workers. Nevertheless, among the benefits these pieces of equipment provide is the opportunity to minimize the amount of contact with contaminated medical devices during cleaning, thereby reducing the risk of exposure to potentially infectious fluids and aerosols *(129,133)*. Proper technique when handling contaminated patient-care items remains an important part of the process when loading the items into the automated equipment for cleaning.

Even though properly attired with PPE, healthcare workers in the CSS unit are still at risk for injuries and infections by puncturing themselves with sharp, contaminated instruments. Disposable sharps need to be discarded in an approved sharps container at the point of use. Reusable instruments should be placed in a puncture-resistant container for safe transport to the decontamination area *(133)*.

Occupational Risks Associated with Ethylene Oxide Sterilization

ETO has been produced commercially and used as a sterilizing agent for many years. ETO is both combustible and flammable, and it was common to find ETO mixed with inert gas to reduce these hazards. However, more recently, ETO is supplied in small canisters of 100% ETO as a result of technological improvements in the sterilizer equipment and the rising costs of gas blends (22). Its use as a sterilant of choice for heat-sensitive devices, however, is limited in healthcare settings mainly because of environmental concerns relating to emissions and inherent health risks for both CSS workers and patients who come in contact with ETO vapors and surface residuals, respectively. ETO has produced tumors, teratogenic effects, and maternal toxicity when injected into mice *(134,135)*. ETO is a known carcinogen for humans; some studies have noted an increase in the incidence of lymphoid tumors and hematopoietic cancer among workers with ETO exposure, but particularly among male workers in those work settings *(136–138)*. Study of spontaneous abortions in hospital staff suggested that exposure to ETO in hospitals may carry a risk of spontaneous abortion among CSS staff *(139,140)*. Items (e.g., prosthetic devices, instruments, or catheters) improperly aerated can cause serious chemical burns or tissue irritation and have been shown to be neurotoxic (*141–143*,144,*145*). Aeration will reduce some of these residuals on the sterilized items, but the extended time needed to accomplish this makes ETO sterilization somewhat impractical in the face of increasing demands for short turnover of instruments. Nevertheless, ETO sterilization still plays an important role among the reprocessing options in a CSS unit.

To use ETO in the safest possible manner, three guidelines need to be followed: (a) provide safe devices that are sterile, unaltered, and with no undesirable residues; (b) protect workers from chronic ETO exposure; and (c) take steps to prevent hazardous episodes of leaks, fires, or explosions (22,*143*).

Aeration of Instruments, Devices, and Items After Ethylene Oxide Sterilization Use of ETO as a sterilant will generate ETO by-products, primarily ethylene glycol and ethylene chlorohydrins. ETO and ethylene chlorohydrin can be removed from items by aeration. It is imperative that all instruments and devices subjected to ETO sterilization are fully aerated to eliminate these residuals prior to handling and use (22). Ethylene glycol, however, is not removed by aeration. Therefore, precautions such as

making certain that no liquid exists in the load, selection of a quality gas source, and routine maintenance of the sterilizer are needed to prevent its formation (22).

Aeration of ETO-reprocessed instruments and patient-care items at ambient conditions in an open, unrestricted area is unacceptable, because it would unnecessarily expose workers to ETO. The basic elements for controlling ETO emissions during aeration are process enclosure, local exhaust ventilation, PPE, and equipment functional design *(146)*. To protect CCS unit workers from ETO exposure, the United States EPA requires as of February 28, 2010, that facilities use a single chamber process (i.e., sterilization and aeration occurring in the same chamber) when using an ETO sterilizer for the terminal reprocessing of heat-sensitive instruments *(147)*. Adequate aeration time must be allowed after sterilization so that residual ETO can be reduced to a level safe for both personnel and patients. Length of aeration depends on many variables, including (a) composition, form, density, and weight of the sterilized item; (b) product packing, loading, and mass; (c) type of ETO sterilization system used; (d) temperature of the aeration chamber; (e) number of filtered ACH and air flow characteristics; and (f) intended use of the item (i.e., external application or implantable device) (24,*143*,144). Polyvinyl chloride is one of the most challenging materials from which ETO residue must be eliminated. No standard times for aeration can be reliably given without consulting the device, sterilizer, and packaging manufacturers. Items can require as short as a few hours or as long as several days in an aeration cabinet to reduce ETO to safe levels.

In 1978, the FDA proposed limits on the amount of residual ETO (30 μg/kg/day for 30 days) that can remain on sterilized medical devices for human patients. These limits were based on histologic and hematologic studies in rodents and dogs *(145)*. The FDA has raised the allowable residual limit of ETO to 250 parts per million (ppm) on devices subjected to ETO sterilization, with the exception of those devices used in donor and patient blood collection (product codes 81GKT and 81KSR). More recently, the ISO and AAMI have adopted a philosophy that the limit should depend on the intended use of the device and the length of contact with human tissue so that the dose to tissue is considered, not just the amount retained in the device (68,*148,149*).

Preventing Occupational Exposure to Ethylene Oxide In the late 1980s/early 1990s, the National Institute for Occupational Safety and Health estimated that 270,000 workers in the United States were potentially exposed to ETO, the majority of which were working in hospitals and other healthcare settings *(150)*. With the development of more effective engineering controls, work practices, and workplace design requirements, the risk of occupational exposure has been minimized over the last two decades. Nevertheless, CSS unit personnel who work with ETO must be informed of the possible health effects of ETO exposure. This information must include an explanation of the requirements of the Occupational Safety and Health Administration (OSHA) standard on occupational exposure to ETO and must identify the areas and tasks in which there is potential exposure to ETO emissions *(151)*.

OSHA published a final ruling on ETO in 1984 that reduced the permissible worker 8-hour time-weighted exposure level of ETO from 50 ppm of air to 1 ppm of air. In 1988, OSHA amended its existing standard by adopting an excursion limit for ETO of 5 ppm of air averaged over a 15-minute sampling period *(58,151)*. Workers who are exposed to ETO emissions at or above the action level (0.5 ppm) for at least 30 days per year, even if an approved respirator is used, must have medical examinations at least annually. Trend data for US hospitals have shown that facility efforts to monitor occupational exposures to ETO increased dramatically after the implementation of the OSHA regulation, but current surveillance is documenting a general decline in adherence to and enforcement of the OSHA ETO standard *(152,153)*. Hospitals should maintain responsible employee and environmental monitoring as part of a comprehensive worker safety program.

Restrictions on ETO use have included the amount permitted to exit the sterilizers to the atmosphere. These restrictions have been imposed by individual states and air pollution control boards *(154)*. These restrictions not only ensure that occupational exposure to ETO is minimized but also prevent the passive exposure of patients, other hospital workers, visitors, and individuals in or near the healthcare facility. All ETO sterilizers and aerators must be directly vented out of the workplace to the outside atmosphere (4). The vent line must not terminate within 25 ft (7.6 m) of any building air intake. A greater distance may be needed in some situations, depending on the direction of prevailing winds and the location of buildings (68,*154*).

Desirable ETO sterilizer safety features include, but are not limited to (a) purge of the system at the end of cycle, (b) door-locking and sealing mechanisms, (c) audible alarm at the end of the ETO cycle, (d) automatic door controls, and (e) audible and/or visual alarms for system failures. Scrubbers that convert ETO to less toxic ethylene glycol have been used successfully to control ETO emissions (68,*143*).

CSS personnel should ask instrument and device manufacturers for written instructions on the proper sterilization and aeration times for their products when ETO is the recommended sterilant for successful reprocessing. CSS personnel also have to develop, implement, and enforce aeration policies and procedures. Aeration recommendations should be carried out in an uninterrupted cycle to prevent unnecessary operator exposure to ETO due to opening the aerator door. Policies regarding early removal of devices that have not been completely aerated must be established through the hospital's infection control committee, legal counsel, and/or risk management committee (144).

For a more in-depth discussion of the safe use of ETO in hospitals and other workplaces, the reader is referred to a recent guide published by OSHA (155).

CONCLUSION

CSS is an example of the person–machine interface that is so visible in the delivery of healthcare. The processes and products coming from a CSS unit impact virtually all of the care activities provided in a healthcare facility, ranging from distributing patient-care supplies to providing sterilized

surgical instruments and sterile textiles. Sterility assurance depends on the performance of both employees and equipment. Several low-temperature sterilization processes are widely available (e.g., ozone, hydrogen peroxide plasma, hydrogen peroxide liquid) and along with ETO provide more options to sterilize heat-sensitive items. Advances in sterilization technology and automation necessitate that CSS unit professionals have a solid scientific understanding of the basic principles of cleaning, decontamination, disinfection and sterilization, and current clinical practices in order to best evaluate innovations and to enhance patient safety *(156)*.

CHAPTER 71

Healthcare-Associated Infections and the Environment

Andrew J. Streifel

ENVIRONMENTAL RESERVOIRS AND THE EPIDEMIOLOGIC CHAIN

The relationship between the physical environment of healthcare facilities and infection control has long been debated. Continuing advances in medical technology and pharmacology have given physicians many options, unrelated to the physical environment, for preventing healthcare-associated infections. Restrictive and time-consuming barriers and procedures such as laminar-flow rooms with attendant aseptic technique have generally been in disfavor relative to the pharmacologic approach to preserving immune competence. At the same time, passive environmental controls such as filtration and pressurization systems to provide spore-free environments continue to be used in increasingly sophisticated ways. Legitimate questions remain as to the extent to which environmental reservoirs contribute to healthcare-associated infections. An argument can legitimately be made that cleanliness needs no further epidemiologic justification and that all hospitalized patients are entitled to a clean and odor-free environment. However, legitimate questions can also be raised as to allocation of resources to environmental controls that have no epidemiologic basis. An example is the extent to which chemical germicides should be used on environmental surfaces as opposed to nongermicidal cleaning methods that appear to yield equivalent microbiologic reductions *(1)*. With such issues, new technology is adapting to the means of real-time sampling using indicators such as environmental adenosine triphosphate (ATP) *(2)* for determining cleanliness.

One reason for continued disagreement over the importance of environmental reservoirs is failure to consider historical perspective and thus the starting point for measuring significance. People have rightly come to expect a high level of sanitation in medical facilities, a level that has already achieved a major reduction in infection incidence, and are now dealing with a very different set of infection determinants focusing largely on patient susceptibility factors. The writings of Florence Nightingale based on her experiences in the Crimean War in the 1850s reveal the striking contrasts between conditions then and now *(3)*. She devoted whole chapters to pure air, pure water, efficient drainage, cleanliness, and light, which she considered the cornerstones of good health and prevention of mortality. In her detailed journals, she documented survival data in the hospital where she cared for British soldiers of the Crimean War. She documented dramatic changes in mortality from February 1855 (420/1,000) to September 1855 (22/1,000), which she attributed to "nursing care and sanitary measures" *(4)*. Her changes included such basics as scrub brushes, laundry tubs, and clean dressings for wounds, all replacing abominably filthy conditions associated with the pest houses of the time. Thus, the question that should be addressed today is not whether the environment is important—it obviously is—but how best to use available infection control practices most cost effectively to protect patients and healthcare workers from infectious hazards. In this chapter, a variety of environmental reservoirs are reviewed relative to evidence linking these reservoirs to disease and a distinction is made between proven linkage to disease and simple evidence of lower contamination levels (which may or may not be worthwhile, regardless of disease linkage). In this chapter, two developments are emphasized, which are considered the most significant in this ongoing attempt to define the role of the physical environment in healthcare-associated infections. First, as antibiotic resistance problems mount and higher percentages of infections become more difficult to treat, one has little choice but to fall back on environmental cleanliness as a cornerstone preventive component of infection control. The second development is the continuing refinement of DNA fingerprinting technology, which more and more enables identification of specific sources of infection and determines the relatedness of infection clusters. A number of examples are cited and predictions are made that this technology will eventually shed further light on the importance of environmental controls.

LITERATURE REVIEW

Association of Reservoirs with Healthcare-Associated Infections

Although the literature is replete with accounts of microbial contamination in a great variety of hospital settings, most of these articles describe contamination levels, not infection levels, and prescriptions for reducing these contamination levels do not necessarily translate into

reduced incidence of healthcare-associated infection. Even when specific correlation to infection rates is suggested, the evidence is often tenuous, and direct association to an environmental source is difficult to prove. One area where investigators seem to be convinced that environmental sources contribute to infection is that of *Aspergillus* infections in severely immunocompromised patients. Humphries et al. *(5)* attributed two invasive *Aspergillus* infections in an intensive therapy unit to spores accumulating in fibrous insulation material above a perforated metal ceiling. Arnow et al. *(6)* similarly attributed an increase in *Aspergillosis* incidence to growth of microorganisms on filters and claimed that improved environmental maintenance and filter replacement were associated with a fourfold reduction in aspergillosis incidence over a 2-year period. Table 71-1 lists environmental sources of fungi in the hospital (*6*,7,*8–13*,14,*15–19*).

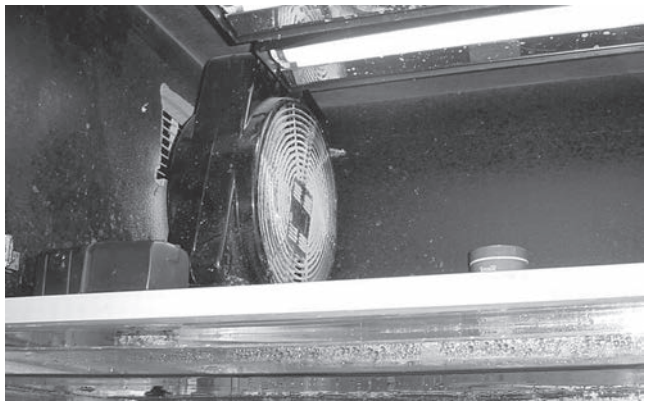

FIGURE 71-1 Aquarium fan lint with *A. fumigatus* contamination due to growth on fish food. This contamination was implicated in burn patient infections (unpublished data).

Air

The controversy over the role of airborne microbes as a source of surgical site infections has gone on for many decades. In theory, a surgical site exposing sterile tissue is susceptible to invading microorganisms from many sources. Certainly, rigid aseptic techniques and the need to sterilize any item entering a surgical site has long been accepted practice. Similarly, the need for filtration and high dilution rates of operating room air has also been accepted. However, proof of airborne infection of surgical sites has been hard to come by, and demonstrated effectiveness of specific controls as a means of reducing infection incidence has similarly been hard to prove. Walter et al. *(20)* claimed to have demonstrated a specific airborne surgical infection, and Hart *(21)* published the results of a 29-year study claiming the significant benefits of ultraviolet installations for limiting surgical site infection. Other investigators, however, have failed to confirm these conclusions. In particular, Ayliffe and Beard *(22)* and Howe and Marston *(23)*, while confirming that good filtration and dilution could reduce airborne contamination levels, could find no association of such reductions with infection prevention. In a general review of indoor microbial aerosols, Spendlove and Fannin (24) made the point that little is known about the true significance of these aerosols relative to human health and that continued research is needed. The sources of mold are many in the biologic world and the indoor environment can be controlled when emphasis is placed on filtration, air exchanges, and pressure management *(25)*. It becomes imperative to control sources close to the patients at risk from opportunistic microbes such as *Aspergillus fumigatus* (see also Chapter 41). Such practice of source management also works for industrial hazards. These settings, however, provide easier identification for source management.

TABLE 71-1

Environmental Fungal Sources in Hospitals

Source	*Reference*	*Patient Infection Claim*
Ventilation system	Fox (7)	Surgical wounds
Fireproofing material	Aisner *(8)*	Yes

Water Reservoirs

The literature is replete with reports of improperly disinfected medical devices that are implicated in healthcare-associated infections, particularly devices such as respiratory therapy equipment that are associated with water reservoirs of one kind or another *(26)* or devices that have hard-to-clean channels such as fiberoptic endoscopes *(27)*. Similarly, a number of environmental water reservoirs have quite clearly been associated with infection involving aerosolization from these sources. Examples include faucet aerators associated with *Pseudomonas* infections *(28)* and shower heads associated with legionellosis (29,*30*) (see also Chapter 36). Weber et al. *(31)* recently confirmed by pulsed-field gel electrophoresis that faucet aerators were contaminated with identical strains of *Stenotrophomonas maltophilia* found to colonize a cluster of patients in a surgical intensive care unit. They attributed the problem to low-level contamination of potable water subsequently amplified in the faucet aerators. Jonas et al. *(32)* used three methods of DNA typing to compare environmental and patient isolates of *Legionella pneumophila*. Although all three methods detected one prominent genotype, amplified fragment length polymorphism had better interassay reproducibility and concordance than either macrorestriction analysis (MRA) or arbitrarily primed polymerase chain reaction (AP-PCR). MRA was also cited as an important tool for epidemiologic investigation of healthcare-associated

infections by Luck et al. *(33)* who used that technique to match *Legionella* isolates from four patients with identical strains isolated from the hot water supply of the hospital. Legionellosis is a disease, important in the lexicon of healthcare-associated infections, for which an environmental reservoir has clearly been identified (warm water reservoirs in buildings) and for which specific preventive environmental protocols are recommended and generally accepted. Edelstein *(34)* reviewed some of these recommendations. They include hyperchlorination (6–20 mg/L) followed by long-term continuous chlorination at 1 to 2 mg/L or intermittent elevation of water temperature to 60°C to 70°C with or without chlorination. An additional example of aerosolization from a water reservoir was reported by Grieble et al. *(35)*. They associated a rise in gram-negative septicemias with aerosolization from a waste hydropulping system that had been installed in a new Veterans Administration hospital. They also suggested that closing down the system halted the outbreak.

Hydrotherapy pools and tanks are another water reservoir wherein the combination of organic debris from infected patients and elevated water temperature clearly supports growth of microorganisms; not surprisingly, several investigators have associated these tanks with infections. Examples include McGuckin et al. *(36)* reporting on an outbreak of *Pseudomonas aeruginosa* wound infection and Mayhall et al. *(37)* describing a bacteremia outbreak of *Enterobacter cloacae*. Rutala and Weber *(38)* reviewed the subject of water reservoirs of healthcare-associated pathogens. They listed more than a dozen such reservoirs identified in hospitals, including potable water, sinks, faucet aerators, showers, ice and ice machines, eyewash stations, dental-unit water systems, dialysis water, water baths, ice baths, tub immersion, toilets, and flower vases. All these sources have been specifically shown to harbor healthcare-associated pathogens, and regardless of the uncertain epidemiologic significance of such reservoirs, prudent control measures are available to limit microbial growth and such measures should be used. The authors also pointed out the growing importance of molecular epidemiology for typing pathogens in these reservoirs. DNA fingerprinting by pulsed-field gel electrophoresis is an example of a technique that can be used to match clinical and environmental strains. That technique was used by Buttery et al. *(39)* to link a *P. aeruginosa* outbreak to water-retaining bath toys in a toy box. Finally, Verweij et al. *(40)* used random arbitrary polymorphic DNA PCR analysis to link an infant death from *S. maltophilia* infection to contaminated tap water. They concluded that preterm infants should not be washed using tap water. Water has been implicated as a potential reservoir for filamentous fungi *(41,42)*, and it is logical that spores could become entrapped in water and distributed to susceptible patients. This contamination was not associated with growth in water, but at the interface of water and air (43). Although eliminating all of these microbes seems easy to do with high-efficiency particulate air (HEPA)-quality filters, it would seem more effective to provide sterile water for drinking. The potential pathogenic sources in municipal water include soil, expansion tanks, evaporative pans, or accumulated biofilm within the water distribution system. Water usage is decreasing in healthcare facilities due to sustainable and green building concepts. Use of air-cooled med gas machines, digital radiology processors, and waterless hand cleaning is remarkably reducing water consumption. For example, at the University of Minnesota Medical Center, since 1990 the water usage volume has dropped from 164,000 to 82,000 g/day. This drop in water usage promotes stagnation, which increases bacteria levels in water. Incidents investigated by this author regarding resistant gram-negative bacteria confirm transmission from sink to patient with respiratory therapy equipment and feeding tubes. Inappropriate use of tap water is often the cause of such transmissions.

Infant Formula

As early as 1990, Clark et al. *(44)* used plasmid analysis, chromosomal restriction endonuclease analysis, ribotyping, and multilocus enzyme electrophoresis to match isolates of *Enterobacter sakazakii* from patients with isolates from infant formula, strongly implicating the formula as the source of those infections.

Environmental Surfaces

Environmental surfaces have long been something of an enigma for healthcare facilities. Although no one disputes the desirability of keeping these facilities clean or that esthetic considerations alone justify the cost of routine housekeeping, it is more difficult to justify the routine use of costly disinfectants on hospital floors and furnishings. No one has seriously proposed that such products in themselves can prevent healthcare-associated infections. It was demonstrated in the 1960s by Vesley and Michaelsen *(45)* and by Finegold et al. *(46)* that detergents (or even hot tap water) without chemical disinfectants can achieve microbial reduction equivalent to that of disinfectants. It has also been demonstrated by Vesley et al. (1) that dry cleaning with a chemically treated mop before wet cleaning accounts for most of the microbial load reduction on floor surfaces in hospitals. Dharan et al. *(47)* compared germicidal treatments to detergent only cleaning of floors and furniture in a 4-month trial in Switzerland. They concluded that microbial levels could be reduced but failed to observe any change in healthcare-associated infection rates in more than 1,000 patients. Maki et al. *(48)* performed an elaborate study of microbes on floors, walls, and other surfaces of an old hospital; then, before occupancy, they performed the same study in a new hospital that was replacing it. They reported no change in infection rates in the new hospital despite an absence of the surface pathogens immediately on occupancy. The old surface contamination patterns were reestablished in 6 to 12 months, leading the authors to conclude that the environment was contaminated by the patients rather than the other way around. Similarly, Danfoth et al. *(49)* compared infection rates over a 3-month period on eight acute care nursing units that had been cleaned with either a disinfectant or a detergent. The rates were not significantly different (8.0 per 100 discharges in the units cleaned with disinfectant vs. 7.1 per 100 discharges in the units cleaned with a detergent).

ATP technology is providing real-time analysis of surfaces suspected of being contaminated; while a clean look may be useful as an indicator, verification by testing provides greater sanitation assurances (50,51). Boyce has shown that education plus consistent concern for post clean testing improved outcome when checked with the indicator ATP (52). This method attaches bioluminescent material to

the chemical structure of residual protein or ATP left over from living cells. For situations involving the potential environmental microbes like *C. difficile*, methicillin-resistant *Staphylococcus aureus*, and Norovirus, methodically checking touch points in recently cleaned rooms assures a sanitation standard for respective facilities enlightened by quality audits for infection prevention (53).

The emergence of vancomycin-resistant enterococci (VRE) as a major healthcare-associated pathogen in the 1990s has rekindled some of the arguments about the importance of environmental surfaces. Weber and Rutala *(54)* reviewed this subject and hypothesize that "there is sufficient evidence to state that inanimate surfaces likely play a role in the transmission of VRE." They support this view by citing the survival of VRE on environmental surfaces for hours and claim that such contaminants can colonize hands. They also call into question the adequacy of current terminal room cleaning practices for eliminating VRE from environmental surfaces. The seriousness of the VRE problem and recent confirmation of the first vancomycin-resistant *S. aureus* certainly warrants close surveillance of the role of the environment. However, it remains difficult to determine whether such environmental surfaces play a role in initiating infection or, as others have claimed, merely reflect the presence of a source patient contaminating his or her surroundings.

A relationship was established by Alberti et al. *(55)* between the environmental contamination of a hematology–oncology ward and the incidence of invasive healthcare-associated aspergillosis. The conclusions of such evaluations indicate the importance of environmental control of contamination. In other words, the hospital environment should be kept clean for the sake of infection control (56). These concerns are not always detectable with the real-time monitors yet when evaluating aspergillosis incidents, environmental surface sampling is often forgotten for the less sensitive air sample methods. Surfaces retain spores in dust longer than fluid air retains them in a ventilated space. Focused cleaning with specific attention to water damage locations is required to minimize internal sources for fungal spores.

Soiled Linen

Soiled linen is another source of contaminants that has drawn some attention in hospitals. Again, the need for clean bedding is not at issue. Clearly, every patient is entitled to freshly laundered bedding as a matter of routine practice. However, the manipulation of soiled bedding is recognized as a major contributor to airborne contamination, and the question becomes "Does aerosolization contribute to healthcare-associated infection?" For example, Michaelsen and Vesley *(57)* reported a significant increase in air contamination even on the upper stories of a hospital when soiled linen was pulled from a basement chute closet, but the importance of such an observation relative to infection transmission has not been established. Colbeck *(58)* claimed a reduced incidence of skin boils after disinfection of blankets, but the evidence was purely circumstantial.

In 1988 at the University of Minnesota Hospital, an increase in *Aspergillus flavus* infections was observed after having moved 2 years prior into a new ventilated hospital. Investigation with air sampling showed no airborne *A. flavus*, but after a skin infection was observed, there was suspicion of laundry contamination. Further evaluation showed laundry from the storage areas had *A. flavus* contamination when vacuumed in a class 0 clean room. The laundry transport truck did not have a back door, and while the laundry had plastic covering, it did not prevent the contamination from a dirt road over which the truck was required to travel during a road/sewer construction project between the laundry and the University Hospital. The problem went away after putting a back door on the truck and paving the road. Additional laundry incidents have occurred, mostly due to product contamination after cleaning. This author was involved with three such incidents including the above-mentioned problem. Laundry manufacturing, transport, and storage comprise the focus of the Health Care Laundry Accreditation Council whose mission is to assure clean product management in the healthcare industry.

Construction Projects

One correlation of an environmental source relative to patient colonization that has been documented fairly consistently is that of building construction projects and fungal infection. Arnow et al. (14), Sarubbi et al. *(59)*, and Krasinski et al. *(12)* have all demonstrated recovery of *Aspergillus* from patients, which they traced to specific construction activities. Streifel et al. *(13)* reported that careful control measures during a building demolition project successfully prevented patient fungal colonization despite an enormous increase in fungal air contamination resulting from demolition. In a related finding, Streifel et al. *(19)* associated airborne *Penicillium* spores with leaking pipes in a rotting wood cabinet in a medication room (Fig. 71-2). Thus, special precautions to contain contaminants during ongoing remodeling and new construction projects would appear to be one environmental control situation that is justifiable for infection prevention reasons. Carter and Barr *(60)* reviewed construction-related healthcare-associated infection outbreaks, citing particularly *Aspergillus* and *Legionella* as often construction-related. They make specific recommendations for environmental control during construction including barriers, signs, traffic control, and ventilation suggestions.

Information now is available for construction of effective barriers to prevent dissemination of construction aerosols. Anderson et al. *(61)* published a Temporary

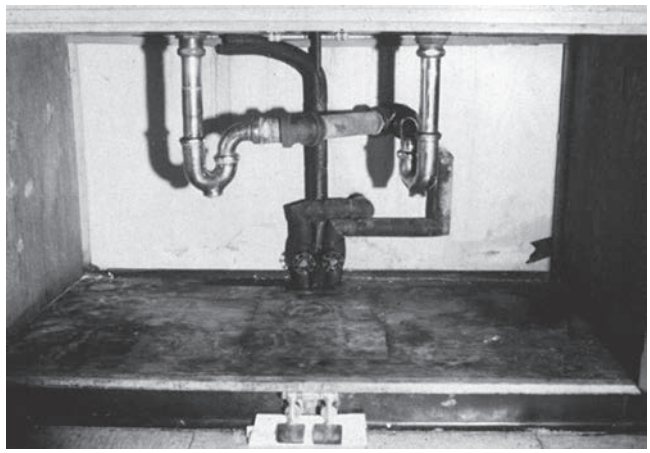

FIGURE 71-2 Mold accumulation in wooden cabinet under hand wash sink.

Negative Pressure for Isolation (TNPI) booklet intended to help show guidance for establishing and monitoring TNPI. Choosing an appropriate barrier for type of job is dependent on length of project or type of disruption. Barriers can be either long-term or short-term. Consideration for the length of a project in a critical space is important for project management. Risk factors that take into account the nature of the healthcare area being remodeled, and what is being disrupted, should be included in the decision making. Streifel *(25)* provided an example of barrier-related differences in microbial counts when a bathroom was dismantled using a substantial barrier and portable HEPA filtration. Also, Rautiala et al. *(62)* provided comparison methods for three types of barriers in controlling microbes during renovation. The study showed that the methods used were effective at preventing movement of microbes to adjacent spaces but did not minimize the exposure to workers in the construction zone. Such efforts demonstrate the effectiveness of barriers when they have negative pressure or airflow from clean areas to dirty areas. The levels of pressurization needed to achieve such control have not been standardized. Levels at or above 2.5 pascal (Pa) would be acceptable for protected environments. Alevantis et al. *(63)* found that a pressure differential of 8 Pa prevented the migration of environmental tobacco smoke. Smoke serves as a good surrogate, so that the barriers where critical control is necessary should be designated as smoke barriers, which is common in healthcare construction because of interim life safety code requirements (64).

Control of internal sources of mold during maintenance and renovation is a challenge, but external construction control is contingent on protecting the external shell of the building from penetration by excavation aerosols. This can be complicated if the building requiring protection is a high rise. The lower portion of a high-rise building has a natural tendency to pull air into the building to satisfy heat rising through the structure. Occupants using close proximity areas for smoking or normal pedestrian traffic may create an opening in the building to enhance the movement of excavation aerosol into the protected clinical structure. Control of entrances to a critical building is essential to protect the building from external projects.

Regardless of the project, a risk assessment is necessary to recognize the status of the clinical areas affected and the type of project impact on those areas. For example, if the windows are to be replaced on a hospital building, efforts to ensure pressure control on the internal connections are critical, and an airlock (ante) egress room may be necessary to ensure air pressure control. Likewise, if work is scheduled on a roof, efforts to protect that roof surface from puncture are critical for water damage control. Water damage control is essential for ensuring minimal mold growth inside of a building. If water damage occurs because of leaks, broken piping, or heavy rainfall, mold growth on modern building material such as gypsum board will occur if drying does not occur within 72 hours. Unprotected elevator shafts have resulted in multistory mold contamination occurring in a university hospital that required removal of the elevator shaft fire–rated gypsum board. A specification in the construction documents stating that the gypsum board was to be installed and protected from weather conditions required that the moldy board be removed at the contractor's expense. This is still cheaper than the litigation potential if the moldy board was left in place while the hospital initiated a program for bone marrow transplantation and a patient developed a mold infection. Under such circumstances, the knowledge that the elevator shafts were moldy and not removed would make them be suspected as the source of infection and thus become the focus of major legal problems. Contract specifications for a construction project should be provided in the bid documents to ensure basic consideration for clean to dirty airflow, construction traffic, roof protection, water damage management, and assurance that the spaces to be occupied by immune-compromised patients (such as bone marrow transplant recipients) have definable protective parameters such as pressure differential, air changes per hour, and filtration (65). The "Guidelines for Environmental Infection Control" (*http://www.cdc.gov/mmwr/pdf/rr/rr5210.pdf*) have certainly added to the coordination of construction management in healthcare facilities as part of the justification involved with the infection control risk assessment (see also Chapter 83). With the abovesaid considerations for construction contract labor in North America, the Carpenter Brotherhood Training Center in Las Vegas has made infection control training available for hospital labor pools. Such efforts have helped ease the risk. In addition, the American Society for Healthcare Engineering (ASHE) has programs for all hospital facility management and contractor supervision as well as programs for contract management in healthcare facilities, including infection prevention. These programs continue to promote quality management principles based on risk factors unique to healthcare facilities.

Food Sources

Another potential environmental source for introduction of opportunistic microorganisms into hospitals is on raw food products. Shooter et al. *(66)* isolated *P. aeruginosa* from salads and other cold foods in London area hospitals and then showed that some patients apparently acquired similar strains. Kominos et al. *(67)* reported on the introduction of *P. aeruginosa* into a hospital via raw vegetables such as carrots, celery, and tomatoes but presented no evidence of direct association with healthcare-associated infection. Sanborn *(68)*, on the other hand, claimed that an outbreak caused by *Salmonella chester* was traced to contamination of a cutting board by a raw turkey, and Levine et al. *(69)* similarly implied that equipment contaminated by egg products was at least partially to blame for numerous cases of salmonellosis reported from nursing homes. Thus, careful attention to the basics of food sanitation can certainly be justified as an infection control practice. This basic food sanitation practice is also provided with real-time quality assurance on the food preparation areas in a hospital food service. The same methods can be used for training purposes, essentially to demonstrate to employees the data as it is developed in the food service area. Employee demonstrations and audits have proved to be an effective learning tool.

Plants and Flowers

Cut flowers, and particularly the vase water in which they are displayed, have been well established as a source of opportunistic pathogens. Taplin and Merz *(70)* detected gentamicin-resistant gram-negative rods in 23 of 75 vases tested in a burn unit and associated the removal of these flowers with a decrease in wound colonization. Schoroth

and Cho *(71)* and Rosenzweig *(72)* also detected gram-negative microorganisms on flowers or in flower water but did not implicate these microorganisms in patient infection. Potted plants have been reported by Staib et al. *(15)*, Burge et al. *(73)*, and Smith et al. *(74)* as potential sources of aerosolized fungal spores, but none of these authors presented evidence of epidemiologic significance for their findings.

Solid Waste

In recent years, most of the attention related to hospital solid wastes has focused on infectious waste issues, particularly on treatment and disposal of these wastes after they leave the hospital. A 1997 report indicated that 3 active cases of tuberculosis and 13 additional conversions resulted from clogged filters in a shredder at a commercial infectious waste treatment facility in Washington *(75)*. The lesson learned is that decontamination must precede shredding to prevent such incidents from occurring. The effect of such wastes within the hospital has received very little attention in recent years, undoubtedly because of the lack of evidence linking such wastes to healthcare-associated infections. An elaborate survey of hospital waste handling and its contribution to microbial contamination of air and surfaces was described by Bond and Michaelsen *(76)*. They concluded that contamination emanating from solid wastes was relatively insignificant and was greatly overshadowed by contamination levels resulting from the handling of soiled laundry. The quantitative and qualitative aspects of that study were detailed by Greene et al. (77,78).

DISCUSSION AND RECOMMENDATIONS

The role of the environment in healthcare-associated infections has been studied and debated for many years. Looking objectively at the evidence, it seems that much of the confusion relates to semantics rather than to scientific differences of opinion. Identification of reservoirs, issues of survival and infectivity of microorganisms, the relative importance of immune suppression, the role of autogenous versus exogenous sources, and the identification of transmission paths and portals of entry are now well understood. The previous sections have identified specific reports wherein environmental reservoirs have been cited (with varying degrees of evidence) as the source of cases or outbreaks of healthcare-associated illness, of colonization without illness, or, even more frequently, simply as reservoirs or hiding places for opportunistic microorganisms without epidemiologic association of any kind. Depending on the definition of environment and particularly of the interface between people, instruments, and equipment and the traditional air, water, or surfaces (floors, walls, and furniture), all of which can conceivably be lumped together as environment, one can conclude a greater or lesser role for environmental transmission. For example, everyone agrees on the importance of hand washing in preventing healthcare-associated infection, but is hand washing an environmental issue (involving products and methods) or is it simply a personal practice issue?

In a 1981 review, McGowan *(79)* suggested that the interest in the role of environmental factors in healthcare-associated infections is that they appear more amenable to control than do other facets of the problem. He argued against the routine monitoring of such environments as being of limited value, a position now shared by almost all practitioners in this field, and argued for selective monitoring only for clearly defined objectives, such as to support epidemiologic investigations or to monitor sterilization processes. Rhame *(18)* reviewed the role of the inanimate environment in healthcare-associated infections and differentiated types of evidence related to environmental involvement. He made the point that many reports merely indicate that a particular microorganism was cultured from a particular fomite with or without proliferation, the implication being that the environment becomes contaminated from infected or colonized patients not the other way around. He correctly downplayed these reports relative to the fewer case-control or prospective epidemiologic studies.

Thus, it is not possible to generalize meaningfully about environmental transmission. Instead, specific items and areas of the institutional environment must be considered separate entities, and environmental manipulation must be consistent with efficient operation and productive infection control practice. For example, there is sufficient evidence for the potential of hot water reservoirs to harbor *Legionella* microorganisms and to transmit those microorganisms to patients to warrant environmental intervention to prevent that problem. Conversely, there is insufficient evidence linking floor contamination to disease transmission to justify the use of expensive disinfectants for routine cleaning. Instead, esthetic cleanliness based on effective soil removal and odor control is clearly justifiable as the expectation of all patients. Recent concepts focus on controlling risk at those critical points of potential transmission. Of course, hand washing before touching the patient plays into the concept of controlling the environment through intervention in human behavior once that control point has been recognized. Such evidence-based concepts are being validated for prevention.

Recommendations for Environmental Control

One is left with having to design, construct, and maintain a complex physical environment for the care of increasingly susceptible hospital patients. Although one may quibble over the epidemiologic significance of this environment, we believe that current knowledge should enable clinicians to proceed with this task in a sensible, science-based, and cost-effective manner, confident that they are enhancing infection control practice and doing their duty for the patients that they are charged with protecting. In the following section, some of these approaches are proposed without apology. Again, "Guidelines for Environmental Infection Control" (*http://www.cdc.gov/mmwr/pdf/rr/rr5210.pdf*) is followed as part of the environment of care, especially as it relates to The Joint Commission's accreditation/certification stipulations mandated by Medicare funding protocols. Such "carrot sticks" will certainly help to define the cost-effective measures necessary to maintain a healthcare facility as a safe environment of care. And with recent rulings tying infection rates to reimbursements, policy changes are beginning to include patient safety priorities relating to infection prevention.

General Considerations A modern healthcare facility should be designed for efficient traffic flow, with particular attention to separation of dirty and clean areas. Among the clean areas, operating rooms and bone marrow transplantation facilities should be considered at the cleanest end

of the spectrum. Unnecessary traffic should be effectively excluded from any critical care area. Such concepts are being formalized into Lean Management principles for efficient patient care. Air-handling systems should be designed flexibly to allow higher volume air circulation in critical areas. Higher air volumes are needed to accommodate varying temperature and humidity conditions but should never be allowed to compromise contamination control airflow patterns. Air should move generally from cleaner to dirtier locations. Air intakes should be well separated from dirty air discharges and located away from loading docks subject to diesel fumes (see also Chapter 84). Redundant systems are necessary due to outages planned and unplanned. Such systems will avoid short-term exposure potentials, often occurring at times when most hospital occupants are unaware of these utility outages. Such short-term environment issues are critical points that beckon careful consideration for vulnerable patient populations. It is amazing to note, from past investigations into clusters of environmental infections such as aspergillosis, how many incidents of probable cause go unreported within the institution and, unfortunately, unreported to the public at large who may well sense the need for more systematic disease control efforts.

Maintenance of Ventilation Systems Duct and fan systems should be subject to routine maintenance and cleaning practices, including regular filter changes. It is important to remove dust and lint accumulations periodically. However, protocols should be developed to ensure that such maintenance does not release accumulated buildup of lint or other debris that could aerosolize opportunistic fungal spores. Figure 71-3 presents an example of heavy lint buildup on a bathroom exhaust grill. Particular attention must also be paid to avoiding high moisture conditions with resultant mold growth in ducts or on insulating materials (Fig. 71-4). Moisture content of >25% water content and 95% relative humidity promote rapid mold growth. Such local conditions should be altered immediately to avoid germination and subsequent sporulation of opportunistic spore forming filamentous fungi. Rapid removal of wet material, proper drying methods, and preservative application will manage spore formation in a critical environment. Rapid response is critical for moisture removal as sporulation can occur under ideal conditions within 96 hours.

FIGURE 71-3 Bathroom exhaust debris.

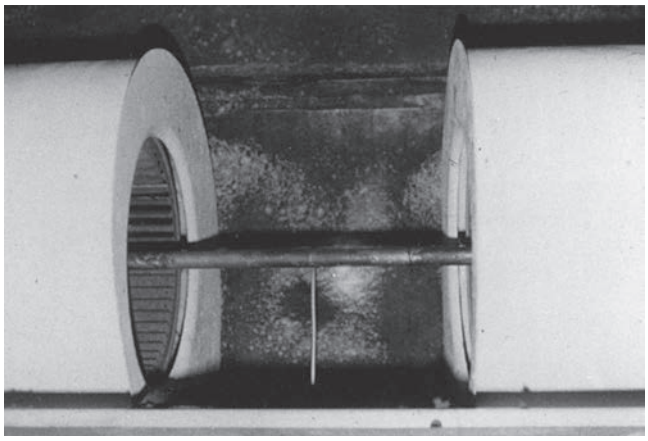

FIGURE 71-4 Fan coil with mold on wet insulation.

Control During Construction Projects The large number of ongoing renovation projects in healthcare facilities requires particular attention to detail to avoid outbursts of airborne fungi or bacteria. Written procedures should be in place to ensure consistency of these efforts, particularly as they pertain to the most critical areas of the facility. Erection of physical barriers to isolate renovation projects may often be necessary. Ventilation systems may need to be shut down temporarily or airflow may need to be rerouted to protect sensitive areas. Control over elevators to facilitate removal of debris or supply of building materials; without mingling workers with patients and staff members, may be necessary. Finally, traffic flow patterns for construction personnel *vis-à-vis* patients and healthcare workers should be defined and monitored. Table 71-2 lists some of the considerations for external project planning. Water damage management, external and internal, can potentially be an important factor for preventing mold colonization of a building. Prolonged wetting of modern building materials such as gypsum board and ceiling tiles can establish

significant mold reservoirs in a building that could be problematic later. Bid specification should address such incidents with a plan for delegating responsibility for drying or removal of the materials before mold contaminates the internal clinical areas of a healthcare facility. New York City Guidelines on assessment and remediation of indoor fungi (*http://www.nyc.gov/html/doh/downloads/pdf/epi/epi-mold-guidelines.pdf*) are helpful for management of mold guidance and for determination of the limit of cleanup by relatively untrained personnel. Careful consideration of cleanup includes realization that when spores dry they "fly." Wetting with surfactant and careful cleanup will help mitigate uncontrolled release of spores. A more common incident than most realize (see also Chapter 83).

General Housekeeping Housekeeping protocols should take into account the need for continuous surveillance over potential buildup of moisture conditions and subsequent fungal proliferation. Dust suppression practices should be emphasized, and cleaning of vents and air conditioners should be routine. Any use of vacuum cleaners should incorporate exhaust filters. Specific spill cleanup procedures should be in place with clear designation of responsibility for such cleanups. Attention should also be paid to ongoing availability of all supplies needed for emergency spill cleanup. Types of chemical disinfectants should be carefully chosen and should follow Centers for Disease Control and Prevention guidelines. Frequently, nongermicidal cleaning products are sufficient at lower cost than sanitizers or disinfectants and have the added benefit of a lower probability of causing chemical sensitivity problems (see also Chapter 80).

Maintenance of Water Reservoirs Specific measures for ensuring the absence of water contaminants such as *Legionella* have been discussed. Control of temperature, periodic superheating, maintenance of chlorine residuals, routine cleaning of storage tanks and other reservoirs, and avoidance of dead-ends or other promoters of stagnation are all important features of preventive maintenance of water reservoirs (see also Chapter 36). In special systems, such as renal dialysis units, ultraviolet light and/or bacterial filters may be appropriate to ensure consistent control. It is remarkable to realize that most buildings under construction, including hospitals, have their pipes filled up to a year before occupancy. Anecdotal experiences have seen high concentrations of gram-negative bacteria, often hard to eliminate if a biofilm has formed (80).

Methods to flush and disinfect water supplies are becoming an important disease control factor due to increasingly resistant strains of bacteria, which occasionally find their way to patient hosts. We must endeavor to better understand plumbing utility management, especially since water usage has begun to shrink in volume used.

CONCLUSIONS

Since this chapter was first drafted about 15 years ago, hundreds of additional articles have been published detailing contamination problems in healthcare facilities. This revision has endeavored to update the original chapter to reflect any significant new developments in the field. The looming threat of antibiotic resistance overcoming pharmacologic innovation clouds the future but brings us again to emphasize the basics of microbial contamination control. Although medical practice, facilities, and equipment for patient care have become more sophisticated and automated, the basic premise of the original chapter has not changed: controlling and minimizing levels of conventional and opportunistic microbial pathogens in healthcare environments is an integral and important aspect of healthcare-associated infection control.

CHAPTER 72

Microbiologic Sampling of the Environment in Healthcare Facilities

Lynne M. Sehulster, Laura J. Rose, and Judith Noble-Wang

In the world of medicine, three developments occurring in the second half of the 20th century have served to increase the complexity of infectious diseases epidemiology—opportunistic pathogens, sophisticated lifesaving medical therapies (e.g., solid organ transplants, bone marrow transplants), and the rapidly increasing diversity and magnitude of antibiotic resistance among bacteria. The experiences gained in dealing with each of these have heightened our awareness of man's interaction with the environment, and the indoor environment in particular. Exposures to environmental pathogens can result in life-threatening infections among the most severely immunosuppressed patients. The identification of antibiotic-resistant bacteria in healthcare environments has drawn scrutiny to care-giving procedures as healthcare personnel move among patients from one area to another; the resistance pattern in one sense becomes a marker to help with the epidemiologic investigation to identify the source(s) of transmission. In the end, there is a renewed interest to understand how the indoor environment influences and/or facilitates transmission of infection. This necessitates the need to sample the environment in a way that is both practical and meaningful. Microbiologic sampling is the approach that most healthcare professionals often choose first when an epidemiologic investigation indicates some evaluation of the environment is needed, but this is not the only method, and it may not be the most appropriate method depending on the circumstances. Furthermore, environmental sampling methods are distinctly different from clinical microbiology methods, and clinical microbiology laboratories are often poorly equipped to carry out environmental sample analyses. This chapter addresses the basic principles and microbiologic methods of sampling indoor environmental surfaces and other environmental sources for microorganisms (1,2). Detailed methods for microbiologic sampling of the environment are included in this chapter since such sampling is frequently used during infectious disease outbreaks (2). Microbiologic sampling in response to a bioterrorism event is beyond the scope of this chapter; the reader is referred to other sources for more specific information about the unique sampling concerns for this endeavor (2).

The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention (CDC). Any use or mention of trade names in this chapter is for identification purposes only and does not represent any endorsement by either the CDC or the U.S. Public Health Service.

GENERAL PRINCIPLES: MICROBIOLOGIC SAMPLING OF THE ENVIRONMENT

Before 1970, US hospitals conducted regularly scheduled culturing of the air and environmental surfaces (e.g., floors, walls, and table tops) *(3)*. By 1970, the Centers for Disease Control and Prevention (CDC) and the American Hospital Association (AHA) were advocating the discontinuation of routine environmental culturing because rates of healthcare-associated infection had not been associated with levels of general microbial contamination of air or environmental surfaces, and because meaningful standards for permissible levels of microbial contamination of environmental surfaces or air did not exist *(4–6)*. During 1970 to 1975, 25% of US hospitals reduced the extent of such routine environmental culturing—a trend that has continued *(7,8)*.

Random, undirected sampling (referred to as "routine" in previous guidelines) differs from the current practice of targeted sampling for defined purposes *(5,9)*. Previous recommendations against routine sampling were not intended to discourage the use of sampling in which sample collection, culture, and interpretation are conducted in accordance with defined protocols *(9)*. In this chapter, targeted microbiologic sampling connotes a monitoring process that includes (a) a written, defined, multidisciplinary protocol for sample collection and culturing; (b) analysis and interpretation of results using scientifically determined or anticipatory baseline values for comparison; and (c) expected actions based on the results obtained. Infection control, in conjunction with laboratorians, should assess the healthcare facility's capability to conduct sampling and determine when expert consultation and/or services are needed.

Microbiologic sampling of air, water, and inanimate surfaces (i.e., environmental sampling) is an expensive and time-consuming process that is complicated by many variables in protocol, analysis, and interpretation. It is therefore indicated for only four situations *(10)*. The first is to support an investigation of an outbreak of disease

or infections when environmental reservoirs or fomites are implicated epidemiologically in disease transmission *(11–13)*. It is important that such culturing be supported by epidemiologic data. Environmental sampling, as with all laboratory testing, should not be conducted if there is no plan for interpreting and acting on the results obtained *(14–16)*. Linking microorganisms from environmental samples with clinical isolates by molecular epidemiology is crucial whenever it is possible to do so.

The second situation for which environmental sampling may be warranted is in research. Well-designed and controlled experimental methods and approaches can provide new information about the spread of healthcare-associated diseases *(17,18)*. A classic example is the study of environmental microbial contamination that compared healthcare-associated infection rates in an old hospital and a new facility before and shortly after occupancy *(19)*.

The third indication for sampling is to monitor a potentially hazardous environmental condition, confirm the presence of a hazardous chemical or biological agent, and validate the successful abatement of the hazard. This type of sampling can be used to (a) detect bioaerosols released from the operation of healthcare equipment (e.g., an ultrasonic cleaner) and determine the success of repairs in containing the hazard *(20)*; (b) detect the release of an agent of bioterrorism in an indoor environmental setting and determine its successful removal or inactivation; and (c) sample for industrial hygiene or safety purposes (e.g., monitoring a "sick building").

The fourth indication is for quality assurance to evaluate the effects of a change in infection-control practice or to ensure that equipment or systems perform according to specifications and expected outcomes. Currently, much of the environmental assessment of practice in healthcare settings involves nonmicrobiologic methods such as covert visual inspection, use of ultraviolet (UV) fluorescent chemical markers, and adenosine triphosphate measurements of bioburden using relative light units recorded with a luminometer device (21,*22*). Nevertheless, any sampling for quality-assurance (QA) purposes (microbiologic sampling or any nonculture method) must follow sound sampling protocols. Microbiologic sampling in particular must address confounding factors through the use of properly selected controls. Results from a single environmental sample are difficult to interpret in the absence of a frame of reference or perspective. Evaluations of a change in infection-control practice are based on the assumption that the effect will be measured over a finite period, usually of short duration. Conducting QA microbiologic sampling on an extended basis, especially in the absence of an adverse outcome, is usually unjustified. A possible exception might be the use of air sampling during major construction periods to qualitatively detect breaks in environmental infection-control measures. In one study, which began as part of an investigation of an outbreak of healthcare-associated aspergillosis, airborne concentrations of *Aspergillus* spores were measured in efforts to evaluate the effectiveness of sealing hospital doors and windows during a period of construction of a nearby building *(23)*. However, the only types of routine environmental microbiologic sampling recommended as part of a QA program are (a) the biological monitoring of sterilization processes by using bacterial spores (24) and (b) the monthly culturing of water used in hemodialysis applications and for the final dialysate use dilution (see Chapter 63 for more information on sampling in dialysis settings).

Microbiologic sampling of the environment involves selecting a representative sample of that environment and collecting microbial contaminants with appropriate sampling devices. The interpretation of results should be based on the understanding of the recovery efficiencies of the materials and the limitations of the processing method (2).

Air Sampling

Biological contaminants occur in the air as aerosols and may include bacteria, fungi, viruses, and pollens *(25,26)*. Aerosols are characterized as solid or liquid particles suspended in air. Talking for 5 minutes and coughing each can produce 3,000 droplet nuclei; sneezing can generate approximately 40,000 droplets that then evaporate to particles in the size range of 0.5 to 12 μm *(27,28)*. Particles in a biological aerosol usually vary in size from <1 to >50 μm. These particles may consist of a single, unattached microorganism or may occur in the form of clumps composed of a number of bacteria. Clumps can also include dust and dried organic or inorganic material. Vegetative forms of bacterial cells and viruses may be present in the air in a lesser number than bacterial spores or fungal spores. Factors that determine the survival of microorganisms within a bioaerosol include (a) the suspending medium; (b) temperature; (c) relative humidity; (d) oxygen sensitivity; and (e) exposure to UV or electromagnetic radiation *(25)*. Many vegetative cells will not survive for lengthy periods of time in the air unless the relative humidity and other factors are favorable for survival and the microorganism is enclosed within some protective cover (e.g., dried organic or inorganic matter) *(26)*. Pathogens that resist drying (e.g., *Staphylococcus* spp., *Streptococcus* spp., and fungal spores) can survive for long periods and can be carried considerable distances via air and still remain viable. They may also settle on surfaces and become airborne again as secondary aerosols during certain activities (e.g., sweeping and bed making) (*26*,29).

Microbiologic air sampling is used to determine the numbers and types of microorganisms, or particulates, in indoor air (30). Air sampling for quality control is, however, problematic because of lack of uniform air-quality standards. Although airborne spores of *Aspergillus* spp. can pose a risk for neutropenic patients, the critical number (i.e., action level) of these spores above which outbreaks of aspergillosis would be expected to occur has not been defined. Healthcare professionals considering the use of air sampling should keep in mind that the results represent indoor air quality at singular points in time, and these may be affected by a variety of factors including (a) indoor traffic; (b) visitors entering the facility; (c) temperature; (d) time of day or year; (e) relative humidity; (f) relative concentration of particles or microorganisms; and (g) the performance of the air-handling system components. To be meaningful, air-sampling results must be compared with those obtained from other defined areas, conditions, or time periods and outside air samples.

Several preliminary concerns must be addressed when designing a microbiologic air-sampling strategy (Box 72-1).

BOX 72-1

Preliminary Concerns for Conducting Air Sampling

- Consider the possible characteristics and conditions of the aerosol, including size range of particles, relative amount of inert material, concentration of microorganisms, and environmental factors.
- Determine the type of sampling instruments, sampling time, and duration of the sampling program.
- Determine the number of samples to be taken.
- Ensure that adequate equipment and supplies are available.
- Determine the method of assay that will ensure optimal recovery of microorganisms.
- Select a laboratory that will provide proper microbiologic support.
- Ensure that samples can be refrigerated if they cannot be assayed in the laboratory promptly.

Because the amount of particulate material and bacteria retained in the respiratory system is largely dependent on the size of the inhaled particles, particle size should be determined when studying airborne microorganisms and their relation to respiratory infections. Particles >5 μm are efficiently trapped in the upper respiratory tract and are removed primarily by ciliary action *(31)*. Particles <5 μm in diameter reach the lung, but the greatest retention in the alveoli is of particles 1 to 2 μm in diameter *(32–34)*.

Bacteria, fungi, and particulates in air can be identified and quantified with the same methods and equipment (Table 72-1). The basic methods include (a) impingement in liquids; (b) impaction on solid surfaces; (c) sedimentation; (d) filtration; (e) centrifugation; (f) electrostatic precipitation; and (g) thermal precipitation (29). Of these, impingement in liquids, impaction on solid surfaces, and sedimentation (on settle plates) have been used for various air-sampling purposes in healthcare settings (30).

Several instruments are available for sampling airborne bacteria and fungi (Box 72-2). Some of the samplers are self-contained units requiring only a power supply and the appropriate collecting medium, but most require additional auxiliary equipment (e.g., a vacuum pump and an airflow measuring device [i.e., a flow meter or anemometer]). Sedimentation or depositional methods use settle plates (Petri plates with agar media) and therefore need no special instruments or equipment. Selection of an instrument for air sampling requires a clear understanding of the type of information desired and the particular determinations that must be made (Box 72-2). Information may be needed regarding: (a) one particular microorganism or all microorganisms that may be present in the air; (b) the concentration of viable particles or of viable microorganisms; (c) the change in concentration with time; and (d) the size distribution of the collected particles. Before sampling begins, decisions should be made regarding whether the results are to be qualitative or quantitative. Comparing quantities of airborne microorganisms to those of outdoor air is also standard operating procedure. Infection preventionists, healthcare epidemiologists, industrial hygienists, and laboratory supervisors, as part of a multidisciplinary team, should discuss the potential need for microbial air sampling to determine if the capacity and expertise to conduct such sampling exist within the facility and when it is appropriate to enlist the services of an environmental microbiologist consultant.

Liquid impinger and solid impactor samplers are the most practical for sampling bacteria, particles, and fungal spores, because they can sample large volumes of air in relatively short periods of time (30). Solid impactor units are available as either "slit" or "sieve" designs. Slit impactors use a rotating disc as support for the collecting surface, which allows determinations of concentration over time. Sieve impactors commonly use stages with calibrated holes of different diameters. Some impactor-type samplers use centrifugal force to impact particles onto agar surfaces. The interior of either device must be made sterile to avoid inadvertent contamination from the sampler. Results obtained from either sampling device can be expressed as microorganisms or particles per unit volume of air (CFU/m^3).

Sampling for bacteria requires special attention, because bacteria may be present as individual microorganisms, as clumps, or mixed with or adhering to dust or covered with a protective coating of dried organic or inorganic substances. Reports of bacterial concentrations determined by air sampling therefore must indicate whether the results represent individual microorganisms or particles bearing multiple cells. Certain types of samplers (e.g., liquid impingers) will completely or partially disintegrate clumps and large particles; the sampling result will therefore reflect the total number of individual microorganisms present in the air.

The task of sizing a bioaerosol is simplified through the use of sieves or slit impactors, because these samplers will separate the particles and microorganisms into size ranges as the sample is collected. These samplers must, however, be calibrated first by sampling aerosols under similar use conditions *(37)*.

The use of settle plates (i.e., the sedimentation or depositional method) is not recommended when sampling air for fungal spores, because single spores can remain suspended in air indefinitely (30). Settle plates have been used mainly to sample for particulates and bacteria either in research studies or during epidemiologic investigations *(11,38–41)*. Results of sedimentation sampling are typically expressed as numbers of viable particles or viable bacteria per unit area per the duration of sampling time (i.e., CFU/area/time); this method cannot quantify the volume of air sampled. Because the survival of microorganisms during air sampling is inversely proportional to the velocity at which the air is taken into the sampler *(25)*, one advantage of using a settle plate is its reliance on gravity to bring microorganisms and particles into contact with its surface, thus enhancing the potential for optimal survival of collected microorganisms. This process, however, takes several hours to complete and may be impractical for some situations.

Air samplers are designed to meet differing measurement requirements. Some samplers are better suited for one form of measurement than others. No one type of sampler and assay procedure can be used to collect and enumerate 100% of airborne microorganisms. The sampler

TABLE 72-1

Air-Sampling Methods and Examples of Equipment

Method	*Principle*	*Suitable for Measuring*	*Collection Media or Surface*	*Rate of Collection (L/min)*	*Auxiliary Equipment Needed*[a]	*Points to Consider*	*Prototype Samplers*[b]
Impingement in liquids	Air drawn through a small jet and directed against a liquid surface	Viable microorganisms and concentration over time. Example use: sampling water aerosols for *Legionella* spp.	Buffered gelatin, tryptose saline, peptone, nutrient broth	12.5	Yes	Antifoaming agent may be needed. Ambient temperature and humidity will influence length of collection time.	Chemical Corps. All Glass Impinger (AGI)
Impaction on solid surfaces	Air drawn into the sampler; particles deposited on a dry surface	Viable particles; viable microorganisms (on nonnutrient surfaces, limited to microorganisms that resist drying and spores); size measurement, and concentration over time. Example use: sampling air for *Aspergillus* spp., fungal spores	Dry surface, coated surfaces, and agar	28 (sieve) 30–800 (slit)	Yes	Available as sieve impactors or slit impactors. Sieve impactors can be set up to measure particle size. Slit impactors have a rotating support stage for agar plates to allow for measurement of concentration over time	Andersen Air Sampler, Surface Air Sampler (PBI Int'l, Italy) (sieve impactor); TDL, Casella MK-2 (slit impactors)
Sedimentation	Particles and microorganisms settle onto surfaces via gravity	Viable particles. Example uses: sampling air for bacteria in the vicinity of and during a medical procedure; general measurements of microbial air quality	Nutrient media (agars) on plates or slides	—	No	Simple and inexpensive; best suited for qualitative sampling; significant airborne fungal spores are too buoyant to settle efficiently for collection using this method	Settle plates
